Preface

Though the majority of animals used in biomedical research at present are mice and rats, a number of other species continue to serve as models in the effort to advance human and animal health. In this regard, *The Laboratory Rabbit, Guinea Pig, Hamster, and Other Rodents* is meant to be an authoritative summary of the basic biology, husbandry, veterinary perspective, and experimental use of these species.

While this is the first edition of *The Laboratory Rabbit, Guinea Pig, Hamster, and Other Rodents*, it should be recognized that this volume builds upon the work of previous volumes in the American College of Laboratory Animal Medicine Series. In particular, we wish to recognize the following works as providing the foundation for the present book:

Biology of the Laboratory Rabbit, 1st Edition (Edited by S. H. Weisbroth, R. E. Flatt, and A. L. Kraus)

Biology of the Laboratory Rabbit, 2nd Edition (Edited by P. J. Manning, D. H. Ringler, and C. E. Newcomer)

The Biology of the Guinea Pig (Edited by J. E. Wagner and P. J. Manning)

Laboratory Hamsters (Edited by G. L. Van Hoosier, Jr., and C. W. McPherson)

The editors and many authors of these books should feel gratified that their efforts have helped guide and inform veterinarians, scientists, students, and technicians with respect to the proper use of these species in work which has benefited many. It is our hope that

we have carried these earlier works forward in a way which will proclaim a similar contribution.

The Laboratory Rabbit, Guinea Pig, Hamster, and Other Rodents combines the content of several books into a single volume along with material on additional species such as the chinchilla, gerbil, and miscellaneous rodents other than laboratory rats and mice. It is meant to be relatively concise, yet sufficiently complete that readers will find ready access to information likely to be of practical use.

As part of the series sponsored by the American College of Laboratory Animal Medicine (ACLAM), *The Laboratory Rabbit, Guinea Pig, Hamster, and Other Rodents* is a component of the ACLAM mission to support the scientific community, in general, and expertise in laboratory animal medicine, in particular. All royalty income from this publication is assigned to support other continuing education activities of the College.

A work such as this represents the collective thoughts and efforts of many contributors and reviewers, and we wish to express our sincere gratitude to all. It is often a challenge to coordinate chapters and timelines with a multi-author work such as this, and we wish to further acknowledge the patience and support of the editorial staff at Elsevier. Though some variation in depth and style between authors in a book such as this is inevitable, it is our hope that readers will view this volume as a valuable reference to be consulted on a frequent basis.

“... by now it is widely recognized that the [most humane] possible treatments of experimental animals, far from being an obstacle, is actually a prerequisite for successful animal experiments.” **Russell and Burch, 1959**
The Principles of Humane Experimental Technique

INTRODUCTION

Like many aspects of life, involvement with animal research presents ethical challenges – areas where competing interests require use of an ethical decision-making

process, to provide guidance. Individuals in the laboratory may face basic competing interests between scientists, technicians, veterinary colleagues, an employing institution, the public, and concern for the animals themselves (e.g., individual health versus health of the colony). According to Tannenbaum, *normative veterinary ethics* refers to the search for correct principles of good and bad, right and wrong, and looks for the correct norms for veterinary professional behavior and attitudes (Tannenbaum, 1995). The intent of this chapter is to provide information which will be useful to all individuals involved in animal-based research, testing and teaching: scientists; technicians; laboratory animal veterinarians; and Institutional Animal Care and Use Committee (IACUC) members. This process might be considered an effort to define *normative laboratory animal use ethics*. The search for an appropriate ethical solution rarely leads to a complete and absolute answer, as science is a very dynamic field and new issues and new insights influence the outcome. This look at *normative laboratory animal use ethics* will examine some general ethical concepts within the context of Tannenbaum's definition of *descriptive [laboratory animal use] ethics*, where descriptive ethics is the study of the actual values or standards of a profession; that is, what members of a profession consider to be right and wrong regarding professional behavior and attitudes (Tannenbaum, 1995). In this chapter, reference will be made to relevant values and standards found in various principles and guidelines developed for use by individuals involved in animal research. Potential ethical challenges which might confront laboratory animal professionals using rodents and rabbits (e.g., challenges related to breeding colonies, genetically modified rodents, use of animals in cancer research, perinatal animal use, and use of animals in neuroscience and behavioral research) will be used as examples. Related ethical questions, and the appropriate principles which may pertain to the situation are discussed. The reader is challenged to test the general rules and principles against his or her own moral experience and intuition and thus create his or her own descriptive laboratory animal ethos. Further, the reader is encouraged to recognize that this is an ongoing process, that one's professional ethos will likely grow and mature as new challenges are encountered.

It is recognized that animal welfare is a "core concern of veterinary ethics ... [and] this subject has gained increased importance as society and the profession endorse ever more strongly the moral imperative to treat animals decently." When discussing laboratory animal ethics, one often uses the term "humane" (Tannenbaum, 1995). The *Guide for the Care and Use of Laboratory Animals (Guide)* states "Humane care means those actions taken to assure that laboratory animals are treated according to high ethical and scientific

standards" (National Research Council, 2011). The *Guide* uses the words 'ethics' or 'ethical' 59 times in either the text or references. The first place 'ethics' is mentioned in the *Guide* is the Preface: "The *Guide* is also intended to assist investigators in fulfilling their obligation to plan and conduct animal experiments in accord with the highest scientific, humane, and ethical principles" (National Research Council, 2011). Humane care, ethics, and animal welfare are closely linked and, for the purposes of this chapter, may be used interchangeably.

ETHICAL CONCEPTS

Moral Theories

Moral theory is an expansive field of study with its own vocabulary and competing points of view. It is beyond the scope of this chapter to provide a comprehensive discussion of the many theories that discuss the humane use of animals. Instead, focus is made on some principles which the authors have found helpful.

Consideration of ethics with respect to use of animals in research begins with the basic idea of where one feels animals (versus people) fit in the moral spectrum. In other words, what is the moral value of an animal relative to a human? Moral status or standing represents "the position or rank of an entity along a moral continuum from minimal to maximal moral significance" (Kraus and Renquist, 2000). Because animals lack moral agency, defined as a uniquely human capacity for making moral judgments (Kraus and Renquist, 2000), it may be concluded that animals, while having some moral status, fall below that accorded to humans. Even when examining the moral status of animals, there are many who accord different levels of moral status for different species. Such a continuum of moral status is essentially a sliding scale where moral status is based on a combination of cognitive and sensory capacities. This concept has been coined "speciesism" by some philosophers who then compare it to other concepts which foster differential treatment based upon a given trait, similar to racism or sexism (Singer, 1975). Regardless of where a species is placed on this Darwinian scale, a commonality shared by all vertebrates is that of sentience. Sentience is the capacity to perceive and process sensory input and thus the ability to feel pain and distress. Moral agents (humans) have obligations or are bound to do certain things out of a sense of duty, custom, or law and have responsibility toward other beings. It is from this obligation that most humans feel it is right to minimize the pain and distress felt by other sentient beings. This obligation may be called non-maleficence and is addressed in greater detail later in this chapter.

In the most general sense, there are two approaches to ethics: utilitarianism and deontology. Utilitarian theories look at the consequences of actions to determine which actions are good and which are bad. The goal is to maximize good consequences and minimize bad ones. In its most basic form, this is similar to what an IACUC protocol review does when it performs a cost or harm/benefit analysis. However, there are different views of the “good” that should be maximized. Utilitarianism is an example of *action-oriented ethical theories*, because it examines the consequences of actions. These theories tend to stress the concepts of duty and obligation. In contrast, deontological theories are also action-oriented ethical theories; however, there are some moral imperatives which are independent of how much “good” results from an action. Some deontologists advocate a set of “obligatory” moral principles but allow some compromise when different moral principles are conflicting (e.g., one principle trumps another). There may also be non-obligatory principles which are desirable but not mandatory to follow.

Other ethical approaches include those based on values and ethics. *Value-based ethics* center around basic values to be sought. These values tend to be hierarchical. There are also *virtue-oriented ethical theories*. A virtue contributes to a good moral life (e.g., honesty, kindness, generosity). These approaches tend to instill “attitudes, feelings, and states of mind central to the virtuous disposition” (Tannenbaum, 1995). It has been suggested that a satisfactory approach to normative ethics must include actions, values, and virtues (Tannenbaum, 1995).

Descriptive Laboratory Animal Use Ethics

Ethical Principles

Descriptive laboratory animal ethics represents an approach for determining appropriate moral behavior and attitude (Tannenbaum, 1995). Principles can be defined as “accepted generalizations about a topic that are frequently endorsed by many and diverse organizations” (National Research Council, 2011); and several sets of principles with relevance to ethical use of laboratory animals will be discussed. It is hoped that application of these principles in the discussion of example ethical challenges later in this chapter will serve as a basis for how other ethical challenges may be approached.

One set of principles, the concept of the “Five Freedoms,” was originally created by the United Kingdom Farm Animal Welfare Advisory Council (FAWC) in 1979 specifically to address issues related to the use of animals in agriculture. Today, the “Five Freedoms” are also often mentioned within the context of animals used in research. The “Five Freedoms” include: (1) freedom from malnutrition; (2) freedom

from thermal or physical discomfort; (3) freedom from injury and disease; (4) freedom to express normal social behavior; and (5) freedom from fear. The Five Freedoms were revised in 1993 to include: (1) freedom from hunger and thirst, by assuring ready access to fresh water and a diet sufficient to maintain full health and vigor; (2) freedom from discomfort, by providing an environment including shelter and a comfortable resting area; (3) freedom from pain, injury and disease, by preventive means or rapid diagnosis and treatment; (4) freedom from fear and distress, by ensuring conditions that avoid mental suffering; and (5) freedom to express normal behavior, by providing sufficient space, proper facilities, and company of the animal’s own kind (Webster, 2001).

In 1996, the United States National Aeronautics and Space Administration (NASA) developed basic principles, referred to as the Sundowner Principles (NASA, 1996). These principles were based upon the Belmont Report which had been written for the protection of human research subjects (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979). These principles of bioethics offer a simple, yet elegant framework for looking at ethical questions:

“The use of animals in research involves responsibility – not only for the stewardship of the animals but to the scientific community and society as well. Stewardship is a universal responsibility that goes beyond the immediate research needs to include acquisition, care and disposition of the animals, while responsibility to the scientific community and society requires an appropriate understanding of, and sensitivity to scientific needs and community attitudes toward the use of animals.

Among the basic principles generally accepted in our culture, three are particularly relevant to the ethics of research using animals: respect for life, societal benefit, and non-maleficence” (NASA, 1996).

Respect for Life

Living creatures deserve respect. This principle requires that animals used in research should be of an appropriate species and health status, and should involve the minimum number required to obtain valid scientific results. It also recognizes that the use of different species may raise different ethical concerns. Selection of appropriate species should consider cognitive capacity and other morally relevant factors. Additionally, methods such as mathematical models, computer simulation, and in vitro systems should be considered and used whenever possible.

Societal Benefit

The advancement of biological knowledge and improvements in the protection of the health and well-being of both humans and other animals provide strong justification for biomedical and behavioral research.

This principle entails that when animals are used, the assessment of the overall ethical value of such use should include consideration of the full range of potential societal goods, the populations affected, and the burdens that are expected to be borne by the subjects of the research.

Non-Maleficence

Based upon the idea that vertebrate animals are sentient, this principle holds that the minimization of distress, pain, and suffering is a moral imperative. Unless the contrary is established, investigators should consider that procedures that cause pain or distress in humans may cause pain or distress in other sentient animals (*Interagency Research Animal Committee, 1985*).

The International Guiding Principles for Biomedical Research Involving Animals (*Table 1.1*) were developed by the Council for International Organizations of Medical Sciences (CIOMS) as a result of extensive international and interdisciplinary consultations spanning 1982–1984 (Bankowski, 1985; *Council for International Organizations of Medical Sciences, 1985*). These principles have a considerable measure of acceptance internationally. European Medical Research Councils (EMRC),

an international association that includes all the West European medical research councils, fully endorsed the CIOMS Guiding Principles in 1984. In the same year, the CIOMS Guiding Principles were endorsed by the World Health Organization (WHO) Advisory Committee on Medical Research. It should be noted that, at the time of writing this chapter, the CIOMS were undergoing revision.

During 1984–1985, the U.S. National Institutes of Health (NIH) convened the U.S. Interagency Research Animal Committee (IRAC) which created a similar set of principles, the U.S. Government Principles for the Utilization and Care of Vertebrate Animals used in Testing, Research and Training (*Table 1.2*) for research funded by the U.S. Public Health Service (PHS) (*Interagency Research Animal Committee, 1985*). These principles were, to a considerable extent, based on the CIOMS Guiding Principles.

As an indication of the wide acceptance of both the IRAC and CIOMS Principles, discussion of the IRAC Principles can be found under the heading “Ethics and Animal Use” in the *Guide* (*National Research Council, 2011*). NASA and CIOMS are also listed in Appendix A of the *Guide* under the heading “Ethics and Welfare”

TABLE 1.1 Council for International Organizations of Medical Sciences (CIOMS) *Basic Principles* (1985)

-
- I. The advancement of biological knowledge and the development of improved means for the protection of the health and well-being both of man and of animals require recourse to experimentation on intact live animals of a wide variety of species
 - II. Methods such as mathematical models, computer simulation and in vitro biological systems should be used wherever appropriate
 - III. Animal experiments should be undertaken only after due consideration of their relevance for human or animal health and the advancement of biological knowledge
 - IV. The animals selected for an experiment should be of an appropriate species and quality, and the minimum number required to obtain scientifically valid results
 - V. Investigators and other personnel should never fail to treat animals as sentient, and should regard their proper care and use and the avoidance or minimization of discomfort, distress, or pain as ethical imperatives
 - VI. Investigators should assume that procedures that would cause pain in human beings cause pain in other vertebrate species, although more needs to be known about the perception of pain in animals
 - VII. Procedures with animals that may cause more than momentary or minimal pain or distress should be performed with appropriate sedation, analgesia, or anesthesia in accordance with accepted veterinary practice. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents
 - VIII. Where waivers are required in relation to the provisions of article VII, the decisions should not rest solely with the investigators directly concerned but should be made, with due regard to the provisions of articles IV, V, and VI, by a suitably constituted review body. Such waivers should not be made solely for the purposes of teaching or demonstration
 - IX. At the end of, or, when appropriate, during an experiment, animals that would otherwise suffer severe or chronic pain, distress, discomfort, or disablement that cannot be relieved should be painlessly killed
 - X. The best possible living conditions should be maintained for animals kept for biomedical purposes. Normally the care of animals should be under the supervision of veterinarians having experience in laboratory animal science. In any case, veterinary care should be available as required
 - XI. It is the responsibility of the director of an institute or department using animals to ensure that investigators and personnel have appropriate qualifications or experience for conducting procedures on animals. Adequate opportunities shall be provided for in-service training, including the proper and humane concern for the animals under their care
-

(National Research Council, 2011). The complete IRAC Principles are found on the cover of the PHS Policy (Office of Laboratory Animal Welfare, 2002) and Appendix B of the *Guide* (National Research Council, 2011).

There are really no points of conflict and, in fact, there are many points of consensus between the Sundowner, CIOMS, and IRAC principles all of which offer that animal-based research should:

- Acknowledge the importance of research with relevance to human or animal health, advancement of knowledge, or the good of society;
- Stress consideration of alternatives to reduce or replace the use of animals;
- Require avoiding or minimizing discomfort, distress, and pain.

Some items which are addressed in greater detail in the CIOMS and IRAC principles but are more generally under the concept of non-maleficence in the Sundowner Principles include:

- Use of appropriate sedation, analgesia, and anesthesia;
- Establishment of humane endpoints;

- Provision of adequate veterinary care;
- Assurance of appropriate training and qualifications of personnel using and caring for animals.

As previously mentioned, descriptive ethics is the study of actual values or standards of a profession. With respect to ethics governing laboratory animal use, the Sundowner, CIOMS, and IRAC principles could be considered major components.

Commonly accepted ethical principles result in development of professional guidelines. For example, in 1831 in the United Kingdom (U.K.), Marshall Hall, a leading British physiologist, developed guidelines for animal experimentation (Zurlo et al., 1993). The British Association for the Advancement of Science further refined these principles in 1871, 5 years before the first legislation in the U.K. In 1909, Walter B. Cannon developed guidelines for animal experimentation for the American Physiological Association. Many other scientific organizations have also created similar guidelines. Scientists are urged to seek those within their own professional societies. (e.g., Federation of American Societies for Experimental Biology at <http://www.faseb.org>).

TABLE 1.2 Interagency Research Animal Committee (IRAC) U.S. Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training (Interagency Research Animal Committee, 1985)

The development of knowledge necessary for the improvement of the health and well-being of humans as well as other animals requires in vivo experimentation with a wide variety of animal species. Whenever U.S. Government agencies develop requirements for testing, research, or training procedures involving the use of vertebrate animals, the following principles shall be considered; and whenever these agencies actually perform or sponsor such procedures, the responsible Institutional Official shall ensure that these principles are adhered to:

- I. The transportation, care, and use of animals should be in accordance with the Animal Welfare Act (7 U.S.C. 2131 et. seq.) and other applicable Federal laws, guidelines, and policies.
- II. Procedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society.
- III. The animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results. Methods such as mathematical models, computer simulation, and in vitro biological systems should be considered.
- IV. Proper use of animals, including the avoidance or minimization of discomfort, distress, and pain when consistent with sound scientific practices, is imperative. Unless the contrary is established, investigators should consider that procedures that cause pain or distress in human beings may cause pain or distress in other animals.
- V. Procedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anesthesia. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents.
- VI. Animals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure.
- VII. The living conditions of animals should be appropriate for their species and contribute to their health and comfort. Normally, the housing, feeding, and care of all animals used for biomedical purposes must be directed by a veterinarian or other scientist trained and experienced in the proper care, handling, and use of the species being maintained or studied. In any case, veterinary care shall be provided as indicated.
- VIII. Investigators and other personnel shall be appropriately qualified and experienced for conducting procedures on living animals. Adequate arrangements shall be made for their in-service training, including the proper and humane care and use of laboratory animals.
- IX. Where exceptions are required in relation to the provisions of these Principles, the decisions should not rest with the investigators directly concerned but should be made, with due regard to Principle II, by an appropriate review group such as an institutional animal care and use committee. Such exceptions should not be made solely for the purposes of teaching or demonstration (Interagency Research Animal Committee, 1985).

org/Policy-and-Government-Affairs/Science-Policy-Issues/Animals-in-Research-and-Education/Statement-of-Principles.aspx; American Physiological Society at http://www.the-aps.org/pa/resources/policyStmnts/paPolicyStmnts_Guide.htm).

Examples of professional guidelines for laboratory animal veterinarians include the Principles of Veterinary Medical Ethics and Veterinary Oath of the American Veterinary Medical Association (at <http://www.avma.org/issues/policy/ethics.asp>, http://www.avma.org/about_avma/whoweare/oath.asp). Further, many laboratory animal science professionals refer to the Position Statements of the American Association for Laboratory Animal Science (AALAS; http://www.aalas.org/association/position_statements.aspx).

Central to these codes of conduct, principles, statements of ethics, and position statements is the commitment to the humane care and use of research animals.

The Three Rs (Replacement, Reduction, and Refinement)

Several sets of ethical principles and guidelines covering the use of animals in research, testing, and teaching have been mentioned but perhaps the simplest and the one with the greatest impact on animal research today is the ethical concept called “The 3Rs”, a call to apply whenever possible the alternatives of replacement of animals, reduction in the number of animals used, and the refinement in procedures used on animals in research (Russell and Burch, 1959).

The *Guide* was originally published in 1963 and has undergone numerous revisions, with the most recent edition being published in 2011. The Statement of Task of the latest revision committee begins with “The use of laboratory animals for biomedical research, testing and education is guided by the principles of the Three Rs... .” (National Research Council, 2011). The 3Rs are a common theme in the *Guide* which states “Throughout the *Guide*, scientists and institutions are encouraged to give careful and deliberate thought to the decision to use animals taking into consideration the contribution that such use will make to new knowledge, ethical concerns, and the availability of alternatives to animal use. A practical strategy for decision making, [is] the “Three Rs” (Replacement, Reduction, and Refinement) approach, ...”(National Research Council, 2011).

The concept of the 3Rs is also infused in U.S. regulations covering research using animals. Although the United States Department of Agriculture (USDA) Animal Welfare Act (AWA) regulations do not include the word “alternatives” in its section of definitions, the term is used several times in the regulations themselves. For example, in the section on IACUC review of protocols the regulations state protocols must indicate that

“(i) Procedures involving animals will avoid or minimize discomfort, distress, and pain to the animals; (ii) The principle investigator has considered alternatives to procedures that may cause more than momentary or slight pain or distress to the animals, and has provided a written narrative description of the methods and sources, e.g., The Animal Welfare Information Center, used to determine that alternatives were not available” (Office of the Federal Register, 2002). The focus of USDA inspectors on adherence to this section of the regulations can be appreciated when looking at the USDA Research Facility Inspection Guide which instructs inspectors several times to evaluate institutional compliance in this area (USDA, 2009). In addition, the requirement for a search for alternatives is the subject of a specific Animal Care Policy – Policy 12 (Animal and Plant Health Inspection Service, 2000). Strategies to enhance electronic search efficiency using a search filter for PubMed have been published (Hooijmans et al., 2010b). A “Gold Standard Publication Checklist” has been proposed to help fully integrate the 3Rs into systematic reviews of the literature (Hooijmans et al., 2010a).

In a section on personnel qualifications, the AWA Regulations state that the institution should assure adequate training and qualifications and that this is fulfilled in part through the provision of training and instruction on the “concept, availability, and use of research and testing methods that limit the use of animals [Reduction] or minimize animal distress [Refinement]” (Office of the Federal Register, 2002). The AWA Regulations further indicate that research staff should be trained on the “utilization of services (e.g., National Agriculture Library of Medicine) available to find information: ... (ii) On alternatives to the use of live animals in research [Replacement]; ...” (Office of the Federal Register, 2002).

In addition to the specific references above, the AWA Regulations also refer to the use of anesthetics, analgesics, and sedatives, the availability of appropriate veterinary care, the use of appropriate housing; and timely, appropriate euthanasia, all of which demonstrate the practice of “refinement”.

The United States Public Health Service (PHS) Policy contains similar language regarding minimizing discomfort, distress pain, use of appropriate anesthesia, and the use of humane endpoints as examples of refinement. In addition, the PHS Policy refers to the IRAC Principles, requiring institutions receiving PHS funds to use the *Guide* as a basis for their animal care and use programs.

National and international agencies and organizations such as the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) (<http://iccvam.niehs.nih.gov/>), the European Centre for the Validation of Alternative Methods (ECVAM) (<http://ecvam.jrc.ec.europa.eu/>), and the National

Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) (<http://www.nc3rs.org.uk/>) are charged with helping to find and promote the use of alternatives.

With so much official emphasis on the 3Rs, there is sometimes a perception that the concept is not being adequately implemented in practice. Indeed, it has been suggested that scientists and IACUCs do not fully understand the concepts of the 3Rs (Graham, 2002; Schuppli and Fraser, 2005). In addition to incomplete understanding of the concepts, factors believed to negatively influence the full implementation of the 3Rs by IACUCs might include: (1) a belief that the scientists themselves would implement the 3Rs; (2) an assumption that funding agencies have reviewed the use of the 3Rs during proposal review; (3) confidence that sample size, rather than study design, is the sole criterion for reduction; and (4) focus upon potential harm from procedures without consideration for potential distress that animals might experience from husbandry and housing. Although these conclusions were based upon a relatively small number of IACUCs, these are troubling observations and indicate the need for greater emphasis on the 3Rs in training programs for scientists and IACUCs. The authors hope that this chapter can be a resource for that process.

It would be disingenuous to imply that, although well accepted, the concept of the 3Rs is universally accepted. In an article titled "Time to Abandon the Three Rs", Derbyshire wrote that the 3Rs "draw attention away from the value of experimentation and toward the importance of animal welfare" (Derbyshire, 2006). Although the article supports the concept of reducing animal stress for the sake of science, the authors do not clearly recognize the opportunity to balance facilitation of science and application of the 3Rs.

REPLACEMENT

Replacement refers to methods that avoid using animals. The term includes absolute replacements (i.e., replacing animals with inanimate systems such as computer programs) as well as relative replacements (i.e., replacing animals, such as vertebrates, with animals that are lower on the phylogenetic scale) (National Research Council, 2011). Relative replacement may be controversial to some people as it implies "speciesism", the idea that one species has greater moral standing than another (Singer, 1975).

Like many of the ethical considerations relating to animal use, relative replacement is essentially a continuum of moral standing. Society, in general, often differentiates between humans and non-human animals; however, with respect to the animal world, different opinions exist regarding our obligations to some species versus others. For example, non-human primates and

animals commonly kept as pets such as horses, dogs, and cats are often regarded differently than rats and mice, which in turn are regarded differently from fruit flies and worms, and so on.

Development of fully validated and accepted replacement alternatives can be a frustratingly slow process. However, there are significant examples of successful replacement of live animals. For example, one of the most criticized uses of animals for toxicity testing is the Draize test in rabbits. This test was developed to determine ocular toxicity and irritancy caused by products and chemicals. Ocular toxicity tests represent one of the four most commonly conducted product safety tests (Interagency Coordinating Committee on the Validation of Alternative Methods, 2010). The 3Rs were implemented by the development of three validated and accepted replacements for screening products for ocular toxicity: the bovine corneal opacity and permeability test using a cow eye or the isolated chicken eye test (both by-products of the meat industry); and the Cytosensor[®] microphysiometer (Molecular Devices, Inc., Sunnyvale, CA). A balanced preemptive pain management plan for rabbit Draize test studies, when the test is still required, has also been validated and accepted as a refinement (Interagency Coordinating Committee on the Validation of Alternative Methods, 2010).

A second example of implementation of the 3Rs involves the replacement of rabbits in the testing of pharmaceuticals and medical devices for pyrogens by use of an *in vitro* alternative, the Limulus Ameobocyte Lysate (LAL) Test. In the LAL, blood of horseshoe crabs is collected and the animals are returned, unharmed, back to the ocean. Previous tests required the injection of drugs, biologics, medical devices, or raw materials into rabbits to look for a febrile response as an indication of contamination with endotoxins.

REDUCTION

Reduction includes strategies for obtaining comparable levels of information from the use of fewer animals or for maximizing the information obtained from any given number of animals (without increasing pain or distress) so to ultimately require fewer animals to acquire the same scientific information. This approach relies on an analysis of experimental design, applications of newer technologies, the use of appropriate statistical methods, and control of environmentally related variability in animal housing and study areas" (National Research Council, 2011).

Strategies to reduce the numbers of animals needed include improved statistical design of a study (Dell et al., 2002) and improved selection of an animal model, including selection of animals with the most appropriate health and genetic status. Control of the genetic status is an advantage of using rats and mice. The use

of inbred strains of rats and mice allows scientists to control and investigate genetic variation, and to evaluate responses to treatments on specific areas of interest (Festing, 2004). The use of animals without confounding disease or genetic variation results in less variation, thus requiring fewer animals to determine a treatment effect.

Individuals involved with study design, study review, or those participating as a member of the research team, have the ethical imperative to ensure studies use the minimum number of animals necessary to achieve the scientific objective of the study. Scientists should design studies with particular attention to methodology, statistics, and choice of model. Veterinarians and facility staff should collaborate to minimize non-experimental variables in animal care. IACUCs should be diligent during review of the protocol, semiannual program and facility evaluations, and review of post-approval monitoring to assure that the appropriate number of animals have been used. Having a statistician on the IACUC is one strategy that may be helpful.

REFINEMENT

“Refinement refers to modifications of husbandry or experimental procedures to enhance animal well-being and minimize or eliminate pain and distress” (National Research Council, 2011). In the authors’ opinion, refinement is commonly employed by scientists in ongoing efforts to improve their science; that is, better animal welfare leads to higher-quality science. Many scientists do not recognize this as utilization of “alternatives”, even though it clearly falls within the 3Rs. However, this is also an area where scientists, veterinarians, and IACUCs can make significant strides to enhance animal welfare. Use of less invasive procedures (e. g., use of a blood pressure cuff instead of an implanted catheter for blood pressure monitoring) is one method of refinement. However, there are also situations where an invasive procedure, such as implantation of telemetry sensors to allow ongoing collection of real-time data, can result in much less stressful data collection (Stephens et al., 2002). Examples of other refinements include accurate recognition of pain and the use of analgesics and supportive care; implementation of humane endpoints; and enhanced housing and husbandry.

Carbone and Garnett (2008), state, “... the prime ethical concerns in laboratory animal welfare is what animals consciously experience: their pain, distress, fear, boredom, happiness and psychological well being.” The emotional dimension of pain, a characteristic of suffering, requires pain pathways to extend to higher levels of the cortex unique to humans and some other primates (such as apes) (Nuffield Council on Bioethics, 2005), but it has been stated that “... the absence of analogous structures cannot necessarily be taken to

mean that they [animals] are incapable of experiencing pain, suffering or distress or any other higher order states of conscious experience” (Nuffield Council on Bioethics, 2005).

Basic to minimization of pain is the ability to recognize the signs of pain in specific species. It has been suggested that some animals, particularly prey species, may try to mask pain to avoid displaying abnormal activity that might increase their risk of predation (Roughan and Flecknell, 2000). Further, many animals are most active during the dark cycle, when observations are more difficult. Since clinical indices of pain may be very subtle, it is important to be able to recognize a departure from normal behavior and appearance (Table 1.3; National Research Council, 2003). A short list of general signs and measurements that might indicate pain or distress includes: (1) vigorous attempt to escape; (2) changes in biological characteristics such as food and water consumption and body weight; (3) changes in blood levels of hormones and glucose; (4) increased adrenal gland mass; and (5) appearance, posture, and behavior (Moberg, 1985, 2000). Behavioral indicators of pain in mice and rats have also been described (Flecknell, 1999; Kohn et al., 2007; Roughan and Flecknell, 2000, 2001, 2003). In addition, guidelines for the assessment and management of pain in rodents and rabbits have been published by the American College of Laboratory Animal Medicine (ACLAM, 2006).

Scientists sometimes have concerns about the effect of perioperative analgesics on the research. Many studies have been done investigating analgesic effect on a wide variety of parameters (e.g., litter size, body weight,

TABLE 1.3 Indicators of Pain in Rodents and Rabbits

Species	General Behavior	Appearance	Other
Rodents	Decreased activity; excessive licking and scratching; self-mutilation; may be unusually aggressive; abnormal locomotion (stumbling, falling); writhing; does not make nest; hiding	Piloerection; rough/stained haircoat; abnormal stance or arched back; porphyrin staining (rats)	Rapid, shallow respiration; decreased food/water consumption; tremors
Rabbit	Head pressing; teeth grinding; may become more aggressive; increased vocalizations; excessive licking and scratching; reluctant to locomote	Excessive salivation; hunched posture	Rapid, shallow respiration; decreased food/water consumption

No single observation is sufficiently reliable to indicate pain; rather several signs, taken in the context of the animal's situation should be evaluated. The signs of pain may vary with the type of procedure (e.g., orthopedic versus abdominal pain) (National Research Council, 2003)

behavior, and hemodynamic parameters) (Bourque et al., 2010; Goulding et al., 2010; Lamon et al., 2008; McBrier et al., 2009; Valentim et al., 2008). These studies have demonstrated varying effects on parameters of interest, including no effect. Therefore, rather than assuming that analgesics cannot be given, it is recommended that a literature search be conducted to determine if studies have been done to validate the existence of an effect of analgesia on a given experimental parameter. If data do not exist, consideration should be given for conducting and publishing an appropriate study to indicate which analgesics are, or are not, a viable scientific option for future experiments. Investigators should be required to provide scientific justification for withholding analgesia when potentially painful procedures are to be conducted.

Defining distress in animals has proven to be a difficult task. The ILAR Committee on the Recognition and Alleviation of Distress in Laboratory Animals stated “Although most definitions of distress characterize it as an aversive, negative state in which coping and adaptation processes in response to stressors fail to return an organism to physiological and/or psychological homeostasis, philosophical differences center on the inclusion of emotions and feelings affected by this state of being.” (Committee on Recognition and Alleviation of Distress in Laboratory Animals, 2008).

Stress has been defined as “the biological response an animal exhibits in an attempt to cope with threats to its homeostasis” (Stokes, 2000). This response can involve immunologic, metabolic, autonomic, neuroendocrine, and behavioral changes (Moberg, 2000). The type, pattern, and level of the response depend upon the strength, severity, intensity, and duration of the stressor(s). The aversive state of distress results when an animal is unable to adapt. By limiting the frequency, strength, severity, intensity, and/or duration of the stressor(s), it may be possible to limit the level of distress in the animal. One method is to reduce the cumulative stress an animal experiences (allowing recovery or adaptation to a given stressful situation before adding additional stressors) or refining practices and procedures to make the individual stressors less severe or shorter.

The use of humane endpoints contributes to refinement by providing an alternative to experimental endpoints that result in more severe animal pain and distress. Scientific or experimental endpoints are defined as occurring when the objectives of the study have been reached. Humane endpoints occur at the point at which pain or distress is prevented, terminated, or relieved in an experimental animal. In most studies, the scientific and humane endpoints occur at the same time, in other words, the scientific endpoint occurs prior to the development of pain or distress. Studies that may result in severe or chronic pain or significant alterations in the animal’s ability to maintain normal physiology, or

adequately respond to stressors, should contain descriptions of appropriate humane endpoints or provide science-based justification as to why a particular, accepted humane endpoint cannot be employed. Veterinary consultation must occur when pain or distress is beyond the level anticipated in the protocol description or when interventional control is not possible (National Research Council, 2011). Most of the ethical principles guiding humane animal research mention the use of humane endpoints (Bankowski, 1985; Council for International Organizations of Medical Sciences, 1985; Interagency Research Animal Committee, 1985). Stokes (2000, 2002) provides an overview and reviews specific situations where endpoints are appropriately utilized.

The need, criteria, and timing for humane endpoints should be part of pre-study planning and are often best done as a research team including scientists, technicians, and veterinarians (Canadian Council for Animal Care, 1998; NRC, 2003; Organisation for Economic Co-operation and Development, 2000). Endpoints are an important element of IACUC protocol review. Therefore, it is essential that a protocol contain all appropriate information regarding the criteria for humane endpoints, observation schedules, and training of personnel to adequately observe for the agreed-upon criteria. Pilot studies may be useful for gathering this information if it is not known at the time of protocol submission. In addition, the criteria and other details may need to be modified when unexpected adverse events occur. The IACUC should be notified when this happens and the protocol amended as needed.

Development of criteria for humane endpoints may be general and applied to any study. Institutions often adopt standards or policies that cover situations when study-specific endpoints have not been determined. These documents often appear as Standard Operating Procedures (SOPs) or guidelines, and may be developed and instituted by the IACUC, the veterinary staff, the institutional administration, or any collaboration of the above. The policies should encompass generic clinical or behavioral conditions that potentially are associated with pain and distress, and should be widely recognized and accepted by the research staff. General clinical signs which may be monitored include: weight loss, inability to ambulate adequately to obtain food and/or water, and body condition scores (Figure 1.1) (Hickman and Swan, 2010). Anorexia or lack of appetite is a significant observation since parenteral supplementation in rodents is not commonly used. In some cases in these species, clinical abnormalities are only obvious when advanced illness, toxicity, or impending death (e.g., a moribund state) are reached (Toth, 2000). In these situations, decisions to initiate humane endpoints must be made promptly.

FIGURE 1.1 System for body condition scoring (reproduced with permission from Hickman and Swan, 2010).

In some cases, humane endpoints may be developed for a specific type of study (Dennis, 2000; Montgomery, 1987; Olfert, 1996; Olfert and Godson, 2000; Sass, 2000; Workman et al., 2010) or a specific individual study (Hickman and Swan, 2010; Singh et al., 2010). The use of scoring systems has been described and usually utilizes multiple observations which, in total, identify the humane endpoint (Lloyd and Wolfensohn, 1998; Medina, 2004; Morton, 2000). Other systematic approaches to determining humane endpoints have also been reported (Medina, 2004; Morton, 2000). There are excellent references available that review the establishment and use of humane

endpoints to avoid death as an endpoint (National Research Council, 2011).

To be prepared for situations when unanticipated pain and distress occur, the institution should have sufficient veterinary oversight in place to advise when alleviation of negative consequences from experimental procedures should be addressed. This may result in animals receiving veterinary medical care, removal from the experiment, or euthanasia to best align with the scientific objectives of the research. These decisions are ideally made through a collaborative discussion including animal care, scientific, and veterinary staff. However, in cases where the animals are significantly compromised, the veterinarian is obligated to take whatever actions are necessary for animal welfare. When multiple animals receiving the same treatment exhibit severe adverse effects, consideration should be given to adjusting the endpoint in the remaining animals or euthanizing an entire treatment group if experimental objectives can no longer be achieved.

Refinements in husbandry and handling (e.g., provision of species-appropriate enrichment, positive humane interaction and operant training to minimize stress in handling and sample collection), are also ways in which distress and other negative impacts can be minimized. Refinements of handling that may seem minor (e.g., picking up a mouse by using a plastic tunnel or cupped hand instead of the traditional method of grasping the base of the tail) (Hurst and West, 2010) can have significant impact, particularly when applied to a large number of animals.

Many refinements in husbandry rely on a good working knowledge of the ethology (study of animal behavior, generally under natural conditions) of the animal species used. The knowledge of normal species-specific behavior is necessary to recognize abnormal behavior and to create an appropriate environment. But consider an animal's natural environment – what is natural for mice and rats that live in forests, rural areas, and urban environments? Some species are highly adaptable, thus attempting to recreate a natural environment in the laboratory may not only be impractical, but difficult to even define. In addition, most of the rodents and rabbits used in research today are purpose-bred and have been for many generations. The ethograms for such animals would be expected to be different from their wild counterparts (e.g. it would be expected and desirable that rodents and rabbits habituated to humans would be less fearful and easier to handle). However, animals bred for research may retain, and attempt to exhibit, certain intrinsic behaviors. Knowledge of those behaviors can help the laboratory animal scientist develop practical strategies to maximize those behaviors and minimize stress.

When considering the stressors in the laboratory animals' environment, one must consider not only

individual stressors, but also the potential cumulative effect of multiple stressors and plan activities accordingly (Committee on Recognition and Alleviation of Distress in Laboratory Animals, 2008). For example, a laboratory mouse will have been exposed to multiple stressors, such as weaning, transport, and a new environment before it even reaches the laboratory. Allowing adequate time for animals to acclimate to their new environment and recover from these stressors is not only good for animal welfare but good for science (Conour et al., 2006).

Additional stressors may include husbandry and care. For example, most rodent and rabbit species are highly olfactory and loss of their olfactory cues when given a completely clean cage is a stressor (Duke et al., 2001; Sharp et al., 2002). Implementing methods that minimize this impact, such as transfer of the animal along with some nesting material, enrichment device, or at least the same cage mates has been suggested as a means to help mitigate the stress.

Most rodents are nocturnal, yet husbandry and experimental activities are usually performed during the sleep cycle. Reverse light cycles may be an alternative that could reduce the stress to animals of having procedures conducted during the sleep cycle, but most husbandry and research procedures are difficult to perform in a red light environment.

Laboratory rodents and rabbits originated as prey species and thus are not, by nature, comfortable with handling and restraint. Some degree of habituation may be desirable in some species (Moynihan et al., 1992). Positive reinforcement after such handling and restraint has been shown to aid tractability in some species, however there is little published about the use of this technique in rodents and rabbits, and so its use is based upon extrapolation and empirical observations.

The environment in which an animal is housed also impacts on its welfare, and assuring that the environment addresses the physical and behavioral needs of the animal can minimize negative impacts on welfare. Failure of the environment to meet the animal's needs can have a negative impact on both animal welfare and can affect scientific validity of the research (Garner, 2005; National Research Council, 2011; van Praag et al., 2000; Wurbel, 2001). An animal's environment consists of the physical environment and the social environment. Within the physical environment there are many variables, such as temperature, lighting, noise, and primary housing. Discussion here will be limited to that aspect of primary housing considered environmental enrichment. Within the animal's social environment the primary consideration is individual versus social housing.

The goal of environmental enrichment is to provide an animal with some choice, some degree of control over

its environment, and to promote species-specific normal behaviors (National Research Council, 2011). Logically, one must understand the specific normal behaviors and how important those behaviors are to the animal. Examples of environmental enrichment for rodents and rabbits include: (1) elevated shelves (Stauffacher, 1992); (2) shelters for guinea pigs, hamsters, and rats (Baumans, 2005); (3) nesting materials for rats, mice, hamsters, and gerbils (Baumans, 2005); and (4) gnawing material for rats, gerbils, hamsters, and rabbits (Baumans, 2005; Patterson-Kane, 2003). It is important to note that enrichment can, under some circumstances, lead to negative consequences such as increased aggression (Marashi et al., 2003). Further, the response to enrichment may be strain-specific (Nevison et al., 1999; van de Weerd et al., 1994).

To determine the most appropriate social environment for an animal, the species-specific social behavior must be known and the needs of the experiment must be accommodated. It has been demonstrated that group housing of social species such as most rodents and some rabbits is beneficial to the animal and minimizes stress (Hall, 1998; Spani et al., 2003; Van Loo et al., 2001, 2007). Some species and/or genders have a higher risk of incompatibility, such as with male mice of some strains (Jacoby et al., 2002), and adult male rabbits (Suckow et al., 2002). Risk of incompatibility can be reduced if animals are grouped and raised together from a young age, if group composition remains stable, and if the environment is designed to allow escape and minimize competition for resources (National Research Council, 2011). In addition, socially housed groups should be monitored for early signs of aggression and separated if necessary (National Research Council, 2011).

Some potential impacts of an enriched environment on research have been known for decades. For example, enhanced performance on complex learning was reported in rats housed in a more "stimulating" environment (Bingham and Griffiths, 1952; Forgays and Read, 1962). The effect of enrichment on variability of research results has been argued as both increasing variability (Mering et al., 2001; Tsai et al., 2002, 2003) and not affecting variability (Wurbel, 2000). Positive human interaction costs little and it is hard to imagine a negative effect on research outcomes. Therefore, this is only an ethical issue if it does not happen. Operant conditioning does require staff time and thus may only be appropriate for those studies in which procedures are going to be done frequently, or are potentially harmful enough to make the time investment worthwhile. When examining environmental enrichment, in addition to investigating real or potential effects on research, the impact on data obtained from an animal that is more highly stressed if unable to perform normal behaviors must also be considered.

Instituting changes in the environment may affect the ability to compare research results with historical data. In that case, more animals may be required; and this must be balanced against continuing to house animals in environments which do not maximize animal welfare. Who decides what is practical? Literature searches and pilot studies may be helpful in this decision. In summary, enrichment and social housing is not a “one size fits all” and it is important to balance the science with the well-being of the animals (Bayne, 2005; Weed and Raber, 2005). Decisions of where to balance such potentially conflicting interests benefit from consideration of the ethical principles discussed elsewhere in this chapter.

Once various forms of refinement have been applied, how can it be determined if animal welfare has been enhanced? In other words, how can it be determined if the refinement is successful? Assessment of animal welfare can involve examination of physiology, behavior, and gross appearance of the animals. Some physiologic measurements relevant to animal welfare involve indicators of stress, such as levels of corticosteroids and glucose. Blood sampling can cause elevations in stress indicators making interpretation difficult. Instead, the use of fecal corticoid has been reported as a non-invasive, less distressful alternative (Bamberg et al., 2001; Cavigelli et al., 2005). Assessment of reproduction parameters such as number of litters, pups per litter, and number and weight of pups weaned may provide indicators of the level of animal welfare for animals maintained as part of a breeding colony. Behavior and gross appearance are often assessed using scoring systems which, after appropriate training of the observers, can provide readily accessible and reproducible assessments of animal well-being (Lloyd and Wolfensohn, 1998; Lloyd et al., 2000; Morton, 2000). It is worth noting that body weight alone as a measure of animal well-being can be deceiving if the animal is young and in a growth phase, or bears an experimental tumor burden, as these situations often are characterized by changes in body weight that may mask those associated with well-being. Body condition scoring has been advocated as a non-invasive technique to assess health status and well-being (Figure 1.1) (Hickman and Swan, 2010).

ETHICAL CHALLENGES

Some studies, due to their potentially significant animal welfare costs, present a particular ethical challenge to research, husbandry and veterinary staff as well as IACUCs. In such cases, small pilot studies are an option and may help demonstrate whether the procedure will have adverse effects, allowing development of appropriate timelines for observation, treatments, or other interventions, and defined endpoints. Pilot studies are

often done in collaboration with the veterinary staff with reports back to the IACUC prior to approval of a full study.

When considering ethical challenges in the research environment, the authors suggest the following general approach:

- Determining what questions should be asked – some specific examples are found in this chapter. However, this chapter does not offer an exhaustive list but should help get the discussion started.
- Determining the the best approach to answer the questions. Often, solutions to ethical challenges emphasize the importance of a team approach. The collective judgment and cooperation of all members of the research team: scientist; veterinarians; technicians; and the IACUC are important (National Research Council, 2003; Organisation for Economic Co-operation and Development, 2000).
- Deciding who should make decisions with respect to the ethical merit of a study and experimental design. Sometimes regulations and guidelines will dictate who has responsibility for a final decision. For example, regarding the health and welfare of the animals, in the U.S., the attending veterinarian is responsible (Office of the Federal Register, 2002). The person responsible for the technical conduct of a study, is typically the Study Director (Organisation for Economic Co-operation and Development, 2000), though in other circumstances, it may be the Principal Investigator. In still other situations, it may be the enterprise conducting the study that makes the decision. However, in all these cases, the IACUC has the final authority to approve, disapprove, or suspend a study that has previously been approved (National Research Council, 2011; Office of the Federal Register, 2002; Office of Laboratory Animal Welfare, 2002).
- Identifying or developing specific policies that help the decision-making process. The purpose of a policy is to create and document a consistent response to a particular type of situation. Use of an existing policy is an approach to consistently apply defined criteria to all actions by personnel. The ethical principles discussed in this chapter should serve as a basis for development of policies.

To further illustrate this process and application of principles already discussed, examples of common situations presenting ethical challenges are described below.

Breeding Colonies

In addition to many technical challenges, maintenance of rodent breeding colonies can present ethical challenges. Among these are minimizing animal

numbers (prevention of overbreeding), breeding paradigms (monogamous pairs, trios, harem mating), and identification of pups.

Since the rationale for animal numbers is part of the ethical review of the IACUC (reduction) the IACUC should require a justification for the number of breeding animals that will be maintained based upon the numbers of offspring that will be used in the study. Examples of methods to calculate these numbers are available (White, 2007). There is an expectation that institutions will establish mechanisms to document and monitor the number of animals produced and used in research protocols (Office of Laboratory Animal Welfare, 2006, revised 2009). Monitoring these numbers will alert the IACUC if an overproduction will predicate excessive euthanasia of animals.

Ethical concerns may also arise in some breeding schemes where multiple females produce litters in the same cage. This may help pup survival since cross nursing often occurs; however, if multiple litters of various ages are in a cage, older, stronger pups may result in high mortality rates in newborns.

Methods of animal identification are sometimes a concern, particularly for breeding colonies where large numbers of animals need to be identified. There are several ways to identify a rodent if individual identification is necessary. For example, ear notching or application of ear tags, tattoos, and subcutaneous transponders are all relatively non-invasive. In contrast, toe-clipping is an invasive method of identification sometimes used for small rodents that would likely cause distress to the animal; thus, toe-clipping should be used only when no other individual identification method is feasible, although it may be the preferred method for neonatal mice up to 7 days of age, especially if dually used for genotyping, as it appears to have few adverse effects on behavior and well-being at this age (Castelhano-Carlos et al., 2009; Schaefer et al., 2010). If toe-clipping is used, the procedure can be refined by use of aseptic practices and use of anesthesia or analgesia appropriate to the age of the animals (Hankenson et al., 2008, National Research Council, 2011).

Genetically Modified Rodents

The use of genetically modified (GM) rodents (particularly mice) continues to increase. The use of GM rodents offers some unique opportunities to enhance animal welfare and the 3Rs. With careful phenotyping, early indicators of disease may replace the need for development of more serious clinical disease in animals (Brown and Murray, 2006). However, creation and use of GM rodents also raise some distinct ethical/animal welfare questions. Wells et al. (2006) summarized useful current practices, with recommendations for best practices.

Ethical issues may arise in the three phases of establishing and using genetically engineered rodents – the development, production, and/or research use (National Research Council, 2011). In the development of these models, one must consider if it is necessary to have a full spectrum of clinical disease versus the possibility that research questions might be answered with animals having a milder form of the disease or perhaps even having metabolic or biochemical changes in which there are no symptoms at all. The biotechnological procedures related to transgenesis (i.e., microinjection, in vitro culture, embryo transfer) have no significant effect on the normal development of the mice in the post-weaning period, suggesting that the techniques themselves would not be of great ethical concern related to animal welfare (van der Meer et al., 2001).

As the animals are phenotyped during the development phase, animal welfare assessments should be made at various ages. The welfare assessment should include a range of non-invasive indicators. In the neonate, these include skin color, activity, and presence of the milk spot; and, at weaning and in the adult these include appearance, size, coat condition, posture, gait, activity levels, interaction with the environment, and clinical signs. The welfare assessments may be carried out using a checklist as a prompt or reminder (Wells et al., 2006). Additional strategies to refine the development of these animals have been described (Brown and Murray, 2006).

Once the GM model has been developed, one should take what has been learned with respect to the phenotype to determine the optimal housing and breeding strategy. An example of a housing concern would be the need for husbandry modifications if the phenotype involved immunodeficiency, either anticipated or not. Development of breeding strategies for GM animals often requires balancing the animal welfare concerns with the detrimental phenotype and the numbers of animals being produced. (Dennis, 2000).

Both the development and production stages of genetically modified rodents need to assess genotype through DNA analysis. Although many protocols for collecting DNA for genetic testing have been proposed, a study using real-time quantitative polymerase chain reaction (qPCR) analysis to quantify DNA extracted from fecal pellets, hair, buccal swab samples, ear punch samples, and tail biopsy samples found that 2-mm tail biopsy samples yielded significantly more DNA than did the other sources (Garzel et al., 2010). Of course, obtaining the needed samples requires amputation of a terminal section of the tail, a procedure that could impact animal well-being, thus requiring thoughtful consideration. In a study of tail vertebral ossification and behavioral response to tail biopsy, the findings of Hankenson et al. (2008) support the collection of 2 mm

of tail tissue before 17 days of age unless anesthesia or analgesia is provided.

Most of the special considerations involving genetically modified animals are found in the development and production phases of model establishment (Brown and Murray, 2006). Once the animals are in actual use in a research protocol, the ethical questions (i.e., justification of animal numbers, minimization of pain and distress, etc.) would be the same as for any protocol for animal use.

The welfare of GM animals can be enhanced by sharing full documentation of all aspects of the phenotype with all scientists using the animals. Information should be used to create a “welfare profile”, specific to the particular GM line; and templates for the recommended welfare assessment scheme and a “rodent passport” have been developed (Wells et al., 2006). Such sharing of information allows optimal care of the GM animals and planning of experiments.

Cancer Research

The use of animals is essential in understanding the fundamental mechanisms of malignancy and to discover improved methods to prevent, diagnose, and treat cancer. An excellent summary of standards and recommendations for animal care and use in cancer research by Workman et al. (2010) will serve as a basis for this topic. The recommendations include: (1) consideration of study design, statistics, and pilot studies; (2) choice of tumor models (e.g., genetically modified, orthotopic, or metastatic); (3) therapy (including drugs and radiation); (4) humane endpoints (including tumor burden and site); and (5) publication of best practices.

As with other examples of ethical challenges, when designing studies with tumors of unknown *in vivo* growth characteristics, pilot tumor growth studies using small numbers of animals can establish reproducibility of local and metastatic growth. Such small-scale studies can also highlight adverse effects associated with tumor progression allowing development of observation and treatment strategies and allow identification of humane endpoints. For metastatic models, pilot experiments should define the extent and time course of dissemination to internal organs. The use of biomarkers, imaging, and measurement of circulating tumor cells using fluorescence and PCR-based techniques can facilitate determination of humane endpoints in these studies (Glinskii et al., 2003; Komatsubara et al., 2005). Use of aseptic technique, anesthetics, and post-implantation analgesia are recommended for implantation of tumor material as a means of refinement. For injection of cell suspensions, the minimum number of cells in the smallest volume should be used, consistent with the properties of the tumor. Implantation of tumor material into the muscle

requires special justification as it is more likely to affect mobility and cause pain. Footpad injection, which has been traditionally used to potentiate lymphatic dissemination, is generally considered to be unacceptable without exceptional scientific justification and should then only involve a single paw (Workman et al., 2010). When procedures are used to improve tumor take rate (e.g., moderate doses of whole-body irradiation), the added potential impact on animal welfare should be considered.

As a means to reduce the number of animals, studies designed to identify tolerable doses of experimental therapeutics to be used in subsequent efficacy trials, typically use two mice per dose level with a doubling dose-escalation or dose-halving de-escalation. One must balance the potential need for more animals, with reduced toxicity when the dose-escalation design versus the need for fewer animals but chances for increased toxicity when the de-escalation design is used. Animals should be closely monitored, and often they should be examined at least twice daily. When performing studies in which a combination of agents is used, care needs to be taken with respect to individual drug doses and scheduling, particularly if overlapping toxicities are likely.

In vitro and *in silico* pharmacokinetic methods are useful to predict absorption, distribution, metabolism, and elimination (ADME) properties and to help prioritize compounds for evaluation in animals (Singh, 2006). However, at present such methods are unable to predict accurately the full pharmacokinetic profile of an agent. Pharmacokinetic studies should use a validated and sufficiently sensitive detection method, ideally avoiding the need to pool separate blood samples, thereby minimizing animal usage (Workman et al., 2010). Repeat sampling of small volumes of blood from a superficial vein in mice over a series of time points has been established as a way to reduce animal numbers (Abatan et al., 2008; Barfield et al., 2008). In rats, a 5–8 time-point pharmacokinetic profile may be generated using 2–6 animals in total, through repeated blood sampling. “Cassette dosing”, which involves administration of low doses of compound mixtures, should also be considered initially as this can reduce animal usage (Watanabe et al., 2006). Wherever possible, computational compartmental kinetic modeling should be used to predict optimal doses or to design multiple dosing protocols which facilitate more limited sampling (Rowland and Tozer, 1995).

Initial studies of investigational therapies using tumor-bearing animals should aim to determine whether the target, or an appropriate downstream pathway or phenotype, is modulated by using suitably validated pharmacodynamic biomarkers (Collins and Workman, 2006). Simultaneous measurement of drug concentrations and mechanistic biomarkers is recommended to reduce animal numbers and establish

a pharmacokinetic–pharmacodynamic relationship (Workman et al., 2010).

Some cancer studies may involve radiation treatment. In such cases, there is potential for injury to the animal. For example, damage to the skin may occur. Should moist desquamation occur, this should not be allowed to persist for more than 24 hours (Workman et al., 2010). When ulceration occurs, if there is evidence of infection and/or no evidence of tissue repair the animal should be euthanized. A common outcome of radiation exposure is pulmonary fibrosis, and close monitoring of respiratory rate has been recommended as a means to detect symptoms before they become distressful to the animal (Jackson et al., 2010).

Commonly used in studies related to cancer research, intravital microscopic imaging uses a wide variety of optical imaging techniques, often incorporating fluorescent or bioluminescent genetic reporters or markers, including nano-particles (Hoffman, 2005). This method has particular animal welfare issues because it involves surgery to provide optical clarity and visualization on a microscope stage or by using fiber-optic light guides (Weissleder and Pittet, 2008). Surgical implantation of “window” chambers for tumor implantation enables imaging to be performed over days to weeks (Brown et al., 2001; Dewhirst et al., 1987; Lehr et al., 1993; Reyes-Aldasoro et al., 2008). When window chambers are used, general anesthesia is only essential for the initial surgery and imaging may be performed with restrained animals. Strict aseptic technique and good post-operative care and analgesia are essential to optimize animal welfare for all survival surgery (Flecknell, 2008; Richardson and Flecknell, 2005). The potential for development of hypothermia during anesthesia, maintenance of physiologic stability, and exposure to potential pathogens in imaging centers should be considered when developing methods for imaging of animals.

As with all studies, humane endpoints need to be defined for studies involving cancer models. Early endpoints reduce non-specific systemic effects of debilitation and so may increase the precision of the results obtained (Workman et al., 2010). Pilot studies, including autopsy to determine the full extent of tumor growth, will facilitate the definition of robust and refined endpoints. Workman et al. (2010) described general suggestions for endpoints appropriate to some commonly used animal cancer models. The intentional use of death as an endpoint is unacceptable and animals should not be allowed to become moribund unless strong scientific justification is provided.

The anatomic site for implantation of solid tumors will influence the maximum acceptable tumor load and the appropriate humane endpoints. Tumors or cancer cells implanted at sites such as the footpad, tail, eye, or bone are likely to be painful or distressful and require

special justification and earlier endpoints. Similarly, tumors that metastasize to sensitive sites need special consideration (Workman et al., 2010). For example, if tumors in the brain are to be studied, body weight loss is reportedly a sensitive endpoint (Redgate et al., 1991); and MRI or bioluminescent imaging (BLI) techniques can be very useful to assess tumor progression (McCann et al., 2009; Ragel et al., 2008; van Furth et al., 2003).

When determining endpoints, tumor size and burden should be considered. Tumor burden should always be limited to the minimum required to answer the scientific question (e.g., efficacy studies should be terminated once statistically significant therapeutic effects are demonstrated and minimal tumor loads for controls should be designed into therapeutic studies). When assessing the size of superficial tumors, measurement using calipers (usually of two diameters at right angles) is an easy and definable method. For example, when only a single tumor is present, the mean diameter should not normally exceed 1.2cm or 2.5cm in mice, or 1.5 and 2.8cm in rats. Where multiple tumors are present, for example in contralateral flanks, the size should be correspondingly less and the combined diameters should not exceed the maximum burden of a single tumor. Due to the difficulty in determining tumor burden of internal orthotopic cancers, systemic lymphoreticular tumors or metastatic disease, the data obtained in pilot studies allow characterization of the kinetics and patterns of spread, prediction of clinical signs and help define humane endpoints. The use of biomarkers or circulating cancer cells, as previously mentioned, also can be helpful to estimate tumor burden.

Perinatal Animal Use

Perinatal research has given science a better understanding of conditions such as autism, learning disabilities, and fetal alcohol syndrome. Fetal studies must consider the welfare of both the fetus and the mother. There are conflicting opinions on the ability of a rodent or rabbit fetus to experience pain. It has been reported that in precocial young, the fetal brain is too immature initially to support sentience of any state resembling consciousness and when sentience occurs, the animal is maintained in a sleep-like state of unconsciousness controlled by neuroinhibitory factors in the in utero environment (Mellor et al., 2005). The neurologic development necessary for the conscious perception of pain occurs at about 80% of the pregnancy time progression. After that point, it is likely that the perinatal animal can perceive pain if aroused from its unconscious state by noxious stimuli. In altricial young, neurologic immaturity persists throughout pregnancy. However, other studies report that rat fetuses at day E19 showed behavioral responses to an irritating substance (formalin) injected into one

paw which correlates to the expression of c-fos protein (an indicator of neuronal activation) in the spinal cord at day E20 (Yi and Barr, 1997). The *Guidelines for the Care and Use of Mammals in Neuroscience and Behavioral Research* (Committee on Guidelines for the Use of Animals in Neuroscience and Behavioral Research, 2003) advises anesthesia for potentially painful procedures in late-term fetuses (days 19–20 in the rat). However, consideration should be given to the potential effect of in utero drug exposure on physiologic and behavioral development of the fetus (Niesink et al., 1999; Rodier et al., 1986).

There are similar conflicting reports for neonatal rodents. Murrell et al. (2008) report that at 3–14 days of age, REM–non-REM differentiation occurs and there is EEG evidence of conscious wakefulness. In another study, rat pups exhibited behavioral arousal and withdrawal to noxious thermal and mechanical stimulation at 1 day of age (Barr et al., 1992). At 3 days of age, rats showed allodynia and hyperalgesia in response to induced inflammation (Abbott and Guy, 1995).

Neonatal exposure to noxious stimuli has been shown to cause alteration of the developing central and peripheral nervous systems (Bhutta et al., 2001; Mellor et al., 2005), and this may justify the use of anesthesia and/or analgesia even if the neonate is unconscious and unable to experience pain.

The many neonatal physiologic differences versus adults (such as blood–brain barrier permeability, immature hepatobiliary system impacting on drug metabolism, and hypoxia-induced bradycardia) affect the response to anesthetics, analgesics, and euthanasia. Inhalation anesthesia is recommended for neonates when possible. Hypothermia has been reported as safe and effective as the sole method of analgesia for altricial rodents up to about the age of 7 days (Danneman and Mandrell, 1997). However, rapid cooling of non-protected flesh is painful (Wolf and Hardy, 1941) and rats recovering from hypothermia (but not rats recovering from inhalation anesthesia) emit ultrasonic vocalizations during recovery (Hofer and Shair, 1992).

Pups should have regained their righting reflex prior to putting them back with their mother. Strategies such as smearing the pups with bedding and urine of litter mates and temporary fostering have been suggested to minimize chances of cannibalism and neglect when returned to the mother (Committee on Guidelines for the Use of Animals in Neuroscience and Behavioral Research, 2003).

Neuroscience and Behavioral Research

Food and Fluid Restriction

One of the “Five Freedoms” for animals as noted earlier is the freedom from hunger and thirst. Food or water deprivation (beyond that necessary for normal

presurgical preparation) is considered to be a procedure that may cause pain or distress (Animal and Plant Health Inspection Service, 1997).

Food and/or water may be restricted for the purpose of looking at homeostatic regulation, studying motivated behaviors and physiologic mediators of hunger or thirst and/or to motivate animals to perform novel or learned tasks (Toth and Gardiner, 2000). In “the case of conditioned-response research protocols, use of highly preferred food to fluid as positive reinforcement, instead of restriction, is recommended” (National Research Council, 2011). If restriction is necessary, it is recommended to use the “least restriction necessary to achieve the scientific objective while maintaining animal well-being” (National Research Council, 2011).

Sensitivity to food restriction is increased by single housing of animals and by feeding during the illumination phase of the light cycle (Hotz et al., 1987; van Leeuwen et al., 1997). The risk to animals on fluid restriction is reduced if periods of access and total amounts available match the animal’s typical watering schedules and circadian variable (Toth and Gardiner, 2000).

When designing or reviewing these types of studies, examples of questions which should be answered are: (1) What is the proposed schedule of food and water access? (2) Does the schedule take into account the circadian rhythm of feeding? (3) Will the diet provided avoid unintended nutritional imbalances? (4) How will the animals be acclimated to the reduced feeding/watering schedule? (Toth and Gardiner, 2000). Further, additional questions to be answered might include: (1) What is the proposed schedule for monitoring and what does it include (behavioral and physiologic monitoring) to assure that any adverse effects will be promptly recognized? (2) What are the plans for record keeping of daily food or water intake, hydration status, animal appearance, and routine weighing to help adverse effects? and (3) What are the endpoints for intervention (usually with supplemental nutrition and/or hydration)?

Neuroanatomic Studies

Anatomic studies are done for the purpose of studying cellular organization or chemical composition of specific brain lesions. These studies typically use tracer substances to label neural pathways or techniques to create lesions to destroy discrete areas of the brain using electrolytic and radiofrequency techniques as well as neurotoxins. Both approaches generally involve the use of a stereotaxic surgery.

Examples of questions which should be answered are: (1) What is the extent of the clinical impairment that the injection or lesion may cause? (2) What are the chemical properties of the substance injected (e.g., sterility, toxicity, inflammatory response)? (3) Will aseptic technique be used for all injection and lesioning procedures?

(4) What complications might arise from any surgery and how will they be monitored and treated? and (5) Will an implanted device (cranial implant or chamber) be required? If so, it is recommended that the animal be conditioned to the training prior to surgery to avoid surgery in animals that do not adapt to training ([Committee on Guidelines for the Use of Animals in Neuroscience and Behavioral Research, 2003](#)). Will multiple major survival surgeries be done? If so, why; under what circumstances; and when and by whom will it be determined that euthanasia is most appropriate?

Neural Injury and Disease

These types of studies include degenerative diseases such as Alzheimer disease, traumatic injury, infectious disease, pain, and neuroimmunologic neurodevelopmental and psychiatric disorders.

Some factors which will refine these studies include: easier access to food/water; provision of highly palatable, highly nutritious feed; promotion of urination and defecation through the use of massage and laxatives; maintenance of fluid balance; provision of additional bedding; and administration of analgesics or tranquilizers, particularly for studies involving injury or pain. The duration and severity of the condition should be limited to the least amount of time necessary to achieve scientific objectives. As with all studies using animals, intervention on behalf of the animal (i.e., palliative care and treatment, euthanasia) must be identified prior to the start of the study.

When induced lesions of the nervous system are used to create animal models, the clinical consequences can sometimes be refined through the use of reversible lesions. In this technique, the target structure can be temporarily deactivated during different states of the assessment of learning and memory. The clinical consequences of other lesions may be reduced by making unilateral, instead of bilateral, lesions ([Tolwani et al., 1999](#)). Some neurectomy and deafferentation lesions can result in autotomy (self-mutilation). This may be minimized through the use of local anesthetic at the time of lesioning ([Magnusson and Vaccarino, 1996](#)). When designing and reviewing these types of studies it is important to know the expected clinical course of the disease/injury and what intervention or clinical management will be implemented.

Behavioral Studies

These studies generally use appetitive (animal will voluntarily approach) or aversive (animal tries to escape or avoid) stimuli. The same stimuli may be appetitive to some species or individuals and aversive to others. For example, the same dose of alcohol can be aversive in rats but appetitive in mice ([Cunningham et al., 1993](#)). In addition to species, the effects may vary as a function

of genotype, sex, and past experience. These different types of stimuli are necessary because the brain mechanisms, which form the basis of different types of learning and behavior may differ. When deciding which type of stimulus to use, the response variability of species, individuals, and the individual over time must also be considered since there is generally a desire to minimize this variability. Such reduction in variability can serve to reduce the numbers of animals needed. When stimuli are aversive, they are generally considered acceptable if they are well tolerated by the animal and do not produce maladaptive behaviors. If the animal's behavior is dominated by escape-avoidance activity, the behavior is maladaptive, indicating unacceptable levels of pain or distress ([National Research Council, 2009](#)). In situations where the scientific rationale for a motivating stimulus is questioned, one approach may be to perform a pilot study with the proposed stimulus and carefully monitoring the response of the animal, followed by reporting to the IACUC for further consideration.

Behavioral research may call for the use of mazes to study cognitive function (spatial learning and memory) in rodents. Performance in mazes may involve food or water restriction or other stressors which should be considered in determining the overall cumulative stress that a research animal experiences. Due to sensory impairments, lesioned or genetically modified animals may be more likely to experience stress or injury.

Behavioral screening tests (often referred to as functional observational batteries or FOBs) are used in pharmacology, genetics, and health surveillance. These batteries are able to assess multiple behavioral measures. They are justified by the need to evaluate the effect of a drug or chemical on behavior in both humans and animals. This type of testing is sometimes required by regulatory agencies (e.g., FDA or EPA as described in greater detail later in this chapter) ([Weisenburger, 2001](#)). These batteries include sensorimotor and motor tests as well as assessment of anxiety. During these tests, animals should be carefully observed to assure their safety on mechanical devices and to assure minimum duration of the tests consistent with scientific objectives. The degree of anticipated animal impairment should be known, if possible, as tasks may need to be modified. If the level of expected animal impairment is not known, as with other studies mentioned in the chapter, pilot studies are encouraged. And, as with all studies, clear and humane endpoints need to be identified.

Prolonged Restraint and Anesthesia

Restraint of Awake Animals

Restraint of awake animals may occur in a variety of physiological and anatomic studies. To minimize

distress to the animal, restraint devices must be of suitable size and type for the animal involved. Animals must be monitored during restraint periods, and animals exhibiting maladaptive behavior or those which develop lesions should be removed from the restraint and provided veterinary attention.

Animals should be acclimated to the restraint. The duration of restraint should be for the minimal amount of time necessary. The need for prolonged restraint must be scientifically justified.

Prolonged Studies in Anesthetized Animals

Maintaining an appropriate physiological condition in an animal under prolonged anesthesia is a technical challenge. Careful monitoring is essential to assure well-being of the animal. Techniques such as hyperinflation, hydration of inhaled gas, and fluid replacement to help maintain physiologic homeostasis have been described ([Committee on Guidelines for the Use of Animals in Neuroscience and Behavioral Research, 2003](#)).

Some studies require that any self-generated movements by the animal be minimized. This is usually done with some type of neuromuscular blocking drug (NMBD). The primary animal welfare concern is that the usual behavioral indicators of pain and/or distress are then inhibited, thus requiring special considerations to assure adequate anesthetic depth. Adequate anesthesia must be established and verified before the administration of NMBDs to establish and validate the physiological signs that will be monitored in the paralyzed animal. Reducing the level of anesthesia after NMBD administration is strongly discouraged. Even in the absence of other signs, autonomic nervous system changes such as heart rate and blood pressure can be indicators of pain and inadequate anesthetic depth. A trained observer should be present at all times during a prolonged anesthetic procedure because the clinical condition of an animal can change quickly and require intervention ([Committee on Guidelines for the Use of Animals in Neuroscience and Behavioral Research, 2003](#)).

INSTITUTIONAL ANIMAL WELFARE OVERSIGHT

Effective oversight of animal welfare in research, testing and teaching relies on the expertise and collaboration of the senior management of an institution (generally referred to as the Institutional Official or IO in the United States), an appropriately qualified veterinarian with responsibility and authority for the health and well-being of all laboratory animals at the institution and an Institutional Animal Care and Use Committee (IACUC), or equivalent ethical oversight committee ([National Research Council, 2011](#)). In the U.S., the

IACUC's primary role is responsibility for assessment and oversight of the institution's animal care and use program as well as the related facilities. The committee membership is specified by regulations. It is important for research animal users to know which specific regulations apply to their given situation. In general, IACUC membership includes a veterinarian, a scientist, one individual from a non-scientific background, and a public member to represent general community interests. Large institutions with broad research programs may need to choose scientists from a number of disciplines to properly evaluate proposals.

The IACUC provides oversight of animal welfare through its review of animal use protocols and amendments, ongoing review of animal use (often referred to as post approval monitoring or monitoring outcomes), periodic assessment of the animal care and use program and inspection of facilities, assuring personnel working with animals are appropriately qualified and implementation of a process for review of animal welfare concerns. The functions of the IACUC are well described elsewhere ([Anderson, 2007](#); [National Research Council, 2011](#); [Silverman et al., 2007](#)) This section will focus on ethical considerations generated as a result of the protocol review process. The principles of protocol review would be pertinent to both a local review, as would occur in an IACUC, and a remote review, as might occur where regional or national protocol review is required.

The protocol submitted to the IACUC for review must include enough detail to allow a harm or cost/benefit analysis; that is, weighing the cost to the animal against the potential benefit of the study. Clearly, this is a utilitarian approach, with the cost to the individual weighed against the potential benefits to many. Of course, the first question which must be answered is whether animals need to be used at all, or if non-animal alternatives (replacements) can be used to answer the scientific question(s) of the study. There needs to be justification/rationale for the use of animals as well as the species of animal and number of animals. In the authors' experience, to better understand the cost to the animal (implications of the study on animal welfare), the IACUC must understand: the sequential description of the procedures; non-standard housing and husbandry requirements; anticipated adverse clinical effects on the animals; appropriate use of sedation, anesthesia, and analgesia; details of surgical procedures, post-procedural care and observation; a description and rationale for endpoints proposed; criteria and process for timely intervention, method of euthanasia or disposition; and adequacy of training for all personnel involved. Some IACUCs find the use of severity codes or invasiveness levels helpful in both initial and ongoing review.

As previously mentioned, the ethical principles mentioned above are interrelated with dynamic global

regulations, policies, and guidelines. One should bear in mind that regulations and guidelines are evolving and no one text can remain completely current. For example, as this text was being written, a revision of the *Guide for the Care and Use of Laboratory Animals* was released (National Research Council, 2011). The interpretations of this version of *Guide* will continue to progress over time. Compliance with the laws and regulations which govern the use of animals in research is mandatory.

There may conceivably be situations where the law or regulation would require one action but an individual's moral conscience might dictate a different action. In such a case, it may seem that the law is a "bad" law. Violation of a law could potentially lead to a more general disregard for the law and regulations, with resultant great harm. Indeed, some philosophers make the point that disobeying even "bad" laws leads to the tendency to think that one is above the law, leading to wholesale violation of the law (Tannenbaum, 1995).

REGULATIONS AND NON-REGULATORY CONSIDERATIONS

United States Regulatory Considerations

The ethical considerations discussed above have been the basis for many aspects of governmental oversight of the conduct of animal research. Historically, Western societal values have included concern for the welfare of animals. Animal welfare and animal rights organizations have stressed both the rationale and the necessity of laws and regulations that will ensure that animals are handled appropriately. The use of animals in research has been a particularly sensitive and emotional issue, and it is not surprising that extensive legislation has been enacted for the protection of research animals. An overview of the regulatory requirements is presented here.

United States Animal Welfare Act

In the United States, federal laws, regulations, and policies are a critical component influencing the use of research animals. Species covered by the Animal Welfare Act (AWA, 1990) include dogs and cats, non-human primates, rabbits, guinea pigs, and hamsters, aquatic mammals, and, with certain exceptions, any other live or dead warm-blooded animal designated by the Secretary of Agriculture. Birds, rats of the genus *Rattus*, and mice of the genus *Mus* bred for use in research, teaching, or testing, and horses and farm animals intended for use as food or fiber or used in studies to improve production and quality of food and fiber, are specifically excluded. The law clearly states, however, that nothing in the Act should be construed as authorizing the Secretary of

Agriculture to promulgate rules, regulations, or orders with regard to the design or performance of research protocols. It also mandates that the U.S. Department of Agriculture (USDA) may not interrupt the conduct of research during inspections.

The law authorized the USDA to develop and enforce regulations and standards based on the AWA. The regulations, standards, and policies are administered through the USDA, Animal and Plant Health Inspection Service (APHIS), Animal Care (AC) unit.

The complete set of USDA regulations and standards are published in the Code of Regulations (CFR), Title 9, Animals and Animal Products, Subchapter A, Animal Welfare (Office of the Federal Register, 2002). In addition, the USDA has issued the "Animal Care Policy Manual" (http://www.aphis.usda.gov/animal_welfare/policy.shtml) to further clarify its enforcement of the Animal Welfare Act. Each research institution is required to identify an Institutional Official (IO) who is authorized to legally commit on behalf of the institution that the USDA requirements will be met. All research facilities housing regulated species must be registered with the USDA.

The AWA was amended in 1985, specifically to "reflect the importance of the '3 Rs'" (Hamilton, 1991). The 1985 amendment to the AWA required every animal research facility to establish an IACUC as a means to provide oversight of the research facility's program of animal care and use. Congress mandated that the committee include at least three members, with no requirement that research scientists be represented. IACUC members are appointed by the Chief Executive Officer (CEO) of the research facility. The members must possess sufficient experience and expertise to assess animal care, treatment, and practices in experimental research as determined by the needs of the research facility and are to represent society's concerns regarding the welfare of animal subjects. At a minimum, membership must include one doctor of veterinary medicine and one member who is not affiliated in any way with the research facility other than as a member of the IACUC. This member, commonly referred to as the non-affiliated member, cannot be a member of the immediate family of a person who is affiliated with the facility and provides representation for general community interests in the proper care and treatment of animals. In instances where the IACUC consists of more than three members, not more than three members can be from the same administrative unit of the facility.

The IACUC is responsible for conducting a regular review of the animal care and use program. The review, based on USDA regulations, must also include an inspection of all animal study areas and animal facilities at least once every 6 months. An animal study area is defined as a location where animals are housed for more than 12 hours; however, the term is often used to

also include areas where survival surgery is conducted. After each program review and inspection, the committee must file reports of its evaluations with the IO of the research facility.

The IACUC is responsible to review and approve all proposed activities and significant changes in activities related to the care and use of animals, and ensure that all aspects of the research will be conducted in accordance with USDA regulations. All activities must be approved prior to the commencement of the activity. The committee may also suspend an activity if it determines that the activity is not being conducted in accordance with the IACUC-approved procedures. Any suspended activities must be reported to the USDA.

Proposals to conduct an activity or to make changes in an ongoing activity involving animals must provide adequate information to assure that the IACUC can conduct a thorough review. In addition to items previously mentioned, the regulations of the AWA specify that survival surgical procedures must be performed using aseptic technique; appropriate preoperative and postoperative care must be provided, major survival surgery on non-rodents may be conducted only in facilities intended for that purpose under aseptic conditions; any unrelieved pain or distress may continue only for the necessary period of time; and animals that would otherwise experience severe or chronic pain or distress that cannot be relieved must be euthanized during or at the end of the procedure, using methods consistent with the current Report of the American Veterinary Medical Association (AVMA) Panel on Euthanasia.

The regulations require that research activities be performed by appropriately qualified and trained personnel. Specific topics to be covered in the training program are described in the AWA regulations. Scientists are directed to the Animal Welfare Information Center (AWIC) to obtain information on alternatives (the 3Rs). Such database searches are required if painful/distressful procedures are to be conducted ([Animal and Plant Health Inspection Service, 2000](#); [Office of the Federal Register, 2002](#)).

The IACUC is also charged with reviewing, and, if warranted, investigating concerns involving the care and use of research animals through an established reporting procedure. The committee must also establish a mechanism for addressing such concerns.

Each research facility is required to have an attending veterinarian who is authorized to ensure the provision of adequate veterinary care and oversee the adequacy of animal care and use. The veterinarian must have training or experience in laboratory animal science and medicine and have direct or delegated program responsibility for activities involving animals at the research facility. Part-time or consulting veterinarians must provide a written program of veterinary care

and conduct regular scheduled visits to the facility. The veterinarian must be consulted, in advance, if potentially painful procedures are planned, and ensure sedatives, analgesics, or anesthetics are provided, unless withholding them is scientifically justified in writing and approved by the IACUC. The American College of Laboratory Animal Medicine (ACLAM) further defines adequate care, and establishes standards of education, training, experience, and expertise necessary for veterinarians to become qualified as a specialist through board certification ([ACLAM, 1996](#)).

Public Health Service Policy on Humane Care and Use of Animals

The Health Research Extension Act of 1985 (Pub. L. 99-158), Section 495, Animals in Research, establishes standards (Policy) for the proper care and treatment of animals used in biomedical and behavioral research. Any institution receiving support through the U.S. Public Health Service (PHS) for animal research, training, biological testing, or animal-related activities, is required to provide extensive written assurance of their compliance with PHS policy. The assurance statement documents the institution will comply with the PHS policy requirements and provisions of the *Guide* ([National Research Council, 2011](#)). The policy applies to all PHS-conducted or -supported activities involving animals regardless of where they are conducted. The PHS policy requires each IACUC to have a minimum of five members, including a veterinarian, a practicing scientist with experience in research involving animals, a member whose primary concerns are in a non-scientific area, and a non-affiliated member. It allows an individual who meets the requirements of more than one category to fulfill more than one role as long as the committee still has at least five members. The AWA and the 2002 edition of the PHS policy require research institutions to provide training for personnel similar to the AWA. The PHS policy was amended in 2002 regarding the timing of verification of IACUC approval of competing applications or research proposals subsequent to peer review but prior to award (PHS, 2002).

Food and Drug Administration Good Laboratory Practices

In June 1979, the U.S. Food and Drug Administration (FDA) implemented the Good Laboratory Practice (GLP) regulations (21 CFR, Part 58), effective June 1979, and amended in 1987 ([Food and Drug Administration, 2009](#)). Even though the goals of the FDA GLP regulations are intended to assure the quality and integrity of safety data submitted to the FDA in support of an application for a research or marketing permit, they have significant impact on appropriate procedures for the care and use of laboratory animals in safety testing.

An animal care and use program operating under the GLP regulation is a complex and highly regimented situation requiring communication, cooperation, and integrated problem-solving skills that involve multiple units (including quality assurance and pathology) in the facility. It is necessary to maintain a delicate balance to assure all aspects of the program follow both the intention and letter of both the FDA and USDA laws. In brief, the GLP regulations require certain activities and documentation of those activities in minute detail. A summary of the scope of the activities appears here.

Institutions seeking FDA approval of preclinical studies and data must include written protocols, standard operating procedures (SOPs); adequate facilities, equipment, and animal care; properly identified test substances; and meticulous comprehensive records of observations and results. The FDA relies heavily on the quality of documentation. Every study is overseen by a study director, an individual who has ultimate responsibility for implementation of the protocol and technical conduct of the study. The quality assurance unit monitors the conduct of studies and audits every aspect of documentation.

The FDA conducts routine surveillance inspections, data audits, and directed inspections to verify data of pending applications for approval. The FDA may also conduct inspections to investigate potential non-compliance issues, referencing the GLP Act in the animal care and use program. A data audit compares the protocol and amendments, raw data, records, and specimens against the final safety assessment report. Medical records for study animals, only more recently addressed in reporting of data collection, may also be scrutinized by the auditors. Inspection reports are very detailed and objective. There is cooperation with other federal agencies as described below.

Interagency Cooperation

In 1995, authorized representatives of the USDA, NIH, and FDA signed a "Memorandum of Understanding concerning Laboratory Animal Welfare", as instructed by Congress in the AWA ([Office of Laboratory Animal Welfare, 2006](#)). Each agency, operating under its own authority, has specific responsibilities for fostering proper animal care and welfare. This agreement sets forth a framework for reciprocal cooperation which will assist each agency in meeting its responsibilities in promoting proper laboratory animal care and welfare. Implementation of this agreement is intended to maintain and enhance agency effectiveness while avoiding duplication of efforts to achieve required standards for the care and use of laboratory animals.

Features of the Agreement include the promulgation of standards and policies aimed at promoting laboratory animal welfare, the maintenance of

registries/inventories of institutions and facilities subject to agency policies and regulations, the periodic conduct of routine and "for cause" inspections or site visits, efforts designed to promote compliance, and the application of a range of sanctions when necessary. The agreement is renewed every 5 years.

Environmental Protection Agency Good Laboratory Practices

Similar to the FDA, the Environmental Protection Agency (EPA) also has established Good Laboratory Practices (GLPs) for conduct of studies required to register a new pesticide product. The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), enacted in 1947, authorized the administrator of the EPA to register and control the use of pesticides. The EPA conducts a premarket review of potential health and environmental effects, and requires animal tests to be conducted in support of registration. EPA's GLPs differ in some respects from the standards of the FDA. According to the final rules published in 1983, the Toxic Substances Control Act (TSCA) also requires the use of GLP standards for conducting industrial chemical studies required by the TSCA (Environmental Protection Agency, 2002, 2007).

Non-Regulatory Considerations

Institute for Laboratory Animal Research

The Institute for Laboratory Animal Research (ILAR), is a private, non-governmental, non-profit organization that promotes high-quality science through humane animal research and implementation of alternatives. The mission of ILAR is to "evaluate and disseminate information on issues related to the scientific, technological, and ethical use of animals and related biological resources in research, testing, and education" ([Institute for Laboratory Animal Research, 2010](#)). Using reports of expert committees, the *ILAR Journal*, excellent web-based resources, and other means of communication, ILAR functions as a component of the U.S. National Academies to provide independent, objective advice to the federal government, the international biomedical research community, and the public.

The most widely distributed publication from ILAR is the *Guide for the Care and Use of Laboratory Animals* ([National Research Council, 2011](#)), which is recognized by the PHS and the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) as the accepted reference standard on laboratory animal care and use programs. ILAR also publishes the quarterly *ILAR Journal* and important reference documents, including *Occupational Health and Safety in the Care and Use of Research Animals* ([National Research Council, 1997](#)).

Guide for the Care and Use of Laboratory Animals (Guide)

The *Guide* (National Research Council, 2011), written under the auspices of ILAR, applies to all live vertebrate animals, including traditional laboratory animals, farm animals, wildlife, and aquatic animals used in research, teaching, or testing. It emphasizes performance standards, which are less prescriptive and more flexible than engineering standards. The *Guide* also encourages the application of professional judgment when addressing unique circumstances. Recommendations in the *Guide* are based on published data, scientific principles, expert opinion, and experience with methods and practices that are consistent with high-quality, technically and scientifically appropriate, humane animal care and use.

The most recent edition of the *Guide* includes references, and covers the ethics of laboratory animal use; components of effective animal care and use programs; and guidelines for the housing, environment, and enrichment of terrestrial and aquatic animals. Information on biosecurity is addressed, as is information on transportation, pain and distress, euthanasia, and veterinary clinical care. The guidelines regarding institutional policies and responsibilities, personnel and program management, occupational health and safety, and animal facility design and management are essential for developing an effective animal care and use program.

International Regulations, Policies, and Standards

AAALAC, International

The Association for Assessment and Accreditation of Laboratory Animal Care, International (AAALAC) is a non-profit association that conducts voluntary, confidential, peer review, and accreditation of animal care and use programs. AAALAC provides advice and independent assessments to participating institutions and accredits those that meet or exceed applicable standards. AAALAC uses the *Guide for the Care and Use of Laboratory Animals* as a primary reference for program review and evaluation, but it also considers the laws and regulations for the country in which the institution is located. AAALAC also uses other widely accepted standards and references for animal care and use, occupational health, and biosafety. Assessment stresses application of performance standards and professional judgment, rather than inspection and enforcement of engineering standards. The AAALAC website provides information, resources, and links to numerous sources of information regarding accreditation, education, regulations, and IACUC support (AAALAC, 2011).

Canada

The Criminal Code of Canada – Cruelty to Animals Bill, of the federal Criminal Code prohibits anyone from

willfully causing animals to suffer from neglect, pain, or injury, and applies to all animals, regardless of their purpose (Parliament of Canada, 2008).

This legislation is more commonly applied to privately owned animals than those used in research. The Canadian system is primarily based upon a quasi-regulatory system, the Canadian Council for Animal Care (CCAC). Five provinces have enacted their own legislation making it mandatory to comply with CCAC policies. Any research facility in Canada receiving Tri-Council (Canadian Institutes of Health Research-CIHR, Natural Sciences and Engineering Research Council of Canada-NSERC, and Canadian Foundation for Innovation-CFI) funding must adhere to the CCAC Guidelines, including all academic institutions. Institutions importing dogs and non-human primates across the U.S./Canada border must also have a CCAC Good Animal Practice certificate. The Ontario Animals for Research Act is very similar to the U.S. AWA except it covers all vertebrate species, including fish. This is a minimum standards act with unannounced veterinary inspections, additional reporting, and registration requirements. All small companies and businesses must be registered as research facilities to conduct any type of animal research in Ontario (Animals for Research Act, RSO 1990).

The Canadian Council on Animal Care (CCAC), established in 1968, is the national peer review agency responsible for developing and maintaining standards for the care and use of animals used in research, teaching, and testing in Canada. Major Canadian agencies actively support the CCAC's programs to assure ethical and proper treatment of animals used in research. Institutions receiving funding from these agencies must monitor ongoing research involving vertebrates and cephalopods (squid and octopi) and assure compliance with federal and provincial laws, regulations, and guidelines. Participation in the CCAC's assessment program is required, and institutions are required to maintain a valid Certificate of Good Animal Practice confirming compliance with CCAC guidelines and policies. CCAC general guidelines are published in two volumes of *Guide to the Care and Use of Experimental Animals*, available from the CCAC (Canadian Council for Animal Care, 1984, 1993).

In addition, the CCAC published numerous other guidelines and policies which are available on their website, <http://www.ccac.org.ca/>.

European Union

The basis for national legislation on the protection of animals used for scientific purposes is European Union Parliament and Council Directive 2010/63/EU, revised in 2010 (European Union, 2010). One of the main goals of this legislation is to minimize the disparities between member states that arose from the original Directive of

1986. Although member states do have some flexibility, the 2010 Directive and accompanying Appendix, set minimum standards. Once the Directive is fully ratified, member states are given 2 years to develop and implement national legislation which is consistent with the Directive.

In addition to vertebrate animals, cephalopods are also covered, as are fetal forms of mammals in the last trimester of gestation. Consistent with many of the general principles mentioned earlier in this chapter, the principles of the 3Rs are stressed including strategies to use non-animal alternatives when possible, minimize animal numbers, and minimize pain and distress through refinement of procedures, use of humane endpoints, and appropriate euthanasia procedures. For transparency purposes, reporting is required based upon actual severity levels of procedures. These are spelled out in more detail in Annex IX of the Directive. Regular inspections of facilities are also required. There are requirements for adequate training of all personnel. Appropriate veterinary care and the use of an internal animal welfare body (AWB) to oversee animal welfare are also included. Review of projects, including a harm:benefit analysis is conducted by “competent authorities”, usually at the regional or national level.

Chapter II of the Directive covers the provisions on the use of certain animals in procedures. The pertinent items on rodents and rabbits would include those circumstances where animals would be taken from the wild and when use of rodents and rabbits bred for research must be used. Chapter III includes information on procedures such as how methods are chosen, anesthesia, severity classification, reuse, and endpoints. Chapter IV, Section 1 includes requirements for breeders, suppliers, and users and discusses such topics as competence of personnel, veterinary care, details of the AWB, record keeping and, through reference to Annex IV, care and accommodation requirements of animals. Section 2 includes further details on inspections and Section 3 covers requirements for project authorization, and retrospective assessment, often called post approval monitoring. Chapter V discusses avoidance of duplication and alternative approaches. Chapter VI, entitled, Final Provisions, provides information on implementation (EU, 2010).

Particularly important is Annex III, the requirements for the care and accommodation of animals. This Annex begins with a general section covering such things as facility design, environment, health care, handling, and husbandry. This is followed by Section B, the species-specific section, where tables provide details on enclosures, exercise where appropriate, weaning, and other topics. Annex IV covers methods of killing animals and includes a detailed chart of accepted methods by species.

Pacific Rim

AUSTRALIA

Australian animal welfare legislation is established by each state and territory, with guidance from the Australian National Health and Medical Research Council. The Council provides resources and oversight through the Animal Welfare Committee, regarding issues pertaining to the conduct and ethics of using animals for scientific purposes. A model code of practice, *The Australian Code of Practice for the Care and Use of Animals for Scientific Purposes* is prepared by the Animal Welfare Committee and is available from each state and territory to set minimum animal welfare standards (Australian National Health and Medical Research Council, 2004). The Australian and New Zealand Council for the Care of Animals in Research and Teaching Ltd (ANZCCART) was established in 1987 in response to particular concerns from scientific communities about the use of animals in research and teaching. The Council addresses scientific, ethical, and social issues associated with the use of animals for scientific purposes (Australian New Zealand Council for the Care of Animals in Research and Teaching, 1987).

NEW ZEALAND

In New Zealand, the Animal Welfare Act 1999, Part 6, controls animal use in research, testing, and teaching (Ministry of Agriculture and Forestry of New Zealand, 1999). The Ministry of Agriculture and Forestry (MAF) leads and facilitates the management of animal welfare policy and practice, and promotes policies for the humane treatment of animals. An Animal Ethics Committee (AEC) and measures to minimize animal pain or suffering are required.

JAPAN

Animal care in Japan is regulated by the Japan Law for the Humane Treatment and Management of Animals (1973), however, the actual conduct of research is not specifically regulated (Kurosawa, 2007). Guidelines compiled by relevant government agencies, such as The Fundamental Guidelines for Proper Conduct of Animal Experiment and Related Activities developed by the Ministry of Education, Culture, Sports, Science and Technology (2006), the *Guidelines for Proper Conduct of Animal Experiments* developed by the Science Council of Japan (Science Council of Japan, 2006), and the *Policy for Animal Experimentation* published by the Japanese Association for Laboratory Animal Science (Japanese Association for Laboratory Animal Science, 2007) are used to provide guidance for animal research on a local level. Self-regulation is practiced and proper management of laboratory animals, and minimization of pain during experimental procedures are emphasized.

SOUTH KOREA

Korean Animal Protection Law provides legislation for the protection of animals. Sections 13 and 14 of this Law focus on experiments with animals and the formation of an Ethics Committee ([Korean Ministry of Agriculture and Forestry, 2007](#)). The 1996 ILAR *Guide* ([National Research Council, 1996](#)) has been translated into Korean and serves as a reference for Korean laboratory animal science practices.

PHILIPPINES

In the Philippines, the Animal Welfare Act known as *The Animal Welfare Act of 1998* covers animals and facilities used for breeding, maintaining, keeping, treating, or training of all animals as objects of trade or household pets ([Congress of the Philippines, 1998](#)). The Act does not specifically mention the use of animals in research.

THAILAND

The National Research Council of Thailand has developed *Ethical Principles and Guidelines for the Use of Animals for Scientific Purposes* ([National Research Council of Thailand, 1999](#)). These *Guidelines* call for valuing the life of animals. The concepts of the 3Rs (although not mentioned by name) are covered. The *Guidelines* mention the necessity of users being adequately skilled and require an institutional Committee to manage and be accountable for animal use (including project review) as well as a national Committee to investigate and oversee animal use.

CHINA

Beginning in 1983, the People's Republic of China enacted the first legislation to regulate the care and use of laboratory animals. In 1988, the Ministry of Science and Technology (MOST) established primary administrative responsibility for laboratory animal science in China with the Statute on the Administration of Laboratory Animals used in research, education, and testing ([Ministry of Science and Technology, 1988](#)). The Statute was approved by China's State Council, and covers licenses for production of laboratory animals as well as regulation regarding control of epidemics, protection of wildlife, and biosafety management requirements for laboratories with microorganisms. The regulation focuses more on laboratory animal quality than welfare. Many provinces, municipalities, and autonomous regions have passed local legislation, creating a Provincial Department of Science and Technology (PDST) responsible for the local Administration Office of Laboratory Animal Science (AOLS). An example of this for Beijing includes the requirement for ethical reviews of animal experiments, specialized training for personnel using animals, and an occupational health and safety program for animal users. It covers both the production and utilization of laboratory

animals and provides for inspections by the Municipal Administrative Department of Science and Technology ([Ministry of Science and Technology, 1988](#)).

The Laboratory Animal Development Program Plan established a national laboratory animal quality control network, which is subject to the Regulation on the Management of Laboratory Animal Quality Control and determines requirements for lab animal quality monitoring ([Ministry of Science and Technology, 1997](#)). Regulation GB14925-2001, *Laboratory Animal—Requirement of Environment and Housing Facilities*, 2001 was issued by China's General Administration of Quality Supervision and mandates requirements for facility construction; separation of animals according to species and strain, disease status, and experimental use; food, water, and bedding quality; quarantine; preventative medicine; and animal transportation ([Conour et al., 2008](#)). In 2006, MOST issued the first broad laboratory animal welfare regulations with the *Guidelines for the Humane Treatment of Laboratory Animals* ([Kong and Qin, 2010](#); Ministry of Education, Culture, Sports, Science and Technology, 2006). The guidelines require each institution to establish an IACUC to oversee and evaluate all aspects of its animal care and use programs as well as covering general requirements, husbandry, experiments, transportation, and methods. The Chinese Association for Laboratory Animal Science (CALAS), established in 1987, is dedicated to the exchange and dissemination of information, expertise, and knowledge about laboratory animal science ([Kong and Qin, 2010](#)).

TAIWAN

In Taiwan, the Animal Protection Law, 1998, provides oversight by the Council of Agriculture (COA). Chapter III of this Act, "Scientific Application of Animals," mandates that the scientific use of animals will minimize pain and requires institutions to establish a management panel to supervise the scientific application of animal experiments. In addition, the central government must establish an ethics committee for laboratory animals to supervise and manage the use of animals in research ([Chen, 2007](#)).

SINGAPORE

In Singapore, the National Advisory Committee on Laboratory Animal Research (NACLAR) was established in 2003 to develop national guidelines for the care and use of animals for scientific purposes in Singapore ([NACLAR, 2004](#)). The NACLAR Guidelines on the Care and Use of Animals for Scientific Purposes were released in October, 2004. The scope of the Guidelines covers all aspects of the care and use of animals for scientific purposes including use in teaching, field trials, environmental studies, research, diagnosis, product testing, and the production of biological

products. The Guidelines promote humane and responsible care and use of animals for scientific purposes in Singapore. In addition, guidelines can be found through the Singapore Association of Laboratory Animal Science.

HONG KONG

In Hong Kong, the *Code of Practice for the Care and Use of Animals for Experimental Purposes* developed by The Hong Kong Animal Welfare Advisory Group of the Agriculture, Fisheries and Conservation Department was published in 2004 (Agriculture Fisheries and Conservation Department of Hong Kong, 2004). This comprehensive document emphasizes the responsibilities of investigators and institutions to assure animal welfare.

CONCLUSION

Using the concepts and principles outlined in this chapter, as well as the references provided for further information, it is hoped individuals will create an approach to develop reasoned arguments for ethical recommendations with respect to the use of animals in research. Because science is so diverse and unique, ambiguous situations may arise as science advances. This makes it important to have performance standards in place, as well as having an ethical framework for implementing those standards.

Tannenbaum (1995) recommends five tests of an acceptable approach to the use of animals in research. Such an approach:

1. Must be as clear as possible in terms of what it says and how it will be applied;
2. Must be internally consistent and coherent;
3. Must be as comprehensive as possible;
4. Must be as simple as possible to be applied without confusion;
5. Must be able to account for the whole range of moral experience.

Normative laboratory animal use ethics must build upon accepted principles yet challenge ordinary beliefs when appropriate.

PRE-ANESTHETIC PREPARATION

Physical Examination

Every animal, no matter how large or small, should have their health assessed before being subjected to any anesthetic protocol. When assessing rabbits and rodents, things to consider include: changes in behavior, appearance, or weight; irregular respiratory patterns; ocular or nasal discharges; and examination of feces and urine in the cage. It is important to initially assess rabbits and rodents in their home cage prior to restraint/manipulation. In addition to the above-mentioned items, rabbits and larger rodents should have their body temperatures measured and their heart and lungs auscultated. Diagnostic tests such as complete blood counts, serum biochemistries, etc., may be warranted depending on the animal's history and/or the nature of the research protocol.

Fasting

Pre-anesthetic fasting for rodents is generally unnecessary unless the experimental procedure requires it. If fasting is warranted, it should be minimized (no more than 2–3 hours) due to the high metabolic rate of small rodents, and water should not be withheld prior to anesthesia. Though there is disagreement regarding pre-anesthetic fasting of rabbits, the recommendation is that rabbits under 3 kg should not have food withheld for greater than 12 hours due to the development of metabolic acidosis and a decline in blood glucose concentration (Bonath et al., 1982). In general, water should not be withheld from rabbits for more than several hours preoperatively (Lipman et al., 2008). Guinea pigs may benefit from a short period (2–3 hours) of pre-anesthetic fasting followed by rinsing of the oral cavity with water using a syringe. This can help decrease the amount of food present within the oral cavity and lessen the risk of aspiration, especially if endotracheal intubation is not being performed.

Stabilization

Transportation stress can affect many physiological systems in laboratory animals and though these changes are short-lived, they may confound research (Obernier and Baldwin, 2006). Therefore, rodents and rabbits should be allowed a minimum stabilization period of 48 h after shipping before being anesthetized and/or used as research subjects (Landi et al., 1982; Toth and January, 1990). This allows acclimation to new environments, restoration of homeostasis, and normalization of physiological status (Obernier and

Baldwin, 2006). Further, this affords the opportunity to evaluate the animals for any abnormalities or clinical signs of disease prior to undergoing anesthesia.

Regulatory Requirements

"The U.S. Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training" (1985), the Public Health Service Policy (IV.C.1.b) (PHS, 2002), and The Animal Welfare Regulations (9CFR 2.c.) (Code of Federal Regulations, 2002) require the administration of appropriate sedatives, analgesics, or anesthetics to animals undergoing procedures that cause more than momentary or slight pain or distress, unless withholding of such agents is scientifically justified. "The Guide for the Care and Use of Laboratory Animals" further emphasizes this point by stating "the proper use of anesthetics and analgesics in research animals is an ethical and scientific imperative." In addition to regulatory obligations, laboratory animal professionals have ethical obligations to avoid/minimize pain or distress in laboratory animals (Koch, 2006).

CONTROLLED SUBSTANCES

Due to their potential for abuse and risk of diversion, many drugs commonly used for anesthesia, analgesia, and sedation are classified as controlled substances. The federal government regulates the manufacture, importation, possession, use, administration, and distribution of controlled substances via the Federal Comprehensive Drug Abuse Prevention and Control Act of 1970 also known as the Controlled Substance Act (CSA). The CSA is enforced by the United States Department of Justice and administered through the Drug Enforcement Administration (DEA). State agencies have similar laws and regulations that must be followed. State laws regarding controlled substances may be stricter than their federal counterpart laws but cannot conflict with federal laws.

Controlled substances are classified into five schedules depending upon their medical use, abuse potential, and risk of physical and psychological dependence. As controlled substance schedules increase, the potential for their abuse and dependence decreases. Schedules are defined in the Controlled Substance Act, Chapter 21 U.S.C. 802, the Code of Federal Regulations, 21 C.F.R. 1308, and state controlled substance regulations. Drugs classified as controlled substances are marked with an uppercase C and the schedule number "C-I, C-II, C-III, C-IV, or C-V".

- **Schedule I (C-I):** No medical use accepted. Only authorized for research use (e.g. heroin, LSD, mescaline).
- **Schedule II (C-II):** Accepted medical use. High potential for addiction (e.g. morphine, cocaine, hydromorphone, pentobarbital, fentanyl).
- **Schedule III (C-III):** Accepted medical use. Low to moderate risk of physical dependence. High risk of psychological dependence (e.g. ketamine, tiletamine-zolazepam, buprenorphine).
- **Schedule IV (C-IV):** Accepted medical use. Limited potential for physical and psychological dependence (e.g. diazepam, midazolam).
- **Schedule V (C-V):** Accepted medical use. Very limited abuse potential (e.g. codeine preparations – 200 mg/100 ml or per 100 g).

The Controlled Substance Act creates a closed system to decrease abuse and diversion of controlled substances. A separate DEA registration is required for each principal place of business or professional practice where controlled substances are manufactured, prepared, distributed, stored, or dispensed. In addition, a state-controlled substance license is usually required, yet this varies between each state depending upon specific state laws and regulations. For those states requiring a controlled substance license, the DEA will not grant a registration until a state license is first acquired since the DEA registration is predicated upon the laws and regulations of the state in which the registrant resides. Once registered, an initial inventory must be performed and detailed records must be maintained for at least 2 years from the date of such records (Title 21 C.F.R. 1304) concerning inventory, usage, transfers, and disposal. In addition to an initial inventory, the DEA requires a biennial inventory to be completed. Depending upon the state, additional inventory and record-keeping requirements may apply. Acquisition of controlled substances can only occur between registered entities. Schedule II drugs require the completion of a DEA 222 triplicate form. One copy is sent to the DEA, the supplier, and a copy remains with the purchaser. All DEA 222 forms must be accounted for and returned to the DEA if unused. A prescription cannot be used to obtain controlled substances from a pharmacy for use in a clinic or research facility. Violations of controlled substance regulations are investigated and conducted by local law enforcement, DEA diversion investigators, and state diversion investigators.

When seeking information regarding controlled substance licensing or DEA registration requirements, one should contact the relevant state licensing board and the DEA for information. For additional

information, one can refer to the DEA website at: <http://www.dea.gov/diversion/index.html/>.

PHARMACOLOGY

Anticholinergics

Anticholinergic agents such as atropine and glycopyrrolate inhibit acetylcholine at muscarinic receptors by acting as competitive antagonists within the parasympathetic nervous system. Their main effects upon cardiac, secretory glands and smooth muscle include tachycardia, mydriasis, decreased intestinal motility, decreased salivation and respiratory secretions, decreased gastric acid secretion, and decreased urinary bladder and urethral tone. Their usefulness in anesthesia is aimed at reducing vagal-mediated bradycardia and decreasing salivation or secretions. Their use is not necessary in most rodent surgical procedures but they may be useful in rabbits and guinea pigs in order to decrease salivation and secretions. Although secretions may be diminished they may become more viscous, resulting in airway obstruction (Quesenberry and Carpenter, 2004). Atropine is a naturally occurring belladonna alkaloid tertiary amine, unlike glycopyrrolate, a synthetic anticholinergic agent. Atropine and glycopyrrolate can be administered intravenously, intramuscularly, intratracheally, and subcutaneously.

Atropine may lower the threshold for ventricular dysrhythmias. The route of elimination for atropine is via ester hydrolyzing enzymes, hepatic metabolism, and urinary excretion. The rabbit is a unique species in that some breeds have higher levels of circulating esterase enzymes in their plasma resulting in rapid inactivation and a resistance to toxicity (Ecobichon and Comeau, 1974). As a result, the duration of action of atropine may be reduced requiring more frequent re-dosing when utilized in rabbits (Sedgwick, 1986). High doses should be used cautiously due to the development of tachycardia and possible dysrhythmias. Alternatively, glycopyrrolate can be utilized in rabbits to elevate the heart rate (0.1 mg/kg IM) (Olson et al., 1994). The metabolism of glycopyrrolate is not affected to the same degree as atropine by rabbit esterase enzymes. The duration of action of glycopyrrolate is approximately 2–4 hours while that of atropine is approximately 60–90 minutes (Muir and Hubbell, 1989). Atropine and glycopyrrolate have minimal effects upon blood pressure unless cardiac output is highly dependent upon heart rate. Due to their ability to increase heart rate, thus increasing myocardial oxygen demand, anticholinergics should be used cautiously in cases or conditions where tachycardia is already present or expected such as excitement, hypotension, or shock.

Phenothiazines

Phenothiazine tranquilizers can be utilized as a premedicant to induce a state of tranquility, calmness, or to diminish anxiety or stress. Their main pharmacologic activity results from blockade of dopamine-1 (D_1) and dopamine-2 (D_2) receptors within the mesolimbic dopamine pathway. In addition to their effects upon the dopamine pathway, phenothiazines can block both histamine (H_1) and cholinergic muscarinic receptors leading to sedation, suppression of oral secretions, tachycardia, urinary retention, and constipation. Phenothiazines do not possess analgesic or muscle-relaxant properties. In addition, they are associated with minimal respiratory depression at therapeutic doses (Thurmon et al., 1996), can induce mild to moderate hypotension due to their blockade of peripheral vasculature α_1 receptors, and moderate hypothermia due to depressed temperature regulation (Flecknell, 1996). Phenothiazine agents have been associated with increased risk of seizure development in human medicine and should be used with caution in animal models prone to seizures (e.g. gerbils) or central nervous system research involving electroencephalogram recordings. Recently, several papers have documented no correlation between the use of acepromazine in dogs with a history of seizures and the recurrence of seizures (McConnell et al., 2007; Tobias et al., 2006). Additional studies will need to be performed in order to thoroughly evaluate the safety of phenothiazine use in animals prone to seizures. Phenothiazines are commonly combined with opioids to enhance sedation (neuroleptanalgesia). These agents are primarily metabolized in the liver with metabolites secreted in the urine. There are no available direct reversal agents for phenothiazines. Acepromazine is the most commonly utilized phenothiazine in veterinary medicine and the research setting. It can be used either alone or in combination with other agents for use as a sedative or as a premedicant prior to surgery. Acepromazine can potentiate the effects of other anesthetic agents so a lower dosage of that agent can be used to produce surgical anesthesia (Flecknell, 1996). Acepromazine is commonly used as a sedative and vasodilator to assist in rabbit phlebotomy. Decreased tear production was observed in New Zealand white rabbits administered acepromazine at 1 mg/kg IM (Ghaffari et al., 2009).

Benzodiazepines

Benzodiazepines are sedative-hypnotics used as single agents, in combination with opioid analgesics as a pre-anesthetic medication, or in conjunction with anesthetic induction agents to enhance sedation and muscle relaxation. The sedative effect varies by species and

marked sedation has been shown to occur in rabbits and rodents (Flecknell, 1996). However, some animals may experience excitement upon IV administration (Papich, 2007). In addition to their sedative and muscle-relaxant properties, benzodiazepines possess anticonvulsant properties. However, benzodiazepines are not effective anesthetics when used alone and possess no analgesic properties. Benzodiazepines used for anesthetic purposes include diazepam and midazolam. Both are available in parenteral dosage forms. Benzodiazepines augment the inhibitory actions of gamma-aminobutyric acid (GABA) by binding to the $GABA_A$ receptor thus enhancing chloride ion influx at neuronal synapses (Johnston, 1996). Benzodiazepines have minimal adverse effects upon the cardiovascular system (Kanto, 1985) making them useful agents in compromised or hemodynamically depressed animals. Guinea pigs administered a diazepam-fentanyl combination displayed a significant increase in mean blood pressure above resting level (Brown et al., 1989). Additive or synergistic sedative and muscle-relaxant effects are observed when benzodiazepines are used in conjunction with opioids (neuroleptanalgesia) or N-Methyl-D-Aspartic Acid antagonists such as ketamine (Dupras et al., 2001; Green et al., 1981). Lower doses of each agent in a neuroleptanalgesic combination can be used to decrease adverse effects observed with higher doses of single agents and to prolong the duration of anesthesia or sedation. Diazepam is dissolved in a non-aqueous solution containing propylene glycol, which can cause pain and irritation upon IM or SC injection, or phlebitis upon IV injection into small vessels (Papich, 2007). Hypotension has been reported when administered by a rapid intravenous bolus. Unlike diazepam, midazolam is water-soluble and can be mixed with other anesthetic agents such as ketamine. Due to its improved absorption properties and water solubility, midazolam is preferred when dosing by the subcutaneous or intramuscular route. The duration of action of midazolam is shorter than diazepam. Flumazenil is a specific inhibitor of benzodiazepines. Both midazolam and diazepam are Schedule IV controlled substances.

Alpha₂-Agonists

Alpha₂-agonists such as xylazine and medetomidine are sedative-hypnotic agents that provide sedation, muscle relaxation, and analgesia. Medetomidine is the racemic mixture of the active D-enantiomer (dexmedetomidine) and the inactive L-enantiomer. Medetomidine is no longer commercially available and has been replaced by its racemic isomer dexmedetomidine (Dexdomitor®). Other alpha₂-agonists include romifidine and detomidine, which are generally reserved for use in cattle and horses.

Alpha₂-agonists exert their clinical effects by binding to presynaptic alpha₂ receptors leading to a negative feedback and a reduction in norepinephrine from central and peripheral neurons. Alpha₂ receptors located in the dorsal spinal cord modulate and relay pain transmission (Pan et al., 2008). Alpha₂-agonists are located in the central nervous system, gastrointestinal tract, uterus, kidneys, and platelets (Paddleford, 1999). These drugs vary in their selectivity for the various alpha-receptors. A study by Virtanen et al. (1988) showed that the α_2/α_1 selectivity was as follows: medetomidine (1620:1), detomidine (260:1), clonidine (220:1), and xylazine (160:1). Therefore, medetomidine is the most potent and will require a lower dose for effect than clonidine or xylazine. There will also be fewer α_1 effects with the more selective α_2 agents. Peripheral α_1 adrenoreceptor activation can lead to vasoconstriction, salivation, piloerection, and mydriasis while central α_1 adrenoreceptor activation can lead to increased locomotor activity and arousal (Duteil et al., 1990).

Alpha₂-agonists can be used as single agents to produce sedation and muscle relaxation for facilitating short-term restraint or can be used to provide sedation and analgesia for minor diagnostic procedures.

In addition, alpha₂-agonists have been used as premedicants to anesthesia either as single agents or in combination with opioids or tranquilizers in healthy animals with minimal cardiovascular or respiratory dysfunction (Ko et al., 1992). When administered with opioids profound sedation and enhanced analgesia are common. The risk of bradycardia is increased with this combination due to enhanced effects upon vagal tone secondary to G-protein-coupled receptor synergy. Administration of anticholinergic agents to reduce the occurrence of bradycardia is generally not recommended as it has been shown to cause dysrhythmias (Short, 1991), hypertension, and increase myocardial oxygen demand and workload (Monteiro et al., 2009). If the bradycardia is severe and placing the patient at risk, the most appropriate course of action would be to reverse the α_2 agonist with an α_2 adrenoreceptor antagonist (Pypendop et al., 1998; Sinclair, 2003).

The sedative effects, analgesic, and muscle-relaxant properties of alpha₂-agonists make them useful adjuncts when combined with a N-methyl-D-aspartic acid (NMDA) antagonist such as ketamine for producing short-term immobilization and surgical anesthesia (Difilippo et al., 2004; Henke et al., 2005; Marini et al., 1992; Mero et al., 1989). In rabbits, the combination of ketamine and medetomidine produced surgical anesthesia of medium duration (Hellebrekers et al., 1997). Orr et al. (2005) showed that a medetomidine-ketamine dose of 0.25/15mg/kg with supplemental isoflurane provided sufficient anesthesia for orchiectomy or ovari-hysterectomy. Intramuscular administration was

associated with more rapid onset of anesthesia but a higher level of discomfort in the rabbit than subcutaneous administration. Due to the respiratory depression seen with this combination, the authors advised intubation so supplemental oxygen could be provided. The medetomidine was reversed with atipamazole but it should be noted that this will also reverse the analgesic properties as well. Hedenqvist et al. (2001) also showed that a medetomidine-ketamine dose of 0.25/15mg/kg would provide 15–30 minutes of surgical anesthesia. In contrast to rabbits, a medetomidine-ketamine dose of 0.5/40mg/kg only provided immobilization in guinea pigs and did not produce adequate surgical anesthesia (Nevalainen et al., 1989). Dang et al. (2008) compared the level of anesthesia provided by ketamine-xylazine (30/2.5mg/kg IM, SC, and IP), medetomidine (0.5mg/kg IM), and pentobarbital (37mg/kg IP) in guinea pigs. Ketamine-xylazine was found to produce reliable anesthesia for a 45-minute procedure, while medetomidine alone was found to induce sedation but not anesthesia. Henke et al. (2004) compared several anesthetic regimens in chinchillas and showed that ketamine-xylazine (40/2.0mg/kg IM) produced the longest period of surgical anesthesia followed by medetomidine-ketamine (0.06/5.0mg/kg IM), and finally midazolam-medetomidine-fentanyl (1.0/0.05/0.02mg/kg IM). However, recovery time was shortest in the latter two groups. The maintenance requirement for inhalant anesthetic agents is generally drastically reduced when used in conjunction with alpha₂-agonists.

Yohimbine and atipamazole are alpha₂-antagonists used to reverse the effects of xylazine and medetomidine or dexmedetomidine respectively (Lipman et al., 1987). A study by Virtanen et al. (1989) showed an α_2/α_1 receptor selectivity of 8526:1 for atipamazole and 40:1 for yohimbine. Therefore, atipamazole is a more potent α_2 receptor antagonist than yohimbine and is the preferred antagonist for medetomidine and dexmedetomidine. Administration of either atipamazole or yohimbine IV can induce hypotension and tachycardia (Maze et al., 1991) so IM administration is recommended.

Side effects of alpha₂-agonists include an initial increase in systemic vascular resistance in peripheral tissues leading to a reflex bradycardia followed by a centrally mediated decrease in cardiac output and subsequent hypotension. Due to potential cardiovascular adverse effects alpha₂-agonists should not be used in hemodynamic or cardiac compromised animals (Greene, 2002). However, in certain heart failure models (e.g. ventricular outflow obstruction due to hypertrophic cardiomyopathy), the bradycardia and increased afterload that occurs with the use of alpha₂-agonists may be beneficial to the animal (Lamont et al., 2002). Xylazine has variable effects on the respiratory system while medetomidine is associated with significant

respiratory depression when used at higher doses or in conjunction with other tranquilizers, opioids, or anesthetics (Paddleford, 1999). As a result, supplemental oxygen is advised with the use of α_2 -agonists. Chang et al. (2009) showed that dexmedetomidine produced less ventilatory depression in rabbits when combined with sevoflurane than propofol or midazolam but induced more hypotension and bradycardia. Henke et al. (2005) showed that in rabbits, medetomidine/ketamine administration resulted in a transient hypertension but the mean arterial pressure (MAP) decreased to pre-anesthetic levels. This was significantly higher than the MAP for the xylazine-ketamine group of rabbits.

Systemic Analgesics

Opioids

Opioid analgesics are useful agents for treating mild to severe pain. In addition to their analgesic properties, opioids can provide sedation and be used in balanced anesthetic techniques to augment injectable or inhalant anesthetics. As a result, lower anesthetic doses of each agent can be utilized, thus decreasing adverse side effects associated with higher doses of a single agent. Opioid analgesics mimic the response of endogenous opioid peptides such as endorphins and enkephalins and mediate descending inhibition of pain-modulating pathways within the brain and dorsal horn of the spinal cord.

Opioids act upon G-protein-coupled receptors, which share significant homology. Three opioid receptor types, mu, kappa, and delta, have been identified (Mansour et al., 1995). In addition, studies in receptor knockout mice have shown that all three opioid receptors can mediate antinociception (Kieffer and Gaveriaux-Ruff, 2002). In general, binding of an opioid analgesic agent to a G-protein-coupled receptor activates second messenger pathways causing hyperpolarization of neuronal cells, thus increasing their threshold for activation. Although complicated cell signaling events occur secondarily to the activation of opioid receptors, the end result is to provide analgesia, sedation, and modulate pain nociception.

Opioid analgesics differ in their opioid receptor affinity and intrinsic activity. Opioids are usually classified as agonists, partial agonists or agonist-antagonists, and antagonists. Full agonist agents are useful for treating moderate to severe pain. Partial agonists are best suited for conditions associated with mild to moderate pain or where extra sedation is needed. Opioids may differ in potency, yet may have similar intrinsic activity or analgesia activity. For example, the dose of hydromorphone is seven times less compared to morphine, yet both agents provide equivalent analgesia.

Moderate to severe pain is best treated with full agonist opioids that bind primarily to mu receptors. For most species, activation of these receptors provides

excellent analgesia, sedation, and euphoria, however, this can be species- and strain-specific. Commonly used opioid agents for treating moderate to severe pain that bind to mu opioid receptors include morphine, hydromorphone, fentanyl, and oxymorphone.

Buprenorphine is classified as a partial agonist or agonist-antagonist. It has partial agonist actions at the mu receptors and antagonist actions at the kappa and delta receptors. Buprenorphine has a slightly longer onset of action and longer duration of action compared to other opioids. As a partial agonist, buprenorphine has an analgesic and respiratory depression ceiling effect. As a result, it is useful for providing mild to moderate analgesia and sedation. Depending upon the species and type of surgery, severe pain may require treatment with a full agonist such as morphine, fentanyl, or hydromorphone. However, when buprenorphine is used prior to surgery it can prolong anesthesia and decrease the dosage of anesthetic that needs to be used. Murphy et al. (2010) demonstrated that surgical anesthesia with medetomidine-ketamine was prolonged when rabbits received 0.03 mg/kg of buprenorphine SC 1 hour before anesthesia. Shafford and Schadt (2008) showed that if given (0.06 mg IV) prior to colorectal distension in rabbits, it decreased the animal's response to this noxious stimulus. They therefore concluded that it is an acceptable agent for visceral analgesia if used preemptively. Its high affinity and long duration of action require potentially larger and more frequent dosing with an antagonist such as naloxone for reversal purposes. In addition, supplemental analgesia may require higher doses of a full agonist opioid to compete with the binding properties of buprenorphine. Side effects in rodents and rabbits can include ileus, pica, and loss of appetite (Flecknell et al., 2000).

Butorphanol is classified as an agonist-antagonist with antagonist actions at the mu receptors and agonist actions at the kappa receptors. As an agonist-antagonist it has an analgesic and respiratory depression ceiling effect. It is useful for providing mild to moderate analgesia and sedation. Butorphanol is a useful agent for providing partial reversal to reestablish breathing parameters, yet not completely reverse analgesia. Portnoy and Hustead (1992) determined the half-life of butorphanol in rabbits to be 1.64 hours after IV administration and 3.16 hours after SC administration. Therefore, this drug requires more frequent re-dosing if used for post-operative analgesia.

Fentanyl is a potent mu receptor agonist and has a rapid onset and short duration of action. It can be administered via a constant rate infusion during surgery and the post-operative period. Fentanyl patches can also be used in rabbits. Plumb (2005) recommends use of half of a 25 µg/hour patch for a 3-kg rabbit every

3 days for post-operative analgesia. The patch must not be cut but the half that is not in use should be covered with tape. The fur along the lateral thorax should be clipped close (the site should not be shaved and depilatory agents should not be used as this will alter fentanyl absorption) with a 1-cm margin and the patch applied to the skin. The patch should be held in place with a gloved hand to improve the adhesive bond to the skin and covered with a clear, adhesive bandage (Plumb, 2005). Weight and appetite should be carefully monitored in rabbits when using fentanyl patches (Foley et al., 2001). Along with inhalant anesthetics, constant rate infusions of fentanyl can be used in conjunction with propofol or ketamine infusions. Due to the rapid clearance of fentanyl, recoveries are generally rapid and smooth.

Morphine is an agonist at the mu, kappa, and delta receptors. It is the opioid most likely to cause GI side effects, especially in rabbits and guinea pigs. Therefore it is best to use this drug only once prior to surgery or to use it as an epidural agent. The kappa receptors are thought to be responsible for its efficacy as an epidural. If given as an epidural, the preservative-free (PF) solution should be used. This can be an excellent technique to provide analgesia for abdominal and hindlimb procedures in rabbits. The analgesia will last for about 12–24 hours and side effects are minimal. Morphine can be combined with a local anesthetic, such as lidocaine or bupivacaine (Gaynor and Muir, 2009). The rabbit should be placed in ventral or lateral recumbency and the coxofemoral and lumbosacral joints hyperflexed to open up the lumbosacral space. The landmarks for this technique include the wings of the ilium and the dorsal prominence of the first sacral vertebrae (Gaynor and Muir, 2009). The spinal cord in rabbits does continue through the sacral vertebrae so care should be taken when performing a lumbosacral epidural as the spinal cord can be punctured accidentally (Greenaway et al., 2001).

Opioids can be used in combination with inhalant anesthetics to provide additional analgesia and sedation. This usually allows for lower concentrations of inhalant agents to maintain anesthesia and reduces inhalant-associated hypotension.

Side effects of opioids vary depending upon the receptor activity and species. Main side effects include respiratory depression, mild hypoxemia, vagal-induced bradycardia, decreased intestinal motility, and urinary retention (Shafford and Schadt, 2008). Opioids can be combined with an α_2 -agonist or non-steroidal anti-inflammatory agents for additive analgesia effects. When combined with α_2 -agonists profound respiratory depression and bradycardia is commonly observed. As a result, lower doses of each agent should be utilized and α_2 -antagonists administered in emergency situations (i.e. severe bradycardia that is

life-threatening). Gut stasis is often mentioned, especially for rabbits and guinea pigs, as a side effect of opioid use but a study by Cooper et al. (2009) showed no difference in food consumption, weight, or fecal production between rabbits given buprenorphine (0.03 mg/kg IM q 12 hours for 48 hours) and meloxicam (0.2 mg/kg SC q 24 hours for 48 hours) post-operatively. However, when using these agents, close post-operative monitoring should be performed.

Depending upon their intrinsic activity and potential for abuse, the majority of opioids are controlled substances with schedules ranging from II–IV. Schedule II opioids used for anesthesia, sedation and analgesia include morphine, hydromorphone, fentanyl, and oxymorphone. Buprenorphine is classified by the DEA as a Schedule III agent, while butorphanol is classified by the DEA as a Schedule IV agent.

Non-Steroidal Anti-Inflammatory Drugs (NSAIDs)

Non-steroidal anti-inflammatory drugs exert their effects via inhibition of cyclooxygenase-derived inflammatory eicosanoids known as prostaglandins and thromboxane. NSAIDs inhibit the enzyme cyclooxygenase (COX) which catalyzes the production of prostaglandins, prostacyclins, and thromboxane A_2 from arachidonic acid. There are currently two recognized isoforms of cyclooxygenase, COX-1 and COX-2. A third COX isoform (COX-3) has been described and found to be expressed by various tissues but its function remains unknown at this time (Hersh et al., 2005). COX-1 is a constitutive enzyme responsible for normal physiologic functions such as maintaining a gastro-protective mucosal barrier and renal blood flow, while the COX-2 enzyme is induced and responsible for producing prostaglandin mediators associated with swelling, fever, and pain. However, it has been shown that completely blocking COX-2 can be harmful to some normal physiologic functions. Although considered equally efficacious for treating pain, COX-2 inhibitors (COX-1 sparing) are generally preferred over COX-1 NSAIDs due to their potential gastro-renal protective effects. COX-1 versus COX-2 selectivity may vary depending upon species, enzyme location, and dose (Bergh and Budberg, 2005). The selectivity is assessed by studying the concentration of the drug that is needed to block each COX isoenzyme (Gaynor and Muir, 2009). Examples of non-selective COX inhibitors are aspirin, ketoprofen, and ketorolac. Examples of drugs with COX-2-selective inhibition include carprofen, etodolac, meloxicam, and deracoxib. Few studies have been done investigating the use of these medications in the species covered by this book, but clinical experience seems to suggest that the COX-2-selective inhibitors produce fewer side effects in rabbits, guinea pigs, and other small mammals. Several studies have investigated the use of meloxicam

in rabbits. [Cooper et al. \(2009\)](#) showed no significant difference in body weight, food consumption, or fecal production between the meloxicam-treated group (0.2mg/kg SC q 24 hours) and the buprenorphine-treated group (0.03mg/kg IM q 12 hours) after undergoing ovariohysterectomy. Both of these groups did better post-operatively than the group that received only incisional infiltration with bupivacaine. [Carpenter et al. \(2009\)](#) documented a half-life of approximately 8 hours in rabbits after giving meloxicam at 0.2mg/kg orally. However, [Leach et al. \(2009\)](#) showed that only high-dose oral meloxicam (1mg/kg initially, followed by 0.5mg/kg/day) induced some degree of analgesia after ovariohysterectomy in rabbits. This may indicate that parenteral administration (SC) of meloxicam is more efficacious post-operatively, possibly due to decreased appetite and therefore differences in absorption of the drug from the gastrointestinal tract. Further studies are needed to better assess dosages and routes of administration in rabbits and other small mammals.

The main side effects associated with NSAID usage are gastric ulceration, renal disease, and platelet inhibition. The COX-2-selective drugs show less of a tendency to cause renal disease and platelet inhibition than the non-selective COX inhibitors ([Gaynor and Muir, 2009](#)). Due to their inhibition of prostaglandins, which could alter vasodilation, NSAIDs should be avoided in patients with preexisting renal disease or dehydration. Furthermore, NSAIDs should be used with caution in patients with bleeding disorders, expected surgical hemorrhage, or gastric ulceration. Carprofen has been shown to be safe to administer pre-operatively to dogs, even those that had changes in renal function and hemostasis due to trauma ([Bergmann et al., 2005](#)).

Tramadol

Tramadol is a centrally acting analgesic that binds to mu receptors, but is not related to opioids, and inhibits uptake of norepinephrine and serotonin ([Gaynor and Muir, 2009](#)). It can be used for mild to moderate pain control and has increased efficacy when combined with an NSAID. Side effects are usually gastrointestinal in nature (e.g. constipation, diarrhea, nausea) but are relatively infrequent. [Souza et al. \(2008\)](#) examined the pharmacokinetics of orally administered tramadol (11mg/kg once) in rabbits. No adverse effects were observed in healthy animals and the half life was 145.4 minutes while the mean maximum plasma concentration was 135.3ng/mL. This is well below the level required to produce analgesia in humans so additional studies need to be performed to determine whether this dose or higher dosages would provide sufficient post-operative analgesia in rabbits as well as whether addition of an NSAID improved analgesic efficacy. A study by [Egger et al. \(2009\)](#) showed a significant

but clinically unimportant decrease in the minimum alveolar concentration (MAC) of isoflurane in rabbits given IV tramadol (4.4mg/kg over 1 minute). They caution against using higher IV doses during anesthesia as some cardiovascular depression was observed at this dosage. Finally, a study by [Herbert et al. \(2007\)](#) showed that the most potent metabolite of tramadol (O-desmethyltramadol) did inhibit peristalsis in the guinea pig small intestine. However, in vivo studies in guinea pigs using tramadol need to be performed to determine the relevance of this observation.

Gabapentin

Gabapentin is a structural analog of gamma-aminobutyric acid (GABA) and was originally used as an antiepileptic drug ([Gaynor et al., 2009](#)). Its mechanism of analgesic action is unknown as it does not appear to have activity at GABA, NMDA, or opioid receptors or modulate COX activity or dopamine, serotonin, or norepinephrine uptake ([Gaynor and Muir, 2009](#)). It seems to be most useful for pain related to neuropathic conditions, osteoarthritis, or neoplasia. Like tramadol, it seems to be most effective when used in a multimodal approach (e.g. gabapentin + NSAID). Side effects reported in humans include sleepiness, fatigue, and weight gain after long periods of use ([Gaynor and Muir, 2009](#)). A study by [Fox et al. \(2003\)](#) used oral gabapentin in guinea pigs following partial ligation of the left sciatic nerve. They demonstrated good reversal of neuropathic mechanical hyperalgesia when gabapentin was dosed twice daily but poor reversal when it was dosed once daily. Further studies are needed to determine optimum dose and dosing interval.

Amantadine

Amantadine was originally used as an anti-viral agent but has been shown to have antagonist effects at the NMDA receptor. Like gabapentin, it has been used in humans for treatment of neuropathic pain. In dogs and cats, it has been shown to reduce windup and allodynia, allowing a reduced dosage of opioids to be used while improving their analgesic action ([Gaynor and Muir, 2009](#)). It also increases the efficacy of NSAIDs in dogs with osteoarthritis. Side effects in dogs include anxiety, restlessness, and dry mouth. Caution should be used when administering to patients with renal impairment as it is excreted in the urine. There have not been any studies done on the use of amantadine in the species covered by this book but like gabapentin, it may prove useful in animals used in neuropathic pain studies.

Local Anesthetics

Local anesthetics are used peripherally in order to block transmission from nerve endings or fibers via inhibition of sodium channels within the nerve membrane

(Gaynor and Muir, 2009). The susceptibility of nerves to these agents depends on size and myelination and usually follows the listed order: pain, warmth, touch, deep pressure, and motor function. The most common agents used include: lidocaine (60–120-minute duration of action) and bupivacaine (180–480-minute duration of action). Local anesthetics can be used topically (e.g. EMLA cream), as an epidural (usually combined with morphine PF), as an incisional line block, as a continuous infiltration along an incision via a catheter (common after thoracotomies), or in various peripheral nerve blocks (e.g. intercostal, intra-articular). Peripheral nerve blocks require good knowledge of the local anatomy in order to be performed correctly. Local anesthetics can be absorbed systemically and can lead to unwanted side effects, such as cardiac dysrhythmias (Gaynor and Muir, 2009).

If a catheter is going to be placed prior to anesthesia or if a blood sample needs to be drawn, a eutectic mixture of lidocaine and prilocaine (EMLA) cream can be applied topically to the ear or foreleg to facilitate placement and improve comfort in rabbits. For maximum efficacy, this cream needs to be applied to a shaved surface, approximately 60 minutes before venipuncture, and covered by an occlusive dressing for the 60-minute period (Flecknell et al., 1990).

Glucocorticoids

Glucocorticoids are mainly used post-operatively for their anti-inflammatory effects. These are achieved via inhibition of phospholipase A2 which is the precursor of arachidonic acid. This leads to decreased production of prostaglandins and leukotrienes, which prevents lowering of the nociceptive threshold (Gaynor and Muir, 2009).

Glucocorticoids can be used as a multi-modal approach to analgesia post-operatively but also can be used intra-operatively (e.g. intra-articular administration, epidural administration, wound irrigation).

Caution should be used when administering glucocorticoids as there are many potential adverse effects, including: delayed wound healing, gastric ulceration (do not combine with NSAIDs; rabbits are especially susceptible and if needed, a gastric protectant should also be administered), electrolyte and fluid imbalances, and immunosuppression.

N-Methyl-D-Aspartic Acid (NMDA) Antagonist

NMDA antagonists such as ketamine or tiletamine cause a catatonic or dissociative state characterized by analgesia, amnesia, immobility, and a detachment from surroundings. The animal's eyes may remain open and variable hypertonic contractions and gross muscle movement may occur independent of surgical stimulation. Pharyngeal reflexes are maintained as well as spontaneous breathing so animals are more prone to

laryngospasm upon intubation. This can be mitigated by use of another anesthetic agent or use of a topical anesthetic (e.g. lidocaine, cetacaine). Since ocular and pharyngeal reflexes are retained, or attenuated less, with ketamine than with other anesthetic agents, this can make traditional monitoring of anesthetic depth, using observation of physical signs, misleading.

Ketamine

Ketamine, is a water-soluble phencyclidine derivative available commercially as a racemic mixture. It possesses analgesia activity due to its ability to block pain impulses to cortical-thalamic regions of the brain. Ketamine is generally administered by intravenous, intraperitoneal, or intramuscular routes of injection. Due to its low pH, pain and irritation can be observed with intramuscular injection leading to self-mutilation (Beyers and Richardson, 1991). Ketamine undergoes hepatic metabolism to norketamine with renal and biliary excretion of metabolites.

Ketamine increases the sympathetic tone causing increases in heart rate, cardiac contractility, cardiac output, pulmonary arterial blood pressure, systemic vascular resistance, and myocardial oxygen demand. Ketamine should be avoided in conditions associated with high sympathetic tone and depleted catecholamine stores such as shock or with conditions such as hypertrophic cardiomyopathy due to its ability to cause diminished cardiac output and hypotension (Greene, 2002).

High doses of ketamine may be required for surgical anesthesia when ketamine is used alone (Green et al., 1981). Its use is associated with poor muscle relaxation and rough recoveries. Ketamine is generally used in combination with a benzodiazepine such as diazepam or midazolam or with an α_2 -agonist such as xylazine, medetomidine, or dexmedetomidine. In hamsters, intraperitoneal ketamine doses of 50–200 mg/kg combined with xylazine 10 mg/kg provided general anesthesia (Curl and Peters, 1983). The addition of an α_2 -agonist to ketamine augments analgesia and prolongs the duration of surgical anesthesia, yet is associated with dose-dependent bradycardia, respiratory depression, hypoxemia, and acidemia in rabbits (Hobbs et al., 1991; Lipman et al., 1990; Marini et al., 1992; Peeters et al., 1988; Popilskis et al., 1991; Sanford and Colby, 1980; Wyatt et al., 1989). In guinea pigs, ketamine–xylazine was associated with minimal respiratory depression, yet was associated with reductions in blood pressure and heart rate (Schwenke and Cragg, 2004). Supplemental oxygen is recommended. A study in rats by Olivar et al. (1999) demonstrated that ketamine was an effective analgesic for acute visceral nociceptive stimulation but was only effective on somatic pathways when injury or inflammation was present. A similar study in humans (Strigo et al., 2005) demonstrated analgesic efficacy for acute visceral pain. While

there was a decrease in the unpleasantness associated with acute cutaneous pain there was no change in the intensity noted by the subjects. In rabbits, the combination of xylazine–acepromazine–ketamine produced longer surgical anesthesia, yet was associated with severe hypothermia (Hobbs et al., 1991).

Additional side effects include atropine-responsive salivation, apneustic breathing (prolonged pause following inspiration), and emergence delirium characterized by ataxia, increased motor activity, hyper-reflexia, muscle rigidity, and agitation. Rough recoveries can be ameliorated with a benzodiazepine, phenothiazine tranquilizer, opioid, or α_2 -agonist. When used as an induction agent ketamine is commonly administered with diazepam.

Ketamine is a unique agent as it antagonizes the NMDA receptor, a glutamate excitatory receptor associated with dorsal horn neuronal sensitization, hyperalgesia, allodynia, and the temporal summation (wind-up) that is often associated with chronic pain. Ketamine and tiletamine–zolazepam are Schedule III controlled substances.

Tiletamine–Zolazepam

Tiletamine–zolazepam (Telazol®) is an NMDA antagonist–benzodiazepine tranquilizer combination of equal amounts with the dose based upon the combined weight of both drugs. Tiletamine is more potent and has a longer duration of action compared to ketamine. Tiletamine–zolazepam is used as an alternative to ketamine combinations (ketamine + opioid, benzodiazepine, or α_2 -agonist) to produce immobilization, sedation, or surgical anesthesia for minor to moderate procedures. Depending upon the dose and species, tiletamine–zolazepam may be associated with prolonged recoveries. Ocular, laryngeal, pharyngeal, and pedal reflexes remain intact. Side effects associated with tiletamine–zolazepam include dose-dependent decrease in cardiac output and hypotension.

In rabbits, tiletamine–zolazepam has been associated with renal toxicity when used at surgical anesthetic doses (Brammer et al., 1991). Renal toxicity was linked to the tiletamine component. When used at lower doses in combination with xylazine, tiletamine–zolazepam produced mean surgical anesthesia duration of 72 minutes versus 35 minutes for xylazine–ketamine with no nephrotoxicity observed (Doerning et al., 1992). In guinea pigs, tiletamine–zolazepam doses up to 50 mg/kg produced short-term immobilization, but inadequate surgical anesthesia (Radde et al., 1996). In hamsters, anesthesia but not analgesia was achieved at doses of 50–80 mg/kg (Silverman et al., 1983).

Propofol

Propofol is an intravenous sedative hypnotic agent solution used for the induction of general anesthesia,

endotracheal intubation, or maintenance of anesthesia. Propofol is not water-soluble and is commercially available as an oil-in-water emulsion. Due to the potential to support bacterial growth, propofol preparations should be immediately used within 6–12 hours of opening. This recommendation can vary by manufacturer so the package insert should always be consulted prior to reconstitution and use. Propofol has high lipid solubility and a rapid onset of action. Propofol is efficiently metabolized and has a clearance rate with minimal cumulative effects. As a result, propofol infusions are associated with rapid recovery and minimal residual central nervous system (CNS) effects.

Propofol use is best reserved for anesthesia induction or for maintaining unconsciousness for short procedures via intermittent boluses. A constant rate infusion via an infusion pump must be utilized for longer procedures or surgeries. Propofol does not possess analgesic properties and an analgesic should be used when performing procedures associated with intra-operative or post-operative pain. Premedication with a tranquilizer, an opioid, or an α_2 -agonist augments the sedative actions of propofol and reduces the dose or infusion rate needed to maintain surgical anesthesia (Hellebrekers et al., 1997; Ko et al., 1992; Luo et al., 1995). Propofol has been combined with opioids to provide total intravenous anesthesia (De Mulder et al., 1997).

Propofol is associated with rapid CNS depression and unconsciousness. Intraocular pressure, cerebral blood flow, and intracranial pressure are reduced with propofol. Dose-dependent respiratory depression is observed with the development of apnea during induction or after large doses. Additional side effects include hypotension secondary to vasodilation, decreased cardiac contractility, and diminished cardiac output. Hypotension is greater with large doses, rapid infusion, and pre-existing hypovolemia. Injection site pain, twitching, and myoclonus can occur, especially in non-pre-medicated patients. Due to the potential for respiratory depression and apnea, supplemental oxygen should be provided before and during a propofol infusion. Endotracheal intubation is recommended.

Because of the lack of easy venous access, propofol is reserved for larger species such as rabbits. However, propofol can be administered to smaller species such as guinea pigs or chinchillas via an intraosseous catheter (Lichtenberger and Ko, 2007). In rabbits, hypotension and hypoxemia were reported along with smooth inductions and rapid or slow recoveries depending upon the duration of anesthesia (Aeschbacher and Webb, 1993). However, propofol seems to be less effective in rabbits than other species (Flecknell, 1996). They require very high doses (>10 mg/kg IV) to even produce sedation but these doses provide little reflex depression or antinociception. Use of propofol as a continuous rate

infusion (CRI) in rabbits may lead to tolerance and eventually fatal propofol infusion syndrome after extended use (>26 hours) (Glen, 1980; Ypsilantis et al., 2006, 2007, 2009). There was no improvement in effect when propofol phosphate, a water-soluble propofol pro-drug was used. A dose of 64.5mg/kg IV only produced slight ataxia and a dose of 150mg/kg IV only produced only mild sedation prior to death at 158 minutes post-injection (Banaszczyk et al., 2002). Propofol should be used very cautiously in rabbits.

Initial studies involving intraperitoneal propofol in mice have shown variability in sedation and surgical anesthesia response. Propofol administered intraperitoneally either as a single agent or in combination with potent opioids did not maintain adequate sedation or anesthesia in mice (Alves et al., 2007). However, when combined with an opioid- α_2 -agonist combination, propofol produced short-term anesthesia with a fast recovery (Alves et al., 2009). It is unknown at this time whether similar effects would be observed in guinea pigs, hamsters, gerbils, and other small rodents administered propofol by the intraperitoneal route, though it seems appropriate that such use should be undertaken with caution.

Barbiturates

Pentobarbital is an oxybarbiturate analog of barbituric acid. Pentobarbital can be utilized as a sedative-hypnotic, anesthetic, and anticonvulsant. Pentobarbital's mechanism of action is similar to that of benzodiazepines and propofol in that GABA_A receptors are activated resulting in enhanced GABA binding and opening of transmembrane chloride channels leading to cellular hyperpolarization within the central nervous system. Administration of pentobarbital produces dose-dependent sedation, hypnosis, muscle relaxation, and depression of the sensory cortex and reticular activating system.

As with all GABA_A agonists, pentobarbital has little or no analgesic activity. Pentobarbital produces dose-dependent respiratory depression which may require respiratory assistance (Peeters et al., 1988). At higher doses, pentobarbital possesses anticonvulsant and hypotensive properties. Hypotension results from vasodilation, diminished myocardial contractility, and reduced cardiac output. These and other cardiovascular effects depend upon the route of administration and tend to be less pronounced with IP rather than IV administration. This is due to the fact that peak blood concentration is reached more slowly than with IV administration and the portion of drug absorbed into the portal system is subject to early destruction in the liver. Hypothermia is common and has been reported in gerbils (Weinandy et al., 2005). Hypothermia is most likely a result of decreased basal metabolism and vasodilation. Additive

sedation and respiratory depression can occur if pentobarbital is administered in conjunction with tranquilizers, benzodiazepines, opioids, α_2 -agonists, propofol, and inhalant anesthetic agents. Animals administered pentobarbital should be supplied supplemental oxygen or monitored with pulse oximetry. General anesthetic doses may require respiratory support or endotracheal intubation.

When pentobarbital is administered, a supplemental heat source should be applied to the animal during the surgical period and continued until full recovery to prevent hypothermia. Pentobarbital can be administered intraperitoneally or intravenously. When used as a general anesthetic, pentobarbital can be administered as a bolus (Borkowski et al., 1990) or CRI. Commercial solutions commonly contain propylene glycol, which can cause pain upon injection and thrombophlebitis. For this reason, the subcutaneous and intramuscular routes of injection are not recommended.

Inhalation Anesthetics

Isoflurane and sevoflurane are volatile inhalant anesthetics with low blood/gas solubility in blood and body tissues. Both agents are dose-dependent CNS depressants used for induction and maintenance of general anesthesia. Due to their intrinsic low solubility, rapid inductions, rapid changes in anesthetic depth, and fast recoveries are associated with both agents. Both isoflurane and sevoflurane are vasodilators and cause a dose-dependent decline in systemic vascular resistance and blood pressure. In addition, dose-dependent respiratory depression is observed with both. Cardiac output decreases when higher concentrations are used.

Sevoflurane and isoflurane showed similar effects upon intracranial pressure and cerebral blood flow in rabbits while the cranial cerebral metabolic rate for oxygen was reduced nearly 50% with both agents at an end-tidal 1.0 MAC (Scheller et al., 1988).

Isoflurane and sevoflurane require separate vaporizers since vaporizers for both agents must be calibrated to the specific vapor pressure of each anesthetic agent.

Isoflurane and sevoflurane undergo minimal hepatic metabolism and elimination is primarily through alveolar exchange. Direct renal-hepatic effects are not observed with clinically used concentrations of isoflurane or sevoflurane. In Wistar rats, sevoflurane was reported to react with soda lime to produce a nephrotoxic compound, (olefin-compound A) (Gonsowski et al., 1994a, 1994b). This has not been clinically observed in humans, dogs, and horses and is very unlikely to be a problem with the fresh gas flow rates used in non-rebreathing circuits (Gentz and Malan, 2001; Kharasch, 1998; Muir and Gadawski, 1998). Isoflurane and sevoflurane are not listed as controlled substances.

Inhalant agents are dosed to effect or by using their minimum alveolar concentration (MAC), the concentration that will inhibit gross purposeful movement in 50% of patients. MAC is a measure of potency, but not intrinsic efficacy. In general, agents with higher potencies have a lower MAC. A recent study in gerbils showed the isoflurane MAC was lower compared to the sevoflurane MAC ($1.55 \pm 0.08\%$ versus $2.90 \pm 0.12\%$), yet cardiac and respiratory parameters were not significantly different between the two agents (de Segura et al., 2009).

In humans, sevoflurane is reported to be non-pungent, less irritating, and more pleasant smelling than isoflurane, making it the preferred agent for mask inductions (Goa et al., 1999). However, this effect was not observed in rabbits who were reported to struggle and breath hold during inductions with sevoflurane and isoflurane (Flecknell et al., 1999). Mask or inhalant induction anesthetic techniques should not be used in cardiovascular-compromised or debilitated animals since the higher concentrations can severely affect cardiac output and respiratory function. Moreover, non-pre-medicated or non-sedated rabbits should not be induced via facemask due to the risk of injury secondary to struggling upon induction. For this reason, a pre-medication to enhance sedation and the use of an induction chamber is recommended if injectable agents will not be used to induce anesthesia.

Since induction times with inhalant anesthetics are generally slower than intravenous agents such as propofol and ketamine, struggling, breath holding, and excitement may occur. Due to their minimal effects upon the cardiovascular system, a benzodiazepine, opioid, or benzodiazepine–opioid combination can be used as a premedication to provide sedation and muscle relaxation prior to induction with an inhalant anesthetic, resulting in a shorter and smoother induction (Mutoh, 2007; Mutoh et al., 2001). In addition, lower inhalant concentrations should be used initially with facemasks or induction chambers and gradually increased as the animal loses its fighting reflex. Due to the higher concentrations used for facemask or chamber induction, a down-draft table or fume hood should be used with induction chambers to minimize personnel exposure to anesthetic vapors.

Disadvantages to the use of inhalant anesthetics include initial investment of equipment including a calibrated vaporizer, endotracheal tubes, breathing circuits, induction chambers, facemasks, and waste gas scavenging equipment. Waste gas exposure must be kept below the National Institute for Occupational Safety and Health (NIOSH) standard of 8 parts per million (ppm) per 8-hour time period. The advantages of using inhalant anesthesia far outweigh any disadvantages when considering moment-to-moment control

of anesthetic depth and faster recoveries. In the authors' opinion, with proper monitoring, complications leading to morbidity and mortality are reduced with inhalant anesthesia compared to injectable anesthesia. In addition, less recovery and post-operative monitoring time are required with inhalant anesthetic use allowing for allocation of resources and efficient workflow practices.

ANESTHESIA CIRCUITS

Induction Chambers

Induction chambers are widely used for the anesthetic induction of small and difficult-to-handle research animals. The major feature of induction chambers is very minimal or slight rebreathing of expired gases, therefore expired carbon dioxide is removed by dilution. The approximate fill time for the chamber can be estimated via the following equation: chamber volume/flow rate = time to fill (Flecknell, 1996). This time to fill (τ) value can be used to control and predict the concentration of anesthetic gas within the induction chamber. This rate of change is a function of the exponential wash-in and wash-out function (Meyer, 2008). Advantages of induction chambers include: low-cost equipment that facilitates sedation of animals without handling (Figure 2.1) and they have minimal resistance to breathing. Disadvantages of this type of induction system include: a large amount of the anesthetic gas is vaporized, the anesthetic gas may be irritating for the animal (it may be useful to apply eye lubricant prior to placement in the induction chamber), and it requires relatively high flow rates to prevent dilution with room air. There is usually no ventilation method with basic units, but new multiplex units now have vacuum removal of waste gases (Muir et al., 2007).

FIGURE 2.1 Commercial Plexiglass Small Mammal Induction Chambers (Smiths Medical PM, Inc., Waukesha, Wisconsin).

Breathing Circuits

The purpose of breathing circuits is to provide the patient with oxygen and inhalant while simultaneously removing carbon dioxide. Rebreathing systems are used for larger animals (>7kg) and will not be discussed in detail in this book chapter.

Non-rebreathing systems (e.g. Bain, Mapleson A thru F, Norman Elbow, Ayre's T-piece, Magill) are the most commonly used systems in biomedical research for small rodents and animals. This type of system relies on a relatively high, fresh gas flow rate to remove carbon dioxide, and the amount of rebreathing that occurs is largely dependent upon this flow rate (Meyer, 2008). The recommended flow rate to decrease rebreathing with this type of system is 2–3 times the minute volume (Thurmon et al., 1996).

Vaporizer Types and Machines

Anesthetic vaporizers volatilize liquid anesthetics and deliver clinically useful concentrations of anesthetic vapor to the common gas outlet and are considered out-of-circuit vaporizers (Muir et al., 2007). There are a wide range of anesthetic machines used for small research animals (Figure 2.2). A full description of the multiple rodent anesthetic machines and of anesthetic machines in general, is beyond the scope of this chapter.

It is possible to adequately induce and maintain anesthesia in rodents and other small animals using virtually any machine equipped with a non-rebreathing circuit. However, others have suggested that the term "rodent anesthesia machine" is usually understood to mean an anesthesia machine lacking all the components of a circle system, and intended for use with a Mapleson-E circuit, or functionally similar design,

without a reservoir bag or adjustable pressure-limiting (APL) valve. Today there are anesthetic units which have multiple breathing circuits and induction chambers to facilitate multiple rodent procedures in a short time frame (Vogler, 2008) (Figure 2.3).

Ventilators

One of the most crucial aspects of providing safe general anesthesia is the maintenance of normal respiratory gas homeostasis. This is defined as the maintenance of arterial carbon dioxide levels within normal limits. The arterial carbon dioxide level usually ranges between 35 and 45 mmHg. A value below 35 mmHg may indicate hyperventilation, while a value above 45 mmHg may indicate hypoventilation (Thurmon et al., 2006). Generally respiratory effort can be verified by observing the movements of the animal's chest and abdominal wall. These movements may be regular and give the appearance of satisfactory gas exchange; they do not ensure adequate movement of air in and out of the lungs (Muir et al., 2007).

Mechanical ventilators are used to free the anesthetist from manually assisting ventilation but require endotracheal intubation of the animal. These are most commonly used in rabbits and other small mammals during thoracotomies as entrance into the chest inhibits the animal's ability to breathe spontaneously. Consultation with a veterinarian as well as equipment manufacturers can be extremely helpful. Ventilators suitable for use with magnetic resonance imaging (MRI) equipment are available in units suitable for patients ranging in size from adult humans to mice.

Regulatory Monitoring Requirements

The Occupational Safety and Health Act requires employers to comply with hazard-specific safety and health standards and provide employees with a workplace free from recognized hazards likely to cause death or serious physical harm (OSHA, 2000). OSHA has guidelines regarding anesthetic gases and workplace exposures, but these guidelines are not regulations; they are intended to assist employers with providing a hazard-free work environment. The National Institute for Occupational Safety and Health (NIOSH) recommends that no one be exposed at ceiling concentrations >2 ppm to any halogenated anesthetic (sampling period not to exceed 1 hour). The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value-time weighted averages (TLV-TWA) for halothane and enflurane for a normal 8-hour workday are 50 ppm and 75 ppm, respectively. Once again, it is important to note that these are guidelines and not standards or regulations.

FIGURE 2.2 Table Top Small Mammal Anesthetic Isoflurane Vaporizer (Smiths Medical PM, Inc., Waukesha, Wisconsin). Red arrow indicates area where a patient breathing circuit can be attached.

FIGURE 2.3 Mapleson-E Nonrebreathing System: The patient inspires fresh anesthetic gas from the corrugated reservoir tube. The patient expires air into the corrugated reservoir tube. Fresh gas is displaced into the expired gas out of the reservoir tube before the animals' next inspiration. Black arrow – where fresh anesthetic gas and oxygen enters the breathing circuit. Red arrow – where expired air exits the circuit. Black star – F/Air canister which contains charcoal and is a method of passive waste gas scavenging.

Anesthesia Waste Gas Scavenging

Two main types of gas scavenging are available, passive and active. Passive systems pipe directly to the atmosphere or to absorption devices (usually containing activated charcoal), while active systems include piped vacuum and active duct systems (Thurmon et al., 1996). Smith et al. (2003) compared the efficacy of three activated charcoal canisters for passive scavenging during rodent anesthesia with isoflurane and found there was great variability between brands and between individual canisters and that several canisters from one particular brand failed (emission of >100ppm isoflurane) prior to the end of their use life (gain of 50g). In another study by Smith et al. (2006), waste anesthetic gases were shown to be highest at the face/port interface when using a traditional rodent anesthesia unit and face mask. This level of exposure was mitigated when a tighter-fitting diaphragm was made for the face mask (better seal). Use of a flow hood during these types of procedures was also recommended (combining active and passive scavenging).

OSHA recommends that monitoring for anesthetic gases be performed every 6 months (OSHA, 2000). Personal, area, and source samples can be taken to evaluate worker exposure level, overall air containment, and leak detection/ineffective scavenger systems, respectively. Engineering controls (scavenging systems), safe work practices, employee training, and a comprehensive written hazard communication program are key in effectively managing anesthetic gas exposure. Specific recommendations for veterinary waste anesthetic gas

scavenging are available on the American College of Veterinary Anesthesiologists' website (<http://www.acva.org/professional/Position/waste.htm>). Proper monitoring and scavenging are extremely important as health consequences to exposed workers can be severe. Shirangi et al. (2008) demonstrated a 2.49-fold significant increase in the risk of spontaneous abortion in female veterinarians exposed to unscavenged anesthetic gases for one or more hours per week. Other possible health consequences include neurological dysfunction, hepatic and renal toxicity, and neoplasia.

ANESTHESIA MONITORING AND SUPPORT

Reflexes or response to surgical stimuli, body temperature, and the cardiopulmonary system should be thoroughly evaluated when monitoring animals under anesthesia. Redondo et al. (2007) evaluated the most common complications in 1281 dogs placed under general anesthesia and they are as follows: hypoventilation (63.4%), hypotension (37.9%), bradycardia (36.3%), hypoxia (16.4%), hypothermia (4.8%), and death (0.9%).

Anesthetic Depth

Pedal withdrawal, ocular and pinna reflexes can be used to assess anesthetic depth in rodents. Rabbit reflexes that can be used to evaluate depth of anesthesia include pinna, pedal withdrawal, corneal, and palpebral reflexes, with the pinna reflex considered to be the most accurate (Borkowski et al., 1990). It is important to note that although most animals lose palpebral responses early during anesthesia, rabbits may maintain this response even at deeper anesthetic planes (Smith and Danneman, 2008). Although the aforementioned reflexes can be used to assess anesthetic depth, response to surgical stimuli is probably the most reliable indicator (Whelan and Flecknell, 1992). While these reflexes, along with physiologic data such as heart rate and blood pressure, can be used, they are insufficient to fully determine anesthetic depth, especially whether or not an animal is unconscious (Antognini et al., 2005). Use of the electroencephalogram (EEG) is the only form of monitoring that has shown promise as a method of determining level of consciousness in both humans and animals (Antognini et al., 2005).

Respiratory Function

It is essential to assess the respiratory system to determine if anesthetized animals have adequate gas exchange. Respiratory rate can be determined in several

ways including: direct observation of the chest/abdominal wall, auscultation, and observation of reservoir bag movement. It may be difficult to visually assess respiratory rate in rodents (Smith and Danneman, 2008). Respiration depth and character must also be monitored for abnormalities such as bradypnea, tachypnea, or apnea.

Blood gas analysis is used to evaluate oxygenation, ventilation, and acid-base status. Arterial blood samples (femoral, metatarsal, auricular, etc.) are preferred for analysis. Once collected, samples should be analyzed immediately. If this is not possible, the samples should be stored on ice and analyzed within 2 hours. Depending on the type of analyzer used, the sample size can be very small (e.g. 95 μ l or less of whole blood for the VetScan i-STAT[®] 1 Handheld Analyzer). Normal pH, PaCO₂, and PaO₂ values are 7.35–7.45, 35–45 mmHg, and >90 mmHg, respectively. Corrective actions (e.g. endotracheal intubation, manual/mechanical ventilation, decreasing anesthesia, improving oxygenation/ventilation, and correcting acidotic/alkalotic states) should be performed as necessary.

Pulse oximetry reflects the oxygen saturation level of hemoglobin. Pulse oximeters also determine heart rate from the pulsatile flow of blood beneath the infrared (IR) diodes. Probes can be placed on the digits/paws, tongue, proximal tail, and the ear. The latter may give low readings in rabbits with use of some anesthetics that cause peripheral vasoconstriction, such as dexmedetomidine (Orr et al., 2005).

Capnography is used to measure CO₂ concentration in inspired and expired air. A capnograph is useful for detecting hypoventilation ($\uparrow$ ETCO₂), hyperventilation ($\downarrow$ ETCO₂), and malpositioned/malfunctioning endotracheal tubes. ETCO₂ has been evaluated in the rabbit and has been reported to reasonably reflect PaCO₂ (pulmonary tip) (Rich et al., 1990). However, this relationship is stronger in animals on controlled ventilation as the last gas exhaled more closely represents an end tidal sample.

Cardiovascular Function

The cardiovascular system must be monitored not only to determine if there is adequate circulation, but also because many anesthetics have cardio-depressive properties. Heart rate monitoring can be achieved by palpation, auscultation with a stethoscope, or use of an esophageal stethoscope. In order to determine the presence of bradycardia or tachycardia, the normal resting heart rate of each species being used should be known. Pulse rate and character can be determined by palpation of an accessible site (i.e. saphenous, carotid, femoral, lingual, auricular, or tail arteries) (Lipman et al., 2008; Smith and Danneman, 2008). Detection of digital

pulse may be difficult/impossible in rodents (Smith and Danneman, 2008). Capillary refill time (CRT) should be less than 2 seconds, and a prolonged CRT may be indicative of inadequate tissue perfusion. Heart rate, pulse rate/character, and CRT should be assessed collectively in order to adequately evaluate cardiac function.

Electrocardiographs (ECG) record the heart's electrical activity and allow heart rate/rhythm to be monitored. However, it is important to note that an ECG measures electrical activity but does not signify appropriate circulatory function. It is possible to have a normal ECG while cardiac output is actually zero (Flecknell, 1996). An ECG may be difficult to interpret in rabbits/rodents due to their rapid heart rate and low amplitude signals. However, ECG may still be a useful indicator of heart rate and presence of arrhythmias (Smith and Danneman, 2008). ECG patches can be used in larger animals, such as rabbits and chinchillas, if the fur in that area is removed but needle electrodes are usually necessary for smaller rodents (Flecknell, 1996). The electrodes can be placed on the left and right forelimb as well as the right hindlimb. Alternatively, there is a six-lead rodent ECG unit (ecgTUNNEL[®] from emka TECHNOLOGIES, Paris, France) that has demonstrated efficacy in conscious hamsters and rodents (Mongue-Din et al., 2007).

Esophageal stethoscopes may be used in rabbits to continuously monitor heart rate. Their use is impractical in small rodents and they may induce regurgitation in guinea pigs (Heard, 2003).

Arterial blood pressure is one type of measurement that can help determine tissue blood flow. For adequate perfusion of autoregulated tissues, the mean blood pressure should be greater than 60 mmHg (Haskins, 1987). Direct arterial monitoring is more ideal and more accurate than indirect monitoring if proper techniques are used. However, due to the invasiveness, difficulty, and monitor expense, the former technique is not frequently used. Indirect (oscillometric monitor and Doppler ultrasonic blood pressure monitor) measurements can be taken on limbs (both hind and fore), tails, and ears (rabbits). An appropriately sized cuff (~40% of limb circumference) is important for accuracy (Heard, 2003). There are a wide variety of rodent non-invasive blood pressure (NIBP) monitors available (e.g. Stoelting Plug-n-Play Non-Invasive Blood Pressure System, Wood Dale, IL) which can be used in mice, rats, guinea pigs, and hamsters.

Temperature

Small laboratory animals are prone to hypothermia due to their high surface area to body mass ratios. Shaving of fur, application of liquid disinfectants, contact with cold surfaces, and administration of some

pre-anesthetic and anesthetic agents (e.g. cold, dry inhalant anesthetics) further exacerbate heat loss. Reynolds et al. (2008) showed that hypothermia during anesthesia in humans predisposed them to post-operative complications such as: prolongation of action of anesthetics (inhaled and injectable), prolonged post-anesthetic recovery, increased blood loss during surgery, increased allogenic transfusion requirements, increased incidence of surgical wound infections, induction of hypoxia at peripheral wound tissues, impaired immune function, and increased risk of adverse post-operative myocardial episodes. Therefore, it is imperative to provide thermal support (e.g. table drapes, heating pads, forced air warming devices, circulating hot water blankets, and warm fluids) during the entire anesthetic period.

An appropriately sized thermometer should be used (when feasible) to measure body temperature. Core body temperature necessitates the use of an esophageal temperature probe. Alternatively, temperature probes are available on most pulse oximeters and can be inserted rectally or applied to a flat surface of the body. There are also feedback-controlled heating devices that utilize rectal temperature probes to maintain an animal's core body temperature within a preset range (e.g. Homeothermic Blanket System from Harvard Apparatus).

Fluid Therapy

Fluid therapy will depend on the patient (i.e. hydration and daily fluid requirements), presence of underlying diseases, and duration and invasiveness of the procedure. Crystalloid solutions (e.g. Lactated Ringer's, 0.9% sodium chloride, Normosol-R) are isotonic and can be used to replace fluid losses that occur during surgical procedures. Such fluid will quickly equilibrate between the intravascular and interstitial fluid compartments so that only 25% of the administered amount will remain in the intravascular space. Therefore, three times the volume needed must be administered in order to appropriately replace any intravascular losses (Thurmon et al., 1996). Colloid solutions (e.g. Hetastarch, Dextran, plasma, whole blood) are suspensions of large particles. The administration of these solutions leads to an increase in osmotic pressure within the vasculature which prevents fluid loss as well as draws water from the interstitial to the intravascular space. These types of solutions can be useful in cases of acute blood or protein loss during surgery. It should be noted that Hetastarch and Dextran are not replacements for blood products as they have no oxygen-carrying ability (Thurmon et al., 1996).

Rodent vessels are not usually amenable to intravenous fluid administration unless a vascular

cut-down procedure is performed, so warmed fluids are usually administered via intraperitoneal or subcutaneous routes. Rodents and rabbits require higher maintenance fluid rates than larger species (100ml/kg every 24 hours) (McKelvey and Hollingshead, 2003). The marginal auricular or cephalic veins are easily catheterized in rabbits, which allows administration of IV fluids. A rate of at least 10ml/kg/h is reported to be adequate for procedures of short to moderate duration (Lipman et al., 2008). Administration of fluids at this high of a rate (10ml/kg/h) for longer procedures (>2 hours) may lead to hemodilution and excessive accumulation of fluid within the interstitial space, so lower rates (5–8ml/kg/h) should be used if longer procedures are planned (Thurmon et al., 1996).

Intubation

Rabbit intubation is reported to be difficult due to the presence of a long/narrow oral cavity, large incisors, thick tongue, limited temporomandibular joint mobility (Lipman et al., 2008), and easily induced laryngospasm (Wixson, 1994). Endotracheal (ET) tubes ranging from 2.0–4.0mm (diameter), cuffed or uncuffed, are used for rabbit intubation. Topical anesthetic may be sprayed on the larynx to help reduce laryngospasm. Reported sequelae of ET intubation in rabbits include tracheal mucosal injury (Grint et al., 2006; Nordin et al., 1977; Phaneuf et al., 2006; Squire et al., 1990), and post-intubation tracheal strictures (Grint et al., 2006).

Guinea pigs are among the more difficult laboratory animals to safely anesthetize (Swindle et al., 2002). Some of the difficulties include: frequently food-filled cheeks, presence of palatal ostium (small opening which allows entry to the glottis) (Timm, 1987), and a small glottis relative to body size (Heard, 2004). Chinchillas also possess a palatal ostium. In addition, the pedal withdrawal reflex may not always reliably indicate anesthetic depth because guinea pigs make involuntary leg movements even under surgical anesthetic planes (Harkness and Wagner, 1995).

Medium- to large-sized rodents (e.g. guinea pigs, chinchillas, and hamsters) can also be intubated for anesthesia. Intravenous catheters (14G–16G) can be used for rodent endotracheal tubes. In guinea pigs, an 8 French modified urinary catheter or a 2.0–2.5-mm Cole or Murphy ET tube can be used for intubation (Johnson, 2010). In chinchillas, an 8 French modified urinary catheter can be used for intubation (Johnson, 2010).

Several methods for ET intubation have been described for rabbits, guinea pigs, chinchillas, and other rodents. The first is blind intubation. This requires proper positioning of the head and neck so the path from the oropharynx to the trachea is as

straight as possible so the ET tube can be directed into the trachea without visualization of the larynx. Proper placement can be determined by laryngeal palpation, patient response (e.g. cough, gag), listening for air flow through the ET tube, and the presence of condensation within the ET tube (Johnson, 2010). Direct visualization of the glottis is possible if an assistant hyperextends the head and neck and opens the mouth with a speculum or loops of gauze around the incisors while the operator uses an otoscope or small-bladed laryngoscope to raise the soft palate and depress the tongue. The ET tube can be placed once the vocal cords are visible (Johnson, 2010). Finally, indirect visualization of the glottis can be achieved by use of an endoscope or video laryngoscope. The endoscope is placed so the larynx can be seen and then the ET tube is passed parallel to it and into the trachea. In some instances, the ET tube can be placed over the endoscope and the entire unit passed directly into the trachea. Once in the trachea, the endoscope can be slid out of the ET tube and removed (Johnson, 2010; Tran et al., 2001). A recent report describes successful nasotracheal intubation in rabbits utilizing lubricated, clear silicon, uncuffed ET tubes (2.0–2.5 mm; 14.5 cm long) (DeValle, 2009).

An alternate method to use of ET intubation has been described for rabbits. Bateman et al. (2005) and Smith et al. (2004), describe the use of laryngeal mask airways (LMA) for inhalation anesthetics. Laryngeal mask airway is a tube which terminates in a cuffed, concave silicon mask which fits over the larynx (Vogler, 2008). Laryngeal mask airways are reported to be easier to place in comparison to ET tubes (Smith et al., 2004), but require a larger rabbit for appropriate fit and placement (>3 kg), emit more waste anesthetic gases (Smith et al., 2004), may lead to lingual cyanosis if the cuff is inflated (Bateman et al., 2005) although this has not been consistent in all studies (Cruz et al., 2000), and may lead to gastric tympany (Bateman et al., 2005). An LMA does allow for intermittent positive-pressure ventilation to be used and reduces the dead space and risk of hypoxia that is often associated with the use of a face mask (Bateman et al., 2005).

SURGICAL ANESTHESIA

Excellent reviews of anesthesia, anesthesia principles, and how they can be applied to small animals such as rabbits, gerbils, hamster, and small mammals are available (Fish et al., 2008; Flecknell, 1996, 2001; Lichtenberger and Ko, 2007).

Emphasis should be placed on using agents with analgesic, sedative, and muscle-relaxant properties

during the pre-surgical, intra-operative and post-operative periods. The unique pharmacologic profiles of each agent should be considered along with additive or synergistic effects when combined with other agents of a different pharmacologic class. By utilizing a multi-drug or multimodal approach one can enhance sedation, analgesia, and maintain general anesthesia with fewer side effects of the combined drugs than either drug when used alone. A general multimodal anesthetic regimen consists of administering an opioid to provide analgesia and sedation prior to surgery. Ketamine and a benzodiazepine can be used for induction to provide additional analgesia and NMDA receptor antagonism, thereby reducing central sensitization, and providing muscle relaxation. An inhalant anesthetic can be used to maintain anesthesia and an NSAID can be administered directly before recovery for post-operative analgesia and to reduce inflammation. In addition, local anesthetic blocks can be used at the surgical site prior to a surgical incision. Although this scenario is not practical for all cases, it demonstrates the utility of using a multiple drug approach focusing on the unique pharmacologic mechanisms of action of each drug to provide additive or synergistic anesthesia and analgesia. In addition, reversal agents are available for opioids, benzodiazepines, and α_2 -agonists that can be utilized in conditions or anesthetic scenarios of cardiac and respiratory depression or to hasten recovery. However, use of these agents will also reverse or attenuate the analgesic action of the anesthetic. A good example of using reversal agents to dramatically shorten recovery time was reported in chinchillas where fentanyl, medetomidine, and midazolam were reversed with naloxone, atipamezole, and flumazenil, respectively (Henke et al., 2004).

Administration of a tranquilizer, benzodiazepine, α_2 -agonist, or opioid prior to surgery provides sedation, enhances restraint, and allows for lower doses of injectable induction agents such as propofol or ketamine to be utilized. Use of premedication agents is summarized in Table 2.1. In addition, chamber or mask inductions with inhalant anesthetics are smoother and lower concentrations of inhalants can be utilized during the anesthesia maintenance period with fewer incidences of hypotension.

Although pre-medication with an analgesic-sedative agent or combination is recommended, short-term surgical anesthesia (generally 20–60 minutes) may be obtained with intraperitoneal administration of ketamine combined with an α_2 -agonist or a benzodiazepine in smaller species where intravenous access is not easily accessible. Alternatively, tiletamine-zolazepam can be used as a sole agent for inducing and maintaining anesthesia. Injectable anesthetic

All doses are mg/kg unless stated otherwise and administered 15–30 minutes prior to anesthesia or surgery.

*If also using the opioids for post-operative pain management, please follow the dosing intervals listed in Table 2.3.

combinations and constant rate infusions are summarized in Table 2.2. Due to the difficulty of maintaining moment-to-moment changes in the depth of anesthesia and prolonged recovery periods associated with injectable anesthetic agents, the authors recommend utilizing inhalant agents whenever possible.

POST-OPERATIVE MONITORING AND PAIN ASSESSMENT

Pain Assessment

Assessing pain in rabbits, guinea pigs, and other small mammals post-operatively can be extremely difficult as these are prey species and they have evolved behaviors to mask signs of pain or weakness. Any procedure performed on these animals that would be expected to cause pain in either humans or other animals, should be assumed to cause pain in the species covered by this book. The person assessing the level of post-operative pain should be familiar with the normal behaviors in these species and be as familiar as possible with the normal behaviors of the specific animals. Observing them for several days prior to the surgical procedure can be helpful. The presence of an observer

can often alter their normal behavior so the use of video equipment for post-operative monitoring can be helpful. However, the animals should be acclimated to the presence of this equipment prior to the observation period.

Behaviors to look for in rabbits that may indicate pain, include: anorexia, bruxism, decreased movement, sitting for long periods in a far corner of the cage, rapid fits of locomotion when handled, hunched abdomen, vocalization, decreased respiratory rate with a nasal flare and deep breathing pattern, decreased grooming (scruffy appearance), epiphora, and serous nasal discharge (Gaynor et al., 2009). Leach et al. (2009) documented inactive pain behaviors (twitch, wince, stagger, flinch, press, adjust slow and shuffle) and active pain behaviors (press, shuffle, quiver and arch) that were observed in rabbits after ovariohysterectomy.

Behaviors to look for in guinea pigs, hamsters, and other rodents that may indicate pain are: aggressive behavior, vocalization, decreased activity, decreased grooming (scruffy appearance), hiding in the cage, piloerection, separation from cagemates, and anorexia (Flecknell et al., 2000). Assessing behaviors that are indicative of pain are especially difficult in some species (e.g. hamster, gerbil) as they are nocturnal and therefore normally inactive when laboratory or veterinary staff

All doses are mg/kg unless stated otherwise and administered immediately prior to anesthesia or surgery.

*Only re-dose during surgery with ketamine component at one-third the original dose.

**Propofol should be used with caution in rabbits as extended use may lead to propofol infusion syndrome.

would be most likely to be performing post-operative examinations (Flecknell et al., 2000).

There are numerous pain assessment scoring systems that have been developed for cats and dogs (Gaynor et al., 2009). It may be useful for the laboratory or investigator to develop a similar system for post-operative pain monitoring that is both specific to the species being used and the procedure being performed. This would allow consistency between observers and therefore less of a chance to miss pain behaviors in the animal.

Post-Operative Analgesia

Analgesia and pain-relief protocols should be based upon the species, the procedure to be performed, the pharmacology and pharmacokinetics of available agents, anesthetic–analgesic drug interactions, and adverse effect profiles of individual agents (Table 2.3).

During the post-operative period, combining agents with different mechanisms of analgesia (i.e. multimodal therapy) such as opioids and NSAIDs is useful to augment analgesia and reduce inflammation. Furthermore, the addition of an NSAID prior to recovery may reduce peripheral sensitization and improve the quality of recovery (Katz, 2001). If an opioid was administered as a premedication, there may be some residual analgesia remaining depending upon the length of the surgical

procedure and the duration of action of the drug. In this scenario an NSAID can be administered shortly before or during recovery with re-dosing of the opioid at a later time point. Many opioids have a shorter duration of action compared to daily dosing for some NSAIDs. By incorporating NSAIDs into an analgesic regimen, fewer analgesic doses need to be administered during the day, thus reducing handling and stress for the patient. For severe pain an opioid should be provided immediately after surgery along with an NSAID to allow onset of action time for the NSAID to provide analgesia.

Post-Operative Monitoring

Post-operative monitoring should be performed at least once daily, if not more frequently, for the first 7 days after surgery or until any skin sutures/staples, if present, are removed. Animals should be carefully assessed for the following parameters: appetite, water intake, body weight, urine output, fecal output, hydration status, appearance of the incision site, temperature and vital signs (if possible to obtain without stressing the animal), and evidence of any of the behaviors mentioned above that may indicate pain. This is especially important in rabbits, guinea pigs, and chinchillas because ileus is a common and serious post-operative complication in these species. If ileus does develop,

TABLE 2.3 Post-operative Analgesics

Drug	Rabbit	Guinea Pig	Hamster	Gerbil	Chinchilla
OPIOIDS					
Buprenorphine	0.01–0.05 (SQ, IM, IV) q6–12h	0.05 (SQ, IM) q6–12h	0.1 (SQ) q6–12h	0.1 (SQ) q6–12h	0.05 (SQ, IM) q6–12h

there are several treatment options available. Offering highly palatable treats (e.g. timothy hay, carrots, kale) and dietary supplements (e.g. Critical Care® from Oxbow) are a common first step. Any guinea pig that is inappetent or anorexic should be given parenteral vitamin C in order to prevent the development of scurvy as they cannot produce vitamin C and depend on dietary sources. If the animal appears dehydrated, providing

daily subcutaneous or intravenous crystalloid fluids is important. If none of these treatment options are effective and no gastrointestinal obstruction is present, use of a prokinetic, such as metoclopramide, can help stimulate gastric motility. Reassessing the post-operative analgesic plan is also important, as pain can be a large contributor to the development of ileus.

INTRODUCTION

This chapter reviews information on the clinical biochemistry and hematology of the rabbit (*Oryctolagus cuniculus*), guinea pig (*Cavia porcellus*), hamster (*Mesocricetus auratus*) and other rodents, including the gerbil (*Meriones unguiculatus*), chinchilla (*Chinchilla laniger*), degu (*Octodon degus*), deer mouse (*Peromyscus maniculatus*), dormouse (Gliridae family), kangaroo rat (*Dipodomys* spp.), cotton rat (*Sigmodon hispidus*), and sand rat (*Psammodmys obesus*).

The chapter begins with a review of sample collection and preparation, and a description of commonly measured parameters and analytical techniques. The reference values, sources of variation, and unique characteristics are then presented for each species, as available. We have attempted to include the most current literature on a backdrop of historical information for each of these topics, along with supporting references.

It is important to recognize that many variables affect the parameters of clinical biochemistry and hematology that are presented here, including methods of sample collection and preparation, equipment, reagents, and methods of analysis, as well as the age, sex, breed, and environment of the animals being sampled. Reference ranges are presented according to the most recent and reliable literature available. Some clinical biochemistry and hematology parameters for the less common species covered in this volume are not yet available in the literature.

CLINICAL BIOCHEMISTRY

Introduction

Abnormal clinical conditions are usually associated with specific biochemical changes in the blood and urine, and these changes are detected using specific analytical techniques. Values obtained from a clinical case are usually compared with reference values that are either produced in the same laboratory or in a similar group of animals and cited in the literature.

A joint committee formed by several scientific societies, the International Committee for Harmonization

of Clinical Pathology Testing (IHCPT), formulated a recommended core clinical chemistry panel for safety and toxicity studies in laboratory animals (Weingand et al., 1996). This core panel includes glucose, blood urea nitrogen, creatinine, total protein, albumin, globulin, calcium, sodium, potassium, chloride, and total cholesterol. Additionally recommended are at least two hepatocellular function tests, including alanine aminotransferase, aspartate aminotransferase, sorbitol dehydrogenase, glutamate dehydrogenase, or total bile acids, and two hepatobiliary function tests, including alkaline phosphatase, gamma glutamyltransferase, 5'-nucleotidase, total bilirubin, or bile acids. The U.S. EPA (2008) recommended the additional inclusion of assays for triglycerides, magnesium, protein electrophoresis, inorganic phosphate/cholinesterase, phosphorus, ornithine carbamoyl transferase, lactate dehydrogenase, and creatine (Evans, 2009).

Urinalysis tests recommended by the IHCPT and U.S. EPA include appearance (color and turbidity), volume, specific gravity, pH, microscopic sediment, protein, glucose, ketones, bilirubin, blood, nitrate/nitrite, and urobilinogen (Evans, 2009; U.S. EPA, 2008; Weingand et al., 1996).

Sample Collection

Restraint

Most small laboratory animals are prey species in the wild, and they are easily stressed by the handling and restraint needed to obtain a sample of blood or urine. Pre-conditioning has been shown to reduce plasma corticosterone levels in rats (Fluttert et al., 2000), but this practice is often impossible or impractical in many laboratory rodents, especially for the diagnosis of spontaneous disease. A restraint tube can be used to hold small rodents for obtaining samples if the tube is the appropriate size and is disinfected between animals.

Anesthesia may be needed to obtain samples from laboratory rabbits or rodents in certain situations, especially when larger volumes of blood, or sterile urine samples, are needed. However, anesthesia itself has been shown to produce changes in clinical biochemistry or hematology parameters, including decreased hematocrit, hemoglobin level, and red blood cell count

(Marini et al., 1994; Pilny, 2008). It is important to know what method of restraint was used to obtain samples when interpreting reference clinical biochemistry and hematology values.

Blood Collection

Optimal sites for blood collection vary between laboratory animals and are described in this chapter for each species for which information is available. Small animals typically lack superficial blood vessels, and deeper vessels are often obscured by fat. A variety of peripheral veins, such as the lateral saphenous vein and the cephalic vein, may be used for small samples of blood, as described for individual species. The jugular vein may be used in most species for larger blood samples, although appropriate positioning and restraint can be stressful and may require sedation or anesthesia (Thrall et al., 2004).

Blood collection from the smaller laboratory animals is challenging due to the limited blood volume available and because the restraint or sedation necessary to obtain a sample may alter the results of some assays (Pilny, 2008). A general guideline for the maximum volume of blood that can be safely withdrawn in a single sample is approximately 1% of the animal's body weight, or 10% of the circulating blood volume, in order to avoid hypovolemic shock and anemia. This volume will be replaced within 24 hours in most healthy animals, although a return to normal levels of all blood constituents may take up to 2 weeks (Thrall et al., 2004). An alternate standard states that the blood volume withdrawn should not exceed 7.5% of the total blood volume per week or 10% of the total blood volume every 2 weeks (McGuill and Rowan, 1989).

Clinical chemistry assays have become more sensitive with advances in technology, and successful analysis can now be achieved with smaller volumes of blood. Most clinical chemistry assays require a few milliliters of blood, and some assays now require only a few microliters of blood.

Serum is the preferable sample for most clinical chemistry assays to avoid interference by the actions of an anticoagulant. Some of the anticoagulants, such as ethylenediamine-tetraacetic acid (EDTA), and citrate, prevent clotting by chelating calcium ions, which are often cofactors in enzyme assays. Heparin is usually the preferred anticoagulant because it has minimal or no interference with the majority of clinical chemistry assays (Buetow et al., 1999). Heparin may, however, produce artificially elevated inorganic phosphorus values (Benjamin and McKelvie, 1978).

Serum is produced by collecting blood into tubes with no anticoagulant and allowing it to clot for 30–45 minutes at room temperature. The sample should not

stand for more than 45 minutes without refrigeration because many constituents may change concentration at room temperature, including glucose, phosphates, lipids, and chloride (Mitruka and Rawnsley, 1977). The tube is then centrifuged at approximately 1000g for 15 minutes to yield serum that can be analyzed for clinical chemistry parameters (Buetow et al., 1999).

Plasma is suitable for many clinical chemistry assays and is a practical necessity in many cases because of the small volume of blood available from laboratory rabbits and rodents. Blood samples may be treated with heparin and used for both hematology and clinical chemistry assays. Blood may be collected in a syringe containing 50U of heparin per ml, or placed in a heparinized tube, and centrifuged for 2 minutes at high speed, such as 12000g, to yield platelet-free plasma that can be used for clinical chemistry assays (Lindena and Trautschold, 1986). Alternatively, miniature blood collection tubes, such as those used in human pediatric medicine, can be used for small-volume blood samples. The advantage of using these tubes is that the anticoagulant is lyophilized and does not dilute the sample (Dyer and Cervasio, 2008).

Both serum and plasma samples may be used immediately, stored at 4°C for use in 24–48 hours, or stored frozen at –20°C for up to 90 days or at –70°C for 360 days or longer (Buetow et al., 1999; Cray et al., 2009). However, some enzymes, such as lactate dehydrogenase, are not stable if the sample is frozen (Mitruka and Rawnsley, 1981).

Certain factors, such as lipemia and hemolysis, may interfere with the results of clinical biochemistry assays that are performed by spectrophotometer. The increased turbidity associated with lipemia can produce artificially high values for certain enzymes. Lipemia also interferes with the assays for glucose, bilirubin, total protein, phosphorus, and urates (Saibaba et al., 1998). Hemolysis also produces errors in clinical biochemical values because most serum enzymes are present at high concentrations in red blood cells. Hemolysis causes the release of these enzymes into the bloodstream to yield artificially high serum values. Hemolysis may produce an artificial elevation of serum potassium and inorganic phosphorus levels (Owens et al., 2005; Stankovic and Smith, 2004), as well as bilirubin, transaminases, and lactate dehydrogenase (Gad, 2007).

The method and site of sample collection may also affect resulting values. For example, enzymes found in cardiac muscle, such as creatine kinase, aspartate aminotransferase, lactate dehydrogenase, and alanine aminotransferase, may be artificially elevated in the serum of some species when blood samples are obtained by cardiac puncture (Maxwell et al., 1985).

Urine Collection

Urine samples of satisfactory volume and quality are difficult to obtain from many small laboratory animals. Urine may be collected from most animals following spontaneous urination, manual bladder expression, cystocentesis, or catheterization. Cystocentesis should be used to obtain a sterile sample when a urine culture is needed, as for a bacterial culture and antibiotic sensitivity. A metabolism cage is useful when sequential urine samples are required or when a larger volume of urine needs to accumulate over a specified period of time. The volume of urine that is excreted per day and available for sampling depends on many factors, including food and water consumption, activity level, disease, and environmental temperature.

The simplest method of urine analysis is performed with a commercial dry reagent test strip, or dipstick, which requires only a few microliters of urine per test reagent square. This assay provides semiquantified measures of urine components, such as blood, glucose, ketones, and pH.

The animal's ability to concentrate urine is evaluated with a small drop of urine placed on a refractometer. Normal specific gravity falls in a range of approximately 1.003–1.050 and varies by species and environment. Increased specific gravity may indicate dehydration, heart failure, or shock, and decreased specific gravity may indicate renal failure, diabetes insipidus, or other conditions.

A small volume of 1–2 ml of urine can be centrifuged at approximately 10000g for 10 minutes. The sediment is then analyzed under the microscope for cells, bacteria, and crystals.

Reference values for urine characteristics of the laboratory animals covered in this volume are provided in Table 3.1.

Carbohydrate Metabolism

Glucose

Glucose is the parameter most commonly evaluated as a measure of carbohydrate metabolism. Glucose concentration is affected by many factors, including nutrition, hormones, hibernation, restraint, fasting, and anesthesia. Handling of the blood sample may also affect glucose values because glucose decreases in serum when erythrocytes are present. A decrease in glucose concentration by approximately 7% is reported in blood that sits at room temperature for 1 hour (Tietz, 1976). Therefore, serum should be separated and tested for glucose as soon as possible after a blood sample is taken. Alternatively, a preservative such as thymol or fluoride should be added to inhibit glycolysis, as described for the rat (Ringler and Dabich, 1979). Glucose is usually measured using glucose oxidase/peroxidase-linked chromogenic methods or by measuring hexokinase activity (Evans, 2009).

Reference ranges for serum glucose concentration in the laboratory animals covered in this volume are provided in Table 3.2.

Lipid Metabolism

The primary lipids contained in serum are cholesterol, triglycerides, fatty acids, and phospholipids. Of these, cholesterol and triglycerides are the most commonly measured in laboratory animals. There are significant interspecies differences in the normal serum concentrations of these lipid components. Reference ranges for cholesterol, triglycerides, and total lipids for the laboratory animals covered in this volume are provided in Table 3.2.

High levels of lipids cause lipemia, which can interfere with clinical biochemistry assays performed by photometric analysis. Solubilizers may be used on

TABLE 3.1 Urine Characteristics¹

	Volume (ml/kg/d)	pH	Specific Gravity	Normal Color	Turbidity	Protein (mg/wk)	Cells	Crystals	References

¹Species for which no values are available are not listed.

lipemic samples to decrease this interference (Evans, 2009). Polyethylene glycol 6000 is a precipitating agent that is often used to remove lipoproteins from a serum sample (Thomson and Kunze, 1984).

Cholesterol

Cholesterol is an essential component of cell membranes and an important precursor for the synthesis of bile acids, steroid hormones, and some fat-soluble vitamins. Cholesterol is produced in the liver or obtained in the diet, and it circulates in free and esterified forms. Cholesterol is recycled through metabolism in the liver and excretion in bile into the digestive tract. Cholesterol levels typically peak after a meal, so fasting is required for an accurate assay.

Cholesterol has been the subject of many studies in laboratory animals because high levels of circulating cholesterol are associated with the development of atherosclerosis. There are several valuable laboratory animal models of cholesterolemia and atherosclerosis.

Cholesterol is usually measured using a cholesterol esterase followed by a cholesterol oxidase linked to a peroxidase-chromogen detection system (Richmond, 1992).

Lipoproteins are macromolecules that transport lipids and cholesterol within the bloodstream and can be classified as alpha or beta, or by a density value that varies inversely with size.

- *Low-density lipoproteins (LDL)* are also known as beta lipoproteins and have a diameter of 18–28 nm, density of 1.019–1.063 grams per ml, and carry cholesterol from the liver throughout the body.

- *High-density lipoproteins (HDL)* are also known as alpha lipoproteins and have a diameter of 5–15 nm, density of less than 1.063 grams per ml, and carry cholesterol away from the tissues of the body and back to the liver.

Different lipoprotein fractions can be separated and quantified using microaffinity chromatography columns (Tschantz and Sunahara, 1993), electrophoresis or other methods, including fast protein liquid chromatography, and high-performance liquid chromatography (Evans, 2009).

Triglycerides

Triglycerides are composed of a glycerol molecule bound to three fatty acids and are digested by pancreatic lipase. Triglycerides are a major component of very-low-density lipoprotein (VLDL) and serve as a source of energy. They are broken down in the intestine, absorbed by intestinal cells, and combined with cholesterol and proteins to form chylomicrons that are transported in lymph to the bloodstream.

Triglycerides are measured using enzymatic reagents, including lipase, glycerol kinase, and glycerol-3-phosphate oxidase linked to a peroxidase-chromogen detection system (Evans, 2009).

Enzymes

Enzymes are normally contained within the cells that synthesize them, and increased enzyme levels in serum or plasma are indicative of induction or cell damage. Several

factors affect the activity of enzymes in plasma or serum, including the concentration of enzyme in cells, the extent and duration of cell damage, and the accessibility and persistence of the enzyme in the bloodstream. Diet and nutritional deficiencies can also impact the levels of enzymes measured. The laboratory methods used to measure serum enzyme activity can affect the values obtained.

Enzyme activity is usually represented in International Units (IU), where one unit is the amount of enzyme that reacts with one picomole of substrate per minute. In theory, a standardized method of representing enzyme activities should allow better comparisons between laboratories. However, the choice of enzyme substrates and the experimental conditions used have important effects on the results of enzyme assays (Evans, 2009).

Reference values for several commonly assayed enzymes for laboratory animals covered in this volume are provided in Table 3.3.

Alkaline Phosphatase (ALP)

Alkaline phosphatase (ALP) represents a group of enzymes that remove phosphate groups from molecules such as nucleotides and proteins, and they work most effectively in an alkaline environment of pH 9–10 (Evans, 2009). The highest concentrations of ALP are found in liver and bone, and lower concentrations of ALP are present in kidney tubules, intestinal epithelium, lung, and placenta. Bone growth in young animals produces elevated ALP levels. Concentration of ALP varies according to species but in general is increased by digestion, cholestasis, or injury to intestinal or biliary epithelium. Levels of ALP may be decreased by fasting, hypothyroidism, or pernicious anemia (Fernandez and Kidney, 2007).

Alkaline phosphatase is typically measured using 4-nitrophenol phosphate as a substrate and 2-amino-2-methyl-1-propanol (AMP) or diethanolamine (DEA) as a buffer, although DEA yields higher ALP values. Isoenzymes of ALP can be distinguished using electrophoresis, HPLC, and other methods (Evans, 2009).

Alanine Aminotransferase (ALT)

Alanine aminotransferase (ALT) is a transaminase enzyme that was formerly known as serum glutamate pyruvate transaminase (SGPT). Alanine aminotransferase catalyzes the transfer of an amino group from alanine to alpha-ketoglutarate in the alanine cycle to form pyruvate and glutamate. The ALT enzyme is found in serum and organ tissues, especially liver, although significant concentrations are also found in kidney, skeletal muscle, and myocardium. Lower levels of ALT are present in pancreas, spleen, and lung. Alanine aminotransferase is elevated in serum under

conditions of significant cellular necrosis and is used as a measure of liver function. Levels of ALT may be elevated in cases of hepatitis, congestive heart failure, liver or biliary duct damage, or myopathy. Diet, restraint, and drug administration may also affect plasma ALT in rodents (Evans, 2009).

Concentration of ALT is quantified using the NADH oxidation method.

Aspartate Aminotransferase (AST)

Aspartate aminotransferase (AST) is a transaminase enzyme that catalyzes the conversion of aspartate and alpha-ketoglutarate to oxaloacetate and glutamate. The AST enzyme was formerly known as serum glutamate oxalate transaminase (SGOT) and is present in all tissues except bone, with highest levels in liver and skeletal muscle. Concentration of AST is elevated after bruising, trauma, necrosis, infection, or neoplasia of liver or muscle (Eugster et al., 1966). The AST enzyme is found in cerebrospinal fluid, exudates, and transudates in proportion to the amount of cellular damage. Low concentrations of AST are also found in urine but are not useful for diagnosis of renal damage (Evans, 2009).

AST is measured using the NADH oxidation method.

Lactate Dehydrogenase (LDH)

Lactate dehydrogenase (LDH) is an enzyme that catalyzes the conversion of pyruvate to lactate, along with NADH to NAD⁺, during glycolysis in conditions of hypoxia. The LDH enzyme is present in all cells, but it is concentrated in muscle, liver, and kidney. LDH exists as five isozymes, LDH-1 through LDH-5, each composed of four subunits. Differential LDH isozyme levels are used diagnostically (Markert et al., 1975). Isozyme LDH-1 (4H) has four heart subunits and is the major isozyme in heart. Isozyme LDH-2 (3H1M) has three heart and one muscle subunit and is the major isozyme in the macrophage-monocyte system and serum. The LDH-3 (2H2M) isozyme has two heart and two muscle subunits and is the major isozyme in lungs. Isozyme LDH-4 (1H3M) has one heart and three muscle subunits and is the primary isozyme in kidneys. The LDH-5 (4M) isozyme has four muscle subunits and is the major isozyme in liver and skeletal muscle. The concentration of LDH is elevated in serum as a result of organ infarction and significant cell death that results in loss of cytoplasm. For example, elevations of LDH result from conditions such as hepatitis, shock, hypoxia, extreme hypothermia, and meningitis, among others. The LDH enzyme has often been used in laboratory animals, along with troponin levels, to detect myocardial damage (Evans, 2009; Herman et al., 2006). However, LDH stability is highly susceptible to freezing, and values are affected by storage conditions (Mitruka and Rawnsley, 1981; Tietz, 1976).

N/A = values not available.

¹Species for which no values are available are not listed.

Creatine Kinase (CK)

Creatine kinase (CK) is also known as creatine phosphokinase (CPK) and is an enzyme that catalyzes the phosphorylation of creatine. Creatine kinase is a dimer that exists as isoenzymes with greatest activity in muscle (CK-MM), heart (CK-MB), and brain (CK-BB) (Lang, 1981). An additional form of the CK enzyme exists in mitochondria (CK-Mt). The distribution of CK isoenzymes varies between tissues and species. Creatine kinase is found in serum, plasma, and urine and is elevated by muscle necrosis or disease.

Sorbitol Dehydrogenase (SDH)

Sorbitol dehydrogenase (SDH) is an enzyme that converts the alcohol form of glucose, sorbitol, into fructose, in the presence of NAD. Sorbitol dehydrogenase activity has been detected in liver, kidney, and seminal vesicles of many animals. Increased levels of SDH usually indicate hepatocellular damage (Dooley, 1984), and may be a more sensitive indicator of hepatic damage than ALT or AST, but changes in SDH levels may also be minimal (Evans, 2009).

Amylase

Amylase is a small enzyme that breaks down complex carbohydrates to ultimately form monosaccharides such as glucose. The pancreas produces large amounts of alpha-amylase, which requires calcium and acts as a major digestive enzyme at neutral pH. Amylase is also present in liver and salivary glands. Thus, increased plasma amylase is indicative of tissue damage in pancreas, liver, or salivary glands (Evans, 2009).

Chromogenic and immunologic methods are typically used to measure amylase for the diagnosis of pancreatic disease (Evans, 2009).

Glutamate Dehydrogenase (GDH)

Glutamate dehydrogenase (GDH) is a mitochondrial enzyme that is involved in the metabolism of glutamate to 2-oxoglutarate. The GDH enzyme is found primarily in liver, kidney, and cardiac muscle, with lower levels in brain, skeletal muscle, and leukocytes. The majority of GDH in the serum originates from hepatocytes in healthy as well as diseased animals. The distribution of GDH in the liver is mainly centrilobular, whereas ALT is periportal or centrilobular in rats, and may indicate the site of hepatocyte damage (Carakostas et al., 1986; Merrick et al., 2006). Levels of GDH are normally low in most species, and increased serum GDH is indicative of damaged or necrotic hepatocytes due to liver disease (Evans, 2009).

Hormones

There are many hormones that can be measured in the serum of laboratory animals, but a complete listing is beyond the scope of this chapter. This section will focus

on some of the more relevant hormones in laboratory animals, including adrenal, thyroid, and reproductive hormones. Reference values for hormones in laboratory animals covered in this volume are provided in Table 3.4.

Adrenal Hormones

Cortisol is a glucocorticoid produced by the zona fasciculata of the adrenal cortex and is involved in the response to stress. Cortisol acts to increase blood pressure and blood glucose and has an immunosuppressive action. Levels of cortisol are known to vary according to diurnal rhythm and other environmental influences.

Corticosterone is also produced by the adrenal cortex and is a significant glucocorticoid in some species, including rodents. Corticosterone has functions that are similar to those of cortisol.

Thyroid Hormones

Thyroxine (T4) is secreted by the follicle cells of the thyroid gland and transported in the bloodstream to control metabolic processes in the body. Thyroxine is a prohormone and is converted to the more potent form, *triiodothyronine (T3)* in the tissues of the body. Thyroid hormones are involved in growth and metabolism and act synergistically with other hormones, such as catecholamines and glucocorticoids. Circulating levels of thyroid hormones are affected by many internal and external factors to which an animal is exposed.

Reproductive Hormones

Luteinizing hormone (LH) is a glycoprotein hormone produced by the anterior pituitary gland. In the female, its sudden increase at the end of the follicular phase triggers ovulation and corpus luteum development. In the male, it is also called interstitial cell stimulating hormone, and it triggers testosterone production by the Leydig cells of the testis.

Follicle-stimulating hormone (FSH) is a glycoprotein hormone produced by the anterior pituitary gland. In both males and females, FSH stimulates germ cell maturation and helps regulate growth and sexual maturation.

Estradiol is a steroid hormone that is the predominant female sex hormone and the primary estrogenic hormone. In females, the majority of estradiol is produced by the ovaries, and smaller amounts are produced by the adrenal cortex. In males, small amounts of estradiol are produced by the testes and adrenal cortex.

Progesterone is a steroid hormone that is produced by the corpora lutea of the ovaries, the adrenal glands, and the placenta during pregnancy. Progesterone increases at the time of ovulation and helps support the maintenance of pregnancy.

Prolactin is a peptide hormone produced by the anterior pituitary gland and other organs and is primarily involved in lactation.

¹Species for which no values are available are not listed.

Oxytocin is a peptide hormone produced in the hypothalamus and released from the posterior pituitary. Stimulation of the cervix during delivery causes release of oxytocin, which is involved in lactation and uterine contractions.

Testosterone is a steroid hormone that is the primary sex hormone in males and has anabolic effects. Testosterone is secreted primarily by the testes in males and the ovaries in females. Small amounts of testosterone are also secreted by the adrenal glands.

Most reproductive hormones are evaluated using commercial radioimmunoassay kits.

Liver Function

Enzymes

The aminotransferases, AST and ALT, are normally contained within liver cells and are released into the blood when liver cells are damaged. Increased levels of AST or ALT are therefore usually indicative of liver damage, as discussed above. Reference ranges for these enzymes in the laboratory animals covered in this volume are provided in Table 3.3.

Reference values for other indicators of liver function, including total bilirubin, bile acids, and serum proteins, in the laboratory animals covered in this volume are provided in Table 3.5.

Total Bilirubin

Bilirubin is produced in the macrophage-monocyte system by the breakdown of hemoglobin to biliverdin and then bilirubin. Bilirubin is carried in the plasma to the liver, where it is conjugated to form bilirubin diglucuronide and excreted in the bile. Bilirubin level thus serves as a measure of liver and bile tract function. Total bilirubin includes both the conjugated and unconjugated (free) forms and, if elevated, is usually indicative of liver damage or hemolysis.

Bilirubin oxidizes slowly when exposed to light, so specimens obtained for bilirubin levels should be protected from light exposure. Freezing also artificially alters bilirubin levels in plasma samples (Ringler and Dabich, 1979).

Elevated total bilirubin may be recognized by a visible yellow coloration of the plasma. A standard colorimetric assay for total bilirubin involves a diazotization reaction (Evans, 2009).

Bile Acids

Bile acids are synthesized from cholesterol and conjugated to amino acids in the liver, then stored in the gallbladder. Bile acids are released from the gallbladder during digestion to form micelles that assist in the processing of dietary fats. Bile acid levels are affected in most

species by diet, gastric and intestinal transit time, enteritis, and gallbladder contraction (Center et al., 1995). Bile acid concentration can be determined by gas or liquid chromatography-mass spectrometry (Perwaiz et al., 2001).

Serum Proteins

The liver is the source of many proteins, and liver function is often evaluated by measuring total serum protein, albumin, and globulin levels (Evans, 2009). Serum proteins include albumin and globulins, and total serum proteins represent the sum of these constituents. Protein electrophoresis is used to separate serum proteins, based on their mobility, into fractions of albumin, alpha-, beta-, and gamma-globulins and determine their concentrations (Thrall et al., 2004).

ALBUMIN

Albumin is the first fraction to appear by electrophoresis and is the predominant serum protein. Albumin is produced in the liver and helps maintain osmotic pressure within the intravascular compartment.

GLOBULINS

Alpha-1 and -2 globulins and beta globulins include a group of binding and carrier proteins in the blood. Alpha globulins are increased during acute infections and demonstrate the most rapid electrophoretic mobility of the globulin fractions. Beta globulins are binding proteins in plasma and thus should be measured in plasma rather than serum. Gamma globulins are primarily antibodies and are increased in response to infection.

TOTAL PROTEIN

Total protein levels can be affected by many factors including age, diet, pregnancy, disease, and dehydration. Technical issues such as assay method and sample handling can also impact the results of this assay.

Low total protein, or hypoproteinemia, is often due to chronic malnutrition, malabsorption, or protein loss due to kidney or liver disease. A specific decrease in the albumin fraction is suggestive of liver disease, although chronic malnutrition from poor diet or dental disease may also cause hypoalbuminemia. Reduced cecotrophy in some laboratory animals may also cause a decrease in total protein, especially albumin.

Increased total protein, or hyperproteinemia, is commonly caused by dehydration, but it may also indicate chronic infection, shock, or a metabolic disturbance.

The relative size of the albumin and globulin fractions may help determine the cause of an abnormal total protein value. The albumin to globulin ratio is often calculated as a measure of this relationship and is usually slightly greater than one. A low ratio could be the result of decreased albumin or increased globulins due to myeloma or autoimmune disease. A high ratio

¹Species for which no values are available are not listed.

may be caused by low immunoglobulin levels as occurs in some leukemias.

There are several methods used to measure serum protein levels, and the specific method chosen has an effect on the values obtained. Total proteins can be measured with the biuret method, in which a cupric ion–peptide complex forms in an alkaline solution. The bromocresol green dye method produces higher total protein values than the method of cellulose acetate electrophoresis (Hall, 1992).

Kidney Function

Reference values for blood urea nitrogen and creatinine, which are typically used as indicators of kidney function, are provided in Table 3.6 for the laboratory animals covered in this volume.

Blood Urea Nitrogen (BUN)

Urea is produced by the breakdown of proteins and is excreted in the urine. Blood urea nitrogen (BUN) is often used to evaluate renal function in animals, including laboratory animals. Blood urea nitrogen level is affected by circadian rhythm, diet, liver function, hydration, and intestinal absorption (Melillo, 2007). The concentration of BUN is artificially increased by a high-protein diet or vigorous exercise, whereas BUN is decreased by low protein intake, liver failure, or treatment with anabolic steroids (McLaughlin and Fish, 1994).

Urea is measured using the urease enzyme followed by colorimetric detection methods (Evans, 2009).

Creatinine

Creatinine is a non-protein nitrogenous compound that is produced by the breakdown of creatine in muscle. Creatinine is found in serum, plasma, and urine and is excreted by glomerular filtration at a constant rate and in the same concentration as in plasma. Creatinine is a more reliable indicator of renal function than BUN because it is less influenced by other factors such as diet and hydration. Serum creatinine is increased by deficient glomerular filtration, although both BUN and creatinine remain in the reference range in most animals until 50–75% of renal function is lost (Finco, 1989). Creatinine is also increased by necrosis or atrophy of skeletal muscle, hyperthyroidism, infections, burns, or fractures.

When a renal disorder is suspected, the ratio of BUN to serum creatinine may be useful in diagnosing the location of the problem. A normal ratio is 10–20 mg/dl BUN to 1 mg/dl creatinine. A high (more than 20:1) BUN to creatinine ratio suggests pre-renal disease, whereas a low (less than 10:1) ratio is indicative of renal disease.

Creatinine is measured using an alkaline picrate colorimetric (Jaffé) method, by other enzymatic methods, or by HPLC (Evans, 2009). Endogenous chromogens such as bilirubin and ketones can artificially elevate creatinine values (Palm and Lundblad, 2005).

Electrolytes

Reference values for electrolytes in the laboratory animals covered in this volume are provided in Table 3.7.

Bicarbonate (HCO_3^-)

The bicarbonate anion (HCO_3^-) affects the acid–base balance in the body and is necessary for its buffering capacity in blood. The main influences on bicarbonate levels in the blood are respiratory production of carbon dioxide and renal excretion of bicarbonate after its conversion from carbonic acid (Evans, 2009). Increased levels of bicarbonate are indicative of respiratory acidosis and metabolic alkalosis.

Calcium (Ca)

Calcium is the most prevalent mineral in the body and is involved in bone metabolism and conduction of electrical impulses. Total calcium is the sum of bound and ionized (Ca^{2+}) forms. Approximately half of total calcium is bound to plasma proteins and the other half exists in the free cation form in serum. Ionized calcium is difficult to test but represents the more physiologically important value (Evans, 2009).

Total calcium is affected by diet, serum proteins, metabolism, and disease. Calcium is increased in animals with kidney or bone neoplasia. Calcium is decreased in animals with hypoparathyroidism, chronic renal failure, or magnesium deficiency.

TABLE 3.7 Electrolytes¹

N/A = values not available.

¹Species for which no values are available are not listed.

Total calcium is typically measured using a colorimetric assay. Measurement of ionized calcium is not as common in animals because it requires the use of a selective ion electrode.

Chloride (Cl⁻)

Chloride (Cl⁻) is a major extracellular anion and, along with sodium, is important for the maintenance of osmolality and acid–base balance. Chloride ions are found in serum, plasma, urine, and cerebrospinal fluid and are reabsorbed in the kidney. Elevated chloride occurs in metabolic acidosis or respiratory alkalosis. Chloride is decreased in metabolic alkalosis and conditions of high fluid loss, such as diarrhea and dehydration (Evans, 2009).

Magnesium (Mg²⁺)

The magnesium (Mg²⁺) cation is involved in enzymatic reactions, conduction of electrical stimuli, and bone formation. Approximately half of total magnesium is ionized and the other half is bound to albumin or otherwise complexed (Evans, 2009).

Elevated magnesium may occur with dehydration, hyperthyroidism, tissue trauma, or adrenocortical insufficiency and can depress myocardial contractions. Low magnesium levels may be associated with myopathies.

Magnesium is typically measured using a colorimetric assay (Evans, 2009).

Phosphorus (P)

Phosphorus (P) is present within cells and is required for normal Krebs cycle function and formation of bone and teeth. Serum phosphorus exists mainly as the phosphate anion (PO₄⁻), which is the form normally assayed. Phosphorus is increased in metabolic bone disease, healing fractures, and during anesthetic recovery. Phosphorus is decreased in animals with renal acidosis, hypopituitarism with growth hormone deficiency, and Gram-negative septicemia.

The kidney is the main organ involved in phosphorus balance by regulating glomerular filtration and tubular reabsorption, so phosphate levels are indicative of renal function. Hyperphosphatemia usually indicates pre-renal, renal, or post-renal effects or soft tissue trauma.

Hypophosphatemia occurs but its clinical significance is not known.

Phosphorus is typically measured using a colorimetric assay (Evans, 2009).

Potassium (K⁺)

Potassium (K⁺) is primarily an intracellular cation and is important for maintenance of membrane potential. Intracellular and extracellular potassium levels are regulated by a complex ion exchange mechanism and affected by several compounds, including aldosterone, insulin, and catecholamines (Evans, 2009). Elevated plasma potassium levels increase aldosterone secretion

from the adrenal glands and may also cause arrhythmias and cardiac arrest. Hypokalemia results in decreased aldosterone secretion.

Potassium is usually measured with an ion-selective electrode (Evans, 2009).

Sodium (Na^+)

Sodium (Na^+) is a cation present in all tissue spaces, and its concentration is associated with osmotic homeostasis. Plasma sodium is normally in balance with renal excretion of sodium, with most reabsorption of sodium occurring in the distal tubules and collecting ducts of the kidney. Sodium is increased when there is high fluid loss that spares electrolytes, or with inadequate water intake. Sodium is decreased in conditions of fluid loss when water replacement includes no electrolytes.

Sodium, as with potassium, is typically measured using an ion-selective electrode (Evans, 2009).

RABBIT

Sample Collection

Restraint

Rabbits are relatively docile with repeated handling, but they are easily frightened by unusual noises and movements. If rabbits are not held correctly, the combination of strong hind legs and a fragile skeleton can result in a broken back. A rabbit should be picked up by the scruff of the neck with one hand and supported under the hind end with the other hand to prevent the rabbit from kicking (Brewer, 2006).

Rabbits may be placed in a restraint device, a cat bag, or wrapped in a towel for blood collection without anesthesia.

Blood

The best site for blood collection in a rabbit depends on the volume and number of samples needed and whether or not the rabbit will be anesthetized for blood collection.

The marginal ear vein is the most common site for collection of small blood samples in the unanesthetized rabbit and can be used for single or repeat samples of 1–5 ml. The rabbit should be restrained as described above and the ear warmed by gentle stroking or using a lamp. Acepromazine maleate (1–5 mg/kg IM) may be given to calm the rabbit and aid in vasodilation. Topical oil of wintergreen, xylene, and local anesthetics have all been used to aid in vasodilation (Hrapkiewicz and Medina, 2007). Xylene especially may be irritating if not thoroughly rinsed off the ear after blood withdrawal (Suckow and Douglas, 1997). The collection site should be shaved and then wiped with alcohol or an antiseptic

solution. Blood is first collected from the vein near the base of the ear, with successive samples taken from the alternate ear or by moving distally toward the tip of the ear. A 25G or 26G needle or butterfly catheter may be inserted into the vein while pressure is applied to the vein at the base of the ear. It is difficult to obtain sufficient blood volume using this method in dwarf breed rabbits due to the small size of their ears (Melillo, 2007), and catheterization of this vein in dwarf breeds may lead to vascular necrosis, thrombosis, or sloughing of the ear (Vennen and Mitchell, 2009).

Other peripheral veins that may be used in a rabbit for small blood samples without anesthesia include the lateral saphenous vein and the cephalic vein, both of which can be accessed using a 25G needle, with or without a 1 ml syringe. The lateral saphenous vein runs superficially and is easily visualized on an extended leg when held off at the stifle. Visualization of this vein is assisted by applying alcohol or clipping the overlying fur. Pressure should be placed on the vein after blood withdrawal to prevent hematoma formation (Mader, 2004). The cephalic vein may be used to collect blood samples or for intravenous catheter placement (Vennen and Mitchell, 2009).

The central ear artery can be used for collection of larger volumes of up to 30 ml of arterial blood in the unanesthetized rabbit. The rabbit should be restrained as described above and a 21G or 22G needle or butterfly catheter inserted into the artery near the distal tip of the ear. Blood may be obtained faster using a vacutainer tube or a vacuum ear bleeder (Fox and Laird, 1999). Subsequent samples can be taken from the alternate ear or by moving proximally toward the base of the ear. Several minutes of digital pressure should be applied to ensure hemostasis after blood withdrawal. Potential side effects of blood collection from the ear vessels of rabbits include thrombosis, hematoma, and vascular necrosis of the pinna.

The jugular vein is the preferred sampling site for venous blood volumes greater than 0.5 ml (Vennen and Mitchell, 2009). An unanesthetized rabbit can be positioned with its neck gently extended upward and its front feet held straight down over the edge of a table. Anesthesia is recommended for jugular venipuncture to avoid the stress of restraint. The anesthetized rabbit is placed in dorsal recumbency and the jugular vein occluded near the apex of the sternum. The vein is most easily found by clipping the overlying hair. The dewlap may partially obstruct access to the jugular vein in a large female rabbit (Mader, 2004).

Cardiocentesis (cardiac puncture) may be used as a terminal procedure to collect a large volume of blood from a rabbit under anesthesia. A large-bore (18G–21G) 1.5-inch needle can be used to enter the left ventricle through the chest wall, through the diaphragm,

or from the cranial or caudal end of the sternum, and blood should be withdrawn slowly. A blood volume of 60–200 ml may be obtained using this method, depending on the size of the rabbit.

Urine

The method used for urine collection in a rabbit depends on the need for an uncontaminated sample and whether or not the animal is anesthetized. Normal rabbit urine is dense and rich in minerals and should be centrifuged and filtered before it is analyzed. Urine samples should be assayed immediately or stored refrigerated until used.

If sample contamination is not a concern, urine may be collected from a pan placed beneath the wire grid floor of the cage in which the rabbit is housed. Alternatively, manual expression of the bladder may be performed on an awake or anesthetized rabbit and urine collected directly from the urethra or a collection pan. Manual expression must be performed carefully due to the thin wall of the rabbit bladder, which may rupture if the rabbit struggles or if there is a urethral obstruction.

Repeated urine samples may be collected over a period of time using a metabolism cage, which separates urine output from feces.

Relatively uncontaminated urine samples may be obtained directly from the urinary bladder of a rabbit by catheterization or cystocentesis under sedation or light anesthesia. A sterile lubricated 9 French flexible catheter may be inserted into the external urethral opening and directed into the urinary bladder. Urine is withdrawn by gentle aspiration with an attached syringe, or it flows out due to gentle manual pressure applied to the caudal abdomen. Cystocentesis may be performed on a rabbit placed in dorsal recumbency after aseptic preparation of the caudal ventral abdomen. The bladder is located by palpation cranial to the pelvis, and a 20G–22G needle is attached to a syringe and inserted through the skin and bladder wall at the ventral midline. Urine is withdrawn under gentle aspiration pressure (Vennen and Mitchell, 2009).

Reference Values and Sources of Variation

Blood

Total blood volume of the rabbit is discussed in the Hematology section of this chapter.

Rabbit blood clots fairly rapidly and may be separated by centrifugation at 1100 rpm after it stands for 30–45 minutes at room temperature. If inadequate time is allowed for clotting to occur, fibrin clots may form in the cell-free fraction (Fox and Laird, 1999).

Rabbit blood may require more anticoagulant than other species due to its higher calcium content (Bjoraker and Ketcham, 1981).

Urine

Characteristics and reference ranges of rabbit urine are presented in Table 3.1.

Rabbits have a wide reference range for urine volume, 20–75 ml per kg body weight, collected over 24 hours. Normal rabbit urine has an alkaline pH of 7.6–8.8 and is fairly dilute, with a specific gravity that ranges from 1.003–1.036. Rabbit urine is normally cloudy due to a high concentration of triple phosphate (ammonium magnesium phosphate), calcium carbonate monohydrate, and anhydrous calcium carbonate crystals. Crystals are identified by examining the urine sediment after centrifugation. Trace protein and a few red or white blood cells are commonly found in rabbit urine.

The color of normal rabbit urine can vary from light yellow or straw color to a reddish-brown. Reddish coloration may be due to dietary porphyrins but must be differentiated from the presence of blood. A dipstick may be used to detect hematuria, and a woods lamp will detect porphyrins due to their natural fluorescence. Clear urine suggests low excretion of calcium, which can be due to renal failure, or may be normal in a young rabbit or lactating doe. Excess dietary calcium may cause rabbit urine to be thick and white with a reddish-orange pigment (Harkness and Wagner, 1989).

Abnormalities in rabbit urine are usually identified by simple diagnostic tests using a few drops of urine. Rabbit urine with an acidic pH indicates acidosis due to anorexia, fever, pregnancy toxemia, or hepatic lipidosis.

Hematuria may be caused by several conditions in the rabbit, including uterine adenocarcinoma, uterine polyps, endometrial hyperplasia, abortion, urolithiasis, cystitis, renal infarcts, cystitis, and urinary tract infection.

Glucosuria may be due to stress hyperglycemia. True glucosuria is indicative of hepatic lipidosis or diabetes mellitus. Ketonuria is abnormal in rabbits and is indicative of anorexia, hepatic lipidosis, pregnancy toxemia, or diabetes.

Proteinuria with low specific gravity typically indicates renal disease. Ratio of urine protein to urine creatinine is normal if it is less than 0.6.

Spores of *E. cuniculi* are visualized using Gram or trichrome stain on urinary sediment obtained by centrifugation.

Carbohydrate Metabolism

GLUCOSE

The reference range for blood glucose in rabbits is 75–155 mg/dl (Table 3.2). Blood glucose remains fairly consistent due to the fact that rabbits eat throughout the day and use volatile fatty acids as their primary source of energy (Melillo, 2007). Normal glucose levels are maintained, even after a prolonged fast of up to 96 hours, probably due to coprophagy (Hunt

and Harrington, 1974; Kozma et al., 1974). However, some reports suggest that glucose levels in rabbits are affected by diurnal variation (Fox and Laird, 1970). There is some strain variation in glucose concentration, with higher levels in New Zealand White rabbits than in Dutch Belted or Polish rabbits (Kozma et al., 1974).

Glucose levels in neonatal rabbits increase to a peak level 9 hours after suckling, then decrease at 24 hours. Glycogen stores are depleted by 6 hours in newborns that do not nurse. Glycogen stores typically increase in neonatal rabbits after 9 days old (Mottaz et al., 1989). At 15 days old, rabbits that are fasted for 48 hours have no change in blood glucose, but a decline in concentration of ketone bodies.

Elevated blood glucose in rabbits is usually due to disease or environment. Hyperglycemia may occur in rabbits anesthetized with urethane, halothane, or isoflurane (Bito and Eakins, 1969; Gil et al., 2007). Rabbits with diabetes mellitus may have blood glucose concentrations higher than 500mg/dl, accompanied by the common diabetic symptoms of polyuria, polydipsia, and polyphagia. Hyperglycemia of approximately 350mg/dl may also be caused by acute intestinal blockage or mucoid enteropathy. Other causes of hyperglycemia in rabbits include traumatic or hypovolemic shock, cold stress, and hyperthermia (de la Fuente et al., 2007; Melillo, 2007).

Low blood glucose in rabbits may be the result of prolonged anorexia and metabolism of adipose tissue, which may lead to hepatic lipidosis. Hypoglycemia may also result from acute sepsis, or terminal mucoid enteropathy, liver failure, or other chronic disease (Melillo, 2007). Rabbits housed with unfamiliar rabbits were found to have decreased glucose concentrations (de la Fuente et al., 2007).

Low glucose values may also result from technical handling, which includes allowing blood samples to stand at room temperature for prolonged periods. Glycolytic enzymes are released from platelets and increase in serum with prolonged clotting time, which lowers glucose in the sample (Lindena and Trautschold, 1986).

Lipid Metabolism

The rabbit is recognized as a valuable model for human disturbances in lipid metabolism, such as the metabolic syndrome and hypercholesterolemia leading to atherosclerosis. The lipoprotein profile of rabbits is similar to that of humans, and rabbits have the same cholesteryl ester transfer protein as in humans, which is not present in rodents (Brousseau and Hoeg, 1999). However, the measurement of cholesterol and triglycerides in rabbits may be confounded by cecotrophy in this species.

CHOLESTEROL

The reference range for cholesterol levels in the rabbit is 10–80mg/dl (Table 3.2), with normal variation in cholesterol levels in rabbits depending on age, sex, and time

of day. Cholesterol levels in neonatal rabbits are similar to adult values and then increase to a peak at 25 days old and decline to adult values at 60–80 days old (Laird and Fox, 1970). Serum cholesterol is higher in female than in male New Zealand White rabbits, and cholesterol levels typically increase at the end of the day (Melillo, 2007).

High-cholesterol diets are particularly effective in the rabbit for producing hypercholesterolemia, and the rabbit is often used as a model to study cholesterol metabolism and atherogenesis (Fekete, 1993). Cholesterol levels are particularly elevated in certain strains of rabbit. For example, the Watanabe Heritable Hyperlipidemic (WHHL) rabbit has a single gene defect that produces 8–14 times the reference level of cholesterol in homozygotes and a slight elevation of cholesterol in heterozygotes. The WHHL strain serves as a model for human familial hypercholesterolemia (Kita et al., 1981).

A high-fat diet, obesity, or liver disease may also cause high cholesterol and triglycerides in rabbits. Hypercholesterolemia during anorexia suggests end-stage hepatic lipidosis and has a poor prognosis. High-density lipoproteins have been found to be reduced, and low-density lipoproteins increased, in pregnant rabbits and their cesarean-derived neonates (Bortolotti et al., 1989). Hypercholesterolemia may be seen in rabbits with disease conditions such as pancreatitis, diabetes mellitus, nephrotic syndrome, or chronic renal failure (Saunders and Davies, 2005). Decreased serum cholesterol may be found in rabbits with liver failure, malnutrition, or pregnancy (Matsuoka et al., 2009).

TRIGLYCERIDES

The reference range for triglyceride levels in the rabbit is 15–160mg/dl (Table 3.2). Recent models of hypertriglyceridemia have been produced by mating WHHL strain rabbits with normal Japanese White rabbits. One resulting strain, TGH, has naturally high cholesterol levels of 1000–1500mg/dl and triglycerides greater than 500mg/dl, with widespread atherosclerotic plaques and xanthomas. The other resulting strain, PHT, has postprandial cholesterol of 100–150mg/dl and triglycerides of 500–3000mg/dl, with no atherosclerosis (Mitsuguchi et al., 2008).

Decreased triglycerides have recently been reported in late-gestational pregnant rabbits on a restricted feeding regimen (Matsuoka et al., 2009).

TOTAL LIPIDS

The reference range for total lipid levels in the rabbit is 150–400mg/dl (Table 3.2).

Enzymes

ALKALINE PHOSPHATASE (ALP)

Reference levels of alkaline phosphatase (ALP) in the rabbit are 10–140IU/l (Table 3.3). Levels of ALP have

been found to vary by breed and strain of rabbit (Fox and Laird, 1970; Kozma et al., 1974) but not by sex or diurnal variation (Fox and Laird, 1970; Kozima et al., 1974). Levels of ALP are 2–4 times higher in young rabbits compared to adults (Kramer, 1989).

Rabbits produce three isoenzymes of alkaline phosphatase, including one intestinal form and two different isoenzymes in the liver and kidney. This is in contrast to most other animals, which produce only two ALP isoenzymes.

Elevated ALP in the rabbit is caused by conditions associated with bile stasis in the liver, including lipodosis, coccidiosis, liver lobe torsion, abscesses, and neoplasia (Melillo, 2007). Bone lesions are also associated with elevated ALP in the rabbit.

Alkaline phosphatase is decreased in pregnant rabbits (Viard-Drouet et al., 1984), in contrast to an increase in ALP during late gestation in many other species.

ALANINE AMINOTRANSFERASE (ALT)

Reference levels of alanine aminotransferase (ALT) in the rabbit are 14–80 IU/l (Table 3.3). The ALT enzyme is not specific to the liver in herbivores, including the rabbit. The ALT enzyme has a short half-life of approximately 5 hours in the rabbit and is therefore not a very useful indicator of liver damage in this species (Melillo, 2007). However, ALT is not increased by restraint in the rabbit, so an elevated ALT value is suggestive of tissue damage in this species (Melillo, 2007). The ALT enzyme is found at high concentrations in cardiac muscle in rabbits (Hoffmann et al., 1982).

The ALT enzyme can be mildly elevated in healthy rabbits after exposure to low levels of lead or mycotoxins (Harcourt-Brown, 2002) or halothane anesthesia (Gil et al., 2007). This enzyme may also be elevated in rabbits with advanced hepatic neoplasia (Reznik and Padberg, 1991).

Liver enzymes in rabbits are not liver-specific, since ALT is found in liver and cardiac muscle, and AST is found in liver, as well as muscle, kidney, and pancreas (Vennen and Mitchell, 2009).

High levels of liver enzymes have been described in cases of viral hemorrhagic disease in rabbits (Melillo, 2007).

ASPARTATE AMINOTRANSFERASE (AST)

Reference levels of aspartate aminotransferase (AST) in the rabbit are 14–113 IU/l (Table 3.3). The AST enzyme is found in many tissues in rabbits, including the heart and liver, and it has a relatively short half-life in the rabbit of approximately 5 hours (Melillo, 2007).

Levels of AST may be elevated due to disease, environment, or technical reasons. Increased AST is found in rabbits with liver damage and in rabbits anesthetized with halothane or isoflurane (Gil et al., 2007). Experimental infection with *Eimeria stiedae* has also been shown to produce elevated AST levels in rabbits

(Gomez-Bautista et al., 1987). Experimental heat stress induced by hyperthermia in rabbits causes a three-fold increase in AST (Marder et al., 1990). Decapitation, heart puncture, or aortic incision produces an artificial elevation of AST due to muscle cell damage (Lindena and Trautschold, 1986). The AST value may also be elevated by physical restraint of a rabbit or when the blood sample becomes hemolyzed (Melillo, 2007).

Liver enzymes in rabbits are not liver-specific, since ALT is found in liver and cardiac muscle, and AST is found in liver, as well as muscle, kidney, and pancreas (Vennen and Mitchell, 2009).

High levels of liver enzymes have been described in cases of viral hemorrhagic disease in rabbits (Melillo, 2007).

LACTATE DEHYDROGENASE (LDH)

Reference levels of lactate dehydrogenase (LDH) in the rabbit are 30–140 IU/l (Table 3.3). The LDH enzyme is not usually helpful in disease diagnosis because it is produced by both muscle and liver cells.

The LDH value may be increased by physical restraint of a rabbit or when the blood sample is hemolyzed because of its high concentration in erythrocytes (Melillo, 2007). Rabbits exposed to noise stress have elevated LDH levels (de la Fuente et al., 2007).

CREATINE KINASE (CK)

Reference levels of CK in the rabbit are 150–1000 IU/l (Table 3.3). Dutch rabbits are reported to have elevated levels of the MM isoform of CK compared to other rabbit breeds and other animals (Yi et al., 1991).

Creatine kinase is commonly increased in the serum by physical restraint or the process of blood collection (Melillo, 2007). The different CK isoforms may be elevated depending on the method of blood collection. For example, the CK-MM and CK-BB isoforms are predominant after blood collection from peripheral veins, and the CK-MB isoform is predominant after blood collection by cardiac puncture (Lindena and Trautschold, 1986). Rabbits exposed to stressors, such as cold, noise, and housing with unfamiliar rabbits, have elevated levels of CK (de la Fuente et al., 2007).

SORBITOL DEHYDROGENASE (SDH)

Reference levels of sorbitol dehydrogenase (SDH) in the rabbit are 170–177 IU/l (Table 3.3).

AMYLASE

Reference levels of amylase in the rabbit are 200–500 U/l (Table 3.3).

In the rabbit, amylase is produced almost exclusively in the pancreas, with little contribution from the salivary glands, intestines, or liver. Amylase levels are

lower in the serum of rabbits than in most other animals (Lindena and Trautschold, 1986).

Elevated amylase levels in rabbit serum may be caused by pancreatitis, pancreatic duct obstruction, peritonitis, or renal failure, or treatment with corticosteroids.

Amylase values may be lower in hemolyzed blood samples.

GLUTAMATE DEHYDROGENASE (GDH)

The reference level of glutamate dehydrogenase (GDH) in the rabbit is 6.39 IU/l (Table 3.3). There is little information on the diagnostic value of this enzyme in rabbits. Its concentration in the centrilobular area of the liver could potentially identify the primary site of hepatocyte damage in liver disease in this species, as in others. Rabbits, like guinea pigs, are different from most animals in that GGT is released into the serum as clotting occurs (Clifford and White, 1999).

OTHERS

Atropine esterase is present in approximately one-third of domestic rabbits. This enzyme hydrolyzes atropine and thus interferes with the pharmacologic action of atropine in many rabbits (Hrapkiewicz et al., 1998).

Hormones

ADRENAL HORMONES

Reference levels of adrenal hormones in the rabbit include 2.6–3.8 µg/dl cortisol and 1.54 µg/dl corticosterone (Table 3.4). Cortisol is the predominant steroid hormone found in rabbits (Fecteau et al., 2007).

The stress of handling and restraint in rabbits causes the release of steroids in an age- and strain-related manner (Redgate et al., 1981). Steroids can affect some biochemical assays (Lindena and Krautschold, 1986). Therefore, it is important to standardize handling methods, blood draw technique, and length of anesthesia in rabbits to reduce the impact of stress on assay results.

A study on the effect of inhalant anesthetics in New Zealand White rabbits found that halothane increases serum corticosterone levels, whereas isoflurane increases corticosterone and serotonin levels in this species (Gil et al., 2007). A recent study in New Zealand White rabbits showed that group housing produced lower white blood cell counts and higher plasma cortisol levels than in individually housed rabbits (Fuentes and Newgren, 2008). Heat stress has also been shown to produce increased cortisol levels in rabbits (de la Fuente et al., 2007). Changes in leukocytes correlated with changes in cortisol levels (Toth and Krueger, 1989).

Stress causes an increase in blood pressure due to increased release of adrenocorticotrophic hormone (ACTH) and adrenaline. This results in a decreased

marginal pool of neutrophils as they move to the central pool and are found at higher levels in the venous blood. Halothane anesthesia, which is now rarely used, has also been shown to increase ACTH levels in the rabbit (Gil et al., 2007).

THYROID HORMONES

Reference levels of thyroid hormones in the rabbit include 130–143 ng/dl triiodothyronine (T3), and 1.7–2.4 µg/dl thyroxine (T4) (Table 3.4).

REPRODUCTIVE HORMONES

Reference levels of reproductive hormones in the rabbit include 10–100 ng/ml luteinizing hormone (LH), 2–4.5 ng/ml follicle stimulating hormone (FSH), 3 pg/ml estradiol, <1 ng/ml progesterone, 10 ng/ml prolactin, 10–20 ng/ml oxytocin, and 3–5 pg/ml testosterone (Table 3.4). There was no difference found between adult male and female neutered rabbits in the serum concentrations of several reproductive hormones, including progesterone, 17-hydroxy-progesterone, androstenedione, and testosterone. Elevated prolactin levels and enlarged mammary glands have been described in a 4-year-old female New Zealand White rabbit with a prolactin-secreting pituitary adenoma (Sikoski et al., 2008).

Liver Function

TOTAL BILIRUBIN

Reference levels of total bilirubin in the rabbit are 0–0.8 mg/dl (Table 3.5). The rabbit produces a large amount of bile per body weight when compared with other animals. Biliverdin is the primary component of rabbit bile, comprising approximately 70% of excreted bile. There is no assay available for biliverdin and it is therefore not measured. Approximately one-third of biliverdin is converted to bilirubin, which is measured in the blood.

In the rabbit, bilirubin is secreted by the liver in the monoconjugated form, in contrast to the diconjugated form secreted in most species (McLaughlin and Fish, 1994). Bilirubin comprises approximately 30% of the excreted bile.

Elevated bilirubin concentration is typically a marker of liver dysfunction or hemolytic disease. In rabbits, hyperbilirubinemia is caused primarily by bile flow obstruction. This obstruction can be the result of hepatic coccidiosis in young rabbits or biliary neoplasia, hepatic lipidosis, or liver lobe torsion in older rabbits. Hepatic fibrosis and hyperbilirubinemia may also be a result of aflatoxicosis from ingesting moldy food (Melillo, 2007).

BILE ACIDS

Reference levels of bile acids in the rabbit are 0–40 mMol/l (Table 3.5), although this is not a standard

biochemical assay in this species. Serum bile acids are used as a measure of liver function in other animals by comparing pre- and postprandial levels, but cecotrophy makes it difficult to fast a rabbit for the pre-prandial sample.

Persistently elevated bile acid concentrations have been reported in rabbits with liver disease (Harcourt-Brown, 2002).

SERUM PROTEINS

The reference range for total serum protein levels in the rabbit is 5.4–8.3 g/dl (Table 3.5), which is higher than those in most other animals (Vennen and Mitchell, 2009). Total protein levels vary by rabbit strain, with descending reference values in Polish rabbits, Dutch Belted rabbits, and New Zealand White rabbits, respectively (Kozma et al., 1974). There is also an effect of age on total proteins in the rabbit, as these values are lowest at birth and increase with age to reach adult values by 12 weeks old (Jain, 1986).

The reference range for albumin levels in the rabbit is 2.4–4.6 g/dl, and the reference range for globulin levels is 1.5–2.8 g/dl (Table 3.5). The albumin fraction of the total protein value is higher in female New Zealand White rabbits than in males (Kozma et al., 1974), but lower in pregnant females than in other adults. Caesarian-derived neonates have low total protein levels, with low albumin and high alpha-globulin levels (Bortolotti et al., 1989).

Feed restriction has been shown to result in lower total protein levels, albumin, and triglycerides in late-gestation pregnant rabbits and to produce a high percentage of near-term abortions (Matsuoka et al., 2009).

Kidney and liver disease are usually associated with decreased albumin and total protein, whereas hyperthermia, dehydration, or shock cause elevated total proteins (Marder et al., 1990). Coronavirus infections have been shown to produce increased globulins in rabbits.

Hemolyzed serum samples can produce artificially increased total protein values (Melillo, 2007).

Cold stress causes an increase in total plasma proteins and beta globulins, and a decrease in serum albumin in the rabbit.

Kidney Function

BLOOD UREA NITROGEN (BUN)

The reference range for blood urea nitrogen (BUN) concentration in the rabbit is 10–30 mg/dl (Table 3.6), and these levels vary according to several factors. Rabbit urea levels increase in late afternoon and early evening and are higher in female than in male New Zealand White rabbits (Melillo, 2007). Polish rabbits are reported to have higher BUN levels than New Zealand White or Dutch Belted strains (Kozma et al., 1974).

Some causes of elevated BUN include urolithiasis and obstruction of urine flow, or kidney tumors or ureteral ligation (Adjarov et al., 1976). Low BUN may be due to hepatic insufficiency or loss of muscle mass due to dental disease (Melillo, 2007).

CREATININE

The reference range for creatinine levels in the rabbit is 0.5–2.5 mg/dl (Table 3.6) and can be increased by renal insufficiency or muscle injury. Creatinine, and often BUN, is elevated when there is reduced blood flow to the kidneys associated with 50–70% loss in renal function (Vennen and Mitchell, 2009). Dehydration can cause pre-renal azotemia in rabbits due to the limited ability of this species to concentrate urine. Blood urea nitrogen and creatinine levels are also increased after stroke, cardiac disease, or bleeding within the gastrointestinal tract (Melillo, 2007).

A study on the effect of inhalant anesthetics in New Zealand White rabbits found that halothane and isoflurane both cause increased levels of BUN and creatinine (Gil et al., 2007).

Renal failure in rabbits can be a result of renal disease due to neoplasia, glomerular nephritis, or pyelonephritis. In addition, renal failure can result from pre-renal disease, such as dehydration, or post-renal disease, such as urethral calculi (Vennen and Mitchell, 2009). The parasite *E. cuniculi* is the most common cause of renal failure in rabbits due to granulomas and fibrosis in the renal parenchyma (Melillo, 2007).

Electrolytes

BICARBONATE (HCO_3^-)

The reference range for the bicarbonate anion in the rabbit is 16.2–38.0 mEq/l (Table 3.7). Rabbit kidneys have minimal ability to correct acid–base imbalances, making this species fairly susceptible to electrolyte alterations. Anorexia in rabbits may also result in metabolic acidosis (Melillo, 2007).

CALCIUM (Ca)

Total serum calcium (Ca) concentration is higher in normal rabbits than in other mammals and has a wide range of reference values in this species, from 5.6–17 mg/dl (Table 3.7). Calcitrol is a metabolite of vitamin D and has a major effect on serum calcium levels in most animals by regulating calcium absorption from the gut. In contrast, gut absorption in the rabbit is independent of calcitrol, and serum calcium concentration depends directly on calcium levels in the diet (Brewer, 2006). Total serum calcium concentrations up to 15 mg/dl and higher have been reported in the rabbit (Hrapkiewicz and Medina, 2007; Melillo, 2007). Young rabbits and pregnant does have a higher calcium requirement than normal adult rabbits,

resulting in lower blood calcium levels in these conditions (Melillo, 2007). Ionized calcium (Ca^{2+}) concentration in rabbit serum is similar to that of other animals.

Excess calcium is excreted in the urine of rabbits, compared to bile excretion in other animals (Hrapkiewicz and Medina, 2007), and the Ca level in urine varies with serum calcium concentration. Urinary excretion rate of calcium is 45–60% in rabbits, compared to 2% in most other mammals (Melillo, 2007). This situation predisposes the rabbit to the formation of Ca-rich uroliths. Hypercalcemia can result when rabbits are unable to eliminate excess calcium and may be a sign of renal disease (Melillo, 2007).

Hypocalcemia is rare in rabbits but may be indicative of poor nutrition, hypoalbuminemia, diarrhea, chronic renal failure, or hyperparathyroidism (Vennen and Mitchell, 2009). Parathyroid hormone levels affect blood calcium levels, and calcium is readily moved from the blood to bones in rabbits (Melillo, 2007). Seizures resulting from hypocalcemia have been reported in late-pregnant and lactating does (Kerr, 1989).

CHLORIDE (Cl^-)

Reference levels of chloride (Cl^-) levels in rabbits are 92–120 mEq/l (Table 3.7) and remain fairly constant across different ages and sexes (Fox and Laird, 1999). Differences in chloride levels have been reported when compared among different strains of rabbits (Fox et al., 1970). Chloride levels are increased in rabbits with dehydration or increased dietary salt intake, and decreased in rabbits with diarrhea or low dietary salts (Vennen and Mitchell, 2009).

MAGNESIUM (Mg^{2+})

Magnesium (Mg^{2+}) levels in normal rabbits are 2.0–5.4 mg/dl (Table 3.7) and are not significantly affected by age, sex, or strain. Increased magnesium levels are seen in rabbits with dehydration, hyperthyroidism, tissue trauma, or adrenocortical insufficiency (Fox and Laird, 1999).

In the rabbit, Mg^{2+} ions are excreted mainly in the urine instead of in the bile.

PHOSPHORUS (P)

Phosphorus (P) levels in normal rabbits are 2.3–6.7 mg/dl (Table 3.7) and show significant differences between strains of rabbits (Fox and Laird, 1970).

Increased phosphorus concentration is indicative of renal disease in rabbits, whereas decreased phosphorus occurs with urinary Ca^{2+} excretion (Vennen and Mitchell, 2009).

Hemolysis of the blood sample may cause an artificially elevated phosphorus value.

POTASSIUM (K^+)

The reference range for potassium (K^+) in normal rabbits is 3.5–6.9 mEq/l (Table 3.7) and may fluctuate

physiologically in rabbits, as in other herbivores (Melillo, 2007).

Hyperkalemia in the rabbit is usually due to acute renal failure, obstructed urine flow, or metabolic acidosis. Hyperkalemia in this species can also be due to severe tissue damage and loss of potassium into the extracellular space, or by excess administration of potassium-rich fluids (Melillo, 2007). Artificially elevated potassium values may be obtained when a blood sample is hemolyzed for technical reasons.

Low potassium levels are seen in cases of acute renal failure, starvation, low-potassium diet, or after administration of excess potassium-poor fluids (Vennen and Mitchell, 2009). Hypokalemia can also result from a stress-induced increase in catecholamines. A condition referred to as “floppy rabbit syndrome” has been associated with low potassium levels in the blood (Harcourt-Brown, 2002). Potassium values may also be decreased for technical reasons, including the use of plastic tubes for blood collection (Caisey and Kling, 1980) and hemolysis of serum samples (Melillo, 2007).

SODIUM (Na^+)

The reference range for sodium (Na^+) in rabbits is 131–155 mEq/l (Table 3.7), and levels vary considerably among different strains of rabbits (Fox and Laird, 1970). Sodium level in rabbits is not very useful as a diagnostic indicator. The serum sodium value may be artificially low in rabbits with lipemia or hyperproteinemia. True hyponatremia in the rabbit may be associated with acute or chronic renal failure and polyuria (Melillo, 2007). Sodium depletion may also be the result of polydipsia in fasted rabbits that drink excessively (Cizek, 1961). Sodium is elevated in rabbits with dehydration or fluid loss due to diarrhea, peritonitis, burns, or myiasis (Melillo, 2007).

GUINEA PIG

Sample Collection

Restraint

Guinea pigs are generally docile, especially with frequent and gentle handling. However, guinea pigs are difficult to restrain for blood and urine samples because they resist being held securely, and their short legs and neck make it difficult to access peripheral vessels without anesthesia. Guinea pigs should be held under the trunk with one hand and supported under the hind end with the other hand, being careful not to constrict the thorax or abdomen (Hrapkiewicz and Medina, 2007).

Blood

Venipuncture in guinea pigs is difficult because the peripheral veins in this species are small and often covered by layers of fat. It is often necessary to shave

the skin and apply alcohol to help visualize peripheral veins in this species (Dyer and Cervasio, 2008).

Small volumes of blood can be obtained in unanesthetized guinea pigs from a variety of peripheral veins using a sterile lancet or a 23G–27G needle. A marginal ear vein can be nicked with a 25G needle and blood drops collected directly into a microhematocrit tube. The lateral saphenous vein runs across the tarsal joint and can be sampled with a 1-ml syringe on a 23G–27G needle after applying digital pressure on the thigh to hold off the vein. The cephalic vein and tarsal vein are also accessible on the guinea pig, although only small volumes can be obtained from these sites, and bruising and hemorrhage often result. Alternatively, a toenail can be cut short using a nail clipper to yield small volumes of blood (Clifford and White, 1999).

Larger volumes of blood can be obtained from anesthetized guinea pigs using large central veins, including the jugular vein, cranial vena cava, and femoral vein. The short neck of the guinea pig makes the jugular vein and cranial vena cava difficult to access, but shaving and proper positioning allow optimal exposure (Pilny, 2008). In the guinea pig, the right jugular vein is larger than the left and will yield up to 2.5 ml of blood. A 24G needle on a 1-ml syringe can be directed caudally to enter the jugular vein just cranial to the clavicle (Shomer et al., 1999). The cranial vena cava can be accessed with a 22G or 23G needle on a 3- or 6-ml syringe that is directed caudally into the sternal notch under the first rib. A ketamine–xylazine mixture has been described as the preferable method of anesthesia for this route of blood sampling (Dang et al., 2008). However, the cranial position of the heart makes cardiac hemorrhage a significant risk when blood is sampled from the cranial vena cava (Joslin, 2009). The femoral vein can be used to collect up to 3 ml of blood with the guinea pig under anesthesia, in dorsal recumbency, and with the rear leg abducted. A 23G needle on a 1–3-ml syringe can be directed at a 45–90° angle to the skin and inserted just ventral to the pulsing femoral artery within the femoral triangle (Joslin, 2009).

Alternative sites for blood collection in a guinea pig under anesthesia include an interdigital vein and the retro-orbital sinus. The interdigital vein technique in the guinea pig is adapted from that described in the rat (Snitily et al., 1991). The foot is disinfected with alcohol and stimulated by rubbing with a methyl salicylate soaked gauze. Approximately 0.4 ml of blood is collected into a capillary tube after puncturing the interdigital vein with a 20G needle. The sample is then transferred into a sodium citrate solution, and pressure is applied to the sampling site for hemostasis (Keino et al., 2002). The retro-orbital sinus will also yield small volumes of blood in an anesthetized guinea pig (Joslin, 2009).

Cardiocentesis can be performed as a terminal procedure in an anesthetized guinea pig. The animal is

placed in dorsal recumbency, and a 20G–25G needle is advanced toward the heart under the xiphoid cartilage to enter the left ventricle. Alternatively, up to 15 ml of blood can be obtained from the descending aorta or caudal vena cava following a laparotomy as a terminal procedure in an anesthetized guinea pig (Joslin, 2009). Decapitation, performed by a trained individual, may yield 10–15 ml of trunk blood (Clifford and White, 1999).

Urine

Urine may be readily collected from the guinea pig using a metabolic cage, free catch after manual pressure on the bladder, or placement on a cold surface (Hrapkiewicz and Medina, 2007). If a urine culture is needed, a cystocentesis should be performed using sedation and aseptic preparation, as described for the rabbit and other animals (Riggs, 2009).

Reference Values and Sources of Variation

Blood

Total blood volume and plasma volume of the guinea pig are discussed in the Hematology section of this chapter.

Clotting of guinea pig blood occurs more slowly when collected into plastic tubes (Clifford and White, 1999).

Urine

Characteristics and reference values of normal guinea pig urine are presented in Table 3.1.

Guinea pigs are herbivores and produce alkaline urine, with a pH of 8–9 (Riggs, 2009).

Normal guinea pig urine is yellow to amber in color, and is fairly opaque. Dietary factors may cause the urine to be darker and more orange in color. It is important to distinguish dietary pigmentation from hematuria using a dipstick to detect blood or Wood's lamp to detect porphyrins. Crystalluria is not uncommon in the guinea pig and should prompt a thorough examination for urinary calculi (Riggs, 2009). A study of urinary calculi in guinea pigs found that the vast majority are composed of 100% calcium carbonate (Hawkins et al., 2009).

Urinary tract infections may occur in older female guinea pigs, and uroliths are an occasional finding in this species (Hrapkiewicz and Medina, 2007).

Carbohydrate Metabolism

GLUCOSE

Reference range for blood glucose level in guinea pigs is 60–130 mg/dl (Table 3.2).

Glucose is elevated in guinea pigs with diabetes mellitus, as in other animals. Spontaneous diabetes mellitus has been reported in guinea pigs at 3–6 months old and is associated with hyperglycemia, glucosuria, and often ketonuria (Hrapkiewicz and Medina, 2007).

Differences in serum glucose have been reported in guinea pigs treated with different anesthetics. For example, serum glucose was higher in guinea pigs anesthetized with 30mg/kg ketamine and 2.5mg/kg xylazine IP, compared to 37mg/kg pentobarbital IP prior to blood draw from the cranial vena cava. This difference was thought to be due to xylazine's inhibition of insulin secretion from pancreatic beta cells in the guinea pig, as in other animals (Dang et al., 2008).

Pregnancy toxemia may occur in the guinea pig in late gestation and takes one of two forms, a fasting or metabolic form and a circulatory or toxic form. The fasting or metabolic form is referred to as ketosis and occurs especially in obese guinea pigs in the first or second pregnancy. This condition may be triggered by stress factors, such as a change in environment or feeding routine, and often results in death. Controlled food intake to prevent obesity can help prevent this condition. In the circulatory or toxic form of pregnancy toxemia, the gravid uterus compresses the descending aorta and causes ischemia of the uterus and placenta (Hrapkiewicz and Medina, 2007).

Obese old male guinea pigs may also become ketotic as a result of reduced carbohydrate diet, resulting in mobilization of fat for energy (Hrapkiewicz and Medina, 2007).

Lipid Metabolism

CHOLESTEROL

The reference range for cholesterol levels in guinea pigs is 20–80mg/dl (Table 3.2). These values are reported to increase gradually with age in male guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

The lipoprotein fraction in guinea pigs contains primarily LDL, with little HDL present unless cholesterol is present in the diet. Changes in dietary fiber primarily affect LDL levels (Fernandez et al., 1997).

The intestine is the primary site of cholesterol synthesis in the guinea pig, as it is in humans, whereas the liver serves this function in most species (Clifford and White, 1999). The guinea pig is very sensitive to cholesterol in the diet, with biochemical changes and lesions produced by dietary cholesterol as low as 0.1%. High dietary cholesterol in the guinea pig causes hemolytic anemia, enlarged spleen, and hyperplastic bone marrow, and may result in death prior to the production of atherogenetic plaques (Yamanaka et al., 1967). Hypercholesterolemia in the guinea pig results in fatty infiltration of the liver and other tissues. The guinea pig serves as a good model for hypercholesterolemia in humans (Sullivan et al., 1993).

TRIGLYCERIDES

The reference range for triglyceride levels in the guinea pig is 10–70mg/dl (Table 3.2). Triglyceride

levels have been found to increase gradually with age in male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

Enzymes

ALKALINE PHOSPHATASE (ALP)

The reference range for alkaline phosphatase (ALP) levels in guinea pigs is 80–350IU/l (Table 3.3). The ALP enzyme was found to decrease with body weight, as in other species (Clifford and White, 1999). Levels of ALP are reported to decrease sharply after birth and then level off in male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

A zinc-deficient diet causes an increase in ALP activity (Clifford and White, 1999), whereas fasting and ascorbic acid deficiency cause decreased ALP levels in guinea pigs (Mahmoodian et al., 1996; Tsuchiya and Bates 1994). Hairless Dunkin-Hartley guinea pigs are reported to have lower ALP levels compared to normal Dunkin-Hartley guinea pigs, although the significance of this difference is not known (Waner et al., 1996).

ALANINE AMINOTRANSFERASE (ALT)

The reference range for alanine aminotransferase (ALT) levels in guinea pigs is 10–90IU/l (Table 3.3), and these values are generally lower in this species than in other animals (Clampitt and Hart, 1978).

Elevated ALT is not a specific or sensitive marker of hepatocellular injury in the guinea pig compared to other animals (Clifford and White, 1999).

Hairless Dunkin-Hartley guinea pigs are reported to have higher ALT concentration compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

ASPARTATE AMINOTRANSFERASE (AST)

The reference range for aspartate aminotransferase (AST) levels in guinea pigs is 10–90IU/l (Table 3.3).

As with ALT and ALP, AST levels are reported to be lower in hairless Dunkin-Hartley guinea pigs than in normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

LACTATE DEHYDROGENASE (LDH)

The reference range for lactate dehydrogenase (LDH) levels in guinea pigs is 20–120IU/l (Table 3.3).

CREATINE KINASE (CK)

The reference range for creatine kinase (CK) levels in guinea pigs is 50–150IU/l (Table 3.3).

Hairless Dunkin-Hartley guinea pigs are reported to have higher CK levels than normal Dunkin-Hartley guinea pigs (Waner et al., 1996). The method of anesthesia has been shown to affect CK levels in guinea pigs. For example, guinea pigs anesthetized with 37mg/kg pentobarbital given intraperitoneally have higher CK levels than

those anesthetized with 30mg/kg ketamine and 2.5mg/kg xylazine given intramuscularly (Dang et al., 2008).

Elevated CK may be seen in guinea pigs with myopathy associated with a deficiency of vitamin E and selenium (Hrapkiewicz and Medina, 2007).

AMYLASE

The reference range for amylase levels in guinea pigs is 995–1239 IU/l (Table 3.3).

Hairless Dunkin-Hartley guinea pigs are reported to have higher amylase levels than normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

Hormones

ADRENAL HORMONES

The reference range for cortisol levels in guinea pigs is 5–30 µg/dl (Table 3.4). Cortisol is the primary glucocorticoid produced by the guinea pig, instead of corticosterone, which predominates in the mouse and rat (Clifford and White, 1999). Cortisol and corticosterone are readily interconverted in the guinea pig (Manin et al., 1982). Plasma cortisol levels vary by age and sex in the guinea pig, probably due to differences in its binding to transcortin (El Hani et al., 1980). Transcortin in guinea pigs has a higher binding affinity for cortisol than for progesterone, whereas transcortin binds both hormones with similar affinity in humans (Clifford and White, 1999). Plasma cortisol levels in males are higher than in females at ages greater than 30 days, similar in males and females at 90–120 days, and higher in adult male guinea pigs (Clifford and White, 1999).

THYROID HORMONES

Reference ranges for thyroid hormone levels in guinea pigs are 22–56 ng/dl for triiodothyronine (T3) and 2.3–3.5 µg/dl for thyroxine (T4) (Table 3.4).

REPRODUCTIVE HORMONES

Reference levels of reproductive hormones in guinea pigs include 5–55 ng/ml luteinizing hormone (LH), 100–200 ng/ml follicle stimulating hormone (FSH), 30 pg/ml estradiol, 1 ng/ml progesterone, and <5 ng/ml oxytocin (Table 3.4).

Guinea pigs, like other hystricomorphs, have a progesterone-binding globulin that is present during pregnancy and binds progesterone but not cortisol (Wriston, 1984).

Liver Function

TOTAL BILIRUBIN

The reference range for total bilirubin levels in guinea pigs is 0–1 mg/dl (Table 3.5).

Blood samples exposed to sunlight demonstrate bilirubin decreases up to 50% in 1 hour (Benjamin and McKelvie, 1978). Freezing of serum samples may also

cause an artificial decrease in bilirubin levels (Bayard, 1974).

SERUM PROTEINS

The reference range for total protein levels in guinea pigs is 4–7 g/dl (Table 3.5). Total protein is reported to increase sharply and level off at 150–200 days old in male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

The reference range for albumin levels in guinea pigs is 2–5 g/dl (Table 3.5). Hairless Dunkin-Hartley guinea pigs are reported to have higher total protein and albumin levels compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

The reference range for globulin levels in guinea pigs is 2–4 g/dl (Table 3.5).

Kidney Function

BLOOD UREA NITROGEN (BUN)

The reference range for blood urea nitrogen (BUN) levels in guinea pigs is 9–32 mg/dl (Table 3.6). Levels of BUN were found to increase gradually with age in male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

The concentration of BUN was found to be higher in guinea pigs anesthetized with 37 mg/kg pentobarbital given intraperitoneally compared to 30 mg/kg ketamine and 2.5 mg/kg xylazine given intramuscularly. This difference was thought to be due to pentobarbital's depression of cardiac output, renal blood flow, and glomerular filtration rate (Dang et al., 2008).

Renal disease is a common chronic condition in older guinea pigs, whereas acute renal disease may occur in younger animals. For example, acute renal disease, with elevated BUN and creatinine, has been described in a 1-year-old guinea pig after ingestion of oxalate-containing plants (Holowaychuk, 2006).

CREATININE

The reference range for creatinine levels in guinea pigs is 0.6–2.2 mg/dl (Table 3.6). Creatinine levels were found to increase gradually with age in male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

Hairless Dunkin-Hartley guinea pigs are reported to have higher creatinine levels compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

Electrolytes

CALCIUM (Ca)

The reference range for calcium levels in guinea pigs is 5.3–12.0 mg/dl (Table 3.7).

Hypercalcemia is rare in guinea pigs and is usually associated with poor nutrition and low phosphorus levels (O'Rourke, 2004).

Hairless Dunkin-Hartley guinea pigs are reported to have higher levels of most electrolytes measured compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

CHLORIDE (Cl^-)

The reference range for chloride levels in guinea pigs is 90–115 mEq/l (Table 3.7). Chloride levels are reported to decrease gradually with age in male guinea pigs of the Weiser-Maples strain (Kitagaki et al., 2005).

MAGNESIUM (Mg^{2+})

The reference range for magnesium levels in guinea pigs is 3.5–4.1 (Table 3.7).

A dietary imbalance of minerals, such as low magnesium and high phosphorus, can cause soft tissue calcification in guinea pigs older than 1 year. Mineral deposits may be found in the elbows and ribs or more widespread, in lung, trachea, heart, aorta, liver, and kidney (Hrapkiewicz and Medina, 2007).

PHOSPHORUS (P)

The reference range for phosphorus levels in guinea pigs is 3.0–12.0 mg/dl (Table 3.7).

Phosphorus was found to be higher in guinea pigs anesthetized with 37 mg/kg pentobarbital given intraperitoneally compared to 30 mg/kg ketamine and 2.5 mg/kg xylazine given subcutaneously (Dang et al., 2008).

POTASSIUM (K^+)

The reference range for potassium levels in guinea pigs is 4.0–8.0 mEq/l (Table 3.7).

Serum potassium values may be lower when blood is allowed to clot in plastic rather than glass tubes, because of slower clotting and decreased release of potassium from platelets (Caisey and Kling, 1980).

SODIUM (Na^+)

The reference range for sodium levels in guinea pigs is 120–150 mEq/l (Table 3.7). Sodium levels are reported to increase gradually with age in female guinea pigs of the Weiser-Maples strain (Kitagaki et al., 2005).

In contrast to most electrolytes, sodium levels are reported to be lower in hairless Dunkin-Hartley guinea pigs compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

HAMSTER

Sample Collection

Restraint

Hamsters are fairly docile when handled frequently but are typically more aggressive than mice. Hamsters

can be restrained manually by gathering the loose scruff skin in one hand and supporting the lower body against the palm of the same hand. A hamster may also be placed in a restraint tube for blood collection without anesthesia. Such a tube should have airholes at the nose end and be cleaned frequently to reduce the risk of cross-infection or stress from pheromones (Hem et al., 1998).

Blood

Small blood samples can be obtained in an unanesthetized hamster from the lateral saphenous vein, which runs dorsally and laterally across the tarsal joint. The hamster may be restrained manually or in a restraint tube, as described above, and the vein is held off with gentle pressure above the knee joint. A 20G–25G needle can be inserted into the vein, and blood is collected from the needle hub (Hem et al., 1998). Blood collection occasionally results in bruising, hemorrhage, or temporary favoring of the sampled limb (Joslin, 2009). The lateral vein of the tarsus may also be used to collect small volumes of blood without anesthesia. A clipped toenail, or a small cut in the ear, tail, or footpad, have also been described for obtaining a small blood sample in the hamster (Buetow et al., 1999; Hrapkiewicz and Medina, 2007).

Anesthesia is needed for blood collection from the cephalic vein in a hamster. A tourniquet is placed around the proximal leg, a 25G needle is inserted in the vein, and blood is collected from the needle hub (Joslin, 2009). Other peripheral veins that can be sampled under anesthesia include the jugular vein, femoral vein, sublingual vein, and ear vein (Joslin, 2009).

The retro-orbital venous plexus is commonly used for blood sampling in the hamster and can be accessed by penetrating the conjunctiva midway along the superior border of the eye (Dyer and Cervasio, 2008). A lateral or medial approach to the retro-orbital venous plexus is also described (Buetow et al., 1999). This method may be used by experienced personnel in unanesthetized hamsters, but anesthesia is recommended to avoid stress and damage to the eye. Up to 3 ml of blood can be withdrawn from this site in an adult Syrian hamster (Buetow et al., 1999), but there is risk of ocular damage using this method (Joslin, 2009).

Hamsters can be anesthetized to obtain a 1-ml sample of blood from the cranial vena cava using a 23G–25G needle inserted lateral to the manubrium, cranial to the first rib, and directed caudally. Cardiac puncture has been used for obtaining 1–2 ml of blood in the anesthetized hamster with a 3/8-inch 25G needle (Mitruka and Rawnsley, 1981). However, this technique requires practice, and repeated sampling is associated with a higher risk of mortality (Buetow et al., 1999).

Terminal blood collection of up to 5ml in a Syrian hamster can be performed under anesthesia by cardiocentesis, laparotomy, and venipuncture of the caudal vena cava, or by translumbar vena cava collection (Joslin, 2009).

Urine

Hamsters often urinate when they are picked up, so small urine samples can be obtained by this method. A metabolic cage may be used to collect larger samples of urine from a hamster. This method is advantageous for separating urine from fecal pellets, which are typically mixed on the floor of a conventional hamster cage.

Reference Values and Sources of Variation

Blood

Total blood volume of the hamster is discussed in the Hematology section of this chapter.

Urine

Characteristics and reference values of hamster urine are presented in Table 3.1.

Hamsters produce up to 7ml of urine per day. Chinese hamsters with diabetes mellitus may have significantly increased urine excretion of up to 75ml per day (Fiszer et al., 1979). The pH of hamster urine is normally alkaline and varies from 5.1–8.4.

Hamster urine is cloudy due to the normal presence of crystals and protein. Protein excretion rate in hamster urine is almost 10mg per week, which is approximately ten times higher than that in humans (Tietz, 1976). Cholesterol is the main lipid present in hamster urine, with an excretion rate of 11.7mg per week (Cox and Gökçen, 1973). Hamster urine has variable levels of sodium and potassium, averaging 70mM sodium and 120mM potassium (Fiszer et al., 1979). The primary crystals present in hamster urine include calcium carbonate and triple phosphate (Schuchman, 1980).

Carbohydrate Metabolism

GLUCOSE

The reference range for blood glucose concentration in the hamster is 37–198mg/dl (Table 3.2). Glucose level is affected by many factors, including diet, restraint, anesthesia, hibernation, and diurnal variation, as well as certain disease states (Tomson and Wardrop, 1987). These conditions must be taken into account when evaluating blood glucose concentration.

Blood glucose levels in the hamster are affected by dietary factors, including feeding schedule, duration of fast, and the food content of the stomach (Feldman et al., 1982).

The stress of restraint is likely an important factor producing elevated blood glucose in hamsters. This is demonstrated by higher glucose concentrations in blood samples repeated after 15 minutes. In addition, hamsters sedated for blood sampling yield lower glucose values than those that are unsedated (Tomson and Wardrop, 1987).

Thiobarbiturate anesthesia has been found to increase blood glucose to 300mg/dl in adult male Syrian hamsters, compared to approximately 145mg/dl in unanesthetized controls. This hyperglycemia has been found to persist for several hours (Turner and Howards, 1977).

Elevated glucose levels are reported during hibernation in the hamster. The hamster also has a circadian rhythm of glucose concentrations, with the lowest level just before the start of the dark period and the highest level at the start of the light period (Cincotta and Meier, 1984). This effect may be mediated by melatonin secretion by the pineal gland (Ortega-Corona et al., 1991).

Insulin-induced hypoglycemia is also affected by diurnal factors, with no hypoglycemia at 4 hours after light onset and significant hypoglycemia at 8–20 hours after light onset.

The Chinese hamster is often used as a model of diabetes mellitus due to the high incidence of the disease in this strain. Glucose levels of up to 500mg/dl may be seen in diabetic Chinese hamsters, and this level can be decreased with lithium supplementation in the drinking water (Hu et al., 1997).

Lipid Metabolism

CHOLESTEROL

The reference range for cholesterol concentration in the hamster is 112–210mg/dl (Table 3.2), which represents the highest reference range of normal rodents and rabbits (Cox and Gökçen, 1973). Cholesterol levels in the hamster are affected by a number of factors, including diet, strain, environment, diurnal variation, and temperature, as well as disease.

Cholesterol levels in the hamster are significantly affected by diet. A high-cholesterol, high-triglyceride diet is associated with elevated plasma cholesterol levels in the hamster. These abnormal levels can usually be reduced by fasting (Sullivan et al., 1993). A high-fructose diet produces higher VLDL triglycerides, free cholesterol, and phospholipid levels in the hamster, but no change in apolipoprotein B levels. In addition, a high-fructose diet increases LDL triglycerides, decreases LDL cholesteryl ester, and increases HDL fractions (Wang et al., 2008).

Group housing causes increased cholesterol levels in hamsters fed an atherogenic diet when compared to singly housed controls (Yoganathan et al., 1998).

A decrease in photoperiod from 14 to 10 hours of light reduces cholesterol levels in hamsters.

Photoperiods of 10 hours or less cause a decrease in cholesterol with no effect on other plasma lipids (Gad, 2007). Low environmental temperature causes a decrease in plasma cholesterol but no change in plasma triglycerides (Vaughan et al., 1984), whereas hibernation causes an increase in serum lipids (Gad, 2007).

Disease conditions have an effect on cholesterol levels in the hamster. Chronic hepatitis and biliary disease cause hypercholesterolemia in the hamster, probably due to cholestasis (Brunnert and Altman, 1991). Diabetes in Chinese hamsters, alloxan treatment in Syrian hamsters, pertussis toxin, and amyloidosis are all associated with hypercholesterolemia (Garcia-Sainz et al., 1987; Gerritsen, 1982; Murphy et al., 1984).

TRIGLYCERIDES

The reference range for triglyceride concentration in the hamster is 72–350 mg/dl (Table 3.2). A high-carbohydrate diet increases plasma triglycerides in the hamster. Low environmental temperature is reported to produce no change in plasma triglycerides in the hamster (Vaughan et al., 1984).

TOTAL LIPIDS

The reference range for total circulating lipids in hamsters is 224–466 mg/dl (Table 3.2), which is higher than in other rodents (Cox and Gökçen, 1974; Mitruka and Rawnsley, 1977).

Enzymes

ALKALINE PHOSPHATASE (ALP)

The reference range for alkaline phosphatase (ALP) concentration in the hamster is 50–186 IU/l (Table 3.3). Levels of ALP are affected by the age, sex, and strain of hamster (Maxwell et al., 1985). Immature hamsters have higher ALP levels than adults because of its release from growing bone, as in other animals (Dent, 1977).

Hamster ALP includes isoenzymes from bone, liver, and intestine (Cox and Gökçen, 1973), and placenta (Manning et al., 1970). Bone provides the main isoenzyme in hamster, and intestinal ALP provides 10–15% of the total ALP activity in this species. The liver ALP isoenzyme is sensitive to heat and declines from weaning to undetectable levels in older hamsters (Tomson and Wardrop, 1987).

Increased ALP in the hamster is a sensitive indicator of liver damage resulting from viral-induced hepatitis, as well as chronic hepatitis with biliary disease due to intrahepatic cholestasis and increased ALP synthesis (Brunnert and Altman, 1991). Increased ALP in hamsters has been reported in association with leukemias, prostate gland tumors, and bone and liver cancers (Eugster et al., 1966).

ALANINE AMINOTRANSFERASE (ALT)

The reference range for alanine aminotransferase (ALT) levels in the hamster is 20–128 IU/l (Table 3.3) and may vary due to a variety of factors, including disease or technical issues.

The ALT enzyme is elevated in hamsters with hepatic necrosis caused by virus or acetaminophen toxicity (El-Hage et al., 1983; Rollinson and White, 1983). Elevated ALT is seen in Syrian hamsters with chronic hepatitis and is correlated with the number of affected hepatocytes. Chronic hepatitis can also result in decreased ALT due to decreased hepatocyte numbers (Duncan and Prasse, 1986). Hamsters experimentally infected with pirital virus (Arenaviridae) have increased ALT and AST 5–8 days post-infection (Sbrana et al., 2006).

The cardiac puncture method may result in higher serum levels of several enzymes, including ALT, AST, LDH, and CK, compared to blood sampled from other sites (Tomson and Wardrop, 1987).

ASPARTATE AMINOTRANSFERASE (AST)

The reference range for aspartate aminotransferase (AST) levels in the hamster is 20–150 IU/l (Table 3.3).

The AST enzyme is increased in hamsters with liver neoplasia and metabolic alterations (Eugster et al., 1966).

LACTATE DEHYDROGENASE (LDH)

The reference range for lactate dehydrogenase (LDH) levels in the hamster is 100–300 IU/l (Table 3.3). Levels of LDH are increased in hamsters with hereditary myopathy (Homburger et al., 1966) and after inoculation with some viruses (Eugster et al., 1966).

Freezing of hamster serum samples has been shown to decrease LDH activity (Tietz, 1976).

CREATINE KINASE (CK)

The reference value for creatine kinase (CK) level in the hamster is 23 IU/l (Table 3.3).

Creatine kinase has been found in hamster striated muscle and nervous tissue, and its level is used to diagnose myopathies, muscular dystrophies, and cardiac necrosis in this species. The Syrian hamster has a hereditary myopathy characterized by increased CK levels up to 730 IU/l compared to 23.2 IU/l in controls (Bajusz and Homburger, 1966).

AMYLASE

The reference range for amylase levels in the hamster is 154–196 IU/l (Table 3.3).

Amylase is present in the hamster pancreas, intestine, and liver, as in other animals (Takahashi et al., 1981).

Hormones

ADRENAL HORMONES

The reference range for cortisol levels in the hamster is 2.3–3.2 µg/dl (Table 3.4), which is lower than in many other rodent species. Male hamsters generally have larger adrenal glands and higher cortisol levels than female hamsters.

Pregnancy is associated with increased cortisol levels in hamsters, with elevations from 0.3–30 µg/dl as parturition approaches (Brinck-Johnsen et al., 1981).

Cortisol fecal metabolites have been extracted and measured by radioimmunoassay in hamsters undergoing surgery. Cortisol metabolites were found to increase immediately following surgery and decrease thereafter (Chelini et al., 2006). Plasma cortisol levels were also elevated after chronic stress in the hamster (Ottenweller et al., 1985).

The reference range for corticosterone levels in the hamster is 5.5–9.3 µg/dl (Table 3.4).

The hamster adrenal cortex contains distinct glomerulosa, fasciculata, and reticularis layers, as in other species, and ACTH administration increases adrenal weight (Alpert, 1950).

Adrenal gland activity is sensitive to diurnal variation, with maximal secretion approximately 3 hours before the onset of the dark period (Frenkel et al., 1965).

Cold temperatures do not stimulate ACTH release in the hamster (Frenkel et al., 1965).

THYROID HORMONES

The reference ranges for thyroid hormone levels in the hamster are 30–80 ng/dl for triiodothyronine (T3) and 3–7 µg/dl for thyroxine (T4) (Table 3.4). Several factors affect T3 and T4 levels in the hamster, including hibernation, age, strain, and temperature. Chronic exposure of hamsters to shortened photoperiod and lower temperature, as occurs during periods of hibernation, results in a decrease in levels of TSH, T3, and T4 (Hoffman et al., 1982; Vaughan et al., 1982). Increasing age in the hamster, from 3 to 20 months, is accompanied by decreasing levels of T3 and T4 (Neve et al., 1981). There is also a smaller response to TSH in older hamsters.

Hamsters have decreased protein-bound iodine during pregnancy, which may alter thyroid hormone metabolism during this condition (Galton and Galton, 1966).

REPRODUCTIVE HORMONES

The adult female hamster has a 4-day estrous cycle associated with predictable variations in the reproductive hormones, including follicle stimulating hormone (FSH), luteinizing hormone (LH), and progesterone (PG). The luteal phase includes day 1 (ovulation) and day 2, while the follicular phase, or proestrus, occurs

on day 4 of the cycle. Hormonal fluctuations occur daily in the immature female hamster and shift to the mature 4-day cycle in the adult female (Donham and Stetson, 1991). Reproductive hormone levels have been well characterized in the hamster and are described below.

Reproductive hormone levels for both male and female hamsters are sensitive to photoperiod, with short periods of light producing decreased testosterone levels in males (Furuta et al., 1994), and decreased FSH, LH, and prolactin levels in females (Chandrashekar and Bartke, 1989).

LUTEINIZING HORMONE (LH) The reference range for LH levels in the hamster is 20–40 ng/ml (Table 3.4).

Normal adult female hamsters have one LH peak on the afternoon of proestrus (day 4), approximately 10 hours before ovulation. LH levels are fairly stable during days 1–3 of the estrous cycle in the Syrian hamster (Buetow et al., 1999). A similar pattern for LH has been reported in the Djungarian hamster (Erb and Wynne-Edwards, 1994).

FOLLICLE-STIMULATING HORMONE (FSH) The reference range for FSH levels in the hamster is 100–300 ng/ml (Table 3.4).

In the adult female hamster, FSH normally peaks at the time of the LH peak on the afternoon of proestrus (day 4) and then again on the morning of estrus (day 1), stimulating follicular growth for the next cycle. Levels of FSH are fairly stable during days 2 and 3 of the estrous cycle in the Syrian hamster (Buetow et al., 1999). A similar pattern for FSH has been reported in the Djungarian hamster (Erb and Wynne-Edwards, 1994).

Female Turkish hamsters demonstrate daily FSH variations when in anestrus and at immature stages (Ogilvie et al., 1992).

ESTRADIOL The reference range for estradiol levels in the hamster is 5–10 pg/ml (Table 3.4).

Estradiol levels are low during the luteal phase of the reproductive cycle of the hamster, showing an inverse relationship to levels of progesterone.

PROGESTERONE The reference value for progesterone level in the hamster is 1 ng/ml (Table 3.4).

Progesterone is the predominant reproductive hormone during the luteal phase, or day 1 and 2 of the hamster reproductive cycle. Progesterone then decreases and increases again on day 4, or proestrus (Buetow et al., 1999).

PROLACTIN The reference range for prolactin levels in the hamster is 5–10 ng/ml (Table 3.4).

Prolactin levels in the female hamster typically correspond with the persistence of corpora lutea during pregnancy and the onset of maternal behaviors

at parturition. During the estrous cycle, prolactin peaks each afternoon, with highest concentrations in proestrus. This pattern continues into gestation, but peak concentrations decrease as pregnancy advances (Buetow et al., 1999). In Djungarian hamsters, prolactin levels decrease in midgestation (Edwards et al., 1994).

Prolactin levels in most hamsters respond to photoperiod, although this response is less apparent in the Djungarian hamster (Ebling, 1994).

Prolactin increases in the female hamster in response to ether anesthesia and to the stress of handling (Matt et al., 1983), although similar stresses decrease prolactin and testosterone levels in the male hamster (Huhman et al., 1995).

TESTOSTERONE The reference range for testosterone levels in the hamster is 1.5–2.0 pg/ml (Table 3.4).

Liver Function

TOTAL BILIRUBIN

The reference range for bilirubin levels in the hamster is 0.1–0.9 mg/dl (Table 3.5), which are lower values than bilirubin in humans (Mitruka and Rawnsley, 1981).

Hamsters with hepatic dysfunction do not usually have abnormal serum bilirubin levels (Wardrop and Van Hoosier, 1989).

SERUM PROTEINS

The reference range for total protein concentration in the hamster is 5.2–7.0 g/dl (Table 3.5) and is affected by age, disease, and other factors. There are significant levels of fibrinogen in hamster plasma, making it necessary to accurately measure liver proteins in serum samples. Fibrinogen is linked to alpha-globulin rather than beta-globulin in the hamster.

The reference ranges for albumin and globulin concentrations in the hamster are 3.5–4.9 g/dl and 2.7–4.2 g/dl, respectively (Table 3.5). Albumin concentration decreases during the first year of life, whereas alpha-2-globulin increases by 6 months old, beta-globulin decreases at 8 weeks old, and levels of gamma-globulin and fibrinogen are variable between 8 weeks and 1 year of age (House et al., 1961). The albumin-to-globulin ratio decreases with age in the hamster.

Pregnancy in hamsters alters serum proteins, with decreased albumin and increased alpha-globulins in near-term hamsters. Hibernating hamsters have increased beta-globulin, albumin, and total protein, and decreased levels of gamma-globulin (South and Jeffay, 1958).

Disease states can also produce changes in protein concentrations. Experimentally induced inflammation produces an elevation of gamma-globulins (Betts et al., 1964). Hamsters experimentally infected with pirital virus (Arenaviridae) have decreased albumin 5–8 days post-infection (Sbrana et al., 2006).

Diabetes mellitus is associated with increased alpha-2 globulin levels in Chinese hamsters (Green and Yerganian, 1963). Older hamsters commonly have amyloidosis, which produces decreased levels of albumin and increased levels of gamma-globulin (Gleiser et al., 1971; Murphy et al., 1984).

Kidney Function

BLOOD UREA NITROGEN (BUN)

The reference range for blood urea nitrogen (BUN) concentration in the hamster is 12–26 mg/dl (Table 3.6) and is affected by diet, sex, and disease. Blood urea nitrogen is affected by the quality and quantity of the diet, as well as duration of fasting in the hamster. A diet containing 18–24% protein has been shown to produce a higher BUN level in the hamster than one with 12% protein (Feldman et al., 1982).

Some studies have demonstrated higher BUN values in the female hamster (Feldman et al., 1982; Maxwell et al., 1985), although findings have been variable.

Renal disease is common in older hamsters and is associated with increased BUN (Feldman et al., 1982). *Leptospira pomona* infection in the hamster is associated with elevated BUN, as high as 424 mg/dl, along with renal lesions and renal failure (Abdu and Sleight, 1965). Hamsters experimentally infected with pirital virus (Arenaviridae) were found to have increased BUN, and other abnormalities, 5–8 days post-infection (Sbrana et al., 2006).

CREATININE

The reference range for creatinine concentration in the hamster is 0.4–1.0 mg/dl (Table 3.6) and is affected by sex and age (Murphy et al., 1984) as well as disease states.

Elevated serum creatinine has been found in hamsters with renal amyloidosis and the nephrotic syndrome (Murphy et al., 1984). However, hamsters with chronic hepatitis were found to have no change in serum creatinine (Brunnert and Altman, 1991). Similarly, there is no difference in creatinine levels in inbred hypertensive (CHF 148) hamster strains compared to controls (Thomas et al., 1997).

Electrolytes

In general, electrolyte values in hamsters are similar to those of other rodents (see Table 3.7).

CALCIUM (Ca)

The reference range for calcium concentration in the hamster is 5.3–12.0 mg/dl (Table 3.7).

CHLORIDE (Cl⁻)

The reference range for chloride concentration in the hamster is 93–110 mEq/l (Table 3.7).

PHOSPHORUS (P)

The reference range for phosphorus concentration in the hamster is 3.0–9.9 mg/dl (Table 3.7). These values are higher in younger hamsters than older hamsters (Dent, 1977). Phosphorus levels in blood can be affected by the age, sex, and strain of the hamster (Maxwell et al., 1985).

POTASSIUM (K)

The reference range for potassium concentration in the hamster is 3.9–6.0 mEq/l (Table 3.7).

Hemolysis of blood samples can result in artificially elevated serum potassium levels (Bannon and Friedell, 1966).

SODIUM (Na⁺)

The reference range for sodium concentration in the hamster is 128–150 mEq/l (Table 3.7).

OTHER RODENTS

Gerbil***Sample Collection*****RESTRAINT**

The gerbil may be restrained by grasping the base of the tail with one hand and the scruff of the neck with the other hand. Alternatively, the gerbil may be enclosed within one hand and held firmly in an upright position. Gerbils should not be picked up by the tip of tail due to the risk of degloving. Gerbils are not aggressive but will readily jump in an attempt to escape (Hrapkiewicz and Medina, 2007).

BLOOD

Blood samples can be collected more frequently in the gerbil than in other laboratory animals because of their rapid rate of erythrocyte turnover. The lateral tail vein can be used for blood collection in an unanesthetized gerbil, although caution should be taken because of the increased risk of tail degloving injury in this species (Joslin, 2009). Anesthesia should be used in the gerbil for blood collection from sites other than the tail vein. The saphenous vein or metatarsal vein can be distended using a tourniquet proximal to the stifle and a small blood sample is collected into the hub of a 22G needle. A 0.1–0.3-ml blood sample can be collected from the retro-orbital venous sinus of a gerbil by advancing a microhematocrit tube through the lateral canthus and holding off the external jugular vein behind the mandible (Joslin, 2009). The medial canthus is also a viable approach to the retro-orbital sinus in the gerbil (Dyer and Cervasio, 2008). Alternatively, small volumes of blood may be obtained from the lateral metatarsal vein, or from a clipped toenail. Large volumes of blood can

be obtained by cardiac puncture under anesthesia as a terminal procedure in the gerbil, as in other species (Hrapkiewicz and Medina, 2007).

URINE

The gerbil is a desert species and produces small quantities of concentrated urine. However, a sample can usually be obtained when a gerbil is picked up (Hrapkiewicz et al., 1998). Other methods of urine collection, such as urinary catheterization or cystocentesis, require sedation or anesthesia.

Reference Values and Sources of Variation**BLOOD**

Total blood volume of the gerbil is discussed in the Hematology section of this chapter.

CARBOHYDRATE METABOLISM

GLUCOSE The reference range for glucose concentration in the gerbil is 50–135 mg/dl (Table 3.2).

Gerbils are susceptible to obesity and may develop reduced glucose tolerance and diabetes mellitus.

LIPID METABOLISM

CHOLESTEROL The reference range for cholesterol concentration in the gerbil is 90–150 mg/dl (Table 3.2).

Cholesterol metabolism of the gerbil is similar to that of humans, so this species has been used to study the effects of dietary cholesterol and fats (Gordon and Cekleniak, 1961). Gerbils fed a diet with no cholesterol have higher alpha lipoprotein fractions than pre-beta or beta lipoprotein fractions (Forsythe, 1986). This finding has been confirmed with micro-affinity chromatography (Tschantz and Sunahara, 1993). Gerbils fed high-cholesterol diets often develop gallstones.

Gerbil serum is often lipemic, especially in older gerbils of either gender, although this condition is more common in males. Sunflower seeds in the diet may contribute to lipemic serum in gerbils (Heatley and Harris, 2009). Repeatedly bred male and female gerbils may develop hyperadrenocorticism with associated elevation of serum triglycerides and development of fatty livers (Percy and Barthold, 2007).

ENZYMES

ALKALINE PHOSPHATASE (ALP) The reference range for ALP concentration in the gerbil is 12–37 IU/l (Table 3.3).

HORMONES

ADRENAL HORMONES The gerbil adrenal gland is very large and secretes primarily cortisol.

Repeatedly bred male and female gerbils may develop hyperadrenocorticism with associated mineralization in the aorta and peripheral arteries, as well as

pathology of the pancreas, thymus, and adrenal glands. This condition is also associated with obesity and diabetes (Percy and Barthold, 2007).

LIVER FUNCTION

TOTAL BILIRUBIN The reference range for bilirubin concentration in the gerbil is 0.2–0.6 mg/dl (Table 3.5).

SERUM PROTEINS The reference range for total protein concentration in the gerbil is 4.3–12.5 g/dl (Table 3.5).

The reference ranges for albumin and globulin concentrations in the gerbil are 1.8–5.5 and 1.2–6.0 g/dl, respectively (Table 3.5).

KIDNEY FUNCTION

BLOOD UREA NITROGEN (BUN) The reference range for BUN concentration in the gerbil is 17–27 mg/dl (Table 3.6).

CREATININE The reference range for creatinine concentration in the gerbil is 0.6–1.4 mg/dl (Table 3.6).

ELECTROLYTES

CALCIUM (Ca) The reference range for calcium concentration in the gerbil is 3.7–6.2 mg/dl (Table 3.7).

CHLORIDE (Cl⁻) The reference range for chloride concentration in the gerbil is 93–118 mEq/l (Table 3.7).

PHOSPHORUS (P) The reference range for phosphorus concentration in the gerbil is 3.8–7.0 mg/dl (Table 3.7).

POTASSIUM (K⁺) The reference range for potassium concentration in the gerbil is 3.8–6.3 mEq/l (Table 3.7).

SODIUM (Na⁺) The reference range for sodium concentration in the gerbil is 141–172 mEq/l (Table 3.7).

Chinchilla

Sample Collection

RESTRAINT

Chinchillas are relatively easy to handle and restrain for collection of blood and urine samples, and they rarely bite unless agitated. Chinchillas should be restrained by grasping the base of the tail with one hand and placing the other hand over the shoulders and thorax. Fur slip, or loss of a patch of fur, can occur if a chinchilla is handled roughly (Hrapkiewicz and Medina, 2007).

BLOOD

Blood collection in the chinchilla is best performed using anesthesia to reduce stress, unless the animal is very accustomed to being handled. Peripheral blood

vessels are very small in the chinchilla and yield volumes of blood that are sufficient for assays such as blood glucose and packed cell volumes (Riggs and Mitchell, 2009). Small blood samples can be obtained from several peripheral veins, including the lateral saphenous vein, cephalic vein, lateral abdominal vein, and ventral tail vein (Joslin, 2009). A 23G–27G needle on a 1-ml syringe can be used at these sites. Best success is achieved using a tourniquet or holding off the vein proximally, as in other animals. A toenail clip or needle stick between the toes may also be used for a small blood sample in the chinchilla (Hrapkiewicz and Medina, 2007).

The retro-orbital sinus may be used for blood collection in the anesthetized chinchilla, as in other rodents. Alternatively, the transverse sinus in the chinchilla runs superficially around the auditory bulla and can also serve as a site for blood collection. A 25G butterfly catheter attached to a 1-ml syringe can be used to penetrate this sinus from the dorsal surface of the head near the ear (McClure, 1999).

Larger blood samples, sufficient for a complete blood count or clinical biochemistry panel, may be obtained from the femoral vein, jugular vein, or cranial vena cava in the anesthetized chinchilla, using methods described for other animals (Joslin, 2009). A 25G needle on a 1-ml or 3-ml syringe can be used to collect a blood sample from these sites (Riggs and Mitchell, 2009). The jugular veins are very superficial in the chinchilla, making them visible and particularly accessible for blood sampling in this species (Pilny, 2008).

Cardiocentesis may be used as a terminal procedure under anesthesia for collection of a large volume of blood in the chinchilla, as in other animals.

URINE

Urine for routine urinalysis can be collected from a chinchilla by clean-catch, from the cage floor, using a metabolic cage, or by manual pressure on the bladder. Urine to be cultured should be collected by cystocentesis, with or without anesthesia. For cystocentesis, the animal is placed in dorsal recumbency, the caudoventral abdomen disinfected, and urine collected percutaneously with a 25G needle attached to a 3-ml syringe (Riggs and Mitchell, 2009).

Reference Values and Sources of Variation

BLOOD

Total blood volume of the chinchilla is discussed in the Hematology section of this chapter.

URINE

Reference values and characteristics of chinchilla urine are listed in Table 3.1.

Normal chinchilla urine is yellow to amber, although dietary porphyrins can produce dark orange urine

that must be distinguished from hematuria. Chinchilla urine is normally alkaline, with a pH of 8–9 (Riggs and Mitchell, 2009).

An overweight female chinchilla with diabetes mellitus has been described with hyperglycemia and severe glucosuria and ketonuria (Marlow, 1995).

CARBOHYDRATE METABOLISM

GLUCOSE The reference range for glucose concentration in the chinchilla is 60–125 mg/dl (Table 3.2).

Serum glucose is lower in blood obtained from chinchillas anesthetized with ketamine and xylazine than in blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

Diabetes mellitus has been described in an overweight female chinchilla that was accompanied by hyperglycemia of greater than 400 mg/dl (Marlow, 1995).

LIPID METABOLISM

CHOLESTEROL The reference range for cholesterol concentration in the chinchilla is 40–300 mg/dl (Table 3.2).

TRIGLYCERIDES The reference range for triglyceride concentration in the chinchilla is 149–198 mg/dl (Table 3.2).

Serum triglycerides are lower in blood obtained from chinchillas anesthetized with ketamine and xylazine than in blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

ENZYMES

ALKALINE PHOSPHATASE (ALP) The reference range for ALP concentration in the chinchilla is 10–70 IU/l (Table 3.3).

ALANINE AMINOTRANSFERASE (ALT) The reference range for ALT concentration in the chinchilla is 10–35 IU/l (Table 3.3).

ASPARTATE AMINOTRANSFERASE (AST) The reference range for AST concentration in the chinchilla is 15–100 IU/l (Table 3.3).

CREATINE KINASE (CK) The reference range for CK concentration in the chinchilla is 0–300 IU/l (Table 3.3).

HORMONES

THYROID HORMONES The reference range for T4 in the chinchilla is 3.4–6.4 µg/dl.

Thyroparathyroidectomy performed on chinchillas to create an animal model of hypothyroidism resulted in 9–89% reduction in thyroxine (T4) levels in 80% of animals at 6–14 days after surgery. This was followed by rapid regrowth of the thyroid gland and a return of T4

to baseline levels in most animals studied (Martin et al., 2005). The average baseline T4 level was 5.25 µg/dl, with no difference between males and females. Sham-operated controls had a significant increase in T4 levels, suggesting a non-specific response to surgery (Martin et al., 2005).

LIVER FUNCTION

TOTAL BILIRUBIN The reference range for bilirubin concentration in the chinchilla is 0.6–1.3 mg/dl (Table 3.5).

SERUM PROTEINS The reference range for total protein concentration in the chinchilla is 3.8–8.0 g/dl (Table 3.5).

The reference ranges for albumin and globulin concentrations in the chinchilla are 2.3–4.1 g/dl and 0.9–4.2 g/dl, respectively (Table 3.5).

KIDNEY FUNCTION

BLOOD UREA NITROGEN (BUN) The reference range for BUN concentration in the chinchilla is 10–40 mg/dl (Table 3.6).

Serum urea is lower in blood obtained from chinchillas anesthetized with ketamine and xylazine than in blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

CREATININE The reference range for creatinine concentration in the chinchilla is 0.4–2.3 mg/dl (Table 3.6).

ELECTROLYTES

CALCIUM (Ca) The reference range for calcium concentration in the chinchilla is 5.6–15 mg/dl (Table 3.7).

CHLORIDE (Cl⁻) The reference range for chloride concentration in the chinchilla is 105–130 mEq/l (Table 3.7).

MAGNESIUM (Mg²⁺) The reference range for magnesium concentration in the chinchilla is 3.6–4.0 mg/dl (Table 3.7).

PHOSPHORUS (P) The reference range for phosphorus concentration in the chinchilla is 4–8 mg/dl (Table 3.7).

POTASSIUM (K⁺) The reference range for potassium concentration in the chinchilla is 3–7 mEq/l (Table 3.7).

SODIUM (Na⁺) The reference range for sodium concentration in the chinchilla is 130–170 mEq/l (Table 3.7).

Degu

Sample Collection

There is no published information available on methods of restraint or sample collection in the degu. In addition, blood volume and urine characteristics have not been reported in the literature.

Reference Values and Sources of Variation

CARBOHYDRATE METABOLISM

GLUCOSE The reference range for glucose concentration in the degu is 74–82 mg/dl (Table 3.2).

The degu is very intolerant of sugar in the diet and is very susceptible to developing diabetes mellitus when exposed to increased dietary glucose (Opazo et al., 2004). Cases of spontaneous diabetes mellitus in the degu may also be exacerbated by a carbohydrate-rich diet (Najecki and Tate, 1999; Nishi and Steiner, 1990). The protein structure of degu insulin and glucagon is similar to that of the guinea pig but varies from that of most other laboratory rodents, suggesting a difference in carbohydrate metabolism in histricomorph rodents (Nishi and Steiner, 1990).

A case of transitional cell carcinoma in a degu was found to be associated with hyperglycemia, increased ALT, and decreased total protein and albumin levels (Lester et al., 2005).

HORMONES

ADRENAL HORMONES The reference value for cortisol concentration in the degu is 15 µg/dl and the reference value for corticosterone in the degu is 1.5 µg/dl (Table 3.4).

The degu has been referred to as semi-precocial and has a more advanced hypothalamic–pituitary–adrenal axis at birth compared to that of more altricial rodents such as rats and mice (Gruss et al., 2006). The adrenal glands of the degu secrete both cortisol and corticosterone, with cortisol showing the greatest increase in response to stress (Kenagy et al., 1999). Plasma corticosterone levels in the degu are approximately 10–20% of cortisol levels (Gruss et al., 2006). Both male and female degus have elevated cortisol and corticosterone levels at birth, low levels at days 3–21, and higher, adult-like levels at days 45 and later (Gruss et al., 2006). There are no gender-dependent differences in these levels at any age.

The stress of parental separation causes elevated cortisol and corticosterone in male and female degus between 3 and 21 days of age. The absence of measurable ACTH activity is thought to be due to lack of degu-specific antibodies (Gruss et al., 2006).

Diurnal cycle affects cortisol levels in male degus, with a peak at the beginning of the light cycle and a trough near the end of a 12-hour light cycle (Mohawk et al., 2005).

KIDNEY FUNCTION

A case of transitional cell carcinoma in a degu was found to be associated with increased BUN, creatinine, and phosphorus levels (Lester et al., 2005).

Deer Mouse

Sample Collection

RESTRAINT

Peromyscus species readily adapt to the laboratory environment and may be handled in a similar manner to *Mus musculus*.

BLOOD

Blood can be collected from tail veins of the deer mouse under light anesthesia (Sealand, 1961). Larger blood samples may be collected directly from the heart in animals under deep terminal anesthesia (Gough and Kilgore, 1964).

There is very little information available in the literature regarding clinical biochemistry parameters in the deer mouse.

Reference Values and Sources of Variation

ENZYMES

ALKALINE PHOSPHATASE (ALP) The reference range for ALP concentration in the deer mouse is 6–7 IU/l (Table 3.3).

Deer mice infected with *Capillaria hepatica* were found to have increased concentrations of alkaline phosphatase compared with uninfected controls (Meagher, 1998).

LIVER FUNCTION

SERUM PROTEINS Deer mice infected with *Capillaria hepatica* were found to have increased total proteins and decreased albumin levels compared with uninfected controls (Meagher, 1998).

Dormouse

Sample Collection

BLOOD

Little information is available on obtaining blood samples from the dormouse. Blood samples of 1 ml were obtained by cardiac puncture in the anesthetized dormouse (Jallageas and Assenmacher, 1986).

Very little information is available in the literature regarding clinical biochemical parameters in the dormouse.

Reference Values and Sources of Variation

CARBOHYDRATE METABOLISM

GLUCOSE Glucose-induced insulin release was studied in the perfused pancreas of the edible dormouse (*Glis glis*) and demonstrated seasonal variation in this species. Exposure of the dormouse to 302 mg/dl glucose caused highest insulin release in the fall and winter and decreased glucose sensitivity in the spring and summer (Castex and Sutter, 1981).

HORMONES

THYROID HORMONES Artificially controlled photoperiod pattern and constant warm temperatures were found to interfere with the normal annual cycle of thyroxine levels in the dormouse (Jallageas and Assenmacher, 1986).

REPRODUCTIVE HORMONES The annual cycle of plasma testosterone levels in the dormouse is parallel and correlated to thyroxine concentrations (Jallageas and Assenmacher, 1983). Testosterone levels are decreased compared to reference levels in the dormouse when the thyroid gland is removed in June, at the beginning of the breeding season (Jallageas et al., 1992). Constant pattern of photoperiod and warm temperatures were found to interfere with the normal annual cycle of testosterone levels in this species (Jallageas and Assenmacher, 1986).

Kangaroo Rat

Sample Collection

RESTRAINT

The kangaroo rat has a fragile tail that should not be used for restraint. The recommended method of restraining a kangaroo rat is by grasping the loose skin at the nape of the neck (Fine et al., 1986).

BLOOD

Blood withdrawal from the kangaroo rat is best accomplished using sedation or light anesthesia. Blood sampling from the infraorbital sinus has been described in this species under light anesthesia (Banta and Holcombe, 2002). Blood samples can be obtained by tail clipping in the unanesthetized kangaroo rat (Scelza and Knoll, 1982).

URINE

Kangaroo rats rarely drink water in the wild and use internal metabolically derived water and concentration of urine to survive in an arid or semiarid environment. Kangaroo rats will drink water in captivity, but it is difficult to obtain a sufficient urine sample from this species to run a urinalysis (Donnelly and Quimby, 2002). A metabolism cage has been used successfully to evaluate urine volume and concentration in the kangaroo rat in one study (Banta and Holcombe, 2002).

Reference Values and Sources of Variation

URINE

Urine produced by kangaroo rats is very concentrated, which represents an adaptation to their desert environment in nature (Tracy and Walsberg, 2002). One

species (*D. panamintinus*) reportedly excretes urine that is concentrated to 3.28M (Intress and Best, 1990).

HORMONES

THYROID HORMONES The reference range for T4 in the kangaroo rat is 0.48–1.92 µg/dl (Table 3.4). Levels of circulating T4 are lower in the kangaroo rat than predicted based on its size and may explain the low metabolic rate in this species (Hulbert et al., 1985; Yousef and Johnson, 1975).

Kangaroo rats implanted subcutaneously with slow-release thyroxine pellets producing 0 (placebo) to 111.1 µg per day showed a dose-dependent increase in plasma thyroxine and basal metabolic rate, with no increase in urinary water loss (Banta and Holcombe, 2002).

KIDNEY FUNCTION

BLOOD UREA NITROGEN (BUN) The reference value for BUN in the kangaroo rat is 30 mg/dl (Table 3.6).

The kangaroo rat produces uric acid as the final product of purine metabolism, and it is excreted in the feces. This process is metabolically complex but advantageous for a desert-dwelling rodent because it conserves water.

It is possible to produce a condition similar to diabetes insipidus in the kangaroo rat if it is allowed to drink water ad libitum (Eisenberg and Isaac, 1963).

Cotton Rat

Sample Collection

RESTRAINT

Cotton rats are challenging to restrain for sample collection because they move quickly, jump vertically, and may attempt to bite when picked up. The tail skin is susceptible to degloving, so the tail should not be used to pick up a cotton rat (Donnelly and Quimby, 2002). Restraint with a leather glove followed by anesthesia is recommended to attain sufficient control for sample collection (Prince, 1994).

BLOOD

Cotton rats have tail veins that are not accessible for blood sampling, although blood samples can be obtained from the cut tip of the tail without anesthesia (Dolyak and Leone, 1953). A blood sample of up to 500 µl (per 100-g animal) may be collected from the retro-orbital venous sinus of an anesthetized cotton rat (Prince, 1994; Webb et al., 2003). Blood flow may be increased by applying pressure to the ipsilateral jugular vein (Prince, 1994). Blood sampling directly from the

heart of anesthetized cotton rats has also been reported (Dolyak and Leone, 1953).

Reference Values and Sources of Variation

CARBOHYDRATE METABOLISM

CHOLESTEROL The reference range for glucose level in the non-fasted cotton rat is 115–216 mg/dl (Table 3.2), or 78–124 mg/dl after a 24-hour period of fasting (Dolyak and Leone, 1953).

LIPID METABOLISM

GLUCOSE The reference range for cholesterol in the cotton rat is 134–165 mg/dl (Table 3.2).

ENZYMES

ALKALINE PHOSPHATASE (ALP) The reference range for ALP in the cotton rat is 10–14 IU/l (Table 3.3).

LIVER FUNCTION

SERUM PROTEINS The reference range for total protein in the cotton rat is 6.1–6.9 g/dl (Table 3.5).

The reference ranges for albumin and globulins in the cotton rat are 4.2–5.2 g/dl and 1.4–2.2 g/dl, respectively (Table 3.5).

KIDNEY FUNCTION

BLOOD UREA NITROGEN (BUN) The reference range for BUN in the cotton rat is 13–14 mg/dl (Table 3.6).

CREATININE The reference range for creatinine in the cotton rat is 0.9–1.5 mg/dl (Table 3.6).

ELECTROLYTES

BICARBONATE (HCO_3^-) The reference range for bicarbonate anion concentration in the cotton rat is 12.6–15.9 mEq/l (Table 3.7).

PHOSPHORUS (P) The reference range for phosphorus concentration in the cotton rat is 6.0–7.9 mg/dl (Table 3.7).

Sand Rat

Sample Collection

BLOOD

Blood samples of 100 μ l or more may be collected from the sand rat by cutting the tip of the tail (Frenkel and Kraicer, 1972).

URINE

Urine samples from sand rats may be collected using metabolic cages (Frenkel and Kraicer, 1972).

Very little information is available on the clinical biochemistry parameters of the sand rat.

Reference Values and Sources of Variation

CARBOHYDRATE METABOLISM

GLUCOSE The reference range for glucose concentration in the sand rat is 68–71 mg/dl (Table 3.2). This value does not vary significantly during a 60-hour period of fasting (Frenkel and Kraicer, 1972).

HEMATOLOGY

Introduction

Hematology is the study of blood and blood-forming organs, including the diagnosis, treatment, and prevention of diseases of the blood, bone marrow, and immunologic, hemostatic, and vascular systems. Hematologic analysis is often used for the diagnosis and treatment of animal diseases. As analytical methods have become more sensitive, requiring smaller sample volumes, hematology has become more important for disease recognition and treatment in the smaller laboratory animals.

Several physiologic and physical factors can affect the results of hematologic assays and make it difficult to establish reference values. Physiologic factors include age, breed and strain, gender, season and time of day, nutrition, disease, stress, and trauma. Important physical factors include site of blood withdrawal, presence and type of anticoagulant, and sample handling and preparation (Dyer and Cervasio, 2008). Interpretation of results must take these factors into consideration.

A joint committee formed by several scientific societies formulated a recommended core panel of hematology tests for safety and toxicity studies in laboratory animals (Weingand et al., 1996). This core panel includes total leukocyte count, differential leukocyte count, erythrocyte count, erythrocyte morphology, platelet count, hemoglobin concentration, hematocrit or packed cell volume, mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration. Blood smears can be used for reticulocyte counts, and bone marrow cytology should be collected and evaluated if indicated. Tests of hemostasis recommended by the committee include prothrombin time, activated partial thromboplastin time, and platelet count (Weingand et al., 1996).

Blood Collection and Sample Preparation

Blood Collection

RESTRAINT

General approach and methods of restraint for blood collection in laboratory animals are discussed above in the Clinical Chemistry section of this chapter.

SAMPLE VOLUME

The size of the animal determines the total volume of blood that can be safely collected in a single sample. The standard safe volume of a single sample is 1% of the animal's body weight every 14 days, although a smaller volume is recommended in older animals or those with suspected anemia or hypoproteinemia. Blood volume is usually restored within 24 hours, but the return of some blood components to normal levels can take up to 2 weeks after blood collection (Joslin, 2009).

COLLECTION SITES

Many of the same peripheral vessels used for blood collection in larger animals can be used in laboratory animals, although the unique anatomy of certain species determines the success of one site over another. For example, the tail vein is an appropriate site for blood sampling in the mouse and gerbil but is not useful in the hamster. Blood collection sites for the respective species are discussed in the Clinical Biochemistry section of this chapter.

Regardless of the site used for blood collection, the overlying skin should be clipped or shaved and cleaned with an aseptic solution such as chlorhexidine gluconate or povidone iodine. A topical anesthetic, such as lidocaine and prilocaine, may also be applied to the skin prior to blood collection (Joslin, 2009).

Sample Preparation

Hematology parameters are best evaluated on a blood sample that is freshly collected and not hemolyzed or clotted. The blood sample may be collected into a tube with or without an anticoagulant.

Routine hematology assays are usually performed using an anticoagulant such as ethylenediaminetetraacetic acid (EDTA) or lithium heparin. EDTA is preferable to heparin as an anticoagulant because of its minimal alteration of cell morphology and staining characteristics. Coagulation studies are typically performed using sodium citrate.

If no anticoagulant is used, the blood should be well mixed by manually inverting or electronically rotating the tube, to ensure thorough mixing of blood components before removing an aliquot for evaluation. Blood clotting occurs more slowly in plastic tubes than in glass tubes.

Erythrocyte and leukocyte morphology and staining characteristics may be altered by anticoagulants. For this reason, blood smears should be made prior to mixing blood samples with anticoagulant (Dyer and Cervasio, 2008). A small volume of blood can be collected in the hub of a needle and used for blood smear preparation without exposure to anticoagulants.

Blood Volume

Total Blood Volume

Published values for total blood volume in a species can vary up to 10%, depending on the method used for calculation. Blood volume is also affected by physiologic factors such as age and lean body mass. In general, as an animal increases in size, the percentage of blood volume decreases (Joslin, 2009).

Blood volume is measured by the T-1824 or Evans blue dye method due to the high affinity of this azo compound dye to serum albumin.

Plasma Volume

In most animals, plasma volume is approximately 50–60% of the total blood volume. The plasma volume can be estimated from the size of the clear layer above the packed red cells and buffy coat in a microhematocrit tube after centrifugation.

Plasma volume can be calculated using radiolabeled albumin (McGuill and Rowan, 1989).

Reference ranges for blood and plasma volumes in the laboratory animals covered in this volume are provided in Table 3.8.

Peripheral Blood Cells

Erythrocytes

Red blood cells are anucleate and have a biconcave disc shape, which minimizes the distance that hemoglobin must travel to the surface of the red blood cell for gas exchange. The biconcave disc shape also increases the flexibility of the cell for movement through vessels for oxygen delivery.

The number of erythrocytes may be represented by red blood cell count, red blood cell concentration, hematocrit, or packed cell volume.

RED BLOOD CELL COUNT

An automated hematology instrument typically provides the red blood cell count in an isotonic dilution of the blood sample and calculates the red blood cell concentration from this value and the sample volume. Hematocrit and packed cell volume values both indicate the percentage of red blood cells in whole blood and are essentially equivalent but are derived by different methods.

Hematocrit (Hct) is usually calculated in an automated hematology instrument from the red blood cell concentration and mean cell volume (MCV) of red blood cells. Hematocrit is calculated using the formula $Hct = (MCV \times \text{red blood cell concentration})/10$ and is represented as percent.

Packed cell volume (PCV) is usually determined using the microhematocrit method (Goldenfarb et al.,

TABLE 3.8 Blood Values¹

	Total Blood Volume		Single Sample Vol (ml/2 wks)	Exsanguination Vol (ml)	Plasma Volume (ml/kg BW)	Bone Marrow (M:E ratio)	References
	(ml)	(ml/kg BW)

N/A = values not available.

¹Species for which no values are available are not listed.

1971). A microhematocrit tube is filled from the hub of the sampling needle or from the tube of anticoagulant-treated blood. The microhematocrit tube is filled at one end with clay sealant and centrifuged at high speed for 2–3 minutes in a microhematocrit centrifuge. The top clear layer is plasma, the middle white band is the buffy coat representing predominantly leukocytes and platelets, and the bottom red layer is packed erythrocytes. Normal plasma is clear, whereas icteric plasma is yellow, lipemic plasma is white, and hemolytic plasma is red. The PCV value is measured on a microhematocrit card reader by placing the tube on the card so that the sealant boundary with erythrocytes is on the zero line and the top of the plasma column is on the 100 line. The top of the red cell column then represents the percentage of the sample that is composed of red blood cells.

Errors of up to 8% can occur due to improper force or duration of centrifugation (Mitruka and Rawnsley, 1977).

PCV is fairly constant among mammals, whereas total red blood cell count and mean cell size vary among species (Campbell and Ellis, 2007).

HEMOGLOBIN (Hgb)

Hemoglobin is the protein that transports oxygen and carbon dioxide in the blood stream. There are several methods used to determine hemoglobin levels (Mitruka and Rawnsley, 1977).

Hemoglobin level is fairly constant among mammals and is usually approximately one-third of the hematocrit value, or one-third of the packed cell volume (Campbell and Ellis, 2007).

The cyanmethemoglobin method is usually performed by an automated hematology instrument, which uses a lytic dilution of the blood sample to release hemoglobin. Potassium cyanide converts hemoglobin to the stable pigment cyanmethemoglobin. Light absorbed at a specific wavelength is measured by spectrophotometry in a hemoglobinometer. Light is absorbed in proportion to the hemoglobin concentration, using a known concentration as a reference. Hemoglobin concentration is expressed as g/dl.

ERYTHROCYTE LIFESPAN

The lifespan of circulating red blood cells varies somewhat between species but typically ranges from 50–70 days. A variety of methods have been used to estimate this duration, including radiolabeled compounds and alveolar carbon monoxide.

ERYTHROCYTE SIZE AND STAINING

Mean cell volume (MCV) is the average size of red blood cells counted electronically. It is expressed in femtoliters or μ^3 .

Mean cell hemoglobin (MCH) is calculated using the hemoglobin concentration and red blood cell

concentration and therefore provides no additional clinical information. MCH is expressed in pg per cell.

Mean cell hemoglobin concentration (MCHC) is calculated from the hemoglobin concentration and hematocrit and provides the index of Hgb volume in grams relative to PCV in g per dl or percent.

$MCHC (g/dl) = [Hgb (g/dl)/PCV (\%)] \times 100$. Since Hgb is typically one-third the hematocrit value, the MCHC value is usually approximately 30g/dl.

In an automated hematology instrument, hemoglobin and packed cell volume are determined using different aliquots of a blood sample that are diluted separately.

A hemolyzed sample causes a falsely increased MCHC value.

Regenerative anemia causes decreased MCHC if the reticulocyte fraction is >20%. Severe iron-deficiency anemia or microcytic anemia also decreases MCHC due to decreased Hgb content.

$MCHC < 28 g/dl$ is usually due to instrument error.

RETICULOCYTES

Reticulocytes provide an assessment of the bone marrow's response to anemia. The rate of reticulocyte release from the bone marrow indicates the erythroid component of the bone marrow. A reticulocyte stain measures aggregates of residual ribosomes and mitochondria that form clumped granular material called reticulum.

Reticulocytes appear as polychromatophilic cells seen on a Wright- or Wright-Giemsa-stained blood film.

New methylene blue or brilliant cresyl blue are mixed with several drops of blood and incubated for 10 minutes in a tube before making a blood film. Reticulocytes are counted out of 1000 RBCs in a blood film and expressed as percentage of the RBCs. In cases of anemia, the number will be altered, so reticulocyte number per μl is calculated as $RBCs/\mu l \times \% \text{ reticulocytes}$.

Reticulocytes are increased as the bone marrow responds to anemia. A reticulocyte number of less than 10 000 per μl is considered to represent no or minimal regenerative response; 10 000–60 000 per μl is a poor regenerative response; 60 000–200 000 per μl is considered a moderate response; and 200 000–500 000 reticulocytes per μl is a maximal regenerative response.

Reference ranges for erythrocyte parameters in the laboratory animals covered in this volume are provided in Table 3.9.

Leukocytes

TOTAL WHITE BLOOD CELL (WBC) COUNT

Total leukocyte concentration is measured using the Unopette dilution method, automated nucleated particle counter, or by expanded buffy coat analysis. The Unopette system is a commercial kit that dilutes a blood

sample 1:100 in acetic acid, resulting in membrane lysis and removal of erythrocytes and platelets. The remaining nucleated particles are leukocytes and these are quantified within a grid under a microscope. Electronic cell counters use a similar approach, except that red blood cells are lysed with a detergent solution before nucleated particles are quantified. A quantitative buffy coat analysis system (QBC, Becton Dickinson) expands the buffy coat layer in a specialized microhematocrit tube and quantifies the leukocytes by optical scanning. An automated hematology instrument uses lytic dilution of the blood sample to provide white blood cell numbers.

BLOOD SMEAR

The optimal blood smear is a single layer of dispersed cells that accurately represents the distribution of cells in whole blood. The most common method of blood smear preparation is the wedge technique, in which a drop of blood is placed near the end of one glass slide. A second slide is held at a 30–45° angle, backed into the drop, and quickly pushed forward to the end of the first slide. The best area for cell counting is the monolayer of cells (counting area) between the thick region and the feathered edge (Thrall et al., 2004).

BLOOD STAINING

Blood staining is needed to perform a differential leukocyte count and to identify morphologic abnormalities. Romanowsky stains, such as Wright's or Wright-Giemsa stains, are employed in diagnostic laboratories to stain blood smears. Rapid hematology staining kits that mimic the Wright stain are commonly used in clinical settings.

DIFFERENTIAL LEUKOCYTE COUNT

The concentration of individual white blood cell types is the most important indicator of disease, and this is determined in a well-prepared and stained blood smear. The stained counting area is examined under high power to perform a differential count of leukocytes, evaluate blood cell morphology, and determine platelet number. The differential count of leukocytes is performed by classifying 100 consecutively encountered white blood cells as neutrophil, band neutrophil, lymphocyte, monocyte, eosinophil, and basophil. Morphology of white and red blood cells should be noted, and number of platelets per high-powered field recorded.

Flow cytometry can be used to count cell populations based on phenotypic markers and measuring cell functions (Kania, 2008). Antibodies are used that bind specifically to cell surface markers called cluster of differentiation (CD) antigens. The markers may correlate with specific cell functions.

Cell counting is performed with instruments that use light-scattering technology. The degree and angle

of light scatter is used to differentiate different types of cells. Automated differential WBC counting is fairly accurate for normal blood but can be inaccurate if the blood sample is abnormal and can be verified with a manual differential count.

Coulter technology is more commonly used for cell counting. This method is used to measure the size of RBCs, distinguish RBCs from platelets, and differentiate types of WBCs. Suspended cells impede the medium's ability to conduct current. Current deflection is measured as cells and current pass through an opening, and the amount of the deflection is proportional to the size of the cell.

LYMPHOCYTES Lymphocytes are found in blood, bone marrow, lymph nodes, gut-associated lymphoid tissue (GALT), and are associated with immunologic response.

NEUTROPHILS Mammalian neutrophils are phagocytic and function in the destruction of microorganisms. Inflammation, especially that caused by microorganisms, results in an increase in circulating neutrophils.

EOSINOPHILS Eosinophils are involved in the inactivation of histamine in response to allergens and some chronic diseases of the skin, lungs, gastrointestinal tract, and uterus, organs with high concentrations of mast cells.

Eosinophilic granules contain alkaline proteins that stain intensely pink with eosin dye. The granules have a crystalline shape that varies between species.

Eosinophils have phagocytic activity, but this function is much less effective than neutrophils.

Eosinophilia is typically associated with infections with helminth larvae, allergic inflammation, and antigen-antibody complexes (Thrall et al., 2004). Eosinophils primarily act to destroy parasitic microorganisms with the alkaline proteins contained in their granules.

BASOPHILS Basophils are typically the least common of the granulocytes and contain large cytoplasmic granules that stain with basophilic dyes. Basophils function in inflammatory reactions associated with allergies. Basophils contain heparin and histamine and are often found at sites of ectoparasite infection.

MONOCYTES Monocytes have a large nucleus with two lobes. Monocytes function in the immune system to restore the macrophages and dendritic cells in the tissues and respond to inflammatory mediators by differentiating into macrophages and dendritic cells as part of an immune response.

Platelets (Thrombocytes)

Platelets are cytoplasmic fragments from megakaryocytes in the bone marrow and contain cytoplasmic organelles. Platelets form the initial hemostatic plug during clot formation and prevent hemorrhage after damage to small blood vessels. Platelets often appear as clumps in blood smears. Large platelets represent those released early from the bone marrow. Platelets are much smaller than erythrocytes but are typically counted simultaneously by hematology analyzers, according to particle size. An experienced technician can count platelets using a hemocytometer and Unopette kit.

Reference ranges for leukocyte and platelet numbers in the laboratory animals covered in this volume are provided in Table 3.10.

Coagulation

Coagulation of blood is a defense mechanism to prevent excessive blood loss after vascular injury. It involves the formation of a clot at the site of damaged endothelium in response to thrombin, which converts fibrinogen into the fibrin matrix of the clot. After the endothelium has been repaired, the clot dissolves by fibrinolysis.

Prothrombin is the circulating precursor of thrombin, and there are several pro-coagulant proteins that interact to enhance thrombin formation. Endothelial damage initiates a cascade of events. A variety of tests are used to determine the functioning of the coagulation system.

Bleeding Time (BT)

Bleeding time is the time it takes, in minutes, for bleeding to stop after a standardized cut is made in a hairless area of skin. Bleeding stops when a platelet plug forms and BT thus assesses platelet function.

Prothrombin Time (PT)

Prothrombin time is a measure of the function of the extrinsic coagulation pathway. Blood is collected in a tube containing the anticoagulant sodium citrate and centrifuged to yield plasma. Tissue factor (III) is added and the time to clot formation is measured in seconds.

Activated Partial Thromboplastin Time (APTT)

Activated partial thromboplastin time is a measure of the function of the intrinsic and common coagulation pathways. A blood sample is collected into a tube containing citrate, which stops coagulation by binding calcium, and then centrifuged. A phospholipid, activator, and calcium are added to the plasma sample and time to clot formation is measured in seconds.

Thrombin Time (TT)

Thrombin time is also known as thrombin clotting time (TCT) and is a test that measures the time for a clot to form in plasma in a blood sample placed in anticoagulant to which an excess of thrombin is added. This test evaluates the conversion of soluble fibrinogen to insoluble fibrin. Failure to form a clot within 10–15 seconds is indicative of a possible fibrinogen deficiency.

Fibrinogen Concentration

Fibrinogen, or Factor I, originates in the liver and is converted to fibrin by the enzyme thrombin during coagulation. The fibrinogen test evaluates fibrinogen levels when there are suspected abnormalities in this protein that contribute to clotting disorders.

Reference ranges for coagulation tests in the laboratory animals covered in this volume are provided in Table 3.11.

Bone Marrow

Pluripotent stem cells in the bone marrow produce progenitor cells that differentiate into the erythrocyte, granulocyte, megakaryocyte, and monocyte/lymphocyte cell lines. These cells mature and are released into the circulation (Marshall, 2008).

Evaluation of the bone marrow is indicated for hematologic conditions that cannot be completely described by examination of peripheral blood elements. Conditions that may require bone marrow evaluation include non-regenerative anemias, thrombocytopenia, gammopathy, leukemias, and staging of lymphomas and mast cell tumors (Pilny, 2008).

General anesthesia is required for bone marrow aspiration in laboratory animals, and topical anesthetic should also be infiltrated at the sampling site. The proximal femur is the most common sampling site, but the proximal tibia, proximal humerus, and the ilium can also be used in larger animals (Pilny, 2008). Surgical exposure and resection of a bone to recover bone marrow may also be used, but this procedure is more invasive and has a greater risk of complications.

For bone marrow aspiration, the animal is placed in lateral recumbency, and the site to be sampled is shaved and aseptically prepared. A small incision is made in the overlying skin, and then a spinal needle is advanced into the medullary cavity and the stylet removed. A syringe is attached to the needle, and bone marrow is withdrawn. A smear can be prepared from a drop of the sample, and the remainder is usually stored in EDTA to prevent clotting (Pilny, 2008).

A bone marrow smear is prepared by placing a drop of marrow sample on one slide and covering it briefly with a second slide to spread the drop. The second slide is removed and the smear is air dried and stained with Wright-Giemsa or a rapid hematology stain. The smear is examined for normal cell morphology and myeloid vs. erythroid cell types. The myeloid to erythroid (M:E) ratio is calculated as an indication of bone marrow activity, and this ratio varies between 0.5:1 and 3:1 depending on the species. The maturation index, or ratio of proliferating to non-proliferating cells, is also calculated as an assessment of hematopoiesis (Pilny, 2008).

Bone marrow hypoplasia can result from infectious disease, estrogen or chemical toxicity, myelofibrosis, or immunosuppressive therapy or disease. Bone marrow aplasia indicates lack of cells from all lines (Pilny, 2008).

Bone marrow hyperplasia may represent a regenerative response to loss of myeloid or erythroid cells in the peripheral circulation, or it may be due to a lymphoproliferative or myeloproliferative neoplastic disease (Pilny, 2008).

Reference ranges for the myeloid to erythroid (M:E) ratio in the laboratory animals covered in this volume are provided in Table 3.8.

RABBIT

Sample Collection

Blood

Methods of restraint and acceptable sites and volumes of blood samples in the rabbit are described in the Clinical Biochemistry section of this chapter.

Bone Marrow

Bone marrow aspirates should be performed if there is a suspicion of anemia or other abnormalities of blood cell production. Collection of bone marrow should be performed with the rabbit under anesthesia and the sampling site prepared aseptically. Percutaneous aspiration may be used to sample bone marrow from the humerus or the femur with a Rosenthal pediatric needle (Horan et al., 1980) or from the proximal end of the tibia with a 15G needle (Sundberg and Hodgson, 1949). The proximal femur is generally the preferred site in most species, including the rabbit. A spinal needle with stylet is typically used and inserted in the trochanteric ridge of the femur (Vennen and Mitchell, 2009). The femur may also be surgically resected for direct access to the bone marrow (Powsner and Fly, 1962), but this approach is not recommended due to the importance of the rear limb for weight-bearing in the rabbit (Suckow and Douglas, 1997).

Reference Values and Unique Characteristics

Several factors can affect the results of hematology assays in the rabbit, including physiologic factors, such as age, breed or strain, sex, or pregnancy (Murray, 2000), as well as physical factors, such as sample handling and analytical techniques.

Blood Volume

Reference ranges for blood and plasma volumes in the rabbit are provided in Table 3.8.

TOTAL BLOOD VOLUME

The total blood volume of a normal adult New Zealand White rabbit is approximately 160–480ml, or 44–70ml per kg body weight. Rabbits have a higher blood volume during pregnancy (Prince, 1982). Blood volume per body weight in the young rabbit decreases significantly between birth and 4 months old.

Using the general guidelines for blood withdrawal based on body weight, approximately 20–40ml may be safely removed every 2 weeks.

The use of radio-iodinated albumin is preferable for estimating blood volume in a rabbit, instead of the dye T-1824 method often used in dogs (Brewer, 2006).

PLASMA VOLUME

Plasma volume in the rabbit is approximately 28–50ml per kg body weight and decreases significantly between birth and 4 months old.

Peripheral Blood Cells

Peripheral blood cells and elements of hematopoiesis in the rabbit are nicely illustrated in color photomicrographs in a recent publication (Marshall, 2008).

ERYTHROCYTES

There are no known blood groups in rabbits, and blood transfusions are well tolerated in this species (Marshall, 2008).

Reference values for erythrocyte parameters in the rabbit are provided in Table 3.9.

RED BLOOD CELL COUNT The reference range for red blood cell count in rabbits is $4.9\text{--}7.8 \times 10^6$ cells per μl (Table 3.9) and may be affected by several factors. For example, lower erythrocyte counts are reported in young rabbits of less than 12 weeks old (Melillo, 2007). Interestingly, the red blood cell count in a 28-day fetus is similar to that of the doe (Kriesten et al., 1987). The sex of the rabbit has been reported to have little or no effect on hematologic values (Jain, 1986).

An increase in red blood cell number has been reported in response to cold stress (de la Fuente et al., 2007), whereas hemolysis of the blood sample can result in a decreased red blood cell count (Melillo, 2007).

HEMATOCRIT (Hct) OR PACKED CELL VOLUME (PCV) The reference range for hematocrit in rabbits is 31–50% (Table 3.9) and may vary by age and strain. Hematocrit is reported to be high at birth and then falls by 20 days old, followed by a gradual increase to adult levels by 90 days old (Abelson and Simon, 1991). However, other studies report a PCV in neonatal rabbits that is similar to adult rabbits (Bortolotti et al., 1989). Differences exist in hematocrit values between different breeds and strains of rabbits but probably have little clinical significance (Kozma et al., 1974). There also appears to be little or no effect of sex on hematocrit values in the rabbit (Jain, 1986).

A PCV of less than 30% is indicative of anemia. A non-regenerative anemia may suggest the presence of a chronic disease. A regenerative anemia is associated with reticulocyte production and may occur in cases of blood loss due to external or internal hemorrhage, intravascular hemolysis, autoimmune hemolytic anemia, or lead toxicity (Melillo, 2007).

Hematocrit values of 13–31% were described in New Zealand White rabbits with hemolytic anemia resulting from systemic infection with *Achromobacter xylosoxidans* in contaminated intravenous fluids (Allison et al., 2007).

A PCV of more than 45% may indicate dehydration. Elevated PCV has also been reported as a consequence of cold stress and heat stress (de la Fuente et al., 2007).

HEMOGLOBIN (Hgb) The reference range for hemoglobin levels in rabbits is 10–17.4g/dl (Table 3.9). Similar to hematocrit levels, hemoglobin concentrations are high at birth and then fall by 20 days old, followed by a gradual increase to adult levels by 90 days old (Abelson, 1991). As with hematocrit,

hemoglobin differences between breeds and strains of rabbits exist but probably have little clinical significance (Kozma et al., 1974). Gender appears to have little or no effect on hemoglobin values in the rabbit (Jain, 1986).

Hemoglobin levels demonstrate diurnal variation in the rabbit, with hemoglobin levels highest in the morning and lowest in the late afternoon and early evening (Fox and Laird, 1970).

ERYTHROCYTE LIFESPAN Rabbit red blood cells have a short lifespan of 57 days (Table 3.9) and a high turnover rate. This results in polychromasia, which is not clinically significant in the rabbit. A few nucleated red blood cells (1–2%) and occasional Howell-Jolly bodies, which are basophilic nuclear remnants, are normal in the rabbit due to the release of young red blood cells into the circulation (Melillo, 2007).

ERYTHROCYTE SIZE AND STAINING Rabbit erythrocytes have an average diameter of 6.8 microns, although there is significant anisocytosis, with a diameter range of 5.0–7.8 microns (Table 3.9) (Melillo, 2007). Erythrocyte diameter decreases with age from a diameter of approximately 9 microns at birth to adult size by 20–120 days old (Kozma et al., 1974).

It is reported that red blood cells are not as deformable in the rabbit as in humans (Amin and Sirs, 1985). This is thought to be due to higher concentrations of oxygen-free radicals and plasma fibrinogen in the rabbit (Hirayama et al., 1986).

Mean Cell Volume (MCV) The reference range for mean cell volume (MCV) in rabbits is $57.5\text{--}75\mu^3$ (Table 3.9).

This value is reported to be higher in pregnant rabbits (Prince, 1982).

The MCV and erythrocyte diameter both decrease between neonatal and adult ages (Kozma et al., 1974).

Mean Cell Hemoglobin (MCH) The reference range for mean cell hemoglobin (MCH) in rabbits is 17.1–23.9 pg per cell (Table 3.9), and this value is reportedly higher in neonatal rabbits than in adult rabbits (Bortolotti et al., 1989).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for mean cell hemoglobin concentration (MCHC) in rabbits is 28.2–37 g/dl (Table 3.9), and this value is reportedly similar in neonatal and adult rabbits (Bortolotti et al 1989).

RETICULOCYTES The reference range for reticulocyte numbers in the rabbit is 1.7–6.3% (Table 3.9). Reticulocytes are present at 2–4% in young rabbits (Jain,

1986) and after repeated bleedings or hemolytic anemia in adult rabbits (Brunner et al., 1983).

Reticulocytes are distinguishable from mature red blood cells by their larger size and more intense basophilic staining (Marshall, 2008). Reticulocyte count is elevated in neonates and declines with age to stable adult levels at 1 year old (Jain, 1986).

Nucleated red blood cells are found during endothelial changes and regenerative responses (Vennen and Mitchell, 2009).

LEUKOCYTES

Reference ranges for leukocyte parameters in the rabbit are provided in Table 3.10.

TOTAL WHITE BLOOD CELL (WBC) COUNT The reference range for total white blood cell count in rabbits is $5.2\text{--}12.5 \times 10^3$ cells per μl (Table 3.10) and varies with factors such as age, diurnal rhythm, and stress. Leukocyte counts are low in rabbits less than 12 weeks old and then gradually increase to maximum values by 3–6 months old (Jain, 1986; Melillo, 2007). Interestingly, the total white blood cell count in the 28-day rabbit fetus is also much lower than that of adult rabbits (Kriesten et al., 1987). A bimodal increase in leukocytes has been reported in rabbits, with the first peak at 3 months old, representing primarily lymphocytes, and the final peak at over 1 year old, due to an increase in neutrophils (Jain, 1986).

Total leukocyte numbers demonstrate diurnal variation, with lowest counts in the late afternoon and evening (Melillo, 2007).

Stress has been found to produce variable effects on total white blood cell count in rabbits. Some reports state that stress causes leukopenia in the rabbit (Brewer, 2006; Melillo, 2007). Application of electrical current in rabbits was found to produce a 15–30% decrease in the white blood cell count (Kaplan and Timmons, 1979). A recent study found lower white blood cell counts and higher plasma cortisol levels in group-housed compared with individually housed New Zealand White rabbits used for antibody production (Fuentes and Newgren, 2008).

Most studies, however, report that stress induces leukocytosis (Melillo 2007), and changes in leukocyte numbers have been found to correlate with changes in cortisol levels (Toth and Krueger, 1989). The stress associated with routine sample collection causes a physiological leukocytosis in rabbits (Harkness, 1987). It is reported that increased leukocyte numbers following stress consist primarily of mature neutrophils and lymphocytes and decreased eosinophils (Jain, 1986).

Increased white blood cell count is not a common response to infection in the rabbit. Instead, acute infection in rabbits has been shown to result in a

leukopenia of less than 5000 cells per ml and a normal differential count, or a normal white blood cell count with increased heterophils and decreased thrombocytes (Vennen and Mitchell, 2009).

LYMPHOCYTES The reference range for lymphocyte numbers in the rabbit is 30–85% (Table 3.10) and varies with several factors, including diurnal rhythm, stress, and disease. The lymphocyte nucleus is round or oval, acentrically located, and stains deep blue to purple. The cytoplasm of the lymphocyte stains a medium to deep blue, and there is typically a perinuclear halo of non-staining cytoplasm (Jain, 1986).

Lymphocytes are the predominant leukocyte in healthy rabbits, and both small and large lymphocytes are found in circulation. Small lymphocytes are 7–10 microns in diameter, and large lymphocytes are 10–15 microns in diameter. In addition to their presence in the bloodstream, lymphocytes are also found in the spleen, bone marrow, lymph nodes, and the lymphatic tissue of the gastrointestinal tract.

Lymphocyte numbers are typically highest in the early morning and lowest in late afternoon and evening (Fox and Laird, 1970; Melillo, 2007).

Acute stress and the associated increase in adrenaline may cause lymphocytosis, whereas prolonged stress and increased cortisol may induce lymphopenia (Melillo, 2007). However, other reports suggest that the epinephrine release associated with acute stress causes a mature heterophilia and relative lymphopenia (Marshall, 2008).

The stress induced by loud noises can cause an increase in the neutrophil to lymphocyte (NP:LC) ratio in rabbits that persists for 24–48 hours (Melillo, 2007).

Infection in the rabbit may also be accompanied by an increased NP:LC ratio, which is typically 1:1 in a normal adult rabbit (Melillo, 2007).

Increased lymphocyte numbers may indicate an immunologic response, such as occurs after a viral infection. Lymphocytosis may also be caused by lymphoma and lead toxicity (Melillo, 2007). A reversal in the NP:LC ratio due to elevated lymphocyte number was found to occur after experimental inoculation with several bacteria, as well as in spontaneously ill animals.

NEUTROPHILS (HETEROPHILS) The reference range for neutrophil numbers in the rabbit is 20–75% (Table 3.10) and is affected by several factors, including diurnal rhythm, stress, and disease.

Rabbit neutrophils have a diameter of 9–15 microns and have acidophilic cytoplasmic granules that stain with eosin and give them the appearance of eosinophils. For this reason, rabbit neutrophils are often referred to as pseudoeosinophils or, more commonly, heterophils. The neutrophil nucleus has a

polymorphous shape and stains light purple to light blue. The neutrophil cytoplasm stains pink because of numerous small granules, with a reddish hue due to several larger dark-staining granules (Campbell and Ellis, 2007). By electron microscopy, these granules are identified as primary or azurophilic granules and secondary or specific granules, respectively (Jain, 1986). Primary and secondary granules are believed to arise from two different sites on the Golgi apparatus (Marshall, 2008). The small pink granules comprise 80–90% of the neutrophil granules and contain peroxidase, alkaline phosphatase, lipase, and antibacterial activity (Benson and Paul-Murphy, 1999).

Neutrophils of female rabbits and other species may contain a drumstick configuration, which is referred to as the Pelger-Huet anomaly and is likely due to abnormal maturation of these cells (Kozma et al., 1974). The homozygotic form of this disease in rabbits is usually lethal (Jain, 1993).

Neutrophil numbers in the rabbit are lowest in the early morning and increase to peak numbers in late afternoon and evening (Fox and Laird, 1970; Melillo, 2007).

Prolonged stress induces an increase in neutrophils and a concomitant decrease in lymphocytes and eosinophils (Melillo, 2007). This may result in an overall leukopenia in the rabbit (Brewer, 2006). Stress due to loud noises can also cause an increase in the NP:LC ratio in rabbits that persists for 24–48 hours (Melillo, 2007). Acute stress is associated with catecholamine release that results in a mature neutrophilia and relative lymphopenia (Marshall, 2008).

Acute bacteria-induced inflammation causes an increase in neutrophils, which migrate to the site of infection and engulf pathogens. Lysosomal granules in the neutrophil cytoplasm fuse with phagosomes to kill and degrade infectious organisms (Campbell and Ellis, 2007).

Infection in the rabbit is usually associated with an increased NP:LC ratio, although the presence of band neutrophils and a left shift is uncommon. A reversal in the NP:LC ratio has also been reported after experimental inoculation with several bacteria, as well as in spontaneously ill animals. A neutrophil count of 60–80% can occur as a result of inflammation, although there is often a concomitant decrease in lymphocytes, with little or no change in total white blood cells. Alternatively, acute infection in the rabbit has been reported to result in increased neutrophils and decreased thrombocytes (Vennen and Mitchell, 2009).

EOSINOPHILS The reference range for eosinophil numbers in rabbits is 0–5% (Table 3.10) and is affected by several factors, including diurnal rhythm, stress, and disease. A low or absent eosinophil count is common in healthy rabbits.

The rabbit eosinophil has a diameter of 12–16 microns and is larger than the neutrophil. The eosinophil contains large acidophilic granules that fill the cytoplasm and are 3–4 times the size of neutrophil granules. These granules give the cytoplasm of the eosinophil a pink-orange appearance (Benson and Paul-Murphy, 1999). The eosinophil nucleus is bi-lobed or horseshoe-shaped (Vennen and Mitchell, 2009).

Eosinophil numbers are lowest in the early morning and increase to highest numbers in the afternoon or evening (Fox and Laird, 1970; Melillo, 2007).

Stress has been reported to induce a mature eosinophilia in rabbits. However, other reports suggest that glucocorticoid release is associated with eosinopenia.

Diseases of the skin, lungs, gastrointestinal tract, or uterus can result in eosinophilia in rabbits. For example, eosinophilia may be associated with abscesses or healing wounds in the rabbit or in cases of atopy and pyoderma (Melillo, 2007). Elevated eosinophil numbers may be caused by a parasitic disease such as *Encephalitozoon cuniculi* in the rabbit, although eosinophilia is reportedly an uncommon response to parasites or hypersensitivity in this species (Melillo, 2007).

BASOPHILS The reference range for basophil numbers in normal rabbits is 0–10% (Table 3.10), but can be up to 30% of the white blood cell differential count in healthy rabbits (Benson and Paul-Murphy, 1999; Vennen and Mitchell, 2009). The rabbit has higher basophil numbers than most species and may be the only laboratory animal with a significant number of basophils in circulation (Benson and Paul-Murphy, 1999). Circulating basophils are usually inversely proportional to the number of tissue mast cells. Rabbit basophils are 8–12 μm in diameter, which is similar in size to the neutrophil. The nucleus is light purple and is less segmented than the nuclei of eosinophils or neutrophils. The rabbit basophil has many purple-black cytoplasmic granules (Campbell and Ellis, 2007).

The function of the basophil is not well understood. Basophils demonstrate diurnal variation, with lowest numbers in the early morning and highest numbers in late afternoon (Fox and Laird, 1970). Cases of atopy and pyoderma in the rabbit are associated with elevated numbers of basophils and eosinophils (Melillo, 2007).

MONOCYTES The reference range for monocyte numbers in normal rabbits is 1–10% (Table 3.10) and varies according to diurnal rhythm and disease.

The monocyte is the largest white blood cell in the rabbit peripheral circulation. The monocyte nucleus has a horseshoe or bean shape and is lightly stained due to the diffuse nuclear chromatin. The monocyte cytoplasm is blue, with few vacuoles or granules in the healthy rabbit (Jain, 1986). In conditions of non-specific toxicity,

large dark-red granules may be seen in the cytoplasm of the rabbit monocyte (Benson and Paul-Murphy, 1999).

There is diurnal variation of monocytes in the rabbit, with lowest numbers in the early morning and highest numbers in late afternoon (Fox and Laird, 1970).

Elevated monocyte numbers in the rabbit may be caused by chronic inflammation from an abscess, mastitis, or tympanic bulla empyema, although monocyte counts are not always increased in these conditions (Melillo, 2007).

PLATELETS (THROMBOCYTES)

The reference range for platelet numbers in the rabbit is $200\text{--}1000 \times 10^6$ per μl (Table 3.10) and varies according to age, stress, and disease. Thrombocytes are present singly and in groups and appear as oblong or oval bodies measuring 1–3 microns in diameter. Thrombocytes have a pale periphery and a dark purple center when stained with Wright's stain (Kozma et al., 1974). Rabbit platelets have very high serotonin content (Fudge, 2000).

The platelet count in a 28-day rabbit fetus is significantly lower than that of the doe (Kriesten et al., 1987). Cold stress may cause an increase in platelets in rabbits (de la Fuente et al., 2007).

Decreased thrombocyte numbers may be a consequence of acute infection in rabbits (Vennen and Mitchell, 2009).

Coagulation

Rabbit blood clots rapidly at room temperature and must be treated with anticoagulants to evaluate complete blood count and plasma parameters.

Rabbits have high levels of intrinsic clotting factors, including V, VIII, IX, X, XI, and XIII, and low levels of factor I (fibrinogen), II (prothrombin), and XII, compared to other laboratory animals (Fudge, 2000).

Reference ranges for coagulation tests in the rabbit are provided in Table 3.11.

BLEEDING TIME (BT)

Bleeding time (BT) for rabbits is 1.1–2.7 minutes (Table 3.11).

PROTHROMBIN TIME (PT)

Prothrombin time (PT) varies with method but is 7.2–7.8 seconds in the rabbit (Table 3.11). Rabbits have approximately 89% prothrombin levels compared to dog (Kozma et al., 1974). Cold stress causes an increase in clotting time and a decrease in prothrombin time in rabbits (de la Fuente et al., 2007).

ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

Activated partial thromboplastin time (APTT) for the rabbit is approximately 35 seconds (Table 3.11).

THROMBIN TIME (TT)

Thrombin time (TT) for rabbits is 7.8–12.0 seconds (Table 3.11).

FIBRINOGEN CONCENTRATION

Fibrinogen concentration for rabbits is 0.17–0.31 g/dl (Table 3.11).

In the rabbit, fibrinogen degradation products do not stimulate the production of plasma fibrinogen, as occurs in humans (Kessler and Bell, 1980).

Bone Marrow

The maturation sequence and cell types in the rabbit bone marrow are similar to those seen in other species. Color photomicrographs of rabbit bone marrow are available (Sanderson and Phillips, 1981). The myeloid to erythroid ratio in normal adult rabbit bone marrow is approximately 1.1:1 (Sanderson and Phillips, 1981) (Table 3.8). This ratio is approximately 0.9–1 in 1-week-old rabbit kits and increases to adult levels by 4 weeks old (Sabin et al., 1936). Extramedullary hematopoiesis in the rabbit occurs in the liver and spleen.

GUINEA PIG

Sample Collection**Blood**

A discussion of blood sample methods and collection sites in the guinea pig is presented above in the Clinical Biochemistry section of this chapter.

Bone Marrow

Bone marrow in guinea pigs is usually obtained from the proximal end of the femur, as in other species (Feldman et al., 1982).

Reference Values and Unique Characteristics**Blood Volume**

Reference ranges for blood and plasma volumes in the guinea pig are provided in Table 3.8.

TOTAL BLOOD VOLUME

The reference range for total blood volume of the guinea pig is 40–80 ml, or 67–92 ml per kg body weight, (Table 3.8) and varies with age. The highest blood volume is reported at birth, followed by a steady decline in blood volume until the animals weigh approximately 900 grams (Sisk, 1976). The volume of a single sample of blood is 4–12 ml, and exsanguination yields 15–30 ml (Harkness and Wagner, 1995).

PLASMA VOLUME

The reference value for plasma volume of the guinea pig is 39 ml per kg body weight (Table 3.8) and varies with age (Sisk, 1976).

Peripheral Blood Cells

Color photomicrographs of representative peripheral blood cells of the guinea pig are presented in a recent publication (Thrall et al., 2004).

ERYTHROCYTES

Reference values for erythrocyte parameters in the guinea pig are provided in Table 3.9.

RED BLOOD CELL COUNT The reference range for total red blood cell count of guinea pigs is $4\text{--}11 \times 10^6$ per μl (Table 3.9), which is typically lower than in other rodents (Pilny, 2008). In general, most red blood cell indices are lower in the guinea pig than in other laboratory animals (Feldman et al., 1982).

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit of guinea pigs is 30–50% (Table 3.9).

Hairless Dunkin-Hartley guinea pigs were found to have higher PCV, hemoglobin concentration, MCV, MCH, and MCHC compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

A low hematocrit, or anemia, in the guinea pig is characterized by polychromasia and macrocytosis (Pilny, 2008). Anemia may be associated with cavian leukemia (Hrapkiewitz and Medina, 2007).

HEMOGLOBIN (Hgb) The reference range for hemoglobin level of guinea pigs is 11–17 g/dl (Table 3.9).

ERYTHROCYTE SIZE AND STAINING The reference range for diameter of guinea pig erythrocytes is 6.6–7.9 microns (Table 3.9), with normal anisocytosis and occasional microcytes of 3.5 microns in diameter.

Polychromasia varies with age, with approximately 25% in neonates, 4.5% in juveniles, and 1.5% in adults.

Mean Cell Volume (MCV) The reference range for MCV value in guinea pigs is 70–95 μ^3 (Table 3.9).

Mean Cell Hemoglobin (MCH) The reference range for MCH value in guinea pigs is 23–27 pg/cell (Table 3.9).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for MCHC value in guinea pigs is 25–40 g/dl (Table 3.9).

RETICULOCYTES The reference range for reticulocyte number in guinea pigs is 0–6.1% (Table 3.9).

Reticulocytes were found to decrease in young male Weiser-Maples guinea pigs, then level off between 200 and 300 days old. There was no age-related change in female reticulocytes (Kitagaki et al., 2005).

LEUKOCYTES

Reference values for guinea pig leukocyte differential counts are provided in Table 3.10.

TOTAL WHITE BLOOD CELL (WBC) COUNT The reference range for white blood cell count in guinea pigs is $6\text{--}17 \times 10^3$ cells per μl (Table 3.10) and varies with age, strain, stress, and disease. Several studies have reported an age-related increase in total white blood cells (Kitagaki et al., 2005). Hairless Dunkin-Hartley guinea pigs were found to have a lower total leukocyte number compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

Stress can produce leukocytosis in the guinea pig. In addition, cavian leukemia is usually accompanied by a severe leukocytosis of 25000–500000 cells per mm^3 and is associated with high mortality and poor response to treatment (Pilny, 2008).

LYMPHOCYTES The reference range for lymphocyte number in guinea pigs is 30–80% (Table 3.10), making the lymphocyte the predominant circulating white blood cell in normal guinea pigs. There are small and large lymphocytes in the guinea pig, and the appearance of these cells is similar to lymphocytes in other species. The small well-differentiated lymphocytes predominate and are only slightly larger than red blood cells. These lymphocytes have a round dark nucleus surrounded by a narrow band of cytoplasm. The less common larger lymphocytes are approximately twice the size of the small lymphocytes, have a less densely stained more oval-shaped nucleus, and usually have small to large azurophilic granules.

Lymphocytes were found to decrease in number with increasing age in both male and female guinea pigs of the inbred Weiser-Maples strain (Kitagaki et al., 2005).

Hairless Dunkin-Hartley guinea pigs were found to have a lower number of lymphocytes, compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

NEUTROPHILS (HETEROPHILS) The reference range for neutrophil number in guinea pigs is 20–60% (Table 3.10) and varies with age and disease. The guinea pig neutrophil is the predominant circulating granulocyte in this species and has the same function as the neutrophil in other animals. As in several other laboratory animals, neutrophils are also known as heterophils or pseudoeosinophils in guinea pigs because of their staining characteristics. Guinea pig neutrophils are 10–12 microns in diameter and have more visible cytoplasm than eosinophils that contains small acidophilic granules. The neutrophil nucleus contains dense chromatin, is usually purple, and can have five or more segments (Feldman et al., 1984). In female guinea pigs, some neutrophils have a drumstick-shaped sex chromatin lobe.

Guinea pig neutrophils have moderate alkaline phosphatase activity (Tamburlin and Glomski, 1988).

Neutrophils lack myeloperoxidase, which is responsible for liquid purulent exudates, so abscess content in guinea pigs is caseous rather than liquid (Vennen and Mitchell, 2009).

The total neutrophil number was found to increase with increasing age in both male and female Weiser-Maples guinea pigs (Kitagaki et al., 2005).

The inflammatory response in the guinea pig is typically characterized by an increase in number of neutrophils while total leukocytes may remain constant (Riggs, 2009). Experimental infection with the skin mite, *Trixacarus caviae*, was found to cause an increase in neutrophils and other leukocytes (Rothwell et al., 1991).

EOSINOPHILS The reference range for eosinophil number in guinea pigs is 0–7% (Table 3.10). Guinea pig eosinophils are 10–15 microns in diameter, which is slightly larger than the diameter of neutrophils. The eosinophil nucleus is indented but less segmented than that of the neutrophil. The cytoplasm of eosinophils is completely full of large brightly eosinophilic granules. Cytoplasmic granules of eosinophils are larger than those of neutrophils and are round, rod-shaped, or trapezoidal and almost completely fill the cytoplasm (Jain, 1984).

Experimental infection with the skin mite, *Trixacarus caviae*, caused increased eosinophils and other white blood cells (Rothwell et al., 1991). Similarly, infestation with the tick, *Amblyomma americanum*, caused increased eosinophils in guinea pigs (Brown and Askenase, 1982). Syphilis infections induced with *Treponema pallidum* has been associated with eosinophilia in guinea pigs (Wicher et al., 1998).

BASOPHILS Basophils are rarely found in guinea pig differential counts, where the reference range for basophil number is 0–3% (Table 3.10). The basophil is approximately the same size as the neutrophil and has a purple-stained lobulated nucleus and round purple cytoplasmic granules of varying size.

Basophils were found to decrease sharply by 1 year of age in female Weiser-Maples guinea pigs using automated hematology analysis (Kitagaki et al., 2005). Other reports show no change in basophils due to age or sex using manual counts (Feldman et al., 2000).

Experimental infection with the skin mite, *Trixacarus caviae*, caused an increased number of basophils and other leukocytes (Rothwell et al., 1991). Tick infestation with either *Amblyomma americanum* or *Rhipicephalus sanguineus* produced basophilia in guinea pigs (Brown and Askenase, 1982; Szabo et al., 2003).

MONOCYTES The reference range for monocyte number in guinea pigs is 1–12% (Table 3.10). The

monocyte is the largest white blood cell in guinea pig circulation. The monocyte nucleus is oval and has less condensed chromatin and a variable shape, surrounded by blue-gray cytoplasm that is darker than the cytoplasm of lymphocytes (Jain, 1974).

Monocyte numbers were found to increase gradually with increasing age in male Weiser-Maples guinea pigs older than 300 days of age (Kitagaki et al., 2005).

Experimental infection with the skin mite, *Trixacarus caviae*, caused increased monocytes and other white blood cells (Rothwell et al., 1991).

FOA-KURLOFF CELLS Foa-Kurloff cells are a type of specialized mononuclear cell that are unique to guinea pigs and make up 3–4% of the differential leukocyte count in this species (Moore, 2000). These cells are approximately the same size as large lymphocytes and have a large granular intracytoplasmic inclusion called a Kurloff body. The Kurloff body is composed of sulfated proteoglycan that is rich in mucopolysaccharide and appears homogeneous, finely granular, or slightly vacuolated (Jain, 2004). The Kurloff body stains with toluidine blue and is PAS-positive. The nucleus of Foa-Kurloff cells is large and round and is usually eccentrically placed.

The exact origin and function of Foa-Kurloff cells are not known, but they lack lysosomes and phagocytic activity and may serve as natural killer (NK) cells in circulation (Pouliot et al., 1996). Foa-Kurloff cells are rarely seen in young animals or in males, and their presence in females is correlated with estrogen levels (Percy and Barthold, 2007). These cells are common in pregnant guinea pigs and may be induced by estrogen to shift from the lungs and red pulp of spleen to the thymus and placenta (Moore, 2000). It is thought that Foa-Kurloff cells may help form a barrier between mother and fetus during pregnancy by protecting fetal antigens in the placenta (Pilny, 2008).

PLATELETS (THROMBOCYTES)

The reference range for platelet number in guinea pigs is $250\text{--}850 \times 10^6$ per μl (Table 3.10), although the values are variable in the literature (Feldman et al., 1982). Guinea pig platelets have an irregular oval shape of approximately 2–3 microns in length, a pale periphery, and a darkly staining center.

Platelet numbers in guinea pigs are affected by factors such as age, strain, and disease. Platelet numbers were found to decrease between 100 and 200 days of age, followed by an increase, in male Weiser-Maples guinea pigs (Kitagaki et al., 2005). The hairless strain of Dunkin-Hartley guinea pigs were found to have higher platelet numbers compared to normal Dunkin-Hartley guinea pigs (Waner et al., 1996).

Inflammation in the guinea pig is associated with an increase in platelets, which can exceed one million per microliter without an increase in total leukocyte numbers (Riggs, 2009).

Bone Marrow

The reference range for myeloid to erythroid ratio in normal guinea pigs is 1.5:1 to 1.9:1 (Table 3.8).

HAMSTER

Sample Collection

Blood

Blood collection in the hamster is described in Clinical Biochemistry section above.

Reference Values and Unique Characteristics

Blood Volume

Reference values for blood and plasma volumes in the hamster are provided in Table 3.8.

TOTAL BLOOD VOLUME

The reference range for blood volume of the Syrian hamster is 6.8–12 ml or 65–80 ml per kg body weight (Table 3.8).

Due to the hamster's ability to conserve water, 72 hours of water deprivation in this species causes decreased whole blood volume and plasma volumes with little or no change in hematocrit (Kutscher, 1968). Hibernation in the hamster causes an increase in blood volume and other hematologic parameters (Hrapkiewicz and Medina, 2007). However, the site of blood collection reportedly has little effect on hematologic parameters in the hamster.

The volume of a single blood sample in the hamster is 0.5–1.3 ml per 2 weeks (Table 3.8).

The total exsanguination volume in the hamster is 3–5 ml (Table 3.8).

PLASMA VOLUME

Water deprivation for 72 hours was found to decrease plasma volume in the hamster (Kutscher, 1968).

Peripheral Blood Cells

ERYTHROCYTES

Reference values for erythrocyte parameters in the hamster are provided in Table 3.9.

RED BLOOD CELL COUNT The reference range for total number of red blood cells in the hamster is $2.7\text{--}12.3 \times 10^6$ cells per μl (Table 3.9).

Hibernation in the hamster causes an increase in red blood cell number (Heatley and Harris, 2009; Hrapkiewicz et al., 1998). Castration decreases circulating RBCs by 25–30% in male hamsters due to decreased testosterone levels (Heatley and Harris, 2009). There have been no red blood cell antigen differences identified in hamsters.

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit value in the hamster is 30–59% (Table 3.9) and is affected by several factors (Burns and De Lannoy, 1966). For example, hematocrit increases with age in hamsters. The neonatal hamster is relatively anemic, with a hematocrit of 34–39%. At this age red cells are characterized by hypochromia and macrocytosis, with 10–30% normoblasts (Gad, 2007). Ten to 30% of circulating red blood cells are nucleated in neonatal hamsters, compared to less than 2% in adults (Jain, 1974).

Hibernation in the hamster causes an increase in PCV and other hematologic parameters, accompanied by decreased red blood cell destruction (Hrapkiewicz and Medina, 2007).

HEMOGLOBIN (Hgb) The reference range for hemoglobin level in the hamster is 10–19.2 g/dl (Table 3.9) and is affected by factors such as age and hibernation state. Hemoglobin increases to a maximum concentration in hamsters at 8–9 weeks of age (Gad, 2007), although some studies report little change in hemoglobin levels between 1 and 27 weeks old (Rennie et al., 1981).

Hibernation causes increased Hgb concentration (Heatley and Harris, 2009), and hypothermia causes more complete oxygen saturation of hemoglobin than normothermia (Volkert and Musacchia, 1970).

ERYTHROCYTE LIFESPAN The reference range for erythrocyte lifespan in the hamster is 50–78 days (Table 3.9).

Hibernation causes increased life span of erythrocytes in the hamster (Mitchell and Tully, 2009).

ERYTHROCYTE SIZE AND STAINING The reference range for erythrocyte diameter in the hamster is 5–7 microns (Table 3.9).

Normal young hamsters (4–8 weeks old) have microcytic normochromic red blood cells with some variation in size and shape, as well as occasional spherocytes and target cells. Polychromasia and Howell-Jolly bodies are found normally in healthy hamsters (Pilny, 2008). Polychromasia is seen more often in hamsters than in humans (Gad, 2007). Hamster red blood cells are nucleated 2% of the time.

Mean Cell Volume (MCV)

The reference range for MCV in the hamster is 64–78 μ^3 (Table 3.9).

Most hamster erythrocyte values are similar to those of the rat, although MCV is slightly higher in the hamster (Dent, 1977).

Mean Cell Hemoglobin (MCH)

The reference range for MCH in the hamster is 20–26 pg per cell (Table 3.9).

Mean Cell Hemoglobin Concentration (MCHC)

The reference range for MCHC in the hamster is 28–37 g/dl (Table 3.9).

RETICULOCYTES The end of hibernation in the hamster is associated with an increase in reticulocyte numbers (Hrapkiewicz and Medina, 2007).

LEUKOCYTES

Reference values for leukocyte and platelet numbers in the hamster are provided in Table 3.10.

TOTAL WHITE BLOOD CELL (WBC) COUNT The reference range for total leukocyte count in the hamster is $3\text{--}15 \times 10^3$ cells per μl (Table 3.10) and varies with several factors including age, sex, strain, diurnal rhythm, hibernation, and disease.

Neonatal Syrian hamsters have a total leukocyte count of approximately 2000 cells per microliter. White blood cells increase with age in European hamsters, from 3500 per microliter at 13 days to 8200 per microliter at 65 days and are higher in males than females (Emminger et al., 1975).

Total white blood cell count in Chinese hamsters is higher in the middle of the light cycle than in the middle of the dark cycle (Lappenbusch, 1972).

Hibernation causes a decrease in total white blood cell count in Syrian hamsters from 5000–10000 per microliter to 2500 per microliter (Heatley and Harris, 2009; Mitruka and Rawnsley, 1977), although the NP:LC ratio remained at 1:1 (Hrapkiewicz and Medina, 2007).

In European hamsters, hibernation is also associated with a lower total white blood cell count and platelet count, with unchanged differential distribution (Reznik et al., 1975). White cell numbers fall to a low of 100 per microliter during hibernation in this strain (Heatley and Harris, 2009). After hibernation, a leukocytosis characterized by neutrophilia occurs, with 70–90% neutrophils and a total leukocyte count of 10000–20000 cells per microliter (Heatley and Harris, 2009; Pilny, 2008).

Hamsters experimentally infected with pirital virus, a novel arenavirus isolated from the cotton rat (*Sigmodon astoni*) in Venezuela, demonstrate

leukocytosis, including neutrophilia, eosinophilia, and basophilia on days 5–6 post-infection (Sbrana et al., 2006).

LYMPHOCYTES The reference range for total lymphocyte count in the hamster is 50–96% (Table 3.10). Lymphocytes are the predominant circulating leukocyte in hamsters, comprising 60–80% of the differential leukocyte count (Heatley and Harris, 2009). Most hamster lymphocytes are small round cells with a dark-blue nucleus that occupies the majority of the cell, surrounded by a rim of lighter-blue cytoplasm. Hibernation in the hamster causes decreased WBC numbers, with a 1:1 NP:LC ratio (Hrapkiewicz and Medina, 2007).

NEUTROPHILS (HETEROPHILS) The reference range for total neutrophil count in the hamster is 17–35% (Table 3.10). As in many other rodents, hamster neutrophils are also called heterophils because they resemble eosinophils, with a lobular nucleus and dense pink cytoplasmic granules. Hamster neutrophils have a diameter of approximately 10–12 microns. Hamster neutrophils have moderate alkaline phosphatase activity (Tamburlin and Glomski, 1988) but lack lysozyme activity (Thrall et al., 2004).

Hibernation in the hamster causes decreased WBC numbers, with a 1:1 NP:LC ratio (Hrapkiewicz and Medina, 2007). At the end of hibernation, neutrophilic leukocytosis occurs, with 70–90% neutrophils and total leukocyte count of 10000–20000 cells per microliter (Heatley and Harris, 2009).

EOSINOPHILS The reference range for total eosinophil count in the hamster is 0–5% (Table 3.10). Hamster eosinophils are similar in appearance to those of other rodent species.

BASOPHILS The reference range for total basophil count in the hamster is 0–5% (Table 3.10). Hamster basophils are similar in appearance to those of other rodent species.

MONOCYTES The reference range for total monocyte count in the hamster is 0–5% (Table 3.10). Hamster monocytes are similar in appearance to those of other rodent species.

PLATELETS (THROMBOCYTES)

The reference range for total platelet count in the hamster is $200\text{--}590 \times 10^6$ per μl (Table 3.10) and varies with hibernation and disease. Hibernation causes decreased platelet counts in European hamsters (Reznik et al., 1975) and Syrian hamsters (Heatley and Harris, 2009).

Hamsters experimentally infected with pirital virus had increased platelet numbers on days 5 and 6 post-infection (Sbrana et al., 2006).

Coagulation

Reference values for coagulation tests in the hamster are provided in Table 3.11.

BLEEDING TIME (BT)

The reference range for bleeding time in the hamster is 1.5–2.4 minutes (Table 3.11).

PROTHROMBIN TIME (PT)

The reference range for prothrombin time in the hamster is 10.3–10.7 seconds (Table 3.11).

Female hamsters have shorter prothrombin times than males (Dodds et al., 1977).

Hamsters experimentally infected with pirital virus had increased PT by 8 days post-infection (Sbrana et al., 2006).

FIBRINOGEN CONCENTRATION

The reference range for fibrinogen concentration in the hamster is 188–316 g/dl (Table 3.11). Female hamsters have higher concentrations of fibrinogen and plasminogen than males (Dodds et al., 1977).

Bone Marrow

The adult hamster has a highly cellular bone marrow, with a myeloid to erythroid ratio of approximately 0.9:1 (Table 3.8) (Gad, 2007). The largest cells in the hamster bone marrow are megakaryocytes. There are also significant numbers of eosinophils, plasma cells, histiocytes, and a few mast cells (Gad, 2007). The neonatal hamster bone marrow is primarily erythroblastic. The spleen does not play a major role in erythropoiesis in the hamster and becomes erythropoietically active only when stimulated by T3 (Boussios et al., 1982).

OTHER RODENTS

Gerbil

Sample Collection

BLOOD

Gerbil restraint techniques and blood collection are described in the Clinical Biochemistry section of this chapter.

Reference Values and Unique Characteristics

BLOOD VOLUME

Reference values for blood volume in the gerbil are provided in Table 3.8.

TOTAL BLOOD VOLUME The reference range for blood volume in the gerbil is 4.4–8 ml, or 67 ml per kg body weight (Table 3.8).

A single blood sample volume in the gerbil is 0.4–1.3 ml per 2 weeks (Table 3.8).

The exsanguination volume of blood in the gerbil is 2–4 ml (Table 3.8).

PERIPHERAL BLOOD CELLS

ERYTHROCYTES Reference values for erythrocyte parameters in the gerbil are provided in Table 3.9.

Red Blood Cell (RBC) Count The reference range for red blood cell count in the gerbil is $7\text{--}10 \times 10^6$ cells per μl (Table 3.9).

Neonatal gerbils have erythrocyte counts that are approximately half the adult values but increase to adult values by about 8 weeks of age (Pilny, 2008).

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit in the gerbil is 35–52% (Table 3.9).

Male gerbils have higher hematocrit values than females (Heatley and Harris, 2009).

Hemoglobin (Hgb) The reference range for hemoglobin concentration for the gerbil is 10–17.9 g/dl (Table 3.9).

Erythrocyte Lifespan The erythrocyte lifespan in the gerbil averages 10 days (Table 3.9), which represents a much faster turnover rate than seen in other laboratory animals (Joslin, 2009).

Gerbils up to 20 weeks old have a large number of circulating reticulocytes and erythrocytes with basophilic stippling and polychromasia. These cells are also abundant in older gerbils and are probably associated with the short erythrocyte lifespan (Heatley and Harris, 2009; Pilny, 2008).

Erythrocyte Size and Staining Neonatal gerbils have macrocytic erythrocytes, but this condition resolves by approximately 8 weeks of age (Pilny, 2008).

Mean Cell Volume (MCV) The reference range for MCV in the gerbil is $46.6\text{--}60 \mu^3$ (Table 3.9) and is elevated in neonatal gerbils until approximately 8 weeks old (Pilny, 2008).

Male gerbils have higher MCV values than females (Heatley and Harris, 2009).

Mean Cell Hemoglobin (MCH) The reference range for MCH in the gerbil is 16.1–19.4 pg per cell (Table 3.9).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for MCHC for the gerbil is 30.6–33.3 g/dl (Table 3.9).

MCHC values are higher in male gerbils than in female gerbils (Heatley and Harris, 2009).

Reticulocytes Gerbils up to 20 weeks old have a large number of circulating reticulocytes and erythrocytes with basophilic stippling and polychromasia. These cells are also abundant in older gerbils and are probably associated with the short erythrocyte lifespan (Heatley and Harris, 2009; Pilny, 2008).

LEUKOCYTES Reference values for leukocyte and platelet numbers in the gerbil are provided in Table 3.10.

Total White Blood Cell (WBC) Count The reference range for white blood cell count in the gerbil is $4.3\text{--}21.6 \times 10^3$ cells per μl (Table 3.10).

Neonatal gerbils have panleukocytosis that resolves by approximately 8 weeks old (Pilny, 2008). Male gerbils have higher total leukocyte counts than females (Heatley and Harris, 2009).

Lymphocytes The reference range for lymphocyte count in the gerbil is 32–97% (Table 3.10).

The predominant leukocyte in gerbils is the lymphocyte, which is much more abundant than granulocytes in this species (Dillon and Glomski, 1975).

Male gerbils have higher total leukocyte count due to a higher number of lymphocytes. The lymphocyte-to-heterophil ratio in the male is 6:1 compared to 3:1 in the female (Heatley and Harris, 2009).

Neutrophils (Heterophils) The reference range for neutrophil count in the gerbil is 2–41% (Table 3.10).

Gerbil neutrophils have moderate alkaline phosphatase activity (Tamburlin and Glomski, 1988).

Eosinophils The reference range for eosinophil count in the gerbil is 0–4% (Table 3.10).

Basophils The reference range for basophil count in the gerbil is 0–2% (Table 3.10).

Monocytes The reference range for monocyte count in the gerbil is 0–9% (Table 3.10).

PLATELETS (THROMBOCYTES) The reference range for platelet number in the gerbil is $400\text{--}830 \times 10^6$ per μl (Table 3.10).

BONE MARROW

The reference range for myeloid to erythroid ratio in the gerbil is 0.75:1 to 2.35:1 (Table 3.8).

Chinchilla

Sample Collection

BLOOD

Blood collection in the chinchilla is described above in the section on Clinical Biochemistry.

Reference Values and Unique Characteristics

BLOOD VOLUME

Reference values for blood volume in the chinchilla are provided in Table 3.8.

TOTAL BLOOD VOLUME The reference range for blood volume in the chinchilla is 20–32 ml (Table 3.8).

Volume of a single blood sample in the chinchilla is 2–7 ml per 2 weeks (Table 3.8).

Exsanguination volume in the chinchilla is 8–12 ml (Table 3.8).

PERIPHERAL BLOOD CELLS

ERYTHROCYTES Reference values for erythrocyte parameters in the chinchilla are provided in Table 3.9.

Red Blood Cell Count The reference range for red blood cell count in the chinchilla is $5\text{--}10 \times 10^6$ cells per μl (Table 3.9).

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit in the chinchilla is 30–55% (Table 3.9).

The packed cell volume, hemoglobin concentration, and MCHC values are higher in blood obtained from chinchillas anesthetized with ketamine and xylazine than in blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

Hemoglobin (Hgb) The reference range for hemoglobin concentration for the chinchilla is 9–15 g/dl (Table 3.9).

Erythrocyte Size and Staining

Mean Cell Volume (MCV) The reference range for MCV in the chinchilla is $32.1\text{--}69.2 \mu^3$ (Table 3.9).

Mean Cell Hemoglobin (MCH) The reference range for MCH in the chinchilla is 10.4–19.8 pg/cell (Table 3.9).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for MCHC in the chinchilla is 20–38.5 g/dl (Table 3.9).

LEUKOCYTES Reference values for leukocyte and platelet numbers in the chinchilla are provided in Table 3.10.

Total White Blood Cell (WBC) Count The reference range for leukocyte number in the chinchilla is $4\text{--}25 \times 10^3$ cells per μl (Table 3.10). Total leukocyte number is higher in blood obtained from male chinchillas anesthetized with ketamine and xylazine compared to blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

Lymphocytes The reference range for lymphocyte number in the chinchilla is 19–98% (Table 3.10).

The lymphocyte is the most common circulating leukocyte in the chinchilla. The chinchilla responds to inflammation with an early increase in neutrophils and decrease in lymphocytes, resulting in little change in the total leukocyte count (Riggs and Mitchell, 2009).

Neutrophils The reference range for neutrophil number in the chinchilla is 9–78% (Table 3.10). The neutrophil is the second most common circulating leukocyte in the chinchilla (Riggs and Mitchell, 2009). The chinchilla neutrophil has a nucleus that may be hyposegmented, similar to the Pelger-Huet anomaly in the rabbit. Heterophils lack myeloperoxidase, the enzyme that liquefies purulent material, causing chinchilla pus to be thick and caseous (Riggs and Mitchell, 2009).

Eosinophils The reference range for eosinophil number in the chinchilla is 0–9% (Table 3.10). These cells are uncommon in the circulation of normal chinchillas (Riggs and Mitchell, 2009).

Basophils The reference range for basophil number in the chinchilla is 0–11% (Table 3.10). These cells are uncommon in the circulation of normal chinchillas (Riggs and Mitchell, 2009).

Basophil and monocyte numbers were lower in blood obtained from male chinchillas anesthetized with ketamine and xylazine compared to blood obtained by cardiac puncture post-mortem (de Oliveira Silva et al., 2005).

Monocytes The reference range for monocyte number in the chinchilla is 0–6% (Table 3.10). These cells are uncommon in the circulation of normal chinchillas (Riggs and Mitchell, 2009).

PLATELETS (THROMBOCYTES) The reference range for platelet number in the chinchilla is $300\text{--}600 \times 10^6$ per μl (Table 3.10). A dramatic increase in platelets, of more than 1000 per ml, may occur in response to inflammation in the chinchilla (Riggs and Mitchell, 2009).

Degu

There is little specific information available on the hematologic characteristics of the degu.

The degu is a diurnal rodent and has been the subject of many studies of the effect of circadian rhythm on physiology, behavior, and disease states.

Hematologic and serum protein values for degus of both sexes and all ages studied are reported to be

similar to those of other laboratory rodents (Murphy et al., 1978).

Deer Mouse

Sample Collection

BLOOD

Blood collection in the deer mouse is described above in the section on Clinical Biochemistry.

There is limited information available in the literature regarding hematology parameters in the deer mouse.

Reference Values and Unique Characteristics

PERIPHERAL BLOOD CELLS

ERYTHROCYTES Reference values for erythrocytes in the deer mouse are provided in Table 3.9.

Red Blood Cell Count The reference range for red blood cell count in the deer mouse is $10\text{--}12 \times 10^6$ cells per μl (Table 3.9).

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit in the deer mouse is 38–52% (Table 3.9).

Deer mice infected with *Cuterebra* sp. were found to have lower packed cell volumes than uninfected deer mice (Sealander, 1961). By contrast, deer mice infected with *Capillaria hepatica* had elevated hematocrits compared with uninfected controls (Meagher, 1998).

Hemoglobin (Hgb) The reference range for hemoglobin concentration in the deer mouse is 12–16 g/dl (Table 3.9).

Deer mice infected with *Cuterebra* sp. were found to have a lower hemoglobin concentration than uninfected deer mice trapped during the same period (Sealander, 1961).

Erythrocyte Size and Staining

Mean Cell Volume (MCV) The reference range for MCV in the deer mouse is $36\text{--}46 \mu^3$ (Table 3.9).

Mean Cell Hemoglobin (MCH) The reference range for MCH in the deer mouse is 11–15 pg per cell (Table 3.9).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for MCHC in the deer mouse is 30–35 g/dl (Table 3.9).

LEUKOCYTES Reference values for leukocyte numbers in the deer mouse are provided in Table 3.10.

Total White Blood Cell (WBC) Count The reference range for total leukocyte number in the deer mouse is $1\text{--}4 \times 10^3$ cells per μl (Table 3.10).

Dormouse

There is no information available in the literature regarding hematology values in the dormouse.

Kangaroo Rat

Sample Collection

BLOOD

A discussion of blood sample methods and collection sites in the kangaroo rat is presented above in the Clinical Biochemistry section of this chapter.

Reference Values and Unique Characteristics

PERIPHERAL BLOOD CELLS

ERYTHROCYTES Reference values for erythrocyte characteristics in the kangaroo rat are provided in Table 3.9.

Red Blood Cell Count The reference range for red blood cell count in the kangaroo rat is $7\text{--}9 \times 10^6$ per μl (Table 3.9). Values are lowest in the winter and highest in the summer (Intress and Best, 1990).

Hematocrit (Hct) or Packed Cell Volume (PCV) The reference range for hematocrit in the kangaroo rat is 47–53% (Table 3.9). Values are lowest in the summer and highest in the winter (Scelza and Knoll, 1982).

Hemoglobin (Hgb) The reference range for hemoglobin concentration in the kangaroo rat is 15–17 g/dl (Table 3.9). Values are fairly consistent throughout the year (Scelza and Knoll, 1982).

Erythrocyte Size and Staining

Mean Cell Volume (MCV) The reference range for MCV in the kangaroo rat is $57.3\text{--}66^3$ (Table 3.9).

Mean Cell Hemoglobin (MCH) The reference range for MCH in the kangaroo rat is 18.6–25 pg per cell (Table 3.9). Values are lowest in the summer and variably higher during the other seasons (Intress and Best, 1990).

Mean Cell Hemoglobin Concentration (MCHC) The reference range for MCHC in the kangaroo rat is 30–35 g/dl (Table 3.9). Values are fairly consistent throughout the year (Scelza and Knoll, 1982).

LEUKOCYTES Reference values for leukocyte numbers in the kangaroo rat are provided in Table 3.10.

Total White Blood Cell (WBC) Count The reference range for total leukocyte number in the kangaroo rat is $3-9 \times 10^3$ per μl (Table 3.10). Values are highest in the spring and variable during the other seasons (Intress and Best, 1990; Scelza and Knoll, 1982).

Cotton Rat

Sample Collection

BLOOD

Blood collection in the cotton rat is described in the Clinical Biochemistry section of this chapter.

Reference Values and Unique Characteristics

PERIPHERAL BLOOD CELLS

ERYTHROCYTES Reference values for erythrocyte characteristics in the cotton rat are provided in Table 3.9.

Cotton rats exposed to 1000ppm lead in drinking water showed decreased erythrocyte indices in a dose-dependent manner (McMurry et al., 1995).

Hemoglobin (Hgb) The reference range for hemoglobin concentration in the cotton rat is 13–14g/dl (Table 3.9).

LEUKOCYTES Reference values for leukocyte numbers in the cotton rat are provided in Table 3.10.

Total White Blood Cell (WBC) Count The reference range for total leukocyte number in the cotton rat is $11-13 \times 10^3$ cells per μl (Table 3.10).

Several studies have examined the effect of diet and environmental conditions on hematology and immune function of the cotton rat.

Immunocompetence has been suggested as an important influence on survival in herbivore populations (Robel et al., 1996). Supplementation of food quantity and quality (enhanced methionine) did not have a consistent effect on hematology or immune function in adult male cotton rats, although total leukocyte number was increased (Webb et al., 2003).

Cotton rats exposed to 1000ppm lead in drinking water showed decreased total leukocytes in a dose-dependent manner (McMurry et al., 1995).

Lymphocytes The reference range for lymphocyte number in the cotton rat is 50–54% (Table 3.10).

Neutrophils (Heterophils) The reference range for neutrophil number in the cotton rat is 36–40% (Table 3.10).

Eosinophils The reference range for eosinophil number in the cotton rat is 5–6% (Table 3.10).

Basophils The reference range for basophil number in the cotton rat is 0–0.2% (Table 3.10).

Monocytes The reference range for monocyte number in the cotton rat is 4–5% (Table 3.10).

PLATELETS (THROMBOCYTES) Supplementation of food quantity and quality (enhanced methionine) increased platelet number in the cotton rat (Webb et al., 2003).

Sand Rat

Sample Collection

BLOOD

Blood collection in the sand rat is described above in the section on Clinical Biochemistry.

Reference Values and Unique Characteristics

There is very little information available on hematology parameters in the sand rat.

A study in sand rats found that glucose concentration within red blood cells is higher than in plasma of this species, as it is in other mammals. This phenomenon was explained by loose binding of glucose to macromolecules within the erythrocyte (Halperin and Adler, 1985).

INTRODUCTION

This chapter is designed to give a general overview of euthanasia and necropsy techniques that may be used for laboratory rabbits, guinea pigs, rats, mice, and other rodents. The euthanasia techniques described are those approved by the American Veterinary Medical Association at the time of publication (AVMA, 2007).

EUTHANASIA

Introduction and Background

“Euthanasia” is a noun from Greek origins: *eu* (meaning “good”) and *thanatos* (meaning “death”). In

other words, euthanasia is death that is induced with minimal pain and distress. Euthanasia of an animal should be performed in a humane manner. From a biological standpoint, the techniques used should cause rapid unconsciousness, respiratory or cardiac arrest, and loss of brain function (AVMA, 2007).

Research and animal care staff should handle animals with respect prior to and during the euthanasia procedure. Personnel should be properly trained to ensure that the animal is handled in such a way as to minimize pain and distress to the animal and ensure personnel safety. Euthanasia can be distressing to personnel, especially when performed repeatedly (Reilly and Rose, 2001). To reduce human distress during the euthanasia process, personnel may be provided with counseling, education, and training.

Pain is not experienced if the cerebral cortex and subcortical structures are non-functional (AVMA, 2007). These structures can be made non-functional by induction of hypoxia, the use of various anesthetics and analgesics, or other physical means.

Distress occurs when an animal's response to stimuli interferes with its well-being and comfort. Distress can occur even during a basic activity, such as routine animal husbandry (Sharp et al., 2002, 2003). The amount of distress during handling can vary with the methods used, and factors such as single versus group housing can be very important. Factors such as species, breed, age, size, disease state, previous handling experience, and other variables can heighten or even decrease distress associated with euthanasia. Animals undergoing euthanasia may release pheromones that can cause conspecifics to experience undue distress; thus, it is recommended that animals not be euthanized in the presence of others not being euthanized at that time.

The euthanasia method selected should be irreversible. Death should be verified immediately by confirming cessation of respiration; lack of pulse; lack of heartbeat; loss of color of the mucous membranes; absence of corneal, palpebral, and pedal reflexes; and glazing of the eyes. Experimental endpoints which define the moribund state in the context of the work being performed should be clearly defined to reduce terminal suffering (NRC, 2008; Toth, 1997), which should also help to reduce distress.

Approved methods for euthanasia are typically chemical or physical, and the choice of which method is optimal in a particular situation varies based on age, use, and species differences. For example, inhalant methods of euthanasia may take longer to produce death in neonates because they are resistant to hypoxia (AVMA, 2007; Klaunberg et al., 2004; NIHARAC, 2004; Singer, 1999). Some injectable anesthetic methods of euthanasia involve use of controlled substances, and require appropriate registration with federal authorities and documentation of use. In larger species, it may be appropriate to utilize captive bolt, while cervical dislocation would typically be used only in smaller animals (AVMA, 2007).

The method of euthanasia selected should be based on compatibility with postmortem data collection needs. Agents used for euthanasia may produce changes in research data and should therefore be carefully selected (Artwohl et al., 2006; Reilly and Rose, 2001). Additional criteria to be considered when selecting the method of euthanasia should include safety of personnel. Some physical methods of euthanasia may pose safety issues for personnel; for example, the guillotine, if improperly used, can cause injury to the user; and human exposure to inhalant anesthetics is associated with liver and kidney damage, cancer, and complications during pregnancy (Buring et al., 1985).

Occasionally, specific needs of the research may require the method of euthanasia to deviate from the recommendations of the American Veterinary Medical Association. Such deviations must be scientifically justified and approved by the Institutional Animal Care and Use Committee (IACUC) or a similar body and reviewed by a veterinarian familiar with the species and methods of euthanasia. An example would be the use of cervical dislocation without anesthesia, use of which might be justified when tissues or biological specimens of interest are altered by anesthetics.

Chemical Methods

Inhalants

CARBON DIOXIDE

Carbon dioxide (CO₂) is an inexpensive, non-flammable, non-explosive, nearly odorless gas that is commonly used to euthanize rodents in the laboratory environment. It is naturally present in room air, which is composed of 79% nitrogen, 20.9% oxygen, and <0.1% carbon dioxide, water vapor, and other inert gases (Gill et al., 2002). Carbon dioxide may be obtained as a compressed gas or as dry ice, though use of dry ice as a source of carbon dioxide is unacceptable due to the risk of thermal injury to animals and personnel, as well as the inability to precisely control the concentration of CO₂ within the euthanasia chamber. As dry ice melts, it undergoes sublimation (conversion of a solid directly to a gas), thus producing carbon dioxide. Currently, acceptable delivery of carbon dioxide for euthanasia requires compressed gas because the inflow rate of carbon dioxide gas into the euthanasia chamber (Figure 4.1) can be regulated and the rapid decrease of temperature associated with dry ice can be avoided (Artwohl et al., 1999; AVMA, 2007). The same system may be used to euthanize a single animal or a group of animals. It is recommended that mice and rats have an appropriate dwell time (length of exposure) to the carbon dioxide gas to ensure that death is achieved. It has been the authors' experience that if rodents are removed prior to death and exposed to room air, they recover. Because of the number of cases in which this has occurred, it has been suggested that a second, physical form of euthanasia, such as thoracotomy, be performed to ensure that the animals have been appropriately euthanized (National Institutes of Health, 2002). Unconsciousness and death typically occur when the concentration of carbon dioxide reaches 10% (Gill et al., 2002). The authors recommend verifying that death has occurred with any inhalant method used and perhaps augmenting with a secondary physical method. Commercial systems are available that ensure the dwell time is appropriate by preventing removal of the animals from the euthanasia chamber and providing removal

FIGURE 4.1 Example of CO₂ chambers and CO₂ tank with regulator valve.

of waste gases prior to allowing access to the chamber. Such equipment eliminates the possibility of animals not being euthanized and ensures safety of personnel; the limit for human exposure to carbon dioxide is 0.5% for an 8-hour time-weighted average based on the National Institute of Occupational Safety and Health's permissible exposure limit (PEL) of 5000 parts per million (NIOSH, 2005).

There are other considerations when using carbon dioxide for euthanasia of rodents. Individuals should be properly trained on euthanasia techniques. Euthanasia chambers should not be overcrowded, and it is best not to remove animals from their housing cage or mix animals that have not been previously housed together in the same container because it may be distressing (Artwohl et al., 2006; National Institutes of Health, 2002). It has often been stated that using carbon dioxide for euthanasia of the dam in transgenic mouse colonies may affect the yield of healthy embryos. A controlled study did not reveal a difference between the use of cervical dislocation and carbon dioxide in this regard (Howell et al., 2003).

It is best to use carbon dioxide delivered using a two-stage regulator, with the second stage capable of adjustable fixed flow rates (Artwohl et al., 2006). The recommended flow rate of carbon dioxide is to displace 20% of the chamber volume per minute (AVMA, 2007).

The use of carbon dioxide for euthanasia of rodents and other species has been controversial. For example, disagreement exists with regard to the need to pre-fill the euthanasia chamber with CO₂ prior to introduction of the animals. The Newcastle Consensus Meeting on Carbon Dioxide Euthanasia of Laboratory Animals concluded that concentrations of carbon dioxide >50% caused 10–15 seconds of pain prior to loss of consciousness. This group also concluded that a flow rate of 20% per minute using 100% carbon dioxide can cause loss of

consciousness without evidence of pain (Hawkins et al., 2006). Increasing concentrations of carbon dioxide were judged by human volunteers to be unpleasant (50% CO₂) to painful (100% CO₂) (Danneman et al., 1997). The pain was due to the mixing of carbon dioxide with the moisture in the nares and the subsequent formation of carbonic acid (AVMA, 2007). Although the time to loss of consciousness is minimized in prefilled chambers, adding oxygen to the carbon dioxide may not make the procedure less distressful in rodents (Blackshaw et al., 1988; Coenen et al., 1995; Hewett et al., 1993; Sharp et al., 2006; Smith and Harrap, 1997). Rats and mice showed aversion to flow rates as low as 15% and 20% carbon dioxide compared with their response to room air (Leach et al., 2002; Niel and Weary, 2007; Niel et al., 2008). Even though there are disagreements, based on current data, we recommend that best practices would be to utilize a fill rate of 20% of the chamber volume per minute to achieve euthanasia of rodents.

All methods of euthanasia are associated with specific histological changes in various tissues (Feldman and Gupta, 1976). Although carbon dioxide gas euthanasia may cause perivascular edema and extravasation of blood in the lung (Fawell et al., 1972), it is still considered a suitable method of euthanasia for preventing postmortem histological changes in abdominal and pulmonary viscera (Feldman and Gupta, 1976).

CARBON MONOXIDE

Carbon monoxide (CO) is a colorless, odorless gas that is non-flammable. The use of carbon monoxide is associated with significant safety issues because it can be explosive (at concentrations that exceed 10%) and is toxic to personnel, thus appropriate ventilation is imperative. Carbon monoxide euthanasia has been banned by several states (AVMA, 2009). Death occurs due to fatal hypoxemia; carbon monoxide combines with hemoglobin to form carboxyhemoglobin, thus blocking the uptake of O₂ by red blood cells. Guinea pigs exposed to 8% carbon monoxide collapsed in <2 minutes, and death occurred in 6 minutes (AVMA, 2007). Carbon monoxide is delivered using compressed gas.

INHALANT ANESTHETICS

Various inhalant anesthetics, including halothane, isoflurane, and enflurane, may be used for euthanasia. Threshold levels of these halogenated anesthetics have been established at two parts per million (AVMA, 2007). Enflurane and sevoflurane have been documented to cause seizures in cats (Kurata et al., 1994; Osawa et al., 1994). Among halothane, enflurane, and isoflurane, halothane was the least aversive in rats and mice (Leach et al., 2002). These agents vary in the induction time (time to unconsciousness) and the solubility and amount of odor. Odors may cause the animal to hold its breath,

thus increasing the time until unconsciousness. The induction and recovery times are based on solubility as defined by the relative affinity between gas, blood, and tissue. Halothane is the least soluble and has the longest induction time, followed by enflurane, isoflurane, and sevoflurane, in that order (Preckel and Bolten, 2005).

INERT GASES

Nitrogen (N₂) and argon (Ar) are inert gases that are colorless, odorless, non-flammable, and non-explosive. Use of argon and nitrogen gas as agents for euthanasia is conditionally acceptable in rabbits and rats; animals should be heavily sedated or anesthetized prior to being placed in a prefilled chamber (AVMA, 2007). Convulsions, vocalizations, and gagging occurred in pigs exposed to 90% argon in air or a mixture of 30% carbon dioxide and 60% argon in air (Raj, 1999). Heavy sedation or anesthesia may delay euthanasia. Argon and nitrogen are delivered using compressed gas, are inexpensive, and can be easily administered. Argon is recommended to be used at a concentration of 90%, but rats have shown an aversion to its use when given the opportunity to enter a cage with argon and a food reward. Rats had a median dwell time of 3 seconds, and no food reward was eaten (Niel and Weary, 2007). Argon and nitrogen gases at 100% concentration caused unconsciousness in 54 seconds and >2 minutes, respectively, in rats (Sharp et al., 2006). It is interesting to note that one outcome of the Newcastle Consensus Meeting on Carbon Dioxide Euthanasia of Laboratory Animals was to not recommend argon or nitrogen for euthanasia in rodents (Hawkins et al., 2006) which is in disagreement with the American Veterinary Medical Association Guidelines on Euthanasia (AVMA, 2007).

Injectable Agents

BARBITURATES

Barbiturates act by depressing the nervous system. This depression leads to unconsciousness, respiratory depression, and eventually to cardiac arrest. Barbiturates are given intravenously, intraperitoneally, or intracardially. The intracardiac route should only be used when the animal is heavily sedated, unconscious, or anesthetized (AVMA, 2007). The barbiturate pentobarbital is commonly used for euthanasia in combination with other agents. Commercial euthanasia formulations of pentobarbital, including those combined with other agents such as phenytoin, are listed as schedule III drugs by the United States Drug Enforcement Agency, and appropriate registration and documentation are necessary to obtain and use them in the United States. Pentobarbital should not be combined with a neuromuscular blocking agent for euthanasia (AVMA, 2007). Pentobarbital has been shown to be useful as a euthanasia agent when histopathological

studies of the abdominal viscera or the pulmonary tract are to be performed (Feldman and Gupta, 1976). One commercially available euthanasia compound that incorporated pentobarbital, reduced sperm motility in rats (Stutler et al., 2007). Guarniere et al. (1999) compared the ingredients of three commercially available formulations of pentobarbital and determined that 40% propylene glycol, sterile water, and 40% ethanol contributed to hemolysis when injected intravenously into rabbits. Use of sodium pentobarbital dissolved into 10% ethanol and sterile water for a concentration of 50 mg/ml prevented hemolysis during euthanasia.

POTASSIUM CHLORIDE

A metal halide salt, potassium chloride (KCl), must be used in conjunction with a surgical plane of anesthesia. KCl can be given either intravenously or intracardially (AVMA, 2007; Cartner et al., 2007). Administration of KCl leads to cardiac arrest and death due to depolarization of the cardiac cells.

UNACCEPTABLE INJECTABLE AGENTS

A number of compounds should be avoided for use in the euthanasia of animals due to animal distress associated with their use and/or risk to personnel (AVMA, 2007). These agents include strychnine, nicotine, caffeine, magnesium sulfate, potassium chloride, cleaning agents, solvents, disinfectants, and other toxins or salts, and all neuromuscular blocking agents (AVMA, 2007).

Physical Methods

Physical methods of euthanasia are best used when the animal is anesthetized. If the animal cannot be anesthetized due to research protocol or other justifications, physical methods should be used with care. It is important that personnel are well trained in the method, and that the equipment used is fully operational and well maintained.

Cervical Dislocation

Cervical dislocation is the manual, rapid separation of the cervical vertebrae with accompanying lethal trauma to the spinal cord. Cervical dislocation when performed without prior anesthesia should be scientifically justified and approved by the IACUC and personnel should demonstrate proficiency with the technique (AVMA, 2007). When performed correctly, cervical dislocation appears to be a humane method of euthanasia. This technique may be used in smaller species, typically those weighing less than 200 g. The technique involves immobilization of the head and rapid disarticulation of cervical vertebrae, preferably by use of specialized equipment such as a cervical dislocator, though this may be performed manually by quick and firm traction

and pulling of the body in a direction away from the head (Donovan and Brown, 2006). A study reported in 2007 indicated that cortical function was disrupted in mice within 10 seconds after cervical dislocation was performed (Cartner et al., 2007).

Captive Bolt

Penetrating captive bolts, pointed rods that are propelled into the animal's brain, have been used for euthanasia of several, mostly larger, species and has occasionally been used for euthanasia of rabbits. Adequate restraint is imperative when using the captive bolt, which is powered by either gunpowder or compressed air. The penetrating captive bolt causes concussion and damage to the cerebral hemisphere and brain stem. In contrast, the non-penetrating captive bolt achieves unconsciousness through percussion by a strong blow to the skull, and the brain is not penetrated. The non-penetrating captive bolt should not be used as the sole means of euthanasia and neither the penetrating nor the non-penetrating captive bolt should be used on an unanesthetized animal unless strongly justified (AVMA, 2007). The operator should be well trained to ensure accuracy of stunning. Equipment must be cleaned and serviced regularly according to manufacturer's instructions to decrease the chances of poor stunning.

Decapitation

Decapitation involves direct loss of brain function due to ischemia. Decapitation is a physical means of euthanasia that does not chemically contaminate tissues or alter tissue architecture. The guillotine (Figure 4.2A), which is used to decapitate adult rodents and rabbits, should be properly maintained to ensure that it is sharp and functional, and personnel should be properly trained in its use. Personnel should be cognizant of the potential for injury when utilizing a guillotine. Personnel may prefer to restrain the rodent in a disposable restrainer, such as the DecapiCone® (Figure 4.2B) to ensure proper placement in the guillotine. Exsanguination contributes to the effectiveness of decapitation as a method for euthanasia (AVMA, 2007). Measurements of electroencephalogram (EEG) signals after decapitation in various species ranged from 3 seconds to 40 seconds depending on whether anesthesia was previously used (Holson, 1992). In a study by Sharp et al. (2002), group-housed male Sprague-Dawley rats did not experience significant elevations of their heart rates or mean arterial pressure while in the presence of other rats during decapitation procedures. Nevertheless, because of potential pheromone production or auditory stimuli that could cause undue distress, it is recommended that performing euthanasia by decapitation or other methods in the presence of other animals should be avoided unless approval has been obtained from the IACUC and scientific justification provided.

FIGURE 4.2A Guillotine.

Microwave Irradiation

Focused high-intensity microwave irradiation has been used for euthanasia by neurobiologists for measurement of highly labile substances or metabolites without loss of the anatomic integrity of the brain (Delaney and Geiger, 1996; Ikarashi et al., 1984, 1985; Mayne et al., 1999). It should not be used as a routine method of euthanasia and should be scientifically justified and approved by the Institutional Animal Care and Use Committee. Specialized equipment that is designated for this purpose should be used (Figure 4.3), not appliances that are available for general public use. Euthanasia is accomplished in <3 seconds using this method by heating of the brain tissue. Brains of animals euthanized using microwave irradiation may exhibit some protein denaturation because of the elevated

FIGURE 4.3 Microwave instrument used for euthanasia. Photo courtesy of Dr. Jonathan Geiger at The University of North Dakota, School of Medicine and Health Sciences.

temperature (Ikarashi et al., 1986). Personnel should be trained in this procedure, and the animal should be properly positioned to ensure that the animal's brain is accurately exposed to the field (Close et al., 1997; Ikarashi et al., 1986).

Euthanasia of the Rabbit

The agents and methods for euthanasia that are widely considered to be acceptable in rabbits include the use of barbiturates, inhalant anesthetics, carbon dioxide, carbon monoxide, and potassium chloride combined with general anesthesia. Other agents and methods that would be generally acceptable with justification include nitrogen, argon, cervical dislocation, decapitation, and penetrating captive bolt. Cervical dislocation may be used on rabbits that are <1 kg (AVMA, 2007).

A physiologic mechanism allows burrowing and diving animals to have a high threshold for hypercapnia. Since rabbits are burrowing animals, they should be

monitored closely to ensure the irreversibility of hypoxemia when induced utilizing gases such as carbon dioxide. Because of this physiologic mechanism, rabbits may become immobile during the euthanasia process, and the individual performing the procedure may prematurely withdraw the gas, leading to distress for the rabbit and the operator while the rabbit struggles to regain consciousness. As for all animals undergoing euthanasia, death should be verified.

Euthanasia of the Guinea Pig

Agents and methods generally acceptable for euthanasia of guinea pig adults and neonates include barbiturates, inhalant anesthetics, carbon dioxide, and microwave irradiation. Potassium chloride may be used to euthanize guinea pigs only after induction of general anesthesia.

Guinea pig fetuses less than 34 days old may be euthanized by euthanasia of the dam. Guinea pigs fetuses 35 days old or greater should be euthanized using one of the common methods of euthanasia, including decapitation or injection of chemical anesthetics. Rapid freezing or placing fetuses in a chemical fixative without previous anesthesia is not acceptable (Artwohl et al., 2006; NIHARAC, 2004).

Euthanasia of the Hamster

Agents and methods generally acceptable for euthanasia of adult hamsters include carbon dioxide, carbon monoxide, inhalant anesthetics, barbiturates, microwave irradiation, and potassium chloride while under general anesthesia. Fetal hamsters less than 15 days old may be euthanized by euthanasia of the dam. Fetuses greater than 15 days old can be euthanized using injectable anesthetics; and decapitation or cervical dislocation, if required for the needs of the research. Carbon dioxide may be used for neonatal and fetal hamsters greater than 15 days old, keeping in mind that they are resistant to hypoxia, so prolonged exposure time may be needed (Klaunberg et al., 2004; Ronca and Alberts, 1995; Singer, 1999).

Euthanasia of Mice, Rats, and Other Rodents

Because many rodents are similar in size and physiology to common laboratory mice and rats, euthanasia of these other rodents can be based upon what is known for the latter. In rat and mouse fetuses that are less than 15 days into gestation, it is believed that neural development is minimal and that they are non-viable once the blood supply is eliminated; therefore, euthanasia of the dam is adequate to ensure appropriate euthanasia of the fetuses (Committee on Guidelines for the Use

of Animals in Neuroscience and Behavioral Research, 2003; NIHARAC, 2004; Smotherman and Robinson, 1985). Mouse and rat fetuses may be euthanized using injectable anesthetics, carbon dioxide, decapitation, or cervical dislocation. For studies requiring rapid freezing in liquid nitrogen or whole-body fixation using a chemical fixative or perfusion, fetuses should first be anesthetized. Although fetuses are generally resistant to hypoxia, they may be euthanized by extended exposure to carbon dioxide or other inhalant anesthetics (Artwohl et al., 2006; Klaunberg et al., 2004; NIHARAC, 2004; Ronca and Alberts, 1995). Rats and mice which are 0–10 days post-birth may be euthanized using injectable anesthetics, carbon dioxide, decapitation, or cervical dislocation. Anesthesia should be used prior to immersion in liquid nitrogen or chemical fixatives (Artwohl et al., 2006). Hypothermia may be used in rats and mice less than 6 days old. Inhalant or injectable anesthesia may also be used prior to other forms of euthanasia. In a study in which rats 0–10 days old were exposed to 100% carbon dioxide, it was determined that the time required to euthanize rats increased by 3 minutes for every day of increase in age. The time required for death by carbon dioxide increased inversely based on the age of the rat (Pritchett-Corning, 2009). Inbred mice in this age range were less susceptible to carbon dioxide than outbred mice, especially between 0 and 8 days of age. It was determined that carbon dioxide exposure time could vary from 5 minutes to 60 minutes for mice 0–10 days old (Artwohl et al., 2006; Pritchett et al., 2005). European Union guidelines recommend decapitation, concussion, and hypothermia (Close et al., 1997), but not carbon dioxide, for euthanasia of neonates.

Mice and rats greater than 10 days old may be euthanized using barbiturates, inhalant anesthetics, carbon dioxide, carbon monoxide, and microwave irradiation; cervical dislocation or decapitation may be used, preferably on anesthetized animals unless otherwise justified by the scientific needs of the study. Potassium chloride may be used following induction of general anesthesia. Rats should be <200g if cervical dislocation is used as the sole means of euthanasia (AVMA, 2007).

NECROPSY

General Considerations

Necropsy is an important procedure for diagnostic investigations of laboratory animals and for obtaining valuable data in biomedical research. The origin of the term “necropsy” is from the Greek words *nekros* (meaning “corpse”) and *opsis* (meaning “to view”), and together they mean “to look at the dead body with naked eyes”; that is, macroscopic examination of a dead

body. Although “autopsy” and “necropsy” are synonymous, “necropsy” is the conventional term for postmortem examination of non-human species, and “autopsy” is used only for postmortem examination of humans. Because there is only one opportunity to perform the necropsy of an animal, it is important to conduct a thorough macroscopic examination with identification and detailed description of all lesions. The necropsy procedure includes not only the dissection of the dead animal and macroscopic examination of all organs but also collection of appropriate tissue samples and measurements of the carcass, internal organs, and body fluids (i.e. weight, size, length, volume). The gross lesions observed at necropsy should be documented promptly in a descriptive written report and by taking good-quality photographs (Relyea et al., 2000; Sundberg and Miller, 2000).

Necropsy methods differ between laboratories, pathologists, and experiments. These differences are generated by the objectives of the study, established protocols, and experience of persons performing the necropsy. In planning and determining the appropriate necropsy procedure, several important factors need to be considered in concert with the objectives of the study (Table 4.1). Preparing for and conducting the necropsy, as well as identifying and interpreting the lesions, is a complex process that requires a veterinary pathologist’s expertise. The pathologist should be consulted at the beginning of the experiment for assistance in designing the study, as well as for performing postmortem examinations and evaluation of observed lesions.

Due to postmortem autolytic changes that begin quickly after death of the animal, the necropsy should be performed immediately after euthanasia. The central nervous system, eyes, adrenal medulla, gastrointestinal mucosa, pancreas, liver, and kidney are the first organs affected by postmortem autolysis. Fibrous tissues, muscles, bones, and skin are more resistant to postmortem changes. If necropsy cannot be performed immediately after death of the animal, the carcass should be preserved in a refrigerator until necropsy. Refrigeration slows the autolytic processes of the dead animal. Carcasses should not be frozen before necropsy because the freezing and thawing processes cause severe morphologic artifacts of tissues that obscure the gross and histological lesions.

Tissue artifacts caused by manipulation, dissection, and examination during necropsy and by fixation, trimming, and processing of tissues into histological sections should be minimal or non-existent. Gentle manipulation of tissues during dissection, examination, and sampling will avoid distortion of tissue architecture. Proper fixation of tissues is accomplished by immersing the tissue samples in an adequate amount and type of fixative, quickly after the animal’s death. Trimming of fixed tissue samples and processing of histological sections should be

TABLE 4.1 Issues to Consider in Logistical Planning of Necropsy

- What is the method of euthanasia, and is it compatible with experimental needs?
- What are expected “target organs,” and are any special procedures warranted such as ancillary clinical pathology studies?
- What special prelabeling and identification requirements are needed?
- Do fixatives and/or clinical preservatives need to be prepared fresh?
- Are there randomization issues and/or special timing issues required between experimental groups?
- Are target organs to be weighed, and is exsanguination required?
- Do terminal clinical, clinical chemistry, urinalysis, or hematology specimens need to be collected and, if so, by what method? Is food restriction required before this collection?
- Are microbiology samples to be collected, and is aseptic technique required?
- Are there critical steps that require a “single individual” to collect target tissues for consistency purposes?
- Is a special tissue collection order required for target organ study owing to autolysis issues or biochemistry needs?
- Are special identification methods to be used for multiple or paired tissues?
- Are study protocols, standard operating procedures, and clinical records available to the prosectors?
- Are frozen specimens to be collected and, if so, by what method?
- Are morphometric techniques to be used, and does this require special tissue handling such as organ perfusion?
- Are there special postfixation needs for molecular, ultrastructural, histochemical, or immunohistochemical studies?
- What are the microbial, radiological, and chemical hazards posed by the necropsy procedures, and what precautions are to be used?

From Black, 1986, and Everitt and Gross, 2006.

performed in histology laboratories by skilled histotechnologists. Tissue artifacts and autolytic changes observed at necropsy or microscopic examination should be differentiated from lesions by the pathologist.

Preparation for Necropsy

It is advisable to establish a detailed necropsy protocol before euthanasia and necropsy, preferably when designing the animal experiment. The preparation for necropsy is dictated by the clinical history of the animal, objectives of the experiment, types and methods of treatments/experiments, and tissue samples that need to be collected. All equipment and supplies listed in [Table 4.2](#) should be prepared and instruments and specimen containers prelabeled before euthanasia and necropsy occur. The necropsy should be performed only in designated and adequately equipped necropsy rooms. The person performing the necropsy should wear protective equipment that includes a laboratory coat, protective gloves, and safety eyewear. Additional biosafety measures should be implemented when the animals have been exposed to, or experiments conducted with, biohazardous materials. Aseptic instruments and

TABLE 4.2 Equipment, Instruments, and Materials for Necropsy of Rabbits, Guinea Pigs, Hamsters, Rats, Mice, and Other Rodents

- Laboratory coats, surgical gowns, and safety gloves and glasses
- Biological safety cabinets with equipment for handling biological hazards and animals exposed to biohazardous materials
- Anesthesia and euthanasia chamber with CO₂ tank and regulator valve or other euthanasia equipment
- Vented necropsy table
- Corkboards, Styrofoam boards, and disposable sheets for dissection of animals
- Calibrated balance or scale and weigh trays for measuring body and organ weights
- 1-ml syringe with 20- or 22-gauge needle, tubes with EDTA or heparin, and serum separator tubes for collection of blood samples for hematology and serology tests
- Sharp and blunt-tip hypodermic needles (16- to 25-gauge) and a 5- to 20-ml syringe filled with fixative for infusion of lungs, urinary bladder, intestines, and stomach
- 1-, 5-, 10-, and 20-ml syringes for collection of biological fluids
- Serrated and rat-toothed tissue forceps
- Straight and curved (iris) tissue forceps of different sizes
- Scalpel blades (numbers 11, 20, and 22) with handles or finger scalpels (numbers 10 and 22)
- Large and small scissors, straight and curved, with blunt and sharp points
- Bone-cutting forceps, nail-cutting forceps, bone rongeurs, and a small spatula
- Prelabeled containers, plastic bags, and Eppendorf tubes for specimen collection
- Prelabeled containers with fixative (10% neutral buffered formalin for routine histologic analysis)
- Bacteriological swabs and sterile petri dishes for specimen collection for microbiology tests
- Microscope glass slides for blood smears and cytological preparations
- Clear tape for taking anal and perianal samples, which are then placed on a glass slide for microscopic detection of parasites
- Embedding bags or biopsy bags and tissue cassettes (small and regular size)
- Cryomolds, optimal cutting temperature (OCT) compound, and liquid nitrogen for preparation of frozen tissue samples
- Beaker or squeeze bottle with physiologic saline (0.9% sodium chloride) for rinsing the tissues
- Cotton balls soaked in 70% alcohol or a squeeze bottle of 70% alcohol
- Paper towels, gauze sponges, and silk suture material (3/0, 1/0)
- Push pins, index cards or cardboard, marker, pencil, and pen
- Calipers and metric rulers for measuring masses, cysts, and other lesions
- Dyes for labeling tissue lesions
- Magnifying glass for identifying smaller organs or lesions
- Camera for taking photographs of lesions
- Plastic disposal bags

containers should be available at necropsy for collecting samples for microbiological analyses that are necessary for investigating the etiology of disease or the health status of sentinel animals in the animal colony. Photographic equipment and a dissection microscope or stereomicroscope should be available in the necropsy

room for taking photographs of the lesions during the necropsy procedure. Other imaging techniques, such as radiographs of the entire animal or only target organs, shortly after euthanasia or during the necropsy, may need to be performed in certain experiments. Having readily available instruments, supplies, materials, and prelabeled containers during the necropsy enables the prosector to accomplish quick sampling and immediate fixation of tissues after the animal's death.

Necropsy Procedure

It must be reiterated that there is no single best method of necropsy that will fit all circumstances and desires of the pathologist or investigator performing the necropsy. Any necropsy technique is suitable as long as a thorough examination of all organs is performed, all gross findings are recorded properly, appropriate tissue samples are collected, and the objectives of the experiment and diagnostic investigations are addressed. Therefore, the appropriate method of necropsy should be determined based on the objective of the experiment, clinical history of the animal, planned use of tissue samples, and planned diagnostic tests. It is essential to develop and perform a routine standard necropsy procedure with examination and sampling of all organs in a consistent, systematic sequence. Having a routine will prevent missing lesions or sample collections and will improve considerably the efficiency and speed of performing the necropsy. The necropsy of animals in preclinical drug studies and phenotyping of genetically engineered mice are commonly conducted in a consistent manner in all animals, according to an established protocol or standard operating procedures.

A number of sources provide detailed information regarding the necropsy of rodents and rabbits (Bono, 1994; Bono et al., 2000; Everitt and Gross, 2006; Feinstein, 1994; Feldman and Seely, 1988; Hayward et al., 2007; King et al., 2005; Registry of Industrial Toxicology Animal Data, 2010; Relyea, et al., 2000; Seymour et al., 2004; Sharp and LaRegina, 1998; Silverman, 1987). Further, a detailed anatomy atlas will aid the prosector in dissecting and recognizing the organs (Greene, 1963; Hayakawa and Iwaki, 2008; McLaughlin, 1970; Olds and Olds, 1979; Popesko et al., 1990a, 1990b; Wingerd, 1985).

Any necropsy should begin with identification of the animal and investigation of the clinical history, research protocol, applied experimental procedures, and reason for submission. Subsequently, external examination, body weight, and collection of blood and other tissue samples should be performed. Because the amount of blood sampled can vary greatly from one animal to another, the animal's body weight should be recorded before the collection of blood samples. The sequence of dissection, gross examination, and tissue sampling

of a complete systemic necropsy in laboratory rodents is described below. This necropsy technique has been applied successfully in most types of research and pre-clinical drug studies in our laboratory. Although the mouse is used as an example of necropsy here, a similar necropsy technique can be performed in rabbits, guinea pigs, hamsters, rats, and other rodents. The differences between these species in necropsy procedures will be addressed as appropriate.

Collection of Blood and Urine Samples

Blood samples for diagnostic tests are often collected at necropsy from the anesthetized animal just before euthanasia or immediately after euthanasia and death of animal. In mice, rats, guinea pigs, hamsters, and other rodents, the blood samples can be collected from the following sites: heart, retro-orbital sinus, abdominal aorta, femoral artery, caudal vena cava, and medial saphenous vein. In mice and rats, the tail vein or tail artery can also be used to sample a small volume of blood (Adams, 2002; Everitt and Gross, 2006; Fukuta, 2004; Relyea et al., 2000). For hematological testing, the blood must be collected quickly with minimal tissue trauma and mixed promptly with anticoagulant in plastic lavender-top tubes (Figure 4.4) that contain ethylenediaminetetraacetic acid (EDTA) to prevent clotting of blood (Adams, 2002; Everitt and Gross, 2006; Fukuta, 2004; Relyea et al., 2000). For blood chemistry analysis and other serologic tests, the blood is collected in yellow-top tubes (Figure 4.4). In our experience, collection of blood from the heart by cardiac puncture with a 1–2 ml syringe and 20–25 gauge needle has proven to be a consistently successful technique in mice and rats (Figure 4.4). In rabbits, the blood samples can be collected from the heart, auricular (marginal ear) vein, auricular (central ear) artery, jugular vein, or medial saphenous vein (Bivin, 1994; Hrapkiewicz et al., 2007; Suckow and Douglas, 1997). Blood smears should always be prepared and examined along with hematological testing. The sampling site of blood collection should be consistent in animals from the same study because the values of total and differential white blood cell count, red blood cell count, platelet count, and other hematological parameters are significantly different from one site of sampling to another (Doeing et al., 2003; Nemzek et al., 2001; Schnell et al., 2002). Collection of blood samples by cardiac puncture is most recommended because this technique avoids variations in hematological values caused by various biological factors, manipulation, and other events (Schnell et al., 2002).

When urinalysis is required at the time of euthanasia or necropsy, the urine can be collected either before the euthanasia and collection of blood samples, or during the necropsy directly from the urinary bladder with a sharp needle and syringe. Obtaining a sufficient amount of urine at necropsy is often challenging in mice due to

the small volume of urine that can be found in the urinary bladder after euthanasia. In mice, we recommend collecting the urine from live animals before the anesthesia and euthanasia, because the urinary bladder of euthanized mice is commonly empty of urine at necropsy. The urine can be collected before the anesthesia and euthanasia using the clear-plastic-wrap method (Kurien and Scofield, 1999; Kurien et al., 2004); housing the mouse in a metabolic cage; or by collection of urine in a plastic tube held at the external urethra while gripping the mouse (Fukuta, 2004; Relyea et al., 2000). In our laboratory, we have successfully collected 50–250 µl of fresh non-contaminated urine excreted by an individual mouse on clear plastic wrap. Because rabbits, guinea pigs, hamsters, and rats have a higher volume of urine in the urinary bladder, their urine samples can be collected directly from the urinary bladder during necropsy shortly after euthanasia, with a syringe and sharp needle. In rabbits, the urine can also be collected by catheterization or cystocentesis (Adams, 2002; Bivin, 1994; Hrapkiewicz et al., 2007; Suckow and Douglas, 1997).

Exsanguination and Euthanasia

Once the blood samples are collected, the anesthetized animals can be euthanized by exsanguination and/or other methods of euthanasia. Due to the small total blood volume in mice, the collection of blood samples of approximately 400 µl or more of blood can be used to euthanize an anesthetized animal by exsanguination (Figure 4.4). Exsanguination of rabbits, hamsters, guinea pigs, rats, and other rodents can be accomplished by either cardiac puncture, transection of the abdominal aorta, transection of the vena cava, transection of the axillary and femoral arteries, or decapitation (Everitt and Gross, 2006). Complete exsanguination of animals is recommended for obtaining consistent organ weights, generating better-quality histological sections for chemical and immunohistochemical analysis, and eliminating pooled blood in tissues during dissection (Everitt and Gross, 2006; Sullivan, 1985).

External Examination

The necropsy begins with a thorough external examination. This includes verification of the animal's identification information (animal identification number, sex, date of birth, strain, genotype, and pedigree) and visual inspection and palpation of the animal's fur, skin, oral cavity, nasal mucosa, conjunctiva, eyes, anus, and external genitalia (Figure 4.5). Examination of the skin should include evaluation of the skin for abnormal color, presence of ulcerations, traumatic wounds, ectoparasites, cutaneous or subcutaneous tumors, fur condition and soiling, and any other external abnormalities. Presence of nasal, ocular, or aural discharge should be assessed. The anus and perineal region are examined for diarrhea and traumatic lesions.

The external genital organs and urethra are examined for blood or purulent discharge and for presence of tumors or other abnormalities. Photographs of the entire animal and external lesions should be taken at this time, particularly in research and studies involving the phenotyping of genetically modified mice.

Oral, anal, and skin swabs, skin scrapes, and an anal clear-tape test should be performed immediately after euthanasia and before the immersion of the mouse in disinfectant solution. Similarly, skin samples for bacteriologic or other diagnostic tests should also be collected before the immersion of the mouse in disinfectant. Hair samples should be collected by manual plucking using the thumb and forefinger from an area of skin that is not sampled for histological examination (Relyea et al., 2000). In genetically modified mice, a 1-cm-long section from the tip of the tail is usually sampled in an Eppendorf tube for genetic testing. To prevent contamination, the samples must be collected aseptically using sterile instruments and petri dishes or other sampling containers (Hayward et al., 2007).

Dissection, Gross Examination, and Collection of Tissue Samples

After completing the external examination and collection of appropriate skin samples, the euthanized animal is immersed in a solution of germicidal detergent or 70% alcohol. Alternatively, one can moisten the ventral surface of the body with 70% alcohol or another disinfectant (Figure 4.6). This measure will prevent contamination of tissues with hair. The animal is then positioned in dorsal recumbency on a corkboard, and the legs are pinned down by placing a pushpin through each paw and into the corkboard (Figure 4.6). Immobilization of the carcass increases the precision and speed of dissection and helps to prevent the contamination of instruments and organs during necropsy.

SECTIONING OF SKIN AND EXAMINATION OF SUBCUTANEOUS TISSUES

With scissors, a ventral midline incision of skin is made beginning immediately cranial to the external genitalia and ending at the mandibular symphysis. The skin is then sectioned from the midline inguinal region to the distal region of the tibia on the medial aspect of both hind legs. After that, the skin should be reflected laterally on both sides of the midline incision by applying gentle lateral traction of the skin with forceps and carefully excising the subcutaneous loose connective tissue (Figure 4.7). For better exposure of subcutaneous tissues and to avoid the contamination of internal organs with hair, we recommend pinning down the reflected skin as demonstrated in Figure 4.7. This measure allows good exposure of the salivary glands, mammary glands, preputial or clitoral glands, and subcutaneous lymph nodes (Figures 4.7–4.9). The mammary glands are within the

FIGURE 4.4 Collection of blood samples by cardiac puncture. The yellow-top tube (a) is used for collecting blood for serological tests. The lavender-top tube (b) contains EDTA and is used for hematological tests.

FIGURE 4.9 Sampling of the salivary glands as a single unit.

subcutaneous fat pad attached to the skin (Figure 4.7) and are usually sampled for histological examination together with the adjacent skin (see Figure 4.29). In studies that require detailed histological investigations of the entire mammary tissue, the inguinoabdominal and cervicothoracic mammary glands, including the mammary lymph nodes, are separated from the skin with a scalpel blade together with subcutaneous adipose tissue (Figure 4.10) and attached to a glass slide (Figure 4.11) or paper cardboard. Maintaining the mammary tissue on a glass slide or cardboard for 1–2 minutes before immersion in fixative allows the mammary tissue to stick to the glass slide or cardboard during fixation. This measure will preserve the anatomically flat orientation of the mammary glands during fixation and will facilitate obtaining of histological sections through the entire mammary tissue. Whole-mount preparation of mammary glands is performed in certain investigations. The salivary glands (parotid, submandibular, and sublingual) and submandibular or superficial cervical lymph nodes are collected together in fixative. The connective tissue surrounding the parotid glands near the ear canal is grabbed with forceps, and the parotid, submandibular, and sublingual salivary glands including the submandibular lymph nodes are separated as a single unit by sectioning the connective tissue attachments all the way to the other ear canal (Figure 4.9). The other subcutaneous lymph nodes, the preputial glands in males, and the clitoral glands in females (Figure 4.7) should be collected at this time and placed in fixative.

OPENING THE ABDOMINAL CAVITY

The abdominal cavity is opened by performing a medial incision of the abdominal wall from the pubic symphysis to the xiphoid, through the linea alba. Immediately after opening the abdominal cavity, the presence of abnormal fluid in the abdominal cavity should be noted and collected, uncontaminated, with a syringe for evaluation of volume, color, and consistency, and possible microscopic or microbiologic investigations. Subsequently, the abdominal wall is incised bilaterally from the medial incision toward the spinal column along the rib cage and similarly in the inguinal region through the lateral abdominal wall. This incision will allow adequate exposure of the abdominal viscera (Figures 4.12, 4.13 and 4.15). At this time, before any manipulation and disturbance of organs, it is important to perform *in situ* examination of the abdominal organs to evaluate the anatomical position of the viscera and to collect uncontaminated peritoneal swabs or other tissue samples as needed (Hayward et al., 2007).

UROGENITAL ORGANS

The testicles and epididymides should be collected and immersed in formalin as a single unit, without

sectioning the testicles, in order to preserve the normal histological orientation of the seminiferous tubules. The testicles and epididymides are easily exposed from the scrotum by grasping the epididymal fat with forceps and applying gentle traction. In rabbits, rats, and other rodents, the epididymis can be separated from the testis before fixation, but the testicle should be immersed intact in fixative for 6–12 hours (depending on the type of fixative used and the size of the testicle) before sectioning for faster penetration of fixative. This preliminary fixation will prevent histological distortion of the seminiferous tubules when cutting the testicles.

In order to collect the male reproductive tract, the pelvic cavity should be opened first by sectioning the pubic symphysis with scissors (mice) or bone-cutting forceps (rabbits, rats, and other rodents). The penis, urethra, accessory sex glands, and urinary bladder are collected as one unit by grasping the tip of the penis with forceps and using a scalpel blade or scissors to separate the penis, urethra, accessory sex glands, and urinary bladder from the anus, rectum, colon, and surrounding tissues (Figure 4.14). For preserving the anatomical orientation of reproductive organs during fixation, it is advisable to attach the entire male reproductive tract to a dry glass slide or index card before immersion of the tissues in fixative.

For female animals, the pelvic cavity is opened first as described for males. Then, the vulva, vagina, uterus, ovaries, and urinary bladder should also be collected as one unit by grasping the vulva with forceps and by severing the attachments to surrounding tissues with scissors (see Figure 4.16). Similar to the procedure for males, the entire female urogenital tract should be placed on a dry glass slide or a piece of index card before immersion in fixative in order to preserve the anatomical orientation during fixation. For adequate fixation of the urinary bladder urothelium, fixative should be injected into the urinary bladder with a syringe. This can be accomplished either by inserting a blunt-tip needle through the urethra, followed by ligation of the urethra after infusion of fixative, or by direct injection of fixative with a sharp needle through the urinary bladder wall.

SPLEEN, MESENTERIC LYMPH NODES, PANCREAS, AND DIGESTIVE TRACT

The spleen is collected in a small tray and weighed before being placed in fixative. Frozen-tissue samples and tissue samples for microbiology tests or other molecular investigations must be collected from the spleen and other organs before introducing them into fixative solution. Before removing the digestive tract, the patency of the common bile duct can be demonstrated by opening the proximal duodenum with a longitudinal incision, and subsequently applying pressure on the gallbladder

FIGURE 4.10 Sampling of the inguinoabdominal mammary glands by dissecting the subcutaneous adipose tissue (a).

FIGURE 4.12 Opening of the abdominal cavity by medial incision and bilateral retroflexion of the abdominal wall (a). In situ examination of abdominal organs in a male mouse: liver (b), intestines (c), urinary bladder (d), and testicles (e).

FIGURE 4.13 Examination of abdominal organs: liver (a), stomach (b), spleen (c), pancreas (d), kidney (e), mesenteric lymph nodes (f), small intestine (g), cecum (h), colon (i), seminal vesicles (j), prostate glands (k), and urinary bladder (l).

FIGURE 4.14 After splitting the pubic symphysis, the male urogenital tract is removed as a single unit: seminal vesicles (a), anterior prostate gland or coagulating gland (b), ventral prostate gland (c), urinary bladder (d), urethra (e), penis (f), and preputium (g).

FIGURE 4.15 In situ examination of the female urogenital tract: ovaries (a), uterine horns (b), urinary bladder (c).

(Seymour et al., 2004). If the common bile duct is patent, the bile should be expressed in the duodenum at the bile duct orifice. Among laboratory rodents, rats lack a gallbladder. The mesenteric lymph nodes and the pancreas can be easily located within the mesentery and should be separated from the intestine before the intestinal tract is removed (Figure 4.13).

The stomach and entire gastrointestinal tract are removed as a single unit by first cutting the esophagus caudal to the diaphragm, without sectioning the diaphragm. Then, grasping the stomach with forceps, the intestinal tract is pulled away from the carcass and all mesenteric and other tissue attachments are cut from stomach to anus. The stomach and the entire intestinal tract (duodenum, jejunum, ileum, cecum, colon, rectum, and anus), including the feces, should be examined in more detail at this time (Figure 4.17), and samples for bacteriological, parasitological, or other diagnostic tests should be collected as required. Due to rapid postmortem autolysis of gastrointestinal mucosa, we recommend that fixative be injected into the intestinal lumen in multiple sites using a 5–10ml syringe with a 20–22 gauge needle. Other investigators prefer to ligate one end of the intestine and use the other end for infusing the fixative; that end is subsequently ligated as well in order to maintain the fixative within the intestinal lumen for better fixation of the mucosa. The stomach can be infused with fixative and fixed without cutting the stomach wall, or the stomach can be opened along the greater curvature to examine the mucosa and ingesta and then placed in fixative. The stomachs of rabbits contain a larger amount of ingesta and should always be opened along the greater curvature before immersion in fixative. In mice, rats, guinea pigs, hamsters, and other rodents, the entire intestinal tract is immersed in fixative after intraluminal infusion of fixative. In rabbits, multiple 1–2 cm long segments of intestine from all regions (duodenum, jejunum, ileum, cecum, colon, rectum, and anus) are usually collected in fixative. When the entire length of intestine needs to be examined microscopically in mice, “Swiss rolls” of the small intestine or colon should be prepared in histology cassettes before immersion of the tissue in fixative. When preparing the Swiss roll, the intestine should be infused with fixative first, and then, while the proximal end of the intestine is held in the center of the cassette, the distal end is twisted around in a spiral-like shape (Figure 4.18). It is recommended to make the rolls smaller than the cassettes to avoid draining of fixative while rolling the intestine. It is also recommended to not overinflate the intestine with fixative (Relyea et al., 2000). This technique is practiced in certain types of research and when sentinel mice are examined for the presence of pinworms or other parasites in monitoring the health of the mouse colony. The colon of mice, rats, and other rodents can be fixed in formalin either as Swiss roll preparations or as multiple segments of 1–2 cm.

LIVER, GALLBLADDER, ADRENAL GLANDS, AND KIDNEY

In mice, the liver and gallbladder are collected together and fixed as a single unit. Using forceps, the liver is grasped from the connective tissue under the medial lobe, and with scissors or a scalpel blade, the blood vessels and ligaments are severed without sectioning the diaphragm. The liver with the attached gallbladder should be weighed, and the required samples should be collected before the immersion of liver in the fixative solution. In rats, guinea pigs, hamsters, and other rodents, the liver is removed in a similar manner, but before immersing the liver in fixative, sections of liver at 3–5 mm intervals are recommended for better fixation of tissue. From rabbits, pieces of liver of $1 \times 1 \times 0.5$ cm from each hepatic lobe, including the gallbladder and observed gross lesions, should be collected in fixative.

After removal of the digestive tract and liver, there should be good exposure of the adrenal glands, kidneys, and ureters (Figure 4.19). Before removing the kidneys, the adrenal glands within the adipose tissue at the cranial pole of each kidney should be sampled intact (Figure 4.19). Both adrenal glands are excised without adipose tissue, weighed if the study protocol requires, and placed in a small cassette (Figure 4.20) prior to immersion in fixative. Similarly the kidneys should be collected without the surrounding adipose tissue and weighed before fixation. After examining the surface of the renal capsules, the kidneys should be examined on the cut surface by sectioning the right kidney in a transverse plane and the left kidney in a medial longitudinal plane, through the renal cortex, medulla and pelvis.

THORACIC CAVITY

Cutting the diaphragm and the ribs on both sides of the sternum, dorsal to the chondrocostal junction and from the last rib to the first rib, should open the thoracic cavity (Figure 4.21). The entire sternum with attached ribs is collected in fixative (Figure 4.21, inset). The organs within the thoracic cavity are examined in situ, the presence of abnormal fluids in the thoracic and pericardial cavities is evaluated, and samples for microbiology testing are collected before further manipulation and contamination of tissues (Hayward et al., 2007). The entire respiratory tract, heart, aorta, tongue, larynx, esophagus, thyroid and parathyroid glands, thymus, and mediastinal lymph nodes are collected and fixed as a single unit (Figure 4.22, inset), also known as “the pluck”. To accomplish this, the soft tissues on the medial aspect of the mandible are cut until the oral cavity can be accessed, and then the mandibular symphysis is split. The tongue is grasped with forceps, and while the tongue is gently pulled caudally and away from the carcass, the soft palate and connective tissues around the larynx, trachea, esophagus, and the mediastinum are cut in order to separate the pluck from the carcass

FIGURE 4.16 After the pubic symphysis is split, the female urogenital tract is collected as a single unit and is attached to a glass slide or index card before immersion in fixative. Ovaries (a), uterine horns (b), vagina (c), and urinary bladder (d).

FIGURE 4.19 The adrenal glands (a) found at the cranial pole of the kidneys (b) should be examined and sampled before removing the kidneys. The diaphragm is intact (c).

FIGURE 4.20 The adrenal glands are collected in small cassettes before immersion in fixative.

FIGURE 4.21 Opening of the thoracic cavity and in situ examination of the pleura and thoracic cavity (a), lungs (b), heart (c), and thymus (d). The sternum is collected and placed in fixative (inset).

(Figure 4.22). Due to its small size the heart of the mouse is usually fixed without sectioning. In rabbits, rats, guinea pigs, hamsters, and other rodents, the heart is opened by a section in a median plane through the right and left ventricles and atria, or by other methods of dissection. This sectioning will allow not only exposure and examination of all chambers and walls of the heart, but also a better fixation of the cardiac tissues. After external examination and collection of samples for microbiology testing as necessary, the lungs of rabbits, guinea pigs, hamsters, rats, mice, and other rodents should be infused with fixative to prevent histological artifacts caused by alveolar collapse (Renne et al., 2001). Using a blunt-tip hypodermic needle and a 5–20ml syringe filled with fixative, the needle is introduced into the lumen of trachea through the pharynx, and then the trachea with the inserted needle is clamped down with forceps to prevent backflow of fixative solution (Figure 4.23). Applying gentle pressure, the fixative should be infused into the lungs until the lungs attain the size of the thoracic cavity, and then the entire pluck should be dipped into the fixative. Overinflation of the lungs with fixative will cause artifacts from rupture of the alveolar walls.

SCIATIC NERVE, SKELETAL MUSCLE, BONES, AND JOINTS

The sciatic nerve can be easily located between the muscles of the thigh, close to the femur, as shown in Figure 4.24, and should be placed in a small cassette (Figure 4.24, inset) before immersion in fixative. In mice, rats, guinea pigs, hamsters, and other rodents, the entire front and hind limbs are usually sampled in fixative (Figure 4.25) for the evaluation of skeletal muscle, joints, bone marrow, and bone tissue. Additional samples of skeletal muscle can be collected from muscles along the vertebral column.

EYES, BRAIN, AND SPINAL CORD

The entire spinal column and the head should be separated from the skin and remaining carcass as one unit by starting from the coccygeal region of the spinal column and continuing cranially to the nostrils (Figure 4.26A). In mice and similarly sized rodents, the eyes can be fixed in situ and processed in histological sections together with the cranial bones, or can be extracted from the orbits and fixed individually. In rabbits, rats, guinea pigs, hamsters, and any study that involves ocular histology, it is recommended to extract the eyes from the orbital cavity and fix them individually in Davidson's, Zenker's, or Bouin's fixative to obtain better fixation and high-quality histological sections. For a better fixation, larger ocular globes may need to be infused with fixative into the vitreous chamber before immersion in fixative. The eye globe is usually collected with attached optic nerve and Harderian gland. This can be achieved by grasping the conjunctiva with

forceps and pulling the eye globe out of the orbit, while cutting into the orbital cavity around the eye globe with a small scalpel blade or scissors and severing the optic nerve at the end. To prevent autolytic changes of eye tissues, particularly when the eyes are the target organs of the investigation, they are preferably collected and placed in fixative at the beginning of necropsy.

The head is separated from the spinal column by disarticulating the atlanto-occipital joint as shown in Figure 4.26. The brain is collected by removing first the calvaria, with scissors (mice) or bone-cutting forceps (rats, hamsters, guinea pigs, and rabbits), without damaging the brain tissue. The calvaria is removed by cutting bilaterally the occipital, parietal, and frontal bones beginning at the foramen magnum dorsal to the occipital condyle, and ending at the frontal bones between the orbits (Figure 4.27). With the brain cavity opened and the skull turned upside down to allow gravitational falling of brain, the brain should be extracted intact from the cranial cavity (Figure 4.28). This is accomplished by gently pulling away the brain from the ventral aspect with a small spatula or a scalpel blade, beginning at the foramen magnum and advancing toward the olfactory lobes, and concurrent sectioning of the nerve roots. For all species, the extracted brain should be examined and introduced intact in the fixative (Figure 4.28) unless the protocol of the study requires otherwise. Sectioning the brain before fixation causes severe distortion of the histological architecture of the brain tissue. Once examined, the remaining bones and soft tissues of the head, including the nasal cavity and maxillary and mandibular bones, should be introduced into fixative. Perfusing the nasal cavity with fixative is recommended for proper fixation of nasal tissues (Everitt and Gross, 2006).

After trimming away the ribs and muscles tissues from the spinal column, the cervical, thoracic, lumbar, and sacral regions of the spinal column are separated by transverse sections of the vertebral column (Figure 4.26B). This sectioning enables faster penetration of fixative and better fixation of the spinal cord.

SKIN

Recommended routine samples of the skin should include skin from the dorsal, lateral, and ventral aspects of the body, and from the head, neck, and tail regions (Relyea et al., 2000). These samples, which may also include the mammary glands, are collected from the lumbar and inguinoabdominal regions as shown in Figure 4.29. To avoid undesirable folding of skin during fixation, the subcutaneous surface of the collected skin sample should be attached to a piece of index card before it is immersed in fixative. The skin of the head and neck, including the ear pinna, should be sampled routinely in fixative. In addition to the described routine tissue sampling of all organs, any lesion observed upon gross

FIGURE 4.22 After the mandibular symphysis is split, the respiratory system and adjacent tissues are removed as a single unit (the pluck): tongue (a), trachea (b), thymus (c), heart (d), lungs (e), and mediastinum with mediastinal lymph nodes. The dorsal view of the removed pluck (inset).

examination should be collected in fixative for histological examination.

PATHOLOGY CONSIDERATIONS

Descriptive Pathology

During necropsy, the pathologist or technician must record in the written report the animal's identification information, organ weights, and all lesions observed, using precise measurements and descriptive common terminology but without interpretation of the lesions (i.e. "dark-red area", not "hemorrhage"; "tissue mass", not "neoplasia"). In describing the lesions, it should first be recorded what organs are affected, the distribution or pattern of the lesions, and the percentage of the organ affected or the extent of the lesion. The following characteristics of the lesions should be described using precise terminology: size, number, color, shape, consistency or texture, weight, location, severity, odor, and volume (Bono et al., 2000; Everitt and Gross, 2006; Feldman and Seely, 1988; King et al., 2005). Tissue artifacts caused by handling or dissection during the necropsy or due to postmortem autolysis should be differentiated from pathologic lesions. Following the written report, a veterinary pathologist should interpret the observed gross lesions, give the morphological diagnosis of the lesions found, and elaborate a definitive, differential, or suspected diagnosis. The severity of gross and histological lesions can be graded using a score from 1 to 4 (1 = minimal, 2 = mild, 3 = moderate, 4 = marked). A grade of zero or no grade is used when no lesion is present. Consistency among pathologists in using similar diagnostic terminology and grading scores for histological lesions is particularly important in preclinical drug

studies (Crissman et al., 2004; Shackelford et al., 2002). Accompanying the pathology report, photographs of gross and histological lesions should be included.

In biomedical science, images are an important tool for documenting, analyzing, teaching, learning, and publishing medical knowledge and research data. Therefore, photographs of necropsy specimens should be accurate and of high quality. High quality can be achieved by using adequate photography equipment, preparing gross specimens properly, and learning basic photography skills. Most necropsy laboratories are equipped with a copy stand that has arms with lights and camera support. Digital cameras with autofocus are more commonly used today because they are more practical for routine work, but they are not recommended for taking pictures in macro-focus range. For the latter, because organs and lesions are commonly small in mice and other laboratory rodents, a digital single-lens reflex (SLR) camera with telephoto or close-up lens (50- or 100-mm macro lens) is recommended. The necropsy specimen, as well as the background, should be clean of blood, contaminants, and other materials. A suitable background color with good contrast, an adequate light source, absence of shadows, and good focus on the specimen are needed for obtaining high-quality images. Pictures of the well-exposed organ and/or the lesions should be taken before removing them from the animal, in order to capture their anatomical orientation and relationship with surrounding organs (Sundber and Miller, 2000). Additional photographs with more details of the organ and lesions can be taken after removing the organ. Including a control normal organ in the same picture is recommended when comparison is important. Dissection microscopes or scanning electron microscopes are used for taking photomicrographs of smaller lesions.

Tissues Sampling, Fixation, and Trimming

Tissue samples must be collected with sharp instruments and gentle manipulation to avoid distortion of the cellular and histological architecture of tissues. Histological sections of tissues can be obtained from frozen or fixed tissue samples.

Frozen tissue samples are usually prepared when molecular analysis of tissue or specific immunohistochemical, histochemical, or immunofluorescence stains of histological sections are required. High-quality frozen tissue samples can be obtained by embedding the fresh tissue sample in a cryomold with optimal cutting temperature (OCT) compound, followed by immediate immersion into liquid nitrogen or dry ice. Subsequently, these samples should be preserved in a freezer at -80°C . Freezing of tissue samples is not recommended for routine histological examination because the freezing artifacts damage cellular morphology and tissue architecture, and therefore may obscure or disable recognition of lesions. Routine microscopic examination of tissues is performed on hematoxylin and eosin (H&E) stained sections from tissue samples fixed in 10% neutral buffered formalin.

For obtaining good-quality histological sections, autolysis after the collection of tissues must be prevented by performing appropriate fixation (Eltoum et al., 2001; Grizzle, 2009; Jones, 2001). Proper fixation of tissues can be accomplished by sampling and immersing the tissues in fixative within 15 minutes after euthanasia, by collecting tissue samples no thicker than 5 mm, and by maintaining the tissue samples in an adequate amount of fixative for a minimum of 24–48 hours. An experienced prosector can usually finish a rodent necropsy in 10–15 minutes, which allows rapid collection of tissues in fixative. Considering that the fixative solution penetrates through the surface of the tissue gradually, approximately 1 mm per hour, collecting small pieces of tissue will prevent autolysis within the center of the tissue sample. Most organs in mice can be sampled and fixed without sectioning because of their small size. Rabbits, guinea pigs, rats, and hamsters have larger organs, and therefore tissue samples no thicker than 5–6 mm have to be sectioned from these organs to accomplish adequate fixation. Regardless of size, it is recommended that the brain and testicles be fixed intact for a few hours before sectioning these organs in order to prevent distortion of the histological architecture by cutting. After 6–24 hours of preliminary fixation, depending upon the type of fixative and the size of the organ, the brain and testicles should be sectioned in 3–5 mm thick slices and returned to fixative for another 12–24 hours to complete the fixation. This sequence will enhance the penetration of fixative into the tissue and avoid autolysis within the center of the tissue sample, while preserving the morphology of tissue.

The volume of fixative in the container should be 10–20 times more than the volume of tissues sampled (Everitt and Gross, 2006; Feldman and Seely, 1988; Seymour et al., 2004). Maintaining the container with tissues and fixative on a shaker device during fixation will enhance the exposure of all surfaces of tissues to the fixative and will improve the quality of fixation.

Several chemical solutions are used for fixation of tissues, and all have different advantages and disadvantages, which determines their application in research and diagnostic investigations. Ten percent neutral-buffered formalin solution is the most commonly used fixative for preparation of tissues for histological examination and provides the best preservation of tissue morphology, at a convenient price and with less severe toxic effects than are seen with other fixatives. A major disadvantage of formalin fixation, however, is the continuous formation of cross-linking of amino groups in the tissue sample, resulting in conformational changes in the tertiary and quaternary structures of proteins and thus modifying the epitopes recognized by antibodies (Arnold et al., 1996; Ramos-Vara, 2005; Ramos-Vara and Saetelee, 2007; Ramos-Vara et al., 2008). Therefore, prolonged formalin fixation has a detrimental effect on immunohistochemical staining and RNA preservation of tissues (Leong and Gilham, 1989; van der Loos, 2007; van Maldegem et al., 2008; Werner et al., 2000), although many antibodies can detect antigens following up to 7 weeks of fixation of tissues in formalin (Webster et al., 2009). On the other hand, incomplete fixation of tissue may have a more detrimental effect on immunohistochemical results than overfixation (Webster et al., 2009; Werner et al., 2000; Yaziji and Barry, 2006). Most studies concluded that tissue samples should be immersed in formalin within 30 minutes of the animal's death or collection of a biopsy, and the tissues should be fixed in formalin for 24–48 hours (Werner et al., 2000). After 24–48 hours of fixation, the tissue samples should be extracted from the formalin and immediately trimmed for tissue processing and paraffin embedding. If trimming and tissue processing cannot be performed after the 48-hour fixation period, the tissue samples should be transferred to and maintained in 70% ethanol, which will prevent further cross-linking of peptides by the formalin. However, unlike ethanol, formalin can preserve indefinitely the morphological quality of tissue samples.

In addition to commonly used 10% neutral-buffered formalin and 70% ethanol, there are other fixative solutions that can be used for the fixation of tissues: Davidson's fixative, Bouin's fixative, Tellyesniczky's or Fekete's fixative, B5 fixative, Carnoy's fixative, Clarke's fixative, 4% paraformaldehyde fixative, glutaraldehyde fixative, Karnovsky's fixative, and JB4 fixative. Every fixative has different properties and different applications. The selection of proper fixative and fixation protocol is determined by the objectives of the

experiment, the methods of tissue examination, and the staining techniques required for the diagnostic or research investigation (Relyea et al., 2000).

A special fixation procedure is the perfusion method, which combines euthanasia with fixation (Relyea et al., 2000; Rostgaard et al., 1993). First, the animal is anesthetized; then, the thoracic cavity is opened and the blood samples collected. Next, the walls of the right atrium or the jugular veins are cut, and physiologic saline is injected into the left ventricular chamber of the heart for washing the blood out of the system. Subsequently, while the heart is still contracting, the fixative is injected into the left ventricular chamber of the heart through the same needle until the entire animal becomes stiffened and the animal is euthanized. After this procedure, the necropsy and tissue collection can be performed as usual. This fixation technique is performed when instant fixation of the brain, liver, kidney, or other tissue is necessary.

Once tissues are trimmed into small pieces no thicker than the depth of histology cassettes (2–3 mm) to permit adequate penetration of solvents and paraffin, trimmed pieces of tissue are placed in the desired orientation into labeled histology cassettes for processing and embedding in paraffin blocks. Trimming must be performed with sharp blades and gentle manipulation using toothless forceps in order to avoid damage of tissues and formation of artifacts. When trimming the tissue samples, it is important to capture in the selected section the lesion that was observed grossly and an area of peripheral, less-affected or normal tissue. Standard trimming techniques with specific sections of each organ are presented in previous publications (Bahnmann et al., 1995; Bono et al., 2000; Kittel et al., 2004; Morawietz et al., 2004; Relyea et al., 2000; Ruehl-Fehlert et al., 2003). Each histology cassette can contain one or multiple pieces of tissues. Related tissues of similar size and density or texture may be placed together in the same cassette.

Before trimming and tissue processing, formalin fixed bone tissues have to be decalcified properly with a decalcifying solution such as 5% or 10% formic acid or hydrochloric acid solution. However, excessive decalcification for too long (more than 24–48 hours) will damage the tinctorial properties of tissues and compromise the quality of H&E staining. Decalcified bones must be rinsed in running water for 3–4 hours before processing to avoid inadequate staining of tissues. Histology cassettes containing trimmed tissues that were only fixed or decalcified and rinsed should be placed in a container with 10% formalin or 70% ethanol solution and submitted to the histology laboratory for processing and paraffin embedding (Seymour et al., 2004). The cassettes containing decalcified but not previously rinsed tissues should be placed in water and rinsed thoroughly before introducing them into 70% ethanol. For histologic examination, paraffin-embedded tissues

should be cut in 3–5 µm thick sections mounted on a glass slide, and stained with H&E. Special histochemical or immunohistochemical stains of these tissues may be requested after the histopathological examination of H&E-stained sections.

Standard techniques of tissue sampling, fixation, trimming, embedding, processing, and staining must be applied uniformly to all tissues from the same study to avoid differences in staining quality and from one tissue to another, which could cause misinterpretation of tissue changes. This uniformity is particularly important in studies that require complex digital image analysis or morphometric measurements of tissues and lesions using sophisticated image analysis software. If the histologic sections are used in molecular biology investigations such as in situ hybridization, in situ polymerase chain reaction, and other RNA-based studies, specific protocols of tissue collection and processing must be employed to preserve the biological targets. All details presented here must be considered when performing the necropsy and processing the tissues for microscopic examination.

Acknowledgments

We thank Maurice J. Dufilho IV at The University of Texas MD Anderson Cancer Center for technical support with necropsy.

INTRODUCTION

This chapter will review zoonoses that can be acquired from handling hamsters, guinea pigs, rabbits, and other miscellaneous rodent species. Although the risk of acquiring a disease from many types of laboratory animals has decreased since most laboratory animals are now produced with defined microbiologic profiles, there are still instances when wild animals or field-collected animals are required for research. The use of wild rodents or field-collected rodents may expose the research staff to diseases that have been excluded, if not eliminated, from research colonies. Allergic responses to animals, particularly rodents, can also be a concern.

In general, some of these diseases require vectors for the transmission to humans while others can be directly transmitted. The control of vectors such as biting insects can effectively limit the spread of some vector-transmitted diseases. For some parasitic diseases, humans can serve as an intermediate host; for others humans are the final host of the parasite. In the latter case, the elimination of the intermediate host should prevent the complete lifecycle and protect the laboratory animal worker. Knowledge about the transmission of the disease will play a part in effectively reducing the risk of the pathogen.

The focus here is to review diseases that might be present in research animals and might be transmitted to immunocompetent research staff during experiments. Diseases that might be transmitted specifically to immune-compromised individuals are not covered. Finally, allergic reactions to laboratory animals are discussed because exposure to animal allergens represents a significant risk to personnel who handle animals.

VIRAL DISEASES

Hantavirus

Reservoir and Incidence

Hantavirus is a member of the Bunyaviridae family. At least 20 different viruses are recognized in this genus (Diglisic et al., 1999). Wild rodents are the reservoirs for these viruses (Fox et al., 2002). The incidence of serologic evidence for Hantavirus infection in both the human population and the resident rodent population has been reported by Diglisic et al. (1999). Norway rats in Baltimore, Maryland were reported to have a prevalence rate of 44% although the human rate is 0.74% demonstrating that although the incidence of the infection in the rodent population is prevalent, the human infection rate still remains low (Diglisic, 1999).

In contrast, nine workers at a laboratory animal facility were reported to have become infected with Hantavirus while working with known infected rats (Lee and Johnson, 1982). One person visited the animal housing rooms only twice, before acquiring the infection and being hospitalized for 2 weeks.

Mode of Transmission

Horizontal transmission via aerosolization of urine, feces, and saliva is the most common mode of transmission (Fox, 2002). Transmission can also occur via a rodent bite (Fox et al., 2002). Numerous cases of Hantavirus infection have occurred among laboratory animal facility personnel through exposure to infected rats with outbreaks reported in Korea, Japan, Belgium, France, and England (LeDuc, 1987). Person-to-person transmission has also been reported (Enríe et al., 1995).

Clinical Signs

In humans clinical signs are related to the strain of virus involved. Clinical signs can include fever, back pain, headache, myalgia, anemia, hematuria, gastrointestinal bleeding, and coughing (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Diagnosis and Prevention

Colonies of rodents should be tested for Hantavirus. Animal Biosafety Level 2 is recommended for work conducted with experimentally infected rodent species known not to excrete the virus. All work involving inoculation of the virus into *P. maniculatus* or other permissive species should be conducted at Animal Biosafety Level 4 (Centers for Disease Control, 1994).

Lassa Virus

Reservoir and Incidence

Lassa virus, the causative agent of Lassa fever, is a member of the family Arenaviridae. The multimammate mouse (*Mastomys natalensis*) is the only known non-human host for Lassa virus (Monath et al., 1974). Lassa antibody and antigen were found in 96 (11%) and 46 (5%), respectively, of 884 tested *Mastomys* (Demby et al., 2001). The proportion of Lassa virus-infected *Mastomys* per region in Guinea ranged from 0 to 9% and was highest in the savannah and forest zones. The proportion of infected animals per village varied considerably, even between villages in close proximity. Infected animals tended to cluster in relatively few areas, suggesting the existence of focal "hot spots" of Lassa virus-infected *Mastomys*, possibly accounting for the observed heterogeneous distribution of Lassa fever (Demby et al., 2001).

Mode of Transmission

Infection is believed to be transmitted through contact with the feces and urine of infected rodents. In the multimammate mouse, antibody and antigen were essentially mutually exclusive and showed profiles consistent with vertical transmission of both Lassa virus and antibody (Demby et al., 2001).

Clinical Signs

Lassa virus has a predilection for person-to-person spread within the hospital environment, with a high risk of infection in medical personnel. The hazard to laboratory investigators is also great (Monath et al., 1974). Case-fatality rates vary and have been reported as 18% by Bausch et al. (2001), and 43% among hospitalized patients by Monath et al. (1974).

Diagnosis and Prevention

The infection is not thought to be typically present within well-monitored populations of laboratory animal species. An ELISA antibody detection system exists and has been used to determine the prevalence of the virus in wild rodent populations (Demby et al., 2001).

Lymphocytic Choriomeningitis Virus

Reservoir and Incidence

Mice and hamsters are known to be reservoirs for lymphocytic choriomeningitis virus (LCMV). LCMV is a member of the family, Arenaviridae (Fox et al., 2002).

Mode of Transmission

LCMV can be transmitted among mice horizontally through secretions (urine, saliva, and feces). Offspring develop persistent infections and shed the virus during most of their lives (Jacoby et al., 2002). Infections in humans can occur after inhalation, ingestion, and direct contact with LCMV-contaminated urine, feces, and saliva of infected mice, hamsters, and guinea pigs (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

There are many case reports of zoonotic disease related to LCMV in the literature. One specific case report documented several cases of LCMV transmission to humans from a pet hamster with a propensity for biting its owners (Amman et al., 2007; Gregg, 1975; Hirsch et al., 1974).

Several case reports have been published that traced the source of contamination to hamster tumor lines. One outbreak of 48 human cases occurred between 1971 and 1973. Most cases occurred in personnel visiting or using a photocopier in the basement of the radiotherapy department of a large hospital in upper New York State. The photocopier was located in the same room as about 200

Syrian hamsters. Clinical signs in humans were characterized mainly by sudden onset of fever (102–104°F), severe prostration, headache, and myalgia. Convalescence was protracted, but there was little evidence of meningitis. No deaths were reported with this outbreak (Hotchin et al., 1974). This case report demonstrated that limited contact with persistently infected hamsters is sufficient to transmit the disease to humans. The outbreak was traced to a supplier of hamster tumor lines that were found to be positive for LCMV (Gregg, 1975).

The following year, a nationwide epidemic in the United States in 1973 and 1974 involving 181 human cases was associated with one pet hamster breeder in Birmingham, AL. This breeder was also employed by a biologics firm that sold hamster tumor lines that were implicated in the New York outbreak (Gregg, 1975).

In early April 2005, four recipients of solid-organ transplants in three hospitals in Rhode Island and Massachusetts became gravely ill shortly after transplantation; three subsequently died. All four recipients shared a common donor. LCMV was identified as the etiologic agent. Viral sequences from the organ recipients were identical to those from a pet hamster acquired by the donor's household 17 days before organ donation (Amman et al., 2007). The source of the hamster was found to be a breeding facility in Arkansas. Further investigation by the United States Centers for Disease Control and Prevention (CDC) found that the animals from this breeding colony were distributed to 22 states. The CDC and pet industry are now working toward ways of educating consumers to the risks of owning pet rodents and also developing guidelines to prevent additional infections (Nolen, 2006).

Clinical Signs

Approximately half of the hamsters infected congenitally or as newborns develop a chronic progressive fatal disease characterized by inactivity and weight loss. Other animals infected in vivo or as newborns and young adults develop subclinical infections (Hankenson and Van Hoosier, 2002).

Approximately one-third of human cases of lymphocytic choriomeningitis have been asymptomatic. Humans with the infection manifest symptoms of aseptic meningitis, meningoencephalitis, transverse myelitis, Guillain-Barré syndrome, and permanent or transient hydrocephalus (Barton and Hyndman, 2000). Other clinical signs in humans include: fever, myalgia, headache, photophobia, nausea, and variable involvement of the testes and salivary gland. The disease is rarely fatal. Intrauterine infections of fetuses have been well documented and can result in hydrocephalus, microencephaly, macroencephaly, intracranial calcification, mental retardation, seizures, and fetal death (Barthold and Smith, 2007).

Diagnosis and Prevention

Regular testing of hamster colonies as well as mice and guinea pigs for evidence of LCMV infection should be conducted. If an infection with LCMV is diagnosed, all animals in the colony should be euthanized. If a cell line or transplantable tumor is determined to be the source of the infection, it also should be destroyed.

Rabies Virus

Reservoir and Incidence

Although wild animals were shown to be the reservoir for rabies virus in one study, lagomorphs were not incriminated (Childs et al., 1997). In contrast, another review of cases in New York between 1992 and 2001 documented seven rabid rabbits, and one rabid guinea pig was also described (Eidson et al., 2005). Reports of rabid guinea pigs and wild rodents are extremely rare (Fishbein et al., 1986).

Mode of Transmission

The mode of transmission is through the bite of a rabid animal or the contamination of a wound by saliva from an infected animal.

Clinical Signs

In one review of seven cases of rabies in rabbits, most rabbits presented with neurologic symptoms, although lethargy and inappetance were also noted in one case (Eidson et al., 2005). The one rabid guinea pig reported in the literature became aggressive approximately 21 days after being bitten by a rabid raccoon and bit the owner (Eidson et al., 2005).

Diagnosis and Prevention

Histological examination of the brain is required to confirm a diagnosis of rabies.

The capture of wild rabbits or rodents poses a relatively minor risk of rabies exposure for laboratory personnel. The time from exposure to clinical signs for guinea pigs and rabbits appears to be less than 4 weeks (Eidson et al., 2005). Rabies should be suspected in feral animals with neurologic abnormalities. This disease poses few concerns when using laboratory-raised animals, as it is extremely unlikely for well-maintained laboratory-raised animals to be infected with the rabies virus.

RICKETTSIAL DISEASES

Coxiella burnetii

Reservoir and Incidence

Rickettsial organisms are obligate intracellular, Gram-negative bacteria. *Coxiella burnetii* is the etiologic

agent of Q fever. In national disease surveillance reports for 1948–1986, 1396 human cases were reported, from almost every state (McQuiston and Childs, 2002). Among published individual case reports and outbreak investigations, occupational exposures (i.e., at research facilities, farm environments, and slaughterhouses) were commonly reported, and sheep were most frequently implicated as a possible source of infection. *Coxiella burnetii* was also reported among various wild-animal species, including coyotes, foxes, rodents, skunks, raccoons, rabbits, deer, and birds (McQuiston and Childs, 2002). One human case report documented four patients with atypical pneumonia and a history of exposure to wild rabbits (Thomas et al., 1986).

Mode of Transmission

Inhalation of the organism is the most common mode of transmission. Infection via aerosol may occur directly from parturient fluids of infected animals, and may be associated with newborn animals, placental tissue, or wool. *Coxiella burnetii* is very resistant to inactivation in nature and may survive for several weeks in areas where rodents and rabbits have been present. The organism may also be spread by the wind (Maurin and Raoult 1999).

Clinical Signs

Animals infected with *Coxiella burnetii* do not usually experience symptomatic infections. In the acute phase, the presence of *C. burnetii* may be demonstrated in the blood, lungs, spleen, and liver. Most animals remain totally asymptomatic, including a lack of fever. *C. burnetii* infection often becomes chronic, with persistent shedding of the pathogen in feces and urine (Maurin and Raoult, 1999).

Chronic endocarditis, myocarditis, pericarditis, skin rash, and meningoencephalitis are some of the many clinical signs observed in humans. Infections during pregnancy have been reported in the literature many times, and Maurin and Raoult (1999) summarized 27 of these cases. Premature birth was reported in eight cases; spontaneous abortions were reported in six cases; and death in utero was reported in two cases. Only five healthy infants were born at term in these 27 cases.

Diagnosis and Prevention

Serology is an important tool for diagnosis of Q fever in humans and animals (Thomas et al., 1986). Colonies of animals should be screened for serum antibodies to *C. burnetii* and infected animals eliminated from the colony. Sources of sheep, goats, and cattle should be monitored to assure freedom from infection, and any research involving placental tissues from these species should be considered an additional risk and appropriate precautions taken.

This disease poses few concerns when using laboratory-raised rodents or rabbits, but the use of wild rabbits in research may expose laboratory workers to *C. burnetii*.

Rickettsia akari

Reservoir and Incidence

Rickettsial pox is caused by infection with *Rickettsia akari*. It was originally described along the east coast of the United States, but has recently been reported in the Ukraine and Croatia. The organism has also been isolated from voles in Korea, but the human disease has not been reported in Korea (Krusell et al., 2002). There are also reports of the disease in Russia, Egypt, and South Africa (Fox et al., 2002). Wild mice and voles are reservoirs of the bacteria (Fox et al., 2002; Krusell et al., 2002).

Mode of Transmission

The pathogen is transmitted by the mite *Liponyssoides sanguineus*. Data suggest that silent sylvan cycles of *R. akari* infection exist and that the organism is more widely distributed than generally appreciated (Krusell et al., 2002).

Clinical Signs

There are no clinical signs associated with infection in animals. In man, the rash of rickettsial pox commences as a discrete maculopapular rash which then becomes vesicular. About 90% of affected persons develop an eschar, with a shallow ulcer covered by a brown scab (Fox et al., 2002). The palms of the hands and soles of the feet are not affected.

Diagnosis and Prevention

Ectoparasite control in wild rodent populations is essential, particularly the elimination of free-living mites capable of transmitting the agent (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Rickettsia rickettsii

Reservoir and Incidence

In the western hemisphere, wild rodents and rabbits are reservoirs for *Rickettsia rickettsii*, the causative agent for Rocky Mountain spotted fever (Elliot et al., 1985). In humans, illness is usually seen during the months of high tick activity, however only 60% of the patients have a history of observed tick exposure (Elliot et al., 1985).

Mode of Transmission

Zoonotic transmission of this disease in the laboratory has involved aerosols, accidental parenteral

inoculation, and bites by natural ectoparasites (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Clinical Signs

The disease is asymptomatic in animals. The most common findings in humans are fever (97%); headache (87%); truncal rash (85%); and rash on the palms and soles (62%) (Elliot et al., 1985).

Diagnosis and Prevention

Ectoparasite control in wild rodent populations is essential, particularly the *Rhipicephalus sanguineus* tick which is known to transmit the pathogen (Fox et al., 2002). Often, the control of ectoparasites involves control of wild rodent populations.

CHLAMYDIAL DISEASES

Chlamydophila caviae

Reservoir and Incidence

Guinea pigs can serve as a reservoir for *Chlamydophila caviae*. Rabbits can also be infected with *Chlamydophila caviae* (Lutz-Wohlgroth et al., 2006).

Mode of Transmission

The mode of transmission in the one case reported was never determined (Lutz-Wohlgroth et al., 2006).

Clinical Signs

Only one case of human infection exists in the literature. This report described a single case of seromucous ocular discharge and mild conjunctivitis in a single individual. This person was the owner of approximately 200 guinea pigs. Approximately 25% of these guinea pigs exhibited clinical signs that include ocular discharge, conjunctivitis, chemosis, entropion, keratitis, corneal edema, corneal erosion, nasal discharge, sneezing, stridor, dyspnea, pneumonia, vaginal discharge, and abortion (Lutz-Wohlgroth et al., 2006).

Diagnosis and Prevention

PCR amplification was used to diagnose all cases of the infection (Lutz-Wohlgroth et al., 2006). Due to the paucity of reported cases, it is believed that this disease poses few concerns when using laboratory-raised animals.

Chlamydophila psittaci

Reservoir and Incidence

Chlamydial agents are widely distributed among birds but can also occur in laboratory animals including

mice, guinea pigs, hamsters, rabbits, ruminants, swine, cats, ferrets, muskrats, and frogs (Fox et al., 2002).

Mode of Transmission

The organism is spread to humans from infectious material in exudates, secretions, or desiccated fecal material via direct contact or the aerosol route (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Clinical Signs

Clinical signs in animals can include conjunctivitis, pneumonitis, myocarditis, hepatitis, enteritis, arthritis, meningoencephalitis, endometritis, and abortion (Fox et al., 2002). In humans, clinical signs can include those associated with upper or lower respiratory disease, conjunctivitis, thrombophlebitis, myocarditis, hepatitis, and encephalitis (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Diagnosis and Prevention

Diagnosis can be made by demonstrating serum antibodies to *C. psittaci*, or by using PCR to amplify the bacterial DNA (Hankenson et al., 2003).

BACTERIAL DISEASES

Bordetella bronchiseptica

Reservoir and Incidence

A single case report implicated rabbits as the reservoir for the infection (Gueirard et al., 1995).

Mode of Transmission

The mode of transmission was never determined but assumed to be by nasal inoculation of aerosolized bacteria.

Clinical Signs

It was reported that a 79-year-old woman developed acute febrile bronchopneumonia (Gueirard et al., 1995). She lived on a farm and had significant exposure to a cat and to rabbits, and the cat and the rabbits had symptoms compatible with bordetellosis (cough associated with rhinorrhea, conjunctivitis, and diarrhea). Nasal and pharyngeal swabs were performed on the cat, but *B. bronchiseptica* was not isolated. During a subsequent infection, the cat had no sign of bordetellosis, but the rabbits did. One rabbit was sacrificed, and though cultures from the upper respiratory tract failed to isolate bacteria, *B. bronchiseptica* was isolated in pure culture from the hilus and bronchi (Gueirard et al., 1995).

Diagnosis and Prevention

Bacterial culture of respiratory secretions or tissues of the nasopharynx and respiratory tract is typically used to isolate *B. bronchiseptica* from animals suspected of being infected. This disease poses few concerns when using well-maintained laboratory-raised animals due to low prevalence of infection in such animals.

***Borrelia burgdorferi* (Lyme's Disease)**

Reservoir and Incidence

Sylvilagus floridanus (cottontail rabbit) can serve as a host for the cycle of *Borrelia burgdorferi* (Telford and Spielman, 1989). The disease in humans is called Lyme disease and is endemic in the eastern United States, Europe, and Asia (Steere, 2001).

Mode of Transmission

Ixodes dammini (the deer tick) is the vector which transmits *B. burgdorferi* to susceptible animals. In one study, 90% of cottontail rabbits sampled had serum antibodies against *B. burgdorferi* (Telford and Spielman, 1989). Control of the ticks or tick larvae should limit the exposure to *B. burgdorferi*. Rabbits are not considered to be infectious since an infection cannot be directly transmitted from the rabbit (Telford and Spielman, 1989).

Clinical Signs

Clinical signs related to infection with *B. burgdorferi* have not been reported in rabbits. At least 80% of the infected patients in the United States exhibit a slowly expanding skin lesion, erythema migrans, which occurs at the site of the tick bite. This is frequently accompanied by influenza-like symptoms including malaise, fatigue, headache, arthralgias, myalgias, fever, and regional lymphadenopathy (Steere, 2001). Advanced stages of the disease can be characterized by meningitis, polyneuropathy, encephalopathy, arthritis, and atrio-ventricular block (Steere, 2001).

Diagnosis and Prevention

Serologic analysis to determine if antibodies against *Borrelia burgdorferi* are present is a typical diagnostic approach (Telford and Spielman, 1989). This disease poses few concerns when using laboratory-raised animals.

***Francisella tularensis* (Tularemia)**

Reservoir and Incidence

Rabbits, ticks from rabbits, and deerflies feeding on rabbits are the main reservoirs for *F. tularensis* (Hoff et al., 1975; Klock et al., 1973). In the United States, wild

rabbits of the genus *Sylvilagus* (cottontails, marsh rabbits, and swamp rabbits) present the greatest hazard. Jackrabbits and snowshoe hares are susceptible to tularemia but have rarely been implicated as direct sources of human infection. The domestic rabbit (*Oryctolagus cuniculus*) has not been documented as a source of human tularemia (Centers for Disease Control, 1986).

Mode of Transmission

Exposure of the skin or conjunctiva to blood and other infectious tissue while skinning and dressing rabbits account for most cases. In some instances, pulmonary tularemia has resulted from breathing aerosols generated while handling unopened rabbit carcasses or merely by direct contact with a dead rabbit (Centers for Disease Control, 1986). In 1970, 18 people living in Hungary were diagnosed with tularemia. The source of the infection was wild-caught hamsters and all people involved were hamster trappers (Szekelyfoldi, 1970).

Clinical Signs

In humans the clinical signs depend on the inoculation route. The most common presentation is the ulceroglandular form, due to inoculation of the extremities or the conjunctiva. Ingestion of contaminated food or water or hand-to-mouth contact after handling an infected animal can cause oropharyngeal tularemia. Inhalation of infected material produces pneumonic disease characterized by severe dyspnea (Elliot et al., 1985).

Diagnosis and Prevention

Serology and a history of exposure to wild rabbits or hamsters are important for diagnosis. This disease poses few concerns when using laboratory-raised animals. The maintenance and use of wild rabbits or rodents may pose a minor risk of exposure for laboratory personnel.

***Leptospira* spp.**

Reservoir and Incidence

Leptospira spp. has a worldwide distribution in domestic and wild animals. It can also be isolated from dogs, pigs, sheep, goats, cats, gerbils, and hamsters (Hankenson et al., 2003).

Mode of Transmission

Leptospiral agents are shed in the urine of reservoir animals. Transmission can be by oral ingestion; exposure to contaminated urine, placenta, fetal tissues; and by inhalation. Organisms can also infect hosts through abrasions in the skin or musosal surfaces (Hankenson et al., 2003).

Clinical Signs

Animals are asymptomatic and carry the organism in their renal tubules for years. Mice are believed to harbor the organism for life ([Committee on Occupational Safety and Health in Research Animal Facilities, 1997](#)).

Diagnosis and Prevention

Serology or isolation of the organism is typically used for diagnosis. PCR amplification of *Leptospira* DNA from wild rodent kidney tissue has been reported as a means of diagnosis ([Pezzella et al., 2004](#)). The capture of wild rodents may pose a risk of exposure for laboratory personnel; however this disease poses few concerns when using laboratory-raised animals.

***Salmonella* spp.**

Reservoir and Incidence

Many mammals, as well as non-mammal vertebrates, and wild mice can serve as reservoirs for *Salmonella* spp. ([Meerburg et al., 2006](#); [Pocock et al., 2001](#)). In this regard, wild-caught rodents may pose some risk to personnel, though most rodents available from high-quality commercial vendors are free of *Salmonella*. Hamsters from pet stores or from pet distributors have been demonstrated to be a potential source of infection for humans. In 2004, a pet distributor reported to the Minnesota Department of Health that two hamsters died from salmonellosis. The bacterial isolate involved in this outbreak was determined to be multidrug-resistant *Salmonella typhimurium* ([Swanson et al., 2007](#)). Further epidemiology identified 13 human cases of *Salmonella* from patients who had contact with rodents purchased at retail pet stores ([Centers for Disease Control, 2005](#); [Swanson et al., 2007](#)). Eventually, the strain involved in the outbreak was also found in rodent cages and transport containers from another pet distributor ([Peota, 2007](#); [Swanson et al., 2007](#)).

Mode of Transmission

Ingestion of water or food that has been contaminated by the feces of infected animals is the primary mode of transmission.

Clinical Signs

Enteritis was the clinical presentation in one outbreak in hamsters ([Swanson et al., 2007](#)). This is unusual since enteritis is not usually a clinical feature of *Salmonella* infection in the hamster. The disease is more often characterized by multifocal necrosis of the liver ([Hankenson and Van Hoosier, 2002](#)). Previously, the disease was reported to present in hamsters as septic pulmonary phlebothrombosis ([Innes, 1953](#)).

Diagnosis and Prevention

The use of *Salmonella*-free hamsters bred specifically for research has greatly diminished the concern for this disease in the research laboratory. The use of hamsters from pet store sources may pose a risk for laboratory humans.

Streptobacillus moniliformis

Reservoir and Incidence

Wild or laboratory rats, mice, *Motomys alexis* (Spinifex hopping mice), gerbils, squirrels, guinea pigs, dogs, cats, ferrets, weasels, calves, pigs, turkey, koala, and non-human primates can serve as the reservoir for this bacteria ([Gaastra et al., 2009](#)). When the disease is transmitted via a bite or scratch the disease is called rat bite fever. If humans become orally infected, the disease is called Haverhill fever ([Gaastra et al., 2009](#)).

Mode of Transmission

The bacteria can be transmitted by urine and the secretions of the mouth, nares, or conjunctival sac. The disease can also be transmitted through indirect inoculation via contaminated fomites or through trauma to unprotected skin ([Hankenson et al., 2003](#)). The disease can also occur in individuals who have no history of rat bites, but who reside or work in rat-infested areas ([Fox et al., 2002](#)).

Clinical Signs

The disease is asymptomatic in rodents. Humans can develop chills, fever, headache, myalgia, weakness, regional lymphadenopathy, and joint pain.

Diagnosis and Prevention

Diagnosis is made after the isolation of the agent from the oral cavity, nares, and conjunctival sacs on appropriate culture media. PCR has been successfully used to diagnose the disease ([Gaastra et al., 2009](#)). The exclusion of infected rodents from production colonies by commercial supplies has been largely successful in preventing the disease in laboratory personnel ([Committee on Occupational Safety and Health in Research Animal Facilities, 1997](#)).

Spirillum minus

Reservoir and Incidence

Spirillum minus has been isolated from the oropharynx, blood, and exudates of up to 25% of wild rats. Nasopharyngeal carriage rates of 50–100% in wild rats have also been reported ([Gaastra et al., 2009](#)).

Mode of Transmission

The transmission is the same as for *S. moniliformis*. This disease occurs less frequently than rat bite fever and occurs mainly in Asia. In Japan, the disease is known as sodoku (Gaastra et al., 2009).

Clinical Signs

The disease is asymptomatic in rodents. Humans develop a distinctive rash of red to purple-colored plaques. Compared to *S. moniliformis*, arthritis rarely develops due to infection with this organism (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Diagnosis and Prevention

The agent does not grow well in culture. Diagnosis can be made after animal inoculation of infected tissue or fluid and identification of the organism by dark field microscopy (Hankenson et al., 2003). The exclusion of infected rodents from production colonies of commercial suppliers has been largely successful in eliminating the disease in the laboratory (Committee on Occupational Safety and Health in Research Animal Facilities, 1997).

Yersinia pestis

Reservoir and Incidence

Rabbits and other wild rodents are known to be reservoirs for *Yersinia pestis* (von Reyn et al., 1976). The incidence of this disease has been well documented in areas where people encounter a nidus of sylvatic plague (Kartman, 1970).

Mode of Transmission

The disease is transmitted by the bite of an infected flea, but infections can also occur via cuts or abrasions in the skin or exposure of mucous membranes to infected aerosols (Fox et al., 2002).

Clinical Signs

There are no clinical signs in rabbits infected with *Y. pestis*. The disease in humans presents in three distinct forms: bubonic or suppurative lymphadenopathy; pneumonic; and septicemic plague. All forms of the disease include fever, headache, and weakness as clinical signs.

Diagnosis and Prevention

A presumptive diagnosis of *Y. pestis* is made after identification of Gram-negative bipolar staining rods in sputum or lymph node biopsy samples (Fox et al.,

2002). Infections with *Y. pestis* are rare in laboratory-raised animals. Feral or random source animals acquired from plague-endemic areas should be quarantined and treated with appropriate insecticides to kill fleas (Fox et al., 2002).

FUNGAL DISEASES

Dermatophytosis

Reservoir and Incidence

The most common genera of fungi responsible for disease in animals and humans are the dermatophytes: *Microsporum*, *Epidermophyton*, and *Trichophyton* (Fox et al., 2002). In New Zealand, *Trichophyton mentagrophytes* was found to be widespread among a variety of animals including: mice, rats, hedgehogs, opossums, guinea pigs, cats, dogs, horses, and cows (Smith et al., 1969). In Italy, the eastern cottontail (*Sylvilagus floridanus*) has been shown to be a carrier of several zoonotic dermatophytes (Gallo et al., 2005). Other case reports of fungal infections in guinea pigs (Hironaga et al., 1981), and rabbits (Aho, 1980) are found in the literature. *Microsporum canis* has also been reported in laboratory-housed New Zealand White rabbits (Vogtsberger et al., 1986).

Mode of Transmission

Transmission to humans occurs from direct or indirect contact with symptomatic or carrier animals; contaminated bedding, caging, or other equipment; or fungal contamination of the environment (Fox et al., 2002).

Clinical Signs

The skin lesions on laboratory animals are often localized to the head or trunk. The disease in rabbits is characterized by focal irritation and inflammation of the skin. Crusting lesions, scabs, and hair loss are also common (Chomel, 1992).

Diagnosis and Prevention

Diagnosis is made by identification of hyphae in skin scrapings or by isolation of the dermatophyte on fungal culture media (Chomel, 1992). The use of the ultraviolet Wood's lamp is generally non-diagnostic, since most pathogenic dermatophytes of small mammals do not fluoresce (Pollock, 2003). This disease poses relatively limited concern when using laboratory-raised animals; however, feral or random source animals may pose a greater risk of dermatophytosis to personnel handling such animals.

CESTODE INFECTIONS

Rodentolepis nana

Reservoir and Incidence

This tapeworm of hamsters was formerly known as *Hymenolepis nana*. It can be found in the small intestinal tract of hamsters, mice, rats, non-human primates, and humans (Hankenson and Van Hoosier, 2007).

Mode of Transmission

R. nana can have either a direct or indirect lifecycle. Flour beetles and fleas can serve as the intermediate host. The direct lifecycle is 14–16 days and autoinfection can occur (Hankenson and Van Hoosier, 2002).

Clinical Signs

The condition is often benign, but depends on the number of tapeworms present and the degree of intestinal occlusion (Hankenson and Van Hoosier, 2002). Catarrhal enteritis, chronic enteritis, abscesses of mesenteric lymph nodes, and hyperplasia of Peyer's patches have been observed in infected hamsters (Wagner, 1987). Symptoms in humans include nausea, vomiting, abdominal pain, diarrhea, irritability, restless sleep, and allergic symptoms. One-third of infected humans develop peripheral eosinophilia of greater than 5% (Feldman and Easton, 2006).

Diagnosis and Prevention

Diagnosis can be made by the identification of cestode eggs in the feces or finding adult worms in the gastrointestinal tract. The use of hamsters from colonies free of the infection is recommended. The use of wild rodents may increase the risk for husbandry workers and other individuals handling such animals.

ARTHROPOD INFECTIONS

Cheyletiellosis

Reservoir and Incidence

Cheyletiella mites are non-burrowing mites that have a 36-day life cycle, with two nymphal stages and one larval stage. The rabbit, cat, and dog serve as reservoirs for the mite. All stages of the lifecycle occur on the animal (Parish and Schwartzman, 1993).

Mode of Transmission

This mite can be transmitted to humans through direct contact with infested animals. The mite can also be transmitted by flies, fleas, and lice (Parish and Schwartzman, 1993).

Clinical Signs

The *Cheyletiella* mite produces a non-specific cutaneous scaling with or without pruritus. The lesions on humans vary from vesicles to papules, most often on the trunk and in particular at locations where the infested animal is held against the person's body (Parish and Schwartzman, 1993).

Diagnosis and Prevention

This disease poses few concerns when using laboratory-raised animals. The handling of wild rabbits poses a minor risk of exposure to laboratory personnel.

ALLERGIES

Allergic reaction to animals is common and represents an important occupational health concern. One study of 5641 laboratory workers in Japan found that 23.1% had one or more allergic symptoms related to laboratory animals (Aoyama et al., 1992). Much work on this issue has been done using rat, mouse, and rabbit antigens. Fewer case reports exist that describe the development of symptoms for people working with guinea pigs and hamsters. Lutsky et al. (1983) reviewed the literature and reported that a large number of research animal facilities documented workplace hypersensitivity to rats (72.2%) and rabbits (67.7%), while only a few observed occupational hypersensitivity to hamsters (4.5%).

The most common symptom associated with allergy to animals is rhinitis. In contrast, another study found that allergic reaction to animal dander is estimated to occur in only 6% of the general population (Elliot et al., 1985). Secondary exposure to animal allergens is also well documented. One study performed in Poland described that children of parents who work with laboratory animals presented significantly more positive skin prick tests against allergens from the hair of laboratory animals compared to children of non-exposed parents (Krakowiak et al., 1999). It was thought that the children were secondarily exposed due to poor hygienic conditions at their parents' workplace.

Cross reaction between allergic responses to allergens of different laboratory animal species may occur. The presence of allergy to mice in some laboratory animal technicians who had worked with only rats, but not mice, suggested that there is some cross sensitization between allergens present in rat and mouse urine (Agrup et al., 1986). Cross sensitivity also seems to exist between guinea pig and hamster allergens. One study reported that nine people who were allergic to guinea pigs also reacted to hamsters, although only one had had occupational contact with hamsters (Agrup et al., 1986).

The incidence of laboratory animal allergies increases as a factor of time spent exposed to the animal antigens, but only for the first several years. One report indicated that it is rare for laboratory animal allergies to develop later than 3 years after exposure (Bland et al., 1987); and most workers were found to have developed laboratory animal allergies between 1 and 4 years from the time of first exposure (Lutsky et al., 1983).

Exposure to the environment in which rabbits are housed has been closely studied as a factor in the allergic response to rabbit allergens. Ooms et al. (2008) found that airborne contaminants in rabbit rooms include particulate material, endotoxin, ammonia, carbon dioxide, and rabbit salivary secretions which contain high levels of rabbit salivary protein allergen. Other airborne contaminants in rabbit rooms include fur, epidermal cells, feces, urine, saliva, feed, and bedding. It was shown that the level of rabbit salivary protein in the room increased over the 2-week sampling period but not significantly, indicating that replacement of dirty litter pans did little to decrease environmental contamination with that allergen (Ooms et al., 2008). In contrast to the Ooms' study, Edwards et al. (1983) determined that increasing the humidity from 54% to 77% caused a significant reduction in laboratory animal allergen levels. These two studies strongly implicate the animal room environment, and not just the animal itself, as an important factor in animal-related allergies.

PREVENTION OF ALLERGY AND ZOONOTIC DISEASE

The prevention of laboratory animal allergy has been addressed in several ways. Pre-employment screening of susceptible individuals using a family history of allergy and positive skin prick reactions against environmental allergens has been suggested as one means to mitigate allergy risk (Sjostedt and Willers, 1989). Consideration should be given to protecting workers from environments or objects contaminated by animal allergens rather than just the animal itself (Lutsky, 1987). Engineering controls, workplace protection systems, and personal protective equipment should have a potential role in controlling allergen exposure and the severity of laboratory animal allergies.

Engineering controls are a combination of safety equipment and physical features of the facility that help minimize hazardous exposures of personnel and the surrounding environment. Safety equipment provides a barrier between the worker and the hazard. Physical features can prevent or reduce the exposure to the hazardous agent (Committee on Occupational Safety and Health in Research Animal Facilities, 1997). The principle of dilution and room air turnover rates have not

been shown to be effective in the removal or dilution of submicron aeroallergens except at energy-intensive fresh air exchange rates in excess of 100 air changes per hour (Swanson et al. 1990). However, other engineering controls can be important protective measures. Common engineering controls used to reduce the exposure of workers to animal allergens and zoonoses include: use of isolation cages, air locks, temperature and humidity controls as well as facility ventilation systems that prevent airborne contaminants from leaving the animal facility.

Work practices are another means to reduce the exposure of workers to laboratory animal allergens and zoonoses. Employees should understand the hazard associated with the procedures that they are performing, recognize the route through which they can be exposed and select work practices that minimize exposure (Committee on Occupational Safety and Health in Research Animal Facilities, 1997). One of the easiest ways to prevent exposure is to restrict access to animal areas. Additionally, exposure can be reduced by washing and decontamination of areas and equipment.

The use of personal protective equipment is an important measure for controlling exposure to allergens as well as other potentially hazardous agents. Personal protective equipment provides a physical barrier to hazardous material that might otherwise come into contact with employees' skin, eyes, mucous membranes, and clothing. Proper consultation with occupational safety professionals should occur as part of establishing standards for use of personal protective equipment.

The prevention of pathogen transmission from animals to personnel should be a major concern when working with such agents or animals thought to carry pathogens. The use of pathogen-free animals is not always feasible. When pathogens cannot be eliminated, or when pathogen status of an animal is unknown, the use of protective clothing, personal hygiene, sanitation measures, engineering controls, and workplace protection systems are essential for diminishing exposure risk. When known agents are used, the use of vaccines can also assist in protecting personnel.

The Domestic Rabbit, *Oryctolagus Cuniculus*: Origins and History

Katherine A. Naff and Suzanne Craig

The University of Texas M. D. Anderson Cancer Center, Houston, Texas, USA

OUTLINE

Introduction and Background	157	Domestication and Breed Development	160
Phylogeny and Taxonomy	158	Ecology and Conservation	161
Geographic Origins and Diversity	159	References	162

INTRODUCTION AND BACKGROUND

All varieties of domestic rabbits used in modern biomedical research were developed from the European rabbit, *Oryctolagus cuniculus*. The European rabbit possesses a mixture of features that make it an appealing model for in vivo research: an intermediate body size, tractable disposition, ability to breed readily in captivity, and a short generation time. Given its obvious utility as a research subject, it seems equally obvious that the European rabbit would be richly represented in the scientific literature from the Age of Enlightenment onward. However, the rabbit as a research model rates barely a mention until the mid-19th century, when the Viennese physician Schroff noted that some rabbits were able to thrive on a diet of belladonna, an observation that led to the discovery of atropine esterase and is credited with being the first documented discovery of a heritable response to a pharmacological agent (Liebenberg and Linn, 1980; Stormont and Suzuki, 1970). As breed standards improved and production facilities moved from the backyard to commercial rabbitries, acceptance of rabbits as research models increased. During the early to mid-20th century, the European rabbit became an indispensable tool of

biomedical research, contributing to pivotal discoveries across multiple disciplines including immunology, vaccine development, genetics, and infectious disease research. The suitability of the European rabbit as a research animal was greatly enhanced by the efforts of the Rabbit Experimental Station in Fontana, California. Established by the United States Department of Agriculture in 1928, the Fontana Station operated continuously until 1965 and was dedicated to the improvement of breeding and husbandry of rabbits raised for meat and fur. The techniques developed at the Fontana Station laid the foundation for best practices used in modern large-scale production facilities that now supply healthy laboratory rabbits to academia and industry.

The publication of Russell and Burch's *Principles of Humane Experimental Technique* in 1959 ushered in the postmodern era of in vivo research. The scientific community's adoption of the principles of reduction, replacement, and refinement, combined with the burgeoning of genetic engineering technologies in the last quarter of the 20th century, put the laboratory mouse at the forefront of biomedical research, at least in terms of numbers used. Analyzing international trends in animal use, particularly at the species level, is problematic due to differing reporting requirements and counting

methods (Omoe, 2006); however, the number of rabbits used in research over the last two decades appears to have declined. In the United States, Great Britain, and Canada, where accounting for numbers of rabbits used in research is government-mandated, the numbers reported have leveled off or decreased over the last several years (Gauthier, 2004; Reports of Research Facilities, 1998–2004; Statistics on the use of animals in Great Britain, 2002–2008). In Japan, where animal use data are collected by survey methods and reporting is voluntary, the numbers of all animals used in research, excluding rats and mice, are believed to have decreased since 1991 (Matsuda, 2004). However, it would be incorrect to infer that the European rabbit's usefulness as an animal model has waned. A keyword search of the Ovid MEDLINE database using the terms "experimental model, animal" and "rabbit" resulted in 6329 citations for the period 2000–2010. Clearly, the European rabbit continues to play an essential role in biomedical progress, particularly in safety testing, preclinical studies, and translational research.

At various times throughout history, man has regarded the European rabbit as a game species, agricultural commodity, research model, invasive pest, endangered species, and companion animal. Yet despite the European rabbit's familiarity, economic and ecological significance, and scientific importance, its evolutionary history is still debated, and the story of its domestication is largely a matter of myth and conjecture.

PHYLOGENY AND TAXONOMY

Historically, naturalists have hypothesized a close relationship between rodents and lagomorphs based on their shared characteristic of hypsodontic incisors adapted for gnawing (Meng and Wyss, 2005; Rose, 2006). Linnaeus initially proposed the clade Glires as a way of grouping the rodents, rabbits, and closely related taxa based upon morphological similarity (Douzery and Huchon, 2004; Rose, 2006). Despite its intuitive appeal and the convergence in the last 50 years of the molecular, paleontological, and morphological evidence, the hypothesis that these animals have a monophyletic origin has been debated ever since. Craniodental morphological analyses mainly support the Glires hypothesis (Asher et al., 2005; Frahner, 1999; Mess, 1999), as do most phylogenetic studies based on analysis of mitochondrial and nuclear DNA sequences (Douzery and Huchon, 2004; Huchon et al., 2002; Lin et al., 2002; Meng and Wyss, 2005). Even so, the question "What, if anything, is a rabbit?" (Wood, 1957) lives on into the 21st century. Two recent studies appear to refute the monophyly of Glires altogether. Phylogenetic trees based on probability

analysis of orthologous proteins (Graur et al., 1996) and nuclear genes (Misawa and Janke, 2003) demonstrate that lagomorphs may be more closely related to humans than to rodents, suggesting that at least some of the morphological similarities between lagomorphs and rodents may have evolved independently.

The taxonomic history of the European rabbit is equally convoluted. Originally named *Lepus cuniculus* by Linnaeus in 1758, the European rabbit initially shared this genus with hares and some cottontails. The European rabbit was renamed *Oryctolagus cuniculus* by Lilljeborg in 1873–1874 (Angermann et al., 1990; Hoffman, 1993) but was still considered a subgenus of *Lepus* (Corbet, 1994). The obvious physical and behavioral differences between European rabbits and other leporids ultimately led to the recognition of *Oryctolagus* as a separate genus, with *O. cuniculus* as the only member species. Despite the increasingly complex classification schemes at the genus and species levels, taxonomists continued to classify rabbits, hares, and pikas as rodents until 1912, when they were recognized as distinct and reclassified to the order Lagomorpha (Chapman and Flux, 1990; Gidley, 1912). Today, most taxonomists continue to group rabbits and rodents, with a few exceptions, in the Glires superorder (McKenna and Bell, 1997).

Table 6.1 shows the current classification scheme for the European rabbit from the ordinal to genus level. Within the order Lagomorpha, there are two families and 13 genera. The family Leporidae contains

TABLE 6.1 Classification of Lagomorphs

Order: Lagomorpha
Family: Ochotonidae—Pikas (2 genera and 22 species)
Genus: Ochotona—Pikas (21 species)
Genus: Prolagus—Sardinian Pika (extinct)
Family: Leporidae—Hares and Rabbits (11 genera and 47 species)
Genus: Pentalagus—Ryukyu Rabbit
Genus: Bunolagus—Bushman Rabbit
Genus: Pronolagus—Red Rabbits (3 species)
Genus: Nesolagus—Sumatra Short-eared Rabbit
Genus: Romerolagus—Volcano Rabbit
Genus: Brachylagus—Pygmy Rabbit
Genus: Poelagus—Central African Rabbit
Genus: Caprolagus—Bristly Rabbit
Genus: Lepus—Hares (23 species)
Genus: Sylvilagus—Cottontails (13 species)
Genus: Oryctolagus—European Rabbit

FIGURE 6.2 A cottontail rabbit of the genus *Sylvilagus*. Photo credit: Rachel Rommel, Houston Zoo.

11 genera, including *Lepus* (jackrabbits and hares; Figure 6.1), *Sylvilagus* (cottontails; Figure 6.2), and *Oryctolagus* (European rabbits; Figure 6.3). The family Ochotonidae contains a single surviving genus, *Ochotona* (pikas; Figure 6.4). There are more than 80 recognized species of lagomorphs. In 1999, a new cottontail species, *Sylvilagus varynaensis*, was identified in the Venezuelan lowlands (Durant and Guevara, 2001).

GEOGRAPHIC ORIGINS AND DIVERSITY

An exact determination of the antiquity, evolution, and geographic origins of the European rabbit is complicated by its physical attributes, its behavior, and the history of human-mediated dispersal. All lagomorphs, including *Oryctolagus*, are distinguished by a highly conserved body plan adapted for hopping, and the fossil records are themselves often incomplete, making

FIGURE 6.3 The European rabbit, *Oryctolagus cuniculus*. Photo credit: Jamie Greaver, The University of Texas Health Science Center at Houston.

FIGURE 6.4 A pika, genus *Ochotona*. Photo credit: Rachel Rommel, Houston Zoo.

fine morphological distinctions between genera and species difficult (Chapman and Flux, 1990; Corbet, 1994; Fox, 1994). *Oryctolagus* species have undergone population contractions and expansions congruent with climatic fluctuations, with corresponding increases and decreases in species diversity. European rabbits create and inhabit complex burrows up to 3 meters deep, crossing geological strata and confounding interpretation of archeological records (Corbet, 1994; Thompson, 1955). Finally, *O. cuniculus* was not domesticated until the Middle Ages, and the zooanthropological record does little to clarify the paleontological or molecular evidence.

Until recently, lagomorphs were thought to have diverged in Asia during the Early to Middle Eocene, with diversification into the two representative families, Leporidae (rabbits and hares) and Ochotonidae (pikas), occurring during the late Eocene (Asher et al., 2005). However, a recent molecular study (Springer et al., 2003) and even more recent fossil discoveries in west-central India (Rose et al., 2008) have suggested a much earlier emergence of Lagomorpha during the early Eocene, millions of years earlier than previously believed. In addition, the Indian fossils have tarsal adaptations consistent with those of modern leporids, suggesting that Leporidae and perhaps *Oryctolagus* may have emerged significantly earlier than previously supposed (Rose et al., 2008).

The oldest recorded *Oryctolagus* species, *O. larynsis*, existed at least 3.5 million years ago (Mya) on the Iberian Peninsula and possibly in southeast France (Lopez-Martinez, 2008). Fossil records of *O. cuniculus* from the Iberian Peninsula date to about 0.6Mya (Lopez-Martinez, 2008). Several species of *Oryctolagus* coexisted during the mid-Pleistocene, but by the late Pleistocene, all except *O. cuniculus* were extinct. Competing theories of an African (Ferrand, 2008) or Chinese (Long et al., 2003) origin for *O. cuniculus* have been ruled out by analysis of mitochondrial DNA (mtDNA) and microsatellite markers.

mtDNA analysis (Branco et al., 2000; Hardy et al., 1995) and protein polymorphism (Ferrand and Branco, 2007) of wild European rabbits indicate that two subspecies of *O. cuniculus* presently inhabit the Iberian Peninsula; the date of divergence is estimated to be 1.8Mya (Carneiro et al., 2009). The subspecies *O. c. algirus* is restricted to southern Spain, and *O. c. cuniculus* is found in northern Spain and southern France, with a zone of mixing transecting the center of the Iberian Peninsula running northwest to southeast (Branco et al., 2000, 2002). Molecular markers have confirmed that domestic breeds as well as feral populations in Europe, Britain, and Australia are nearly genetically identical to the *O. c. cuniculus* of southern France (Ferrand, 2008; Queney et al., 2002). The subspecies *O. c. algirus* exhibits a higher degree of polymorphism, despite its restricted home range. The existence of allopatric subspecies may provide new avenues in the development of research models.

DOMESTICATION AND BREED DEVELOPMENT

Long before the fossil record lent support to the hypothesis of a European origin of *O. cuniculus*, man considered the Iberian Peninsula the European rabbit's ancestral home. Credit for discovery of rabbits

generally goes to Phoenician sailors, c. 1000BC, who reported numerous creatures resembling today's rabbits inhabiting the coast of the Iberian Peninsula. Regardless of who receives credit for the discovery, it was the rabbit's prolific breeding capacity under captive conditions that ultimately led to its exploitation for food. This ability of *Oryctolagus* to reproduce easily in captivity set it apart from *Sylvilagus* species and hares, and placed the European rabbit forever in the category of agricultural commodity. Seafaring civilizations from the time of the Phoenicians to the 18th century have left caches of rabbits on islands along shipping routes, where they served as a sustainable game supply for sailors; as a result, feral rabbit populations exist today on more than 800 oceanic islands (Ferrand, 2008; Flux and Fullagar, 1992; Gibb, 1990).

The earliest record of rabbits kept in captivity comes from the Romans, who imported them to Italy beginning around the third century BC (Flux, 1994). The Romans were fond of rabbit meat and considered the newborn kits and unborn fetuses, called laurices, a delicacy. They kept rabbits penned in walled gardens called leporaria for sport hunting (Fox, 1994), setting a precedent that was followed in France, Germany, and Britain into the Middle Ages (Flux, 1994). There is evidence that the Romans captured rabbits and kept them in hutches for fattening, though there are no documented attempts at true domestication (Clutton-Brock, 1999). The Romans, like many societies that followed, quickly discovered that rabbits not only bred astonishingly well in captivity, but were escape artists that rapidly invaded the countryside and became a serious pest problem (Clutton-Brock, 1999; Fox, 1994). Human transport brought rabbits to Western Europe and eventually to the British Isles, where they were introduced during the Norman Conquest, around 1100AD.

Compared with dogs, cats, and ferrets, rabbits are the most recently domesticated small animal species. Perhaps because of their perceived untrainability, lack of natural weapons, and ability to breed in captivity without human assistance or intervention, little effort was made to domesticate rabbits until the 6th century AD. French Catholic monks cultivated rabbits as a sustainable food source and, following the example of the Romans, kept them in walled, paved gardens. In 600AD Pope Gregory I declared that laurices were aquatic and therefore could be classified as fish, thus permitting the monks to enjoy newborn and fetal rabbit as an alternative to meat at Lent. Selection for size may have begun around this time, and by the mid-1500s, variations in size and coat color were well established. In 1595 the Italian monk Agricola described the relatively large rabbits found in his native Verona as piebald, black, and white (Bixby and Whitman, 2005). With the selection of traits for domestication, breed development inevitably

followed. The oldest breed on record is the Champagne d'Argents, developed more than 400 years ago from the "silver-plated" rabbits of France. Himalayan rabbits were first described in 1858, and later in the 19th century the Dutch rabbit was developed. The New Zealand White was developed in the early 20th century by W. S. Preshaw (Verhoef-Verhallen, 1998). A large (maximum weight 12 pounds) albino rabbit originally intended for meat production, the New Zealand White became the model of choice for the acute irritancy test developed by J. H. Draize in 1944. The New Zealand White has since become the breed most commonly used in biomedical research; the Dutch breed is also used, particularly where pigmented or smaller animals are desired. Both the New Zealand White and the Dutch are available from commercial vendors as conventional or specific-pathogen-free stocks.

Currently, 47 breeds of rabbits are recognized by the [American Rabbit Breeders Association](#). Unfortunately, as preferences for meat and fur have changed, some breeds have dwindled in popularity and are now threatened with extinction, leading the [American Livestock Breeds Conservancy](#) to include these historic breeds in its conservation mission. Table 6.2 is a list of currently recognized breeds and their conservation status.

ECOLOGY AND CONSERVATION

Although wild European rabbits exist only in their native habitat of the Iberian Peninsula, *O. cuniculus* today is inarguably one of the most ubiquitous animals on earth. Their ubiquity is primarily the unintended consequence of human introduction of domestic animals followed by accidental or deliberate release into non-native habitats. The rabbits' legendary reproductive capacity, burrowing behavior, and adaptability to a diverse range of climates and herbivorous diets more than compensate for its small size, appeal to predators, and lack of natural defenses, resulting in their colonization, with varying degrees of success, of every major continent except Antarctica and, as mentioned above, more than 800 oceanic islands (Flux and Fullagar, 1992). These free-living populations of European rabbits, descended from domestic animals, are more properly classified as feral (Fox, 1994). In locales where predation, trapping, and hunting keep feral rabbit populations in check, numbers may never rise above nuisance level. This has been the case on the North American mainland (Flux et al., 1990); the only established feral rabbit population in North America resides on the San Juan Islands off the coast of Washington (Couch, 1929; Hall, 1977). However, when rabbits are introduced to an ecosystem where few natural competitors, geological barriers, or predators exist, populations can quickly

get out of hand, with devastating ecological, economic, and public human and animal health consequences. The most stunning example is Australia, where 24 rabbits were deliberately released by an English immigrant in 1859. Within 10 years, the feral population topped 2 million, and by 1881 farmers in the state of Victoria were abandoning their farms (Myers, 1986). While the Australian example is extreme, similar scenarios have occurred in Great Britain, New Zealand, and Argentina (Flux et al., 1990; Novillo and Ojeda, 2008). A non-indigenous species everywhere except the Iberian Peninsula, the European rabbit's destructive impact on non-native habitats is primarily attributable to its voracious appetite. Rabbits overgraze native vegetation,

altering ecosystems by contributing to soil erosion and displacing native species, leaving indigenous prey species vulnerable to overpredation due to loss of protective ground cover (Danoff-Burg, 1993; Lees and Bell, 2008; Novillo and Ojeda, 2008). Their impact on agriculture is equally devastating. In addition to destroying crops outright, rabbit grazing contributes to weediness and insect penetration (Crawley, 1989; Myers et al., 1994) and reduces the carrying capacity of grazing areas, resulting in declines in meat and wool production (Myers et al., 1994; Thompson, 1955).

Ironically, the numbers of native wild rabbits on the Iberian Peninsula have dwindled since the 1950s as a result of habitat loss, overhunting, myxomatosis, and rabbit calicivirus (Delibes-Mateos et al., 2009). The decline of this keystone species has placed survival of other species, including the Iberian lynx (*Lynx pardinus*) and the Iberian imperial eagle (*Aquila adalberti*), in jeopardy (Lees and Bell, 2008; Ward, 2005). Recovery efforts aimed at providing species-friendly habitats, controlling hunting, and removing generalist predators have not succeeded, and rabbit populations remain at only 5% of pre-1950 levels. In 2008, the International Union for Conservation of Nature classified wild *O. cuniculus* as “Near Threatened with extinction” throughout its native range.

RABBIT GENETICS

Introduction

Genetic studies using laboratory rabbits will receive an essential boost with the publication of the complete

European rabbit genome, *Oryctolagus cuniculus*. All domestic rabbits are derived from the European rabbit, which originated in the Iberian Peninsula, and was domesticated in the 6th century. The Broad Institute has compiled a 7× coverage of the rabbit genome

(<http://www.broadinstitute.org/science/projects/mammals-models/rabbit/rabbit-genome-data-links>), National Center for Biotechnology Information (NCBI) accession # AAGW00000000 (published in 2009) from the inbred Thorbecke strain that provides an important data base for rabbit researchers. However, there remain significant gaps in this sequence database. A deeper 7× (seven times) coverage was started in 2007. Today, more than 100 purebred rabbit breeds exist worldwide, and these breeds have provided commercial sources of meat, fur, pets, research animals, and biopharmaceuticals (via transgenics). Researchers using rabbit models to study diverse projects such as infectious diseases, atherosclerosis, anti-viral treatments, toxicology, diabetes, transplantation, eye diseases (both inherited and infectious), milk production, breed sizes, quantitative traits, immunology, and transgenics will all benefit from the upcoming newly compiled *Oryctolagus cuniculus* genomic sequence.

European Rabbit: Genetic Origins of Domestic Rabbit Breeds

Breeding stocks of domestic rabbits are derived from the European rabbit *Oryctolagus cuniculus*, and wild populations of these rabbits are now widely distributed throughout the world via human transportation (Queney et al., 2002). The geographical origins of the European rabbit are confined to the Iberian Peninsula (Hardy et al., 1995; van der Ferrand et al., 1991). Two highly divergent clades of the European rabbit (clades A and B) are found in this region of southern France and Spain (Branco et al., 2000, 2002) and the clades are represented as two subspecies, *O. cuniculus cuniculus* (Clade A) in the south western Iberian region, and *O. cuniculus algirus* (Clade B) in the northeastern region of the Iberian peninsula (Geraldès et al., 2005; Loreille et al., 1997). There are a number of published comparative studies on these wild rabbits that define their genetic diversity, polymorphisms and origins of genetic stocks for domestic rabbit breeds (Branco et al., 2000, 2002; Geraldès et al., 2005, 2006; Hardy et al., 1994, 1995; Payseur, 2009; Terrance et al., 2007; Vieira and Ferrand, 1995; Webb et al., 1995). Ancient mitochondrial DNA (mtDNA) extracted from European rabbit bones has been sequenced to assess genetic diversity in populations from Europe (Hardy et al., 1994, 1995). The studies included rabbit bones that spanned the time period from 11000 years ago to the present day, and examined nucleotide sequence diversity in a fragment of the mitochondrial cytochrome b gene. Unique findings included data that supported a period of genetic stability in rabbit populations until the Middle Ages when a novel type of mtDNA appeared in most wild rabbit populations and which corresponds to the sequence present in modern domestic rabbit breeds (Hardy et al., 1995). The introduction of this unique genetic marker into wild rabbit populations

provides a timeline (2000 to 1000 years ago), to support the documented establishment of rabbit warrens after the tenth century A.D. in Europe, and the widespread development into all regions of France of animals that carried this genetic marker (Hardy et al., 1995). Parallel genetic analyses of mitochondrial DNA in domestic rabbit breeds identify their primary origins from Clade B European rabbits (Geraldès et al., 2005; Loreille et al., 1997).

Domestic Rabbit Breeds

More than 100 breeds of domestic rabbits have been identified (Table 7.1) and vary in body size, coat color, fur characteristics, ear size, and eye color. The American Rabbit Breeders Association (ARBA) additionally provides a resource for authentication of new and existing breeds. Recent genetic tools such as mitochondrial DNA markers have been used to define the matrilineage of some breeds that arise due to interbreed crosses and the genetic management of stocked rabbit breeding populations (Terrance et al., 2007). Earlier work with breeding studies described extensive reports and data on the genetic inheritance of body weight and size, litter size, morphology, blood groups, and mutations (summarized in Fox, 1994).

Breeds and Traits

Coat Color

Substantial breeding studies have been conducted to determine the inheritance of breed coat color and hair characteristics. A number of reviews cover these findings in significant detail and thus need not be duplicated in this chapter (reviewed in Fox, 1994). Rabbit coat color is primarily determined by five major color genes A, B, C, D, and E. The A or Agouti gene, the B or Black/chocolate gene, the C or Color gene, the D or Dense/dilute gene, and the E or Extension gene. The A gene has three forms that include: A for Agouti (wild-type) rabbits; at for otters, tans and martens; and a, which is responsible for “self” colored rabbits. Agouti rabbits include chestnut, opal, chinchilla and ermine, and the at gene produces black otters, sable point martins and blue otters. The B color gene is either dominant BB or recessive bb and black family rabbits are either BB or Bb, whereas chocolate (or brown) family rabbits are bb. The C or color gene controls where and how much color will be expressed in the coat, and has several major mutations. These mutants include C (full color), C_{ch3} (chinchilla-dark), C_{ch2} (chinchilla-medium), C_{ch1} (sable or chinchilla-light), C_H (Himalayan), cc (recessive or albino). The D gene is either DD, Dd (dense color rabbits), or dd (Dilute color rabbits), and controls the amount of coat color. The E/e gene controls whether the basic hair color is extended throughout the hair shaft. Rabbits with the EE and Ee genes are the same color all over, and ee rabbits look shaded in color

due to the short hairs only having full color. Additional color genes include the *v* or Vienna white gene which produces white, blue-eyed rabbits. Other color genes (such as *En*, or English spotted) control whether the coat color is solid, broken, or spotted. Numerous color combinations are possible as suggested by listings in commercial rabbitry web sources (Table 7.1), and review publications (Fontanesi et al., 2006; Fox, 1994).

More recent studies have examined polymorphisms in the melanocortin 1 receptor (MC1R) gene that contributes to coat color (Fontanesi et al., 2006). In mammals, mutations of the MC1R gene causing a constitutively active receptor are dominant and produce black coat color, whereas inactivating mutations are recessive and result in red/yellow pigmentation (reviewed in Cone et al., 1996; Klungland and Vage, 2003). Four MC1R alleles were identified in rabbits in which two wild-type alleles were defined by synonymous single nucleotide polymorphisms (SNPs) (Fontanesi et al., 2006). A third allele with a 30-bp deletion was found to represent the recessive *e* allele at the Extension locus (Fontanesi et al., 2006) as identified through earlier genetic inheritance studies in rabbits (Fox, 1994). Both Agouti and Extension are two genetic loci known to control the amounts of eumelanin (brown-black) and pheomelanin (yellow-red) pigments, and the antagonist/activation interactions of agouti and alpha-melanocyte-stimulating hormone with the MC1R provide molecular pathways for the understanding of the genetics of inherited coat color (Cone et al., 1996).

Hair Characteristics

Additional breeding studies have looked at hair characteristics as an important component of the rabbit wool industry. The Angora rabbit is the most recognized wool/fur breed. Various genetic loci that contribute to hair characteristics include angora, hairless, naked, rex

(short hair), wirehair, and wuzzy (Castle, 1903; Castle and Nachtsheim, 1933; Rafat et al., 2009; Rogers et al., 2006; Sawin, 1955). Recent analyses have used the scanning electron microscope to better understand morphology and variability of the cuticular scale patterns, hair cortex, medullary arrangement and profile of the hairs (Van den et al., 2001), and the optical fiber diameter analyzer to describe the characteristics of Angora rabbit fiber (Rafat et al., 2007). A genetic study looking at single nucleotide polymorphisms (SNPs) in the fibroblast growth factor 5 (FGF5) gene concluded that this gene could be the potential (or linked to the) major gene affecting wool yield in Angora rabbits (Li et al., 2008).

Size Inheritance (Giants and Dwarfism (*Dw/dw*))

Size inheritance from early breeding studies was conducted to assess various morphological characteristics including dwarfism (*Dw/dw*) (Fox, 1994; Sawin, 1955; Wegner, 1997). Domestic breed sizes range for the largest breeds (German Grey and Flemish Giants, 19lb) to the smallest (dwarf, 1.5–2lbs). Some early breeding studies were conducted on size inheritance during selection of large race (III) and small race (X) strains (Latimer and Sawin, 1959). One example of size changes that may occur from inbreeding studies to produce lines from commercially available New Zealand White (NZW) rabbits that showed differential resistance or susceptibility to a regressive strain of cottontail rabbit papillomavirus (CRPV) found that successive generations showed increasing reductions in size until the lines became non-viable (Breitburd et al., 1997).

Growth, Uterine Capacity, Litter Size, Meat Content, and Milk Production

Domestic rabbit breeds supply a thriving industry for meat, fur, and milk in Europe and the US, and

these factors have sparked considerable interest in the genetic inheritance of these commercially important traits (Ferguson et al., 1997; Hamilton et al., 1997; Lukefahr et al., 1989; Ozimba and Lukefahr, 1991a). Earlier studies looked at inherited features of uterine capacity (an important correlative of litter size), meat content (sometimes referred to as butcher traits), growth rate, embryonic development, milk production and fur content (Argente et al., 2003, 2003a; Blasco et al., 1994, 2003, 2005; Hamilton et al., 1997; Hernandez et al., 1997, 2004; Lukefahr et al., 1983; McNitt and Lukefahr, 1990; Medellin and Lukefahr, 2001; Moce et al., 2004a, 2004b; Ozimba and Lukefahr, 1991b; Peiro et al., 2007; Piles et al., 2004). Most of these studies were conducted by careful breeding studies looking for inherited traits and their dominance/recessiveness in F1 and F2 crosses. Some correlative observations demonstrated that increasing uterine capacity increases uterine length and decreases weights of fetus and fetal placenta in rabbits (Argente et al., 2003b). The purpose of these extensive studies was to maximize the commercial potential of various rabbit breeds for the various industry needs such as meat, milk, fur, and fecundity.

A search for genetic markers for some of these traits has revealed some interesting candidate genes including using the method of polymerase chain reaction-single strand conformation polymorphism (PCR-SSCP) for the analysis of the growth hormone receptor (GHR) gene (Deng et al., 2008), and SNPs in the progesterone receptor gene (Peiro et al., 2008) (Table 7.2).

Immunology

Immune function in the rabbit has been a significant area of interest in the area of genetics of immune responses. Blood proteins and blood cells are a convenient source of material for genetic studies on protein polymorphisms in rabbit breeds including both wild (Spanish) and domestic populations of rabbits (Arana et al., 1989; Branco and Ferrand, 2002; Branco et al., 1998), and immune molecules, including serum antibodies, macroglobulins, cytokines, and chemokines as well as immune cells are richly present in these samples. Laboratory rabbits, especially NZW, have been used extensively for the production of specific polyclonal antibodies. The rabbit antibody repertoire is constructed predominantly via gene conversion following initial assemblage from a limited set of VH gene fragments in which most rabbit B-cells have the same VH gene (Knight and Winstead, 1997). This construction contrasts to the development of the B-cell repertoire in humans and mice where VH and VL gene fragments are numerous. Interestingly, specific antibodies that recognize and discriminate between normal and phosphorylated proteins are best developed in rabbits. In the rabbit, these VH regions bear allotypic markers,

and these have provided a focal point in the study of genetic inheritance of antibody allotypes (Gilman-Sachs et al., 1981; Knight and Becker, 1990; Knight et al., 1991; Su and Nei, 1999), and several rabbit strains have been identified that have been used in these analyses (Kelus and Weiss, 1986; Weiss et al., 1982). Another interesting and unique observation regarding rabbit antibody production is that the rabbit genome contains multiple genes coding for the constant regions of IgA heavy chains (Burnett et al., 1989) with associated allotypes (Lammert et al., 1977). These latter observations suggest that lagomorphs may have as many as 13 IgA isotypes and hence a complex secretory immune system (Burnett et al., 1989).

Earlier work looked at the functional properties of a number of blood proteins via red blood cell agglutination assays, and four main blood group antigens were identified (Castle and Keeler, 1933; Keeler and Castle, 1933). These blood group antigens can also be used to study genetic susceptibility of rabbits to rabbit hemorrhagic disease virus (RHDV) infection (Ruvoen-Clouet et al., 2000).

Additional cell-surface immune markers that have been studied in rabbits include the CD1 gene cluster which demonstrate similarities to the CD1 cluster in humans and which both differ from the clusters in inbred mice (Bachvarov et al., 1995; Hayes and Knight, 2001). The genomic sequence of the rabbit has provided the much-needed information in the design of primer pairs for the quantitation of various cytokine mRNAs by Quantitative PCR (Godornes et al., 2007), and will continue to aid researchers interested in the immune responses of domestic rabbits. Production of monoclonal antibodies to various rabbit cytokines and CD markers will also be streamlined and aided by the published rabbit genome.

Genetic Susceptibility and Disease Models

Many mutant rabbit models will be discussed in other chapters. Some interesting models include those for study of inheritance of hyperlipidemia (Kurosawa et al., 1995; Meijer et al., 1992); glaucoma (bu/bu) (Fox et al., 1977); spina bifida (Crary et al., 1966); audiogenic seizures (Asakura and Wada, 1972; Nellhaus, 1958); spontaneous diabetes (Conaway et al., 1980, 1981); megacolon syndrome in homozygous spotted (En En) rabbits (Bodeker et al., 1995); systemic lupus erythematosus (SLE) (Puliyath et al., 2008); congenital simple non-syndromic coronal suture (CS) synostosis (Mooney et al., 1994) (<http://www.hopkinsmedicine.org/craniofacial/Research/RabbitMutation.cfm>); and susceptibility/resistance to infectious diseases such as *Mycobacterium tuberculosis* (Dorman et al., 2004; Lurie et al., 1949, 1952), RHDV (Guillon et al., 2009) and herpes simplex virus (HSV) (Seto et al., 1995). An extensive

TABLE 7.2 Candidate Genes and Genetic Sequences that Correlate with Disease, Markers and Traits in the European Rabbit and Domestic Breeds

Gene or Genetic markers ^a	Disease, Marker or Trait	Genetic Loci, Marker or Probe	Alleles or Genotypes	Reference
CCR5	Myxomatosis susceptibility	Allelic variation with related species	One Unique	(Carmo, et al., 2006)

listing of genetic mutations is presented in summary form by Fox (1994), and a selection of genes and genetic markers that are associated with various mutations and traits are listed in Table 7.2.

Inbred Rabbit Strains

Several inbred strains of rabbits have been developed by various researchers and these rabbits are valuable resources for the research community. Early breeding studies demonstrated some significant difficulties in the establishment of inbred lines due to the well-known phenomena of exposure to deleterious recessive genes, developmental abnormalities, inbreeding depression and inbred lethality (Breitburd et al., 1997; Chai, 1969, 1970; Chai and DeGenhardt, 1962); however, several inbred lines were established initially at the Jackson Laboratory, Bar Harbor, ME (Chai, 1968, 1969, 1970; Chai and DeGenhardt, 1962). Commonly used strategies to establish inbred lines used full-sib mating similarly to the establishment of inbred strains in other laboratory species. Earlier (as well as more recent) studies have established a number of lines as closed colonies with restricted selected breeding to study various diseases and traits (Blasco et al., 2005; Braun, 1974; Braun et al., 1973; Falkenberg and Frensdorff, 1975; Hernandez et al., 2004; Latimer and Sawin, 1955, 1959; Mooney et al., 1994; Rafat et al., 2009). One interesting NZW inbred rabbit line that has been preserved only as tissues is the rabbit that is being used to establish the 7× genome at the Broad Institute, and is known as the Thorbecke strain (Mendez et al., 2008). Some selected inbred lines are discussed below.

B, Y, A, C, and R Inbred Lines (The Jackson Laboratory)

Five inbred strains, B, Y, A, C, and R (the R line has become extinct) were originally developed at the Jackson Laboratory, and maintained by full-sib mating (Chai and

DeGenhardt, 1962; Crary and Fox, 1980). Renamed as inbred lines B/J, R/J, and Y/J, the lines were originally developed by Dr Cohen to study effects on blood group genes (Fox, 1978). Additional inbred strains were developed by Dr Sawin, Dr Chai, and others at the Jackson labs from several stocks that included the partially inbred III line that was used in a study on selected breeding for size traits (Crary and Sawin, 1960; Latimer and Sawin, 1958, 1959; Sawin and Crary, 1956). Inbred lines include the homozygous rapid acetylator inbred strains (B/J, III/J, IIIC/J, III/DwJ, IIIEP/J, and IIIVO/J), and the homozygous slow acetylator inbred strains (ACEP/J, III/cdJ, IIIVO/ahJ, and IIIVO/utJ) (Hein et al., 1982). Additional Jackson inbred strains include AC/J, AX/J, AXBU/J, C/J, OS/J, WH/J, X/J (Usher et al., 1982). Some recent studies with the III/J line looked at levels of liver microsomal progesterone 21-hydroxylase activity (Pendurthi et al., 1990). The audiogenic inbred line, EIII/JC is likely derived also from the original Jackson lines (Hu et al., 2002). The B/Jas line is highly susceptible to HSV encephalitis and thus used as a genetic model to study disease susceptibility to this virus (Seto et al., 1995; Yuasa et al., 1999).

Thorbecke Inbred Line

The Thorbecke inbred line was originally developed from NZW rabbits (>20 generations) by Dr. G.J. Thorbecke, and was previously available commercially from Covance Research Products, Inc. (Denver PA). The strain was used to study susceptibility to *Mycobacterium tuberculosis*, in an aerosolized infection model (Mendez et al., 2008). Thorbecke rabbit tissues have been preserved for DNA source material to establish the 7× genome sequence of the domestic rabbit by the Broad Institute, but this strain is no longer available.

AX/JU and IIIVO/JU Inbred Lines

This pair of inbred lines was originally developed to study the effects of dietary cholesterol in a rabbit model.

Strain IIIVO/JU is not reactive to dietary cholesterol, whereas the other strain (AX/JU) is reactive to dietary cholesterol (de Wolf et al., 2003). These lines make excellent models for various quantitative trait loci (QTL) mapping (Korstanje et al., 2001a, 2001b; van Haeringen et al., 2001, 2002) and for comparative studies such as differential responses to analgesics (Avsaroglu et al., 2003, 2008), polymorphism of biochemical markers (Dieter and Johnson, 1982; Korstanje et al., 2001a), and microsatellites (Korstanje et al., 2001b, 2001c).

WHHL (Watanabe-Heritable Hyperlipidemic) Inbred Line

The WHHL or Watanabe inbred strain was developed initially from spontaneously hyperlipidemic rabbits and is a model for human familial hypercholesterolemia (Bell et al., 1987; Meijer et al., 1992; Shiomi et al., 1987; Watanabe, 1980; Watanabe et al., 1977). Clinical features of this strain include elevated serum lipids, cholesterol (400 +/−70 mg/dl), and beta-lipoprotein levels (Watanabe et al., 1977).

JWY-NIBS and NWY-NIBS Inbred Lines

Two inbred rabbit strains, JWY-NIBS and NWY-NIBS, one derived from Japanese White rabbits, the other from strain III NZW rabbits were established by full-sib mating in the Nippon Institute for Biological Science, Laboratory Animal Research Station (Fukuta et al., 1996; Yazawa et al., 1986). These strains have been used to study comparative traits (Fukuta et al., 1996) including mandible size (Goto et al., 1987).

KHC (Kurosawa and Kusanagi Hypercholesterolemic) Inbred Line

The KHC strain displays inherited and persistent hypercholesterolemia and was produced by inbreeding from mutants discovered in 1985 (Kurosawa et al., 1995). KHC rabbits had serum cholesterol, triglyceride, and phospholipid concentrations that were 8–10 times greater than the concentrations in clinically normal Japanese White rabbits, which were the original source strain for the KHC line (Kurosawa et al. 1995).

Rabbit Lines and Closed Colonies

Various rabbit lines represented as closed colonies, or selected breeding from mutant individuals have been developed that display unique genetic features and which provide important models to study aspects of genetics and immunity. Some selected examples of these lines are listed below.

Gelbsilber (GS) Rabbits

GS rabbits are a closed colony derived from NZW rabbits. These rabbits were found to be high antibody

responders to the lactic dehydrogenase isoenzyme LDH-H4 and thus differ from most New Zealand White (NZW) rabbits which produce no detectable antibody to this antigen (Falkenberg and Frensdorff, 1975; Freyler et al., 1976). It was concluded that in GS rabbits the antibody response to the LDH-H4 antigen is controlled by an Ir gene and that these animals might be a useful model to study genetic control of the immune response in rabbits (Falkenberg and Frensdorff, 1975).

Alicia Rabbits

A mutation of the allotype allele a2 in this rabbit was found and defined as “ali”. The corresponding rabbit strain is called “Alicia” (Allegrucci et al., 1990, 1991; Bernstein et al., 1985; Chen et al., 1993, 1995; DiPietro et al., 1990; Kelus and Weiss, 1986; Sehgal et al., 1998). The mutant ali/ali animals have a deletion in a key variable region gene in the immunoglobulin heavy-chain locus that is present in the related wild-type 2R1/2R1 strain. They are defined for immunoglobulin allotypes, which are allelic variants of antibody heavy and light chains.

Basilea Rabbits

Basilea rabbits contain a mutation in the immunoglobulin genes (Mage et al., 1984; McCartney-Francis et al., 1987; Freedman et al., 1975; Gilman-Sachs et al., 1981), and produce antibodies with lambda light chains when homozygous (Weiss et al., 1977). Basilea rabbits do not produce normal K1b9 light chains but continue to produce immunoglobulins with light chains of the rare K2 isotype and of lambda type (Lamoyi and Mage, 1985; Weiss et al., 1977). These rabbits have been used in earlier studies to characterize immunoglobulin light-chain classes, and to study the genetics of immune responses to various antigens including streptococcal group A-variant polysaccharide (Dubiski et al., 1982; Garcia et al., 1982; Weiss et al., 1977, 1979, 1982; Zhu et al., 1999).

JIRONG Rabbits; Japanese White Rabbits

Countries other than Europe and the US have established their own rabbit strains for research studies. JIRONG rabbits are a line developed in China that originated from European stocks of Rex rabbits. These rabbits have been used in a microsatellite marker study of comparative traits and for parental testing (Han et al., 2005). Japanese White rabbits (Mage et al., 1984) are a breed used as a primary source of several inbred rabbit lines such as the KHC rabbits (Kurosawa et al., 1995) and the JWY-NIBS rabbits (Yazawa et al., 1986).

Research Stocks

NZW rabbits are the major resource rabbit for research laboratories and industry toxicology studies. The main features of this breed that account for this

popularity include the ease of location of surface veins and arteries (especially the ear) for blood collection and the general ease of handling. Other strains available commercially include Dutch-belted and California White. Many research labs have their own unique strains, inbred lines and transgenics, and some of these resources are becoming lost to the research community due to reduced institutional and commercial support. For example, the U. S. National Institutes of Health (NIH) recently advertised competitive research grants to support the maintenance and continuation of unique and valuable antibody allotype-defined rabbit colonies that have been bred and maintained at the NIAID facilities over the past 45 years (<http://grants.nih.gov/grants/guide/notice-files/NOT-AI-08-035.html>). Three valuable strains are included in the colony and are designated as b9/b9, ali/ali (Alicia), and the parental wild-type 2R1/2R1. The b9/b9 rabbits were shown to be optimal for production of chimeric rabbit:human monoclonal antibodies with high affinities and specificity for antigen. These colonies otherwise were to be discontinued. As mentioned previously, the Thorbecke strain used in compilation of the rabbit genome has already been lost. U.S. research facilities that provide rabbits for researchers in the U. S. number more than 700 suppliers (Grannis, 2002).

Genomic Sequence Information and Resources

A variety of genomic databases are now available for the rabbit researcher. Some examples include: EMBL (<http://www.ebi.ac.uk/embl/>), GenBank (<http://www.ncbi.nlm.nih.gov/>), DNA Database of Japan (<http://www.ddbj.nig.ac.jp/>) and the Broad Institute rabbit genome (2X) database (<http://www.broadinstitute.org/science/projects/mammals-models/rabbit/rabbit-genome-data-links>). In addition, several groups have compiled various sets of primer sequences to identify rabbit microsatellite sequences which can then be used for SNPs analyses (Payseur and Cutter, 2006) as well as chromosome “paints” using filter in situ hybridization (FISH) techniques (Hayes et al., 2002; Korstanje et al., 1999), and subsequent cytogenetically anchored rabbit microsatellite maps (Chantry-Darmon et al., 2003, 2005, 2006; Korstanje et al., 2003; Zijlstra et al., 2002). Repetitive DNA sequences can be used in genetic analyses and these include multiple sequences that define a lentiviral subgroup referred to as rabbit endogenous lentivirus type K (RELK) (Katzourakis et al., 2007; van der et al., 2009). Long interspersed repetitive DNA (LINE1 or L1) and short interspersed repeats (SINEs) or C-repeats, represent highly repeated DNA sequences in the rabbit genome that also provide genetic markers for comparative genomic analyses (Demers et al., 1989; Hardison and Printz, 1985; Krane et al., 1991; Price et al., 1992).

Additional repetitive markers (in *Oryctolagus cuniculus*) include mitochondrial DNA that contains a tandem array of 153-bp repeats in the vicinity of the replication origin of the H-stand. Variation among molecules in the number of these repeats results in inter- and intra-individual length polymorphism also known as heteroplasmy (Casane et al., 1994, 1997).

Microsatellite markers have also been identified from the published genome to map various quantitative trait loci (Korstanje et al., 2001b; Mouguel et al., 1997; van Haeringen et al., 2001; van Lith and van Zutphen, 1996), nicely illustrating the value and power of the rabbit genome database. Other research tools for the study of rabbit genetics include rabbit bacterial artificial chromosome (BAC) libraries (Rogel-Gaillard et al., 2001). Together, these data sets and tools provide a wealth of sequence information for comparative genetics for rabbit researchers. A selection of genes and genetic markers that have been linked to various mutations, diseases, traits, and susceptibilities are presented in Table 7.2. We predict that this list will grow more rapidly upon publication of the more complete 7× genome (Abrantes et al., 2008; Bosze et al., 2000; Branco and Ferrand, 1998; Carmo et al., 2006; Deng et al., 2008; Fontanesi et al., 2006; Gage et al., 2006; Hardison and Printz, 1985; Hardy et al., 1995; Hein et al., 1982; Jiang et al., 2008; Korstanje et al., 2001b; Li et al., 2008; Peiro et al., 2008; van Haeringen et al., 1996, 2001; van Lith and van Zutphen, 1996; Vieira and Ferrand, 1995).

TRANSGENIC RABBITS

Introduction

Successful generation of the first transgenic rabbits was reported in 1985 (Hammer et al., 1985), following the creation of the first transgenic mice (giant transgenic mice with overexpression of rat growth hormone) in 1982 (Palmiter et al., 1982). Since then, transgenic rabbits have been generated and used as animal models for a variety of human diseases and as bioreactors for production of pharmaceutical proteins. Although transgenic mice are still dominantly used in biomedical research, it is known that the causative mutations resulting in human diseases do not cause corresponding pathological changes in mice in some instances (Rysinska et al., 1990). Additionally, a number of techniques are difficult to apply to mouse models due to their small size and phylogenetic features, such as for studies of the long QT syndrome (Brunner et al., 2008; Nerbonne, 2004) and hypertrophic cardiomyopathy (Marian et al., 1999; Nagueh et al., 2000). Alternatively, the rabbit (*Oryctolagus cuniculus*) with an intermediate size between rodents and large farm animals and closer phylogenetic features to

primates has attracted more attention in recent years in biomedical and pharmaceutical research. As of July 2009, there had been 180 publications on transgenic rabbits as searched for in Medline, representing an increase of 100% in the last 7 years on the basis of a total of 90 publications between 1985 to 2002 (Fan and Watanabe, 2003). Transgenic rabbits have been most commonly used as models for studies of cardiovascular diseases, such as atherosclerosis, hypertrophic cardiomyopathy, and long QT syndrome, in addition to their use in studies of cancers, AIDS, and other human diseases. Because of their appropriate size and short reproductive cycle, transgenic rabbits have also been used subsequently as bioreactors for production of pharmaceutical proteins. A summary based on current publications obtained from a search of the Medline database focuses on basic methods and strategies for generation of transgenic rabbits, their use as models of important human diseases and application as bioreactors for production of valuable pharmaceutical proteins.

Basic Methods and Strategies for Generation of Transgenic Rabbits

Four methods have been established for generation of transgenic animals, including (1) pronuclear injection of embryos at the single cell stage, (2) injection of genetically modified embryonic stem (ES) cells into blastocysts, (3) sperm-mediated gene transfer, and (4) genetically modified somatic cell and nuclear transfer (cloning). To date, the majority of transgenic rabbits have been produced by microinjection of a DNA construct into the pronucleus of embryos at the single-cell stage although a few labs have reported generation of transgenic rabbits by sperm-mediated gene transfer (Li et al., 2006; Shen et al., 2006) or somatic cell cloning (Skrzyszowska et al., 2006). The production of gene knock-in (targeted insertion of the transgene at a selected locus) or knock-out (elimination of a specific gene) animals by genetically modified ES cell injection into a blastocyst has still been limited only to mice since the true totipotent ES cells essential for this technique have not been available in any other species, including rabbits.

A comprehensive review article has provided a detailed description and discussion for production of transgenic rabbits (Fan and Watanabe, 2003). Until now, DNA microinjection into the pronucleus is still the most reliable method for generation of transgenic rabbit founders. The basic procedures, mostly converted from the method for production of transgenic mice with some modifications, include induction of superovulation (by timed administration of pregnant mare's serum gonadotropin or follicular stimulating hormone and human chorionic gonadotropin), pronuclear

microinjection of a DNA construct, transfer of embryos to the oviducts of a pseudopregnant-induced recipient, identification of transgenic founders, establishment of transgenic lines, and analysis of transgene expression and associated phenotypes. Most of the transgenes are constructed by recombination of a cDNA (lack of introns and regulatory sequences) for a gene of interest and a specific promoter for controlling the transgene expression. A few transgenic rabbit lines carrying yeast artificial chromosome (YAC) or bacteria artificial chromosome (BAC) vectors, which can accommodate large genomic sequences, have been established (Brem et al., 1996; Rouy et al., 1998). It is known that genomic sequences direct higher levels of gene expression and tissue specificity than cDNA (Giraldo and Montoliu, 2001).

Rabbit embryos are larger (160 μ m diameter versus 110 μ m) and slightly more opaque than mouse embryos. The pronuclei in most rabbit embryos are sufficiently visible under phase-contrast microscopy for microinjection. However, pronuclei in approximately 25% of rabbit embryos may not be visible or clear enough for microinjection. One study reported that centrifuging for 10 min at 12000g could make pronuclei of the embryos visible and suitable for microinjection (Hirabayashi et al., 2000). Another characteristic of rabbit embryos is the thicker zona pellucida due to formation of a thin mucin coat. Mucins are high-molecular-weight and heavily glycosylated proteins (glycoconjugates) produced by epithelial cells in the oviducts. Neither the zona pellucida nor the thin mucin coat is difficult to penetrate, nor do they influence microinjection. However, if the mucin coat is too thick, which might be related to delayed harvest of embryos from oviducts, it can make microinjection difficult since the embryo cannot be held stably for insertion of the injection pipette. It is also known that the presence of the mucin coat greatly influences pregnancy by showing a dramatic drop in pregnancy rate in its absence (Moore et al., 1968). Therefore, it is desirable to transfer the embryos to oviducts within 2–3 hours following microinjection to allow formation of the mucin coat prior to the embryos reaching the uterus for implantation.

Microinjected DNA integrates into the host genome at a random site from one to variable multiple copies. The integration site may influence the transgene expression level due to exposure to nearby enhancers or silencers, or enhanced methylation (Jaenisch, 1988). The efficiency of genomic integration following DNA injection for production of transgenic rabbit founders is still quite low, ranging from 0.5–3% (Bosze et al., 2003). Some factors influencing the efficiency of rabbit transgenesis have been addressed (Fan and Watanabe, 2003; Murakami et al., 2002). Several attempts have been made to improve the rate of genomic integration.

A recent study reported that microinjection of DNA into both male and female pronuclei of rabbit embryos significantly increased the transgene integration rate to 8.1% (4/49) in contrast to 3.3% (1/30) in single pronucleus injection (Chrenek et al., 2005). A further study revealed that all founders derived from injection of both pronuclei could transmit the transgene to the next generation in a Mendelian fashion. Results from this preliminary study suggest that injection of both pronuclei might significantly improve the efficiency for production of transgenic rabbit founders.

Another important factor is the stability of transgene transmission to offspring, which is essential for establishment of transgenic lines. Mosaicism in transgenic rabbit founders was a frequent problem involving the transmission of transgenes in early studies (Castro et al., 1999). It has been known that rabbit embryos develop faster at early stages than mouse embryos (Bosze et al., 2003). Therefore, the problem of mosaicism in transgenic rabbit founders could be minimized by precise control of the timing of hormonal administration, mating, embryo collection, and microinjection. To date, none of the transgenic rabbit founders produced in our lab were found with mosaicism as all offspring retained the transgene.

Production of transgenic animals from genetically modified ES cells with addition (knock-in) or deletion (knock-out) of a specific gene through homologous recombination is one of the most important advances in transgenic technology. Unfortunately, this approach is still generally restricted to mice as the only species in which the true totipotent stem cells have been available so far. Although ES-like cells have been derived from rabbits and blastocyst injection of the cells resulted in low chimerism of live-born offspring (Graves and Moreadith, 1993; Schoonjans et al., 1996), no germ line transmission of transgenes from these animals has been reported. More recently, two groups independently reported the generation of rabbit ES cells from blastocysts (Fang et al., 2006; Wang et al., 2007). These ES cells can differentiate into many cell types in vitro and generate teratomas containing tissue types of all three germ layers when injected into SCID mice. However, no study with blastocyst injection of the cells has been reported.

As an alternative to knock-out animals, this limitation has been partially overcome by overexpression of a dominant-negative mutant gene to suppress the expression of an endogenous gene in transgenic rabbits (Brunner et al., 2008). Furthermore, the development of a cloning technique based on nuclear transfer from a cultured and genetically modified somatic cell into an enucleated oocyte has provided a more viable alternative to the ES cell route for production of knock-in or knock-out animals in any mammalian species.

Successful cloning of the first rabbits from somatic cells was reported in 2002 (Chesne et al., 2002). In this study, several healthy and fertile somatic clones of rabbits were produced using freshly collected cumulus cells as nuclear donors. A more recent paper reported the production of cloned transgenic rabbits by a novel technique called chimeric somatic cell cloning (Skrzyszowska et al., 2006). These cloned transgenic rabbits were produced by transfer of skin fibroblast cell nuclei from an adult transgenic rabbit to the cytoplasmic microenvironment of single enucleated blastomeres from two-cell stage rabbit embryos. Results from these studies are very encouraging and have opened a way to the development of knock-in or knock-out rabbits by combining the techniques of culture and genetic modification of somatic cells (as nuclear donor) and cloning by nuclear transfer.

Transgenic Rabbit Models for Major Human Diseases

Transgenic Rabbit Models for Atherosclerosis

Atherosclerosis is a leading cause of death in developed countries. It has been well known that high plasma cholesterol concentration (hypercholesterolemia), especially low-density lipoprotein (LDL) cholesterol, constitutes an important risk factor in atherosclerotic lesion formation. Laboratory rabbits have been widely used for studies of atherosclerosis due to its reasonable size, ease of manipulation, quick response to dietary cholesterol, and similar lipoprotein metabolism to human. Among the animals that have been studied, the rabbit is the only one in which hypercholesterolemia could be induced by administration of a high-cholesterol diet for a few days (Bocan et al., 1993). The cholesterol-fed rabbit has become the classical model for the study of lipoproteins and their roles in atherosclerosis. The unique characteristics of this rabbit model, including low plasma total cholesterol concentrations, high-cholesterol ester transfer protein activity, low hepatic lipase (HL) activity, and lack of an analog of human apolipoprotein (apo) A-II, have been well addressed (Brousseau and Hoeg, 1999). Furthermore, the Watanabe rabbit (Watanabe heritable hyperlipidemic rabbit, WHHL), a genetically altered strain of New Zealand White (NZW) rabbit, constitutes a laboratory animal which mimics human familial hypercholesterolemia and is suitable to study the link between hypercholesterolemia and atherosclerosis (Watanabe, 1980).

In the last decade, use of transgenic rabbits has attracted great interest for studying the pathogenesis of atherosclerosis. Since the report of the first transgenic rabbits in this area (Fan et al., 1994), the number of applications of transgenic rabbit models to the

TABLE 7.3 Transgenic Rabbit Models for Studies of Lipid Metabolism and Atherosclerosis

Transgenes	Major Effects on Lipoproteins and Atherosclerosis	References
Human hepatic lipase	Reduced VLDL, IDL and HDL; attenuated response to diet-induced hypercholesterolemia and atherosclerosis	Fan et al., 1994
Human 15-lipoxygenase	Protection against diet-induced atherosclerosis	Shen et al., 1995
Human apoB-100	Increased LDL; decreased HDL; effect on atherosclerosis not determined	Fan et al., 1995
Human lecithin:cholesterol acyltransferase	Decreased LDL; increased HDL; protection against diet-induced atherosclerosis	Hoeg et al., 1996
Human apoA-I	Protection against diet-induced atherosclerosis	Duverger et al., 1996a
	Impaired endothelium-derived vasorelaxation	Lebuffe et al., 1997
	Increased HDL; ineffective inhibition to atherosclerosis	Boullier et al., 2001
Human apoE2	Development of type III hyperlipoproteinemia and spontaneous atherosclerosis on regular diet	Huang et al., 1997
Human apoE3	Reduced VLDL; increased LDL; effect on diet-induced atherosclerosis not fully determined	Fan et al., 1998
Human apo(a)	Lipoaprotein(a) assembly with rabbit apo B	Rouy et al., 1998
	Increased atherosclerosis on cholesterol-rich diet	Fan et al., 2001a
Human lipoprotein lipase	Protection against diet-induced atherosclerosis at lower plasma cholesterol than controls	Fan et al., 2001b
	Increased small dense LDL and promoted atherosclerosis at equal plasma cholesterol with controls	Ichikawa, 2004
Matrix metalloproteinase-12	Increased atherosclerosis at higher hypercholesterolemia for longer period	Liang et al., 2006
	Accelerated initiation and progression of atherosclerosis by degradation of internal elastic layer or basement membrane	Yamada et al., 2008

VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

studies of lipid metabolism and atherosclerosis has gradually increased. To date, transgenes for nearly a dozen proteins involved in atherogenesis have been successfully expressed in rabbits, including the human apolipoprotein(a) [apo(a)], apoA-I, apoB, apoE2, apoE3, hepatic lipase (HL), lecithin:cholesterol acyltransferase (LCAT), lipoprotein lipase (LPL), 15-lipoxygenase, matrix metalloproteinase-12, and macrophage metalloelastase (Table 7.3). Most of these transgenic rabbit models have been well characterized and discussed in several review articles (Brousseau and Hoeg, 1999; Fan and Watanabe, 2003). These studies in transgenic rabbits have helped to elucidate the metabolic roles of the proteins in atherogenesis.

In 1994, Fan and colleagues reported the generation of transgenic rabbits for studying the effects of human hepatic lipase (HL) in atherosclerosis (Fan et al., 1994). HL overexpression in the transgenic rabbits showed significant effects on plasma lipid and lipoprotein levels. Total cholesterol and triglyceride levels were reduced by 42% and 58%, respectively, in the transgenic rabbits compared to non-transgenic controls.

Lipoprotein analysis revealed a marked reduction of high-density lipoprotein (HDL), very-low-density lipoprotein (VLDL), and intermediate-density lipoprotein (IDL) in the transgenic rabbits. A further study showed that feeding a diet with 0.3% cholesterol resulted in attenuated hypercholesterolemia in the transgenic rabbits compared to non-transgenic littermates (Fan et al., 1995). The attenuated hypercholesterolemia in the HL transgenic rabbits might be associated with a diminished extent of aortic atherosclerosis (Taylor, 1997).

Apolipoprotein(a) [apo(a)] is a component of lipoprotein(a) [Lp(a)], and naturally presents only in Old World monkeys and humans. Apo(a) is bound to apoB-100 by a disulfide linkage resulting in the Lp(a) complex. The elevated plasma level of Lp(a) has been associated with increased incidence of cardiovascular disease, stroke, and restenosis (Maher and Brown, 1995; Utermann et al., 1989). To investigate the Lp(a) assembly and its role in atherosclerosis, transgenic rabbit lines expressing human apo(a) were established by two independent groups (Fan et al., 1999; Rouy et al., 1998).

In the plasma of transgenic rabbits, unlike the plasma of transgenic mice in which human apo(a) can not bind to murine apoB for formation of Lp(a) particles, human apo(a) was shown to be associated with rabbit endogenous apoB for formation of Lp(a) complex. Results from these studies provide new insights into apo(a) expression and Lp(a) assembly. These transgenic rabbits also provide a potential model to further study Lp(a) and its role in promoting atherosclerosis. A further study of these transgenic rabbits showed that the human apo(a) transgenic rabbits fed a 0.3% cholesterol diet for 16 weeks had more extensive atherosclerotic lesions than the non-transgenic controls, although both groups had similarly increased cholesterol levels in their plasma (Fan et al., 2001a). Results from this study suggest that Lp(a) may have proatherogenic effects in the transgenic rabbits fed a cholesterol-rich diet.

Prospective epidemiological studies suggest that HDL cholesterol and apoA-1 limit atherosclerosis development. To study the effect of apoA-1 in the inhibition of atherosclerosis, transgenic rabbits expressing human apoA-1 were generated (Duverger et al., 1996a). When the transgenic rabbits were fed a cholesterol-rich diet (0.48 g cholesterol per 120 g of the diet), it was shown that the plasma level of HDL cholesterol in the transgenic group was twice that of the control group. Correspondingly, the atherosclerotic lesions in the thoracic aorta were reduced by 50% in the transgenic rabbits compared to non-transgenic controls. Results in this study showed that the protective effects of human apoA-1 on cholesterol-rich diet induced atherosclerosis were associated with the increased HDL levels possibly by the mechanism of reverse cholesterol transport (Duverger et al., 1996b). However, a later study showed that human apoA-1 transgenic rabbits with high HDL cholesterol levels were not protected against the development of atherosclerosis when the rabbits were fed a cholesterol-rich diet which induced dramatic hypercholesterolemia (Boullier et al., 2001). Therefore, the role of human apoA-1 in atherogenesis needs to be further characterized.

The development of transgenic rabbits expressing human apoB-100 has also been described (Fan et al., 1995). Analysis of plasma lipid concentrations in the transgenic rabbits demonstrated that total plasma cholesterol and triglyceride levels were 2–3-fold higher than those observed in non-transgenic controls. Nearly all of the cholesterol and human apoB-100 was in the LDL fraction, with striking enrichment of the triglyceride content. It was further found that the transgenic rabbit LDL contained large amounts of apoC-III and apoE, which suggests that hepatic overexpression of apoB-100 might have led to the assembly of nascent triglyceride-rich particles in the animals that had the size and density of LDL rather than of VLDL (Brousseau

and Hoeg, 1999). The atherosclerosis susceptibility was not determined in these transgenic rabbits.

ApoE2 (Cys112, Cys158) is an apoE variant associated with the human genetic disorder, type III hyperlipoproteinemia. Transgenic rabbits expressing high plasma concentrations of human apoE2 were produced and described by Huang and co-workers (1997). Overexpression of human apoE2 (30–70 mg/dl) in transgenic rabbits resulted in a marked accumulation of β -migrating VLDL and significant increases in VLDL and IDL concentrations, the hallmarks of type III hyperlipoproteinemia. Atherosclerosis susceptibility was assessed in both male and female transgenic and non-transgenic rabbits fed a normal rabbit chow. The transgenic rabbits developed spontaneous atherosclerosis in the aortic arch and proximal abdominal aorta. Interestingly, male transgenic rabbits showed more extensive atherosclerosis than transgenic females, which suggests that sex hormones may play a role in modulating type III hyperlipoproteinemia (Huang et al., 1997).

Generation of transgenic rabbits expressing lecithin-cholesterol acyltransferase (LCAT), an enzyme that plays an important role in cholesterol and HDL metabolism, was reported in 1996 (Hoeg et al., 1996). Overexpression of human LCAT in transgenic rabbits resulted in a substantial change in plasma lipid and lipoprotein concentrations. Plasma total, free and esterified cholesterol concentrations, as well as phospholipid concentrations, were significantly increased in both low and high expressors of the transgene compared to control littermates. The elevation in plasma total cholesterol contents was associated with a marked increase in HDL concentration. Analysis of other lipoproteins revealed significantly increased plasma apoA-1 and apoE concentrations, but reduced apoB concentration in the LCAT transgenic rabbits. Furthermore, study of atherosclerosis susceptibility in the rabbits showed significantly reduced atherosclerosis compared to control littermates on a 0.3% cholesterol diet for 17 days (Hoeg et al., 1996).

To study the physiological role of lipoprotein lipase (LPL), a key enzyme in hydrolysis of triglyceride-rich lipoproteins in lipid and lipoprotein metabolism, transgenic rabbits expressing human LPL were established (Araki et al., 2000). In the transgenic rabbits, LPL activity was four times higher than that of non-transgenic controls, and plasma triglyceride was decreased by 80% and HDL by 59%. Analysis of the lipoprotein density fractions revealed that overexpression of the LPL transgene resulted in a remarkable reduction in the levels of VLDL and IDL. The initial study for atherosclerosis susceptibility showed marked protection against diet-induced hypercholesterolemia and development of aortic atherosclerosis (Fan et al., 2001b). However, it should be noted that plasma cholesterol levels in the transgenic rabbits

were significantly lower than those in control rabbits (Ichikawa et al., 2004). To clarify, if the antiatherogenicity was caused by the increased LPL activity itself or if the antiatherogenic effect of LPL was dependent upon the LPL lipid-lowering effect, LPL transgenic rabbits and littermates were fed diets with different amounts of cholesterol (0.3–0.6%) so that their plasma cholesterol concentrations could be adjusted to maintain similarly high levels for 16 weeks (Ichikawa et al., 2004). Interestingly, the subsequent study demonstrated that the transgenic rabbits developed 1.8-fold more extensive aortic atherosclerosis than the control rabbits even though they had the same level of hypercholesterolemia. Overexpression of human LPL in transgenic rabbits reduced remnant lipoproteins (β -VLDL) but concomitantly led to a significant increase of large and small LDLs compared to controls. An in vitro experiment showed that small-sized LDLs of the transgenic rabbits were more susceptible to copper-induced oxidation and had higher affinity to biglycan than large-remnant lipoproteins. Based on the results of these studies, the authors concluded that “LPL exerts a dual function in terms of its atherogenicity, namely antiatherogenicity, through enhancing receptor-mediated remnant lipoprotein catabolism and pro-atherogenicity by the generation of a large amount of small-sized LDLs” (Ichikawa et al., 2004).

Matrix metalloproteinase-12 (MMP-12) was first identified as a potent elastolytic metalloproteinase specifically secreted by macrophages (Shapiro et al., 1993). Increased activity of MMP-12 has been implicated in many inflammatory processes including atherosclerosis (Beaudeux et al., 2004; Watanabe and Ikeda, 2004). It has been demonstrated that expression of MMP-12 was prominently upregulated in atherosclerotic lesions of cholesterol-fed rabbits (Matsumoto et al., 1998). To study the pathophysiological roles of MMP-12 in atherosclerosis, transgenic rabbits with targeted expression of human MMP-12 gene in macrophages were established (Fan et al., 2004; Liang et al., 2006). A preliminary study for atherosclerosis susceptibility found no significant difference in the aortic atherosclerotic lesion size or quality between transgenic and non-transgenic rabbits with lower hypercholesterolemia. In contrast, transgenic rabbits with higher hypercholesterolemia for longer periods developed more extensive atherosclerosis in the aortas and coronary arteries than non-transgenic controls (Liang et al., 2006). Furthermore, increased expression of MMP-12 derived from macrophages was found to be associated with elevated expression of MMP-3. These results suggest that macrophage-derived MMP-12 plays a pivotal role in the cascade action of other MMPs, which may be involved in exacerbating extracellular matrix degradation during the progression of atherosclerosis (Liang et al., 2006). In a subsequent study, the same group investigated macrophage

migration and elastolysis in relation to fatty streaks in MMP-12 transgenic rabbits (Yamada et al., 2008). They found that MMP-12 transgenic rabbits fed a 1% cholesterol diet for 6 weeks developed more pronounced fatty streaks associated with more significant degradation of the internal elastic layer compared to non-transgenic controls. In addition, the transgenic rabbits showed greater numbers of infiltrating macrophages and smooth muscle cells in the lesions than control rabbits. The authors concluded that MMP-12 may be critical to both initiation and progression of atherosclerosis by degradation of the elastic layers and/or basement membrane. These transgenic rabbits may provide a potential system to test specific MMP-12 inhibitors for treatment of progressive atherosclerosis (Yamada et al., 2008).

Other transgenic rabbits which have been used for the study of atherosclerosis include those with modified genes for apoE3 (Fan et al., 1998); apoB mRNA editing enzyme catalytic polypeptide 1 (APOBEC-1) (Yamanaka et al., 1995); and 15-lipoxygenase (Shen et al., 1995). Additionally, generation of double-transgenic rabbits by crossbreeding two different transgenic lines and WHHL transgenic rabbits have been described elsewhere (Brousseau and Hoeg, 1999; Fan and Watanabe, 2003).

Transgenic Rabbit Models for Long QT Syndrome

The long QT (LQT) syndrome is an inherited disorder of cardiac rhythm and is usually associated with autosomal dominant mutations. This disease is characterized by prolongation of the QT interval in the surface electrocardiogram (ECG), spontaneous polymorphic ventricular tachycardia and sudden cardiac death (SCD) in young patients (Moss, 2003). At least nine different forms of the disease have been identified so far, but among the genotyped individuals, mutations in genes encoding repolarizing K^+ channels (LQT1:KCNQ1; LQT2:KCNH2) are found in 90% of affected individuals as the underlying cause and many of the mutations show a dominant negative mechanism (Roden, 2006). In these patients, ventricular arrhythmias and sudden death are often triggered by emotional stress and/or physical exercise. In female LQT syndrome patients, an increase in the incidence of arrhythmias has been reported with menses and during the first postpartum months (Seth et al., 2007).

In some experimental studies, transgenic mouse models of LQT syndrome have been instrumental in understanding the assembly and role of potassium channels in regulating heart repolarization (Nerbonne et al., 2001). However, the mouse heart is small, the resting heart rate is 310 beats/minute, and action potential duration (APD) is very short. Additionally, the main repolarizing currents in mice are carried by

different channels compared with human, which limits the applicability of studies in the mouse to human patients (Nerbonne et al., 2001). In contrast, the rabbit heart is much larger and has a much slower heart rate (130 beats per minute at rest). Most importantly, the rabbit heart is also more similar to the human heart in terms of the contractile proteins that are expressed as well as the ion channels important for repolarization (Vermeulen et al., 1994). Furthermore, the rabbit heart has the same K^+ current components, namely the rapidly activating component (I_{kr}) and the slowly activating component (I_{ks}), which determine the repolarization of the action potential (AP). Thus, the rabbit represents a more physiologically relevant model system to study diseases involving these channels.

Transgenic rabbits expressing pore mutants of the human genes *KCNQ1* (KvLQT1-y315S) and *KCNH2* (HERG-G628S), which lead to LQT1 and LQT2 phenotypes, respectively, have been successfully created and characterized (Brunner et al., 2008). Over-expression of these transgenes is targeted in cardiomyocytes of the rabbit heart under the control of the rabbit β -myosin heavy chain (β -MyHC) promoter. Characterization of the transgenic rabbits revealed that prolongation of the QT interval and APD at 90% repolarization (APD90) were due to the elimination of I_{ks} and I_{kr} currents, respectively. Clinically, the elimination of I_{ks} and I_{kr} has different effects. LQT1 rabbits show QT prolongation but neither spontaneous arrhythmias nor an increase in sudden death. In contrast, LQT2 rabbits have a more pronounced QT prolongation at slow heart rates and show both spontaneous arrhythmias and a significant increase in sudden death after the age of about 6 months, consistent with the end of puberty in rabbits. Additionally, LQT2 females exhibit a high incidence of sudden death during lactation, an observation similar to the increased incidence of arrhythmias in women with the LQT2 syndrome postpartum (Seth et al., 2007). It has been hypothesized that sex hormones modulate cardiac repolarization and arrhythmogenesis in LQT2 females.

This transgenic rabbit model has also been used to study the side effects of anesthetic agents in individuals genetically predisposed to SCD in a subsequent study (Odening et al., 2008). In this study, five common anesthetic agents, including isoflurane, thiopental, midazolam, propofol, and ketamine, were investigated. The results showed that (1) isoflurane resulted in a prolonged QT interval in LQT2 but not in LQT1 rabbits; (2) thiopental prolonged the QT interval in both QT1 and QT2, but less pronounced in LQT1 rabbits; (3) midazolam prolonged the QT duration in both LQT1 and LQT2, but not in controls; and (4) propofol significantly increased the QT interval in both LQT1 and LQT2 rabbits as well as controls. Additionally, signs

of altered repolarization and arrhythmias were noted only in LQT2 rabbits during the monitoring periods under anesthesia. Multiple premature ventricular contractions, which can have a marked effect in humans, occurred in many LQT2 rabbits under midazolam, ketamine, or thiopental. Furthermore, it was also noted that isoflurane and propofol were especially proarrhythmic in LQT2 rabbits and led to sudden death in 30% of LQT2 rabbits. Results from this study indicate the importance of careful study of ECG by anesthesiologists prior to surgery, which may help in selecting more appropriate anesthetic agents. It is anticipated that the transgenic rabbit models could play a major role in identifying mechanisms of SCD and could be used to screen drugs that interact with the Human Ether-à-go-go Related Gene (hERG) potassium channel, causing QT prolongation and potentially fatal arrhythmias.

Transgenic Rabbit Models for Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a genetic disease characterized by cardiac hypertrophy, myocyte disarray, interstitial fibrosis, and left ventricular (LV) dysfunction (Wigle et al., 1995). Certain mutations in genes for sarcomeric proteins have been identified as causes of HCM (Marian and Roberts, 1998). The most common gene responsible for HCM is the β -myosin heavy chain (β -MyHC), in which a point mutation accounts for 35–50% of HCM cases (Watkins et al., 1995). The mechanism and molecular pathogenesis of the mutant sarcomeric proteins, including mutant β -MyHC, in HCM is well understood (Marian and Roberts, 1995). However, a desirable small animal model for identifying new therapeutic targets and diagnostic methods for HCM was not available until the successful generation of a transgenic rabbit model for HCM (Marian et al., 1999). Although transgenic mice expressing a variety of mutant sarcomeric proteins showed the phenotypes of premature death, cardiac myocyte disarray, interstitial fibrosis, and systolic and diastolic dysfunction, the mice did not develop left ventricular hypertrophy, the hallmark of HCM in human patients (Muthuchamy et al., 1999; Oberst et al., 1998; Vikstrom et al., 1996). Additionally, the composition of cardiac sarcomeric proteins between humans and mice are very different, as β -MyHC is pre-dominant in the human ventricle but α -MyHC is pre-dominant in the mouse ventricle (Swynghedauw, 1986). In contrast to the mouse, β -MyHC is the major myosin isoform in rabbit myocardium (Kavinsky et al., 1984), and it has an approximately 98% homology to the human β -MyHC protein (Jaenicke et al., 1990). Since it is known that MyHC isoforms act significantly different in actin-activated My-ATPase activity and cross-bridge kinetics (Sugiura et al., 1998), difference in cardiac sarcomeric

protein composition can affect the phenotypic response of the heart to mutant protein. Therefore, the rabbit provides a more reasonable model for studying HCM compared to mice.

To establish a transgenic rabbit model for HCM, Marian and colleagues (Marian et al., 1999) generated transgenic rabbits by targeted cardiac expression of the mutant β -MyHC-Q403, known to cause HCM in humans (Watkins et al., 1992). Expression of the mutant β -MyHC-Q403 protein in the transgenic rabbits induced virtually identical phenotypes to that of HCM caused by the mutant gene in humans, including cardiac hypertrophy, myocyte and myofibrillar disarray, excess interstitial collagen and high incidence of premature death. The expression of comprehensive phenotype of HCM, plus the feasibility of high-resolution serial echocardiograph, has made the β -MyHC-Q403 transgenic rabbits an ideal model for pathogenic and therapeutic studies of HCM.

In several subsequent studies, this transgenic rabbit model has been used to test a variety of drugs for treatment of HCM. These studies revealed that atorvastatin could prevent development of HCM in young transgenic rabbits (Senthil et al., 2005), and simvastatin induced regression of cardiac hypertrophy and fibrosis and improvement of cardiac function (Patel et al., 2001). Most interestingly, a recent study demonstrated that treatment with N-acetylcysteine, a safe prodrug against oxidation, reversed established cardiac hypertrophy and fibrosis and prevented systolic dysfunction (Lombardi et al., 2009). Furthermore, this transgenic rabbit model has also been used to explore more sensitive and accurate methods for early diagnosis of HCM. It was reported that tissue Doppler imaging could consistently detect myocardial contraction and relaxation abnormalities, irrespective of cardiac hypertrophy in the transgenic rabbits and was shown to be more sensitive than conventional echocardiography for HCM scanning (Nagueh et al., 2000). This finding has been confirmed in human patients with HCM in a study that showed Doppler imaging to be an accurate and sensitive method for an early diagnosis before and independent of hypertrophy (Nagueh et al., 2001).

Transgenic Rabbit Models for HIV-1 Infection and AIDS

A major obstacle to study HIV-1 infection and AIDS development is the lack of a suitable small animal model for testing diagnostic, therapeutic, and preventive modalities. Non-human primate species as the ultimate model are either endangered, not generally available, or expensive. Even among the non-human primates, only the chimpanzee and gibbon ape could be infected by HIV-1 (Agy and Katze, 1993). Native rodents are non-permissive for HIV-1 infection. Even

expression of human CD4 (HuCD4), the known principal receptor for HIV-1, failed to render mouse cells permissive to the HIV-1 infection (Lores et al., 1992). In contrast, the rabbit seems relatively more susceptible to HIV-1 infection compared to rodents, as supported by the reported successful infection of normal rabbit cells (Kulaga et al., 1989) and rabbits (Filice et al., 1988; Gordon et al., 1990; Kulaga et al., 1989; Varnier and Kindt, 1992) although the infection was much less efficient than in human lymphocytes and no consistent signs of AIDS-like disease were observed in the infected rabbits. It was suggested that a rabbit CD4 (RbCD4)-like receptor might be sufficiently homologous to HuCD4 to interact with HIV-1, since soluble human CD4 treatment abrogated infection of rabbit T cells by HIV-1 (Hague et al., 1992). However, sequence comparisons of RbCD4 cloned from a rabbit thymus cDNA library showed that six of the 18 residues implicated in HIV-1 binding by CD4 differ between the human and rabbit proteins, and no correlation between RbCD4 expression by rabbit cell lines and their ability to support HIV-1 infection was seen (Hague et al., 1992). A subsequent study demonstrated that expression of HuCD4 in rabbit peripheral blood mononuclear cells (PBMC) could enhance the infection of the cell by HIV-1 and result in a rapid depletion of the infected cells (Leno et al., 1995). Furthermore, two groups then simultaneously reported the successful generation of HuCD4 transgenic rabbits (Dunn et al., 1995; Snyder et al., 1995). Snyder et al. (1995) reported that HuCD4 expression was restricted to RbCD4 expression lymphocytes, and peripheral blood lymphocytes (PBLs) from HuCD4 transgenic rabbits produced greater amounts of HIV-q p24 core protein following HIV-1 infection in vitro than the cells from non-transgenic rabbits. No in vivo HIV-1 infection study in these transgenic rabbits has been reported, though in vitro studies by Dunn et al. (1995) demonstrated enhanced susceptibility of lymphocytes derived from HuCD4 transgenic rabbits to HIV-1 infection. Furthermore, in vivo HIV-1 infection of the HuCD4 transgenic rabbits was demonstrated by virus isolation, detection of HIV-1-specific DNA in peripheral blood leukocytes (PBLs) and seroconversion to various HIV-1 proteins. However, no signs of AIDS-like disease were observed in the infected transgenic rabbits, indicating that these HuCD4 transgenic rabbits were still not sufficiently susceptible to HIV-1 infection for disease development. One hypothesis was that some co-receptors might be involved in susceptibility to HIV-1 infection, such as the β -chemokine receptor CCR5 which was demonstrated as an essential receptor for HIV-1 entry into cells (Deng et al., 1996; Ghorpade et al., 1998). An in vitro study demonstrated that rabbit cells expressing both HuCD4 and human CCR5 were highly permissive for HIV-1 infection and viral

replication in rabbit cells could approach the level seen in human cells (Speck et al., 1998). Additionally, HIV-1 virions produced in rabbit cells were able to support spreading infection and successfully infected human PBMC. These findings suggested that transgenic rabbits expressing both human CD4 and CCR5 genes might support more reasonable levels of HIV-1 replication in vivo and serve as a useful small animal model. However, such a transgenic rabbit model has not been reported so far, although it has been shown that mice with such transgenes were still insufficient to support HIV-1 infection (Browning et al., 1997). It is very possible that the mechanism for HIV-1 infection might be more complicated than first believed and some additional co-factors might be involved.

Transgenic Rabbit Models for Human Papillomavirus Infection

Papillomaviruses are a group of small DNA viruses associated with neoplasia of skin and other epithelia in some species of animals (Campo, 2002) and humans (zur Hausen, 2002). Due to the restricted species specificity of these viruses, a natural animal model is not available to study the infection and pathogenesis of human papillomaviruses (HPV), most notably the so-called oncogenic HPVs (16, 18, 31, 33) since they are associated with the development of most cervical cancers. Cottontail rabbit papillomavirus (CRPV) has long been used as an animal model to study the pathogenesis and development of prophylactic and therapeutic strategies for oncogenic HPV infection due to its similarity in genomic structure and tumorigenesis (Christensen, 2005; Kreider and Bartlett, 1985).

Epidemiological and molecular studies indicate that, although the oncogenic HPVs have been found in more than 90% of cervical cancers, the viruses alone are insufficient to cause malignant transformation, for which some co-factors (such as inactivation of tumor suppressor genes and/or activating mutation of cellular oncogenes, etc.) could be required (zur Hausen, 2002). Some preliminary studies found that activated Ha-ras, an oncogene found in many human malignant tumors including some HPV 16- or 18-related cervical cancers, was required for malignant transformation of HPV16-immortalized human cervical cells (DiPaolo et al., 1989); and both HPV16 DNA and EJras were required for transformation of primary cells (Matlashewski et al., 1987). To study the interaction between oncogenic papillomavirus and potential cofactors in vivo, transgenic rabbits carrying CRPV genome alone or carrying both CRPV genome and EJras oncogene were generated (Peng et al., 1993). Analyses of these transgenic rabbits showed that the rabbits expressing CRPV E6/E7 alone developed only skin papillomas, but the rabbit expressing both CRPV E6/E7 and EJras oncogene was born

with extensive skin squamous cell carcinomas (SCC). In a subsequent study, transgenic rabbits with targeted expression of EJras in the skin by CRPV upstream regulatory region showed growth of keratoacanthomas in the first week of age (Peng et al., 1999). The keratoacanthomas were morphologically similar to the tumors in humans and spontaneously regressed at about 2 months of age. After complete regression of the keratoacanthomas, the EJras expression was undetectable and there was no growth of new tumors. However, a further study showed that CRPV infection of the skin of the transgenic rabbits at 2 months of age (after regression of keratoacanthomas) could re-initiate the expression of EJras transgene and accelerate tumorigenesis compared to non-transgenic rabbits (Peng et al., 2001). Results from studies of these transgenic rabbits clearly indicate that activated H-ras oncogene could increase the tumorigenesis/carcinogenesis of the oncogenic papillomavirus infection. This synergistic effect has been further confirmed by a recent human study showing that H-ras mutation was identified in 21% of patients with cervical tumors with poor or moderated differentiation (Landro et al., 2008). However, the intrinsic mechanisms of the synergistic effect between activated H-ras and oncogenic papillomaviruses in carcinogenesis need to be further elucidated.

To assess host immune response to HPV infection, preclinical models are required for initial vaccine and immunotherapeutic testing. However, the restricted species specificity of papillomaviruses makes these studies particularly challenging (Fausch et al., 2003). Currently used preclinical models of natural papillomavirus infection include rabbit, dog, and bovine (Campo, 2002). A natural rodent model for papillomavirus infection and testing cell-mediated immune responses is currently not available. The species restriction barriers of papillomaviruses prevent infection and replication of HPVs in all immunocompetent laboratory animals. Among the natural papillomavirus infection models, the cottontail rabbit papillomavirus model offers several advantages as a preclinical model for studying host immunity to papillomavirus infection (Christensen, 2005). One advantage is that papillomas can be generated by direct infection of skin with naked viral DNA (Brandsma and Xiao, 1993; Kreider et al., 1995). This feature provides opportunities for genetic modification of the viral genome by site-directed mutagenesis, which can be used to induce epitopes into the various viral genes for testing specific immunity. It has been shown that an HPV16 E7 T cell epitope can be engineered into the E7 gene of the CRPV genome without influencing the tumorigenesis of the modified virus. To assess immunity to the HPV epitopes in an infection model for papillomaviruses, a transgenic rabbit model expressing HLA-A2.1 gene, a well-characterized human

major histocompatibility complex class I (MHC-I) gene, has been established (Hu et al., 2006, 2007). HLA-A2.1 expresses and co-localizes exclusively with rabbit MHC-I on the cell surface of all transgenic rabbits. The transgenic rabbits vaccinated with a HLA-A2.1-restricted HPV16 E7 multivalent epitope (82-90) DNA vaccine showed complete protection against infection with modified CRPV DNA containing an embedded HPV16 E7/82-90 epitope (Hu et al., 2006). Similar results were observed from testing several HLA-A2.1-restricted epitopes from CRPV E1 in the transgenic rabbits (Hu et al., 2008). Data from these studies indicate that the HLA-A2.1 transgenic rabbit model will provide opportunities to directly test HLA-A2.1-restricted epitopes of HPV proteins in the context of a human MHC class I gene. Furthermore, this transgenic rabbit model may also have potential application in testing CD8⁺ CTL-inducing vaccines against other human pathogens that are permissive or semi-permissive in rabbits, such as human T cell leukemia virus (Franchini et al., 1995), adenovirus (Romanowski et al., 2002), EBV-like viruses (Hayashi et al., 2003), and tuberculosis (Dorman et al., 2004).

Transgenic Rabbit Models for Retinal Degeneration

Retinitis pigmentosa (RP) includes a group of inherited retinal disorders characterized by a progressive loss of rod and cone photoreceptors and eventual atrophy of the entire retina (Hartong et al., 2006). RP is genetically heterogeneous, associated with mutations in several photoreceptor-specific and some non-specific genes (Daiger et al., 2007). To date, mutations in the rhodopsin gene have been identified as the most prevalent class, causing approximately 25–40% of the autosomal dominant RP cases (Dryja et al., 1991).

To develop a model for studying the pathophysiology and developing new treatments for this disease, transgenic rabbits expressing rabbit rhodopsin with a point mutation (Pro347Leu) have been generated (Kondo et al., 2009). In total, six lines of transgenic rabbits were established from pronuclear injection of a BAC (bacterial artificial chromosome) transgenic construct carrying the rabbit rhodopsin mutant gene Pro347Leu. Further studies on two of these lines with high levels of the transgene expression showed rod-dominant progressive retinal degeneration. Retinal histology exhibited a marked regional variation in the loss of photoreceptors with the central retina more severely affected than the peripheral retina. Assessment of retinal function by electroretinograms (ERGs) in the transgenic rabbits indicated early loss of rod function associated with relatively preserved cone function, which is very similar to the clinical signs found in human RP patients with the rhodopsin Pro347Leu mutation (Berson et al., 1991; Oh et al., 2003). Combined

with large eyes and easier handling and breeding, transgenic rabbits may provide a useful animal model for studying the pathophysiology of retinal degeneration and developing novel treatment for this disease.

Transgenic Rabbit Bioreactors for Production of Clinically Useful Proteins

Large and medium-sized transgenic animals, including cows, pigs, sheep, goats, and rabbits, have been used as bioreactors for production of human proteins for potential therapeutic and diagnostic use (Houdebine, 1995, 2000). By controlled tissue-specific expression, large amounts of human recombinant proteins can be produced and purified from milk, blood, or urine of transgenic animals. There are several advantages to obtaining therapeutic proteins from transgenic bioreactors compared to proteins from other sources (Fan and Watanabe, 2003). First, proteins from bioreactors may reduce contamination by pathogens, which is a major concern for using proteins directly isolated from human sources. Second, the native activity of foreign proteins expressed in bioreactors can be better preserved than that of recombinant proteins derived from bacteria or yeast. It has been known that bacteria do not add carbohydrates to polypeptide chains so that not all proteins generated in bacteria can necessarily form their mature native structure. Additionally, the post-synthesis modifications such as carboxylation, glycosylation, and amidation, which are essential for full biological function of many proteins, could be accomplished in the mammary glands of transgenic bioreactors (Houdebine, 1995, 2000). The choice criteria for selecting the most suitable species as bioreactor for production of human proteins is usually based on the quantity of protein needed per year. The production of protein needed in large amounts (tons to hundreds kg per year) should be carried out in cows, sheep, or goats, whereas rabbits can be used as an intermediate producer for proteins needed in moderate amounts (kilograms per year) (Castro et al., 1999). Compared to large farm animals, transgenic rabbits as bioreactors have some unique features. Rabbits have much shorter reproductive cycles and larger litter size; and are ready to breed at most times, including during postpartum, in all different seasons. Therefore, large numbers of rabbits can be produced in a short period of time. Additionally, generation of transgenic rabbit founders is relatively easier and more efficient than generation of other transgenic farm animals. A transgenic lactating doe can yield up to 10kg of milk per year, which can be collected under semi-automatic hygienic conditions (Duby et al., 1993). Rabbit milk, which has been well characterized, naturally contains about 14% protein compared to approximately 3–6% in the milk of goats, cows, and

sheep (Duby et al., 1993). Furthermore, rabbit colonies can be easily maintained under specific pathogen-free conditions in barrier facilities. All these features make rabbits highly attractive to be used as bioreactors for production of recombinant human proteins, especially the proteins expressed in the rabbit mammary glands.

Medical products which can be expressed in transgenic rabbits may be classified into three major categories: (a) therapeutic proteins, (b) hormones and bioactive peptides, and (c) monoclonal antibodies (Bosze et al., 2003). A number of recombinant proteins have been specifically expressed in the milk or blood of transgenic rabbits (Table 7.4). Among these proteins, human alpha-glucosidase derived from transgenic rabbit milk (Bijvoet et al., 1999) is the first transgenic rabbit product that has been used in clinical trials for the treatment of Pompe's disease (Van den Hout et al., 2000, 2001). Pompe's disease is a lysosomal glycogen storage disorder involving heart, smooth and skeletal muscles, caused by acid alpha-glucosidase deficiency. The rapidly progressive infantile form is the most serious form of this disease and is commonly fatal in the first year of life. There is currently no approved treatment for this fatal disease, but several recent clinical trial studies have shed hopeful light for patients of this disease. In an open-label pilot study, four babies (2.5–8 months

old) with typical symptoms of infantile Pompe's disease and virtual absence of alpha-glucosidase were treated by an enzyme replacement therapy with intravenous infusion of recombinant human alpha-glucosidase (rhGLU) purified from transgenic rabbit milk at a starting dose of 15 mg/kg or 20 mg/kg, and then increased to 40 mg/kg. The study demonstrated that alpha-glucosidase activity reached the normal range in all the patients treated with 40 mg/kg rhGLU for 12 weeks. Histological assessment showed lowered lysosomal glycogen storage and improved tissue morphology (Van den Hout et al., 2000). Furthermore, a long-term follow-up study revealed that all the patients survived beyond the age of 4 years, in contrast to untreated patients who succumbed at a median age of 6–8 months (Van den Hout et al., 2004). Additionally, a separate study investigated the therapeutic effect of rhGLU from the rabbit milk in late-onset Pompe's disease. Three patients aged 11, 16, and 32 years respectively were enrolled in the study. All the patients were wheelchair-bound and two of them were ventilator-dependent with a history of deteriorating pulmonary function. After 3 years of treatment with weekly infusion of the hrGLU, the patients showed stabilized pulmonary function and less fatigue. Most impressively, the youngest and least-affected patient could walk without support and finally

abandoned his wheelchair after 72 weeks of treatment (Winkel et al., 2004). These clinical trial studies provide very optimistic evidence for production of a safe and effective medicine in the milk of transgenic rabbits.

Transgenic rabbits have also been developed for the production (in milk) of important vaccine reagents for infectious diseases such as human rotaviruses. Rotaviruses are the main cause of viral gastroenteritis in young children worldwide leading to approximately 500 000 deaths annually, mostly in developing countries (Glass et al., 2004). For unknown reasons, vaccination with the live attenuated rotavirus has been associated with an increased risk of intussusceptions. To develop a safe and effective vaccine for this disease, production of recombinant VP2 and VP6 proteins in transgenic rabbit milk was reported (Soler et al., 2005). Evaluation of the recombinant viral proteins in a preliminary study showed immunogenic effects and significant reduction in viral antigen shedding after challenge with virulent rotavirus in an adult mouse model. This study has opened a new route for development of vaccines by expressing antigenic proteins in transgenic animal milk.

The rabbit has been commonly used in the production of polyclonal antibodies due to their relatively large body size and blood volume, easy access to the vascular system, and the existent of a large body of information on the purification of rabbit immunoglobulins. For many years, researchers have attempted to produce monoclonal antibodies (mAb) in rabbits since rabbits are known to produce antibodies to many antigens that are not especially immunogenic in mice or rats (Weidle et al., 1991). However, a plasmacytoma fusion partner, essential for production of mAb, was not available in rabbits. To obtain a rabbit plasmacytoma cell line that could be used as a fusion partner, Spieker-Polet et al. (1995) generated transgenic rabbits expressing both c-myc and v-able. These rabbits developed plasmacytomas from which several plasmacytoma cell lines were established. When the cells from a clone of one cell line fused with spleen cells of immunized rabbits, stable hybridomas that secreted antibodies specific for the immunogen were produced. This study demonstrated the possibility of using transgenic rabbits for production of mAb although no subsequent study has been reported. A more recent report presented the efficient production of a complex bispecific single-chain antibody in the serum of transgenic rabbits carrying the bi-scFv r28M DNA construct (Grosse-Hovest et al., 2004). Functional analysis showed that the serum purified bispecific protein, r28M with known anti-human melanoma specificity, was stable and fully active in mediating target cell-restricted T cell stimulation and tumor cell killing. This study further explored the possibility of producing high concentrations of fully active therapeutic molecules in transgenic animals.

CONCLUSIONS

The Broad Institute's Rabbit Genome Project is designed to encompass a deep 7× full coverage that will be both a comprehensive and powerful resource for rabbit researchers and the rabbit industry alike. Comparative genomics, disease traits, selection for resistance/susceptibility to important human pathogens (e.g. HIV, tuberculosis) will likely benefit from this new database. In addition, the domestic rabbit is an important research tool to study other genetic predispositions including inherited hyperlipidemia, atherosclerosis, glaucoma, diabetes, and for the production of polyclonal antibodies and biopharmaceuticals via transgenics. Transgenic rabbit models for studying the genetics of specific diseases will continue to expand our knowledge of these processes in humans and provide excellent preclinical models for therapeutic treatments. Rabbits also are excellent models to study immune responses to various pathogens and are used extensively to make specialized antibody reagents for the research community.

INTRODUCTION

The rabbit is a popular model in laboratory animal medicine due to its relatively large size and docile nature. Though rabbits are sometimes mistakenly thought of as rodents, they are in their own Order Lagomorpha. Among the many breeds of rabbits, by far

the most popular in research is the New Zealand White rabbit. Research in these rabbits has contributed to advances in cardiology, orthopedics, dentistry, immunology, and more.

This chapter closely follows the outline presented in the anatomy and physiology chapter of the 1994 edition of *The Laboratory Rabbit*. In fact, the two chapters by

Cruise and Brewer have been extensively cited owing to the unchanging nature of anatomy.

more than females and dominant rabbits marking more than submissive rabbits.

EXTERNAL FEATURES

Rabbits have thin, delicate skin that is generously covered with both underfur and guard hairs (Harcourt-Brown, 2002). The rabbit skin, similar to the rat, has blood vessels immediately under the dermis (Cruise and Brewer, 1994). Unlike the rat, however, the fascia superficialis is well differentiated due to the elastic fibers and dense collagen content (Brewer, 2006). Hair grows in waves starting from the ventrum and grows dorsally and caudally. Thick fur covers the feet in place of footpads. The fragile skin can tear easily and must be handled carefully during any manipulation. Females have a large skin fold on the ventral surface of their neck called the dewlap (Figure 8.1). Breeding females pull hair from this area to create a nest before parturition (Meredith, 2000).

Rabbits have three scent glands: the chin glands, anal glands, and inguinal glands. The chin glands are specialized submandibular glands which open onto the ventral surface of the chin. The inguinal glands are pocket-like perineal glands that lay dorsal to the urogenital opening on either side of the anus. Both males and females have these glands, with males marking

Head and Neck

Rabbits have pinnae that are large, vascular and able to move independently of one another. They can represent a large part of the total body surface area (up to 12% in New Zealand Whites) (Brewer and Cruise, 1994). When dilated by heat, the rabbit ear shows the presence of large arteriovenous shunts and is thus an important mechanism for thermoregulation (Gordon et al., 1953).

Rabbit ears are fragile and should not be used for restraint. The dorsal skin is thick and contains many hair follicles, while the ventral skin has few hair follicles. The skin on the ventral surface of the ears contains large sebaceous glands that provide a convenient medium for carcinogen study, while those in the dorsum are smaller. The main vessels are the central ear artery and two lateral veins. The central ear artery runs towards the ear tip and bifurcates into two major branches showing a U-turn curve halfway up to the pinnae. Thus in the rabbit, the direction of blood flow in the rostral and caudal edges of the ear is from the pinnae to the base of the ear (Ninomiya, 2000). The central ear artery can be used for blood sampling as well as direct blood pressure measurements, though the pressure is approximately 10mmHg less than in the common carotid artery. Though the veins and artery in the ear can be used for catheters and blood draws, forceful venipuncture can cause vasculitis, vascular necrosis, and sloughing of the skin.

The rabbit visual field forms almost a complete sphere (Cruise and Brewer, 1994). Eyes are laterally placed, endowing rabbits with a broad field of vision, except for the area under their mouth, which they compensate for with their vibrissae and sensitive lips. The rabbit cornea is large, occupying up to 30% of the globe (Queensberry and Carpenter, 2004). The lens is spherical and large and the ciliary body is small and poorly developed. The fundus of the rabbit is merangiotic, where only part of the inner retina is supplied by retinal vessels. This is in contrast with a holangiotic fundus, seen in dogs, cats, cattle, goats, sheep, pigs, rats, mice, and primates, where the retinal blood supply is from central or cilioretinal arteries (Buyukmihci, 2010). In practical terms, this results in a band of blood vessels and myelinated nerve fibers crossing the retina in a horizontal plane from the optic disc (Williams, 2007) (blood vessels present only laterally and medially to the optic disc) as opposed to a holangiotic fundus that contains blood vessels throughout the retina (Keil, 2010). Because the optic disc lies above the horizontal midline of the eye, it requires the examiner to look upwards during a retinal exam (Harcourt-Brown, 2002). The

FIGURE 8.1 Female rabbit with prominent dewlap.

FIGURE 8.2 Rabbit with prolapsed gland of the nictitating membrane.

optic disc has a physiologic cup and the eye does not have a tapetum lucidum, similar to pigs, guinea pigs, primates, and birds (Ollivier et al., 2004).

Rabbits have a third eyelid that moves across the cornea during anesthesia, though it only covers two-thirds of the cornea (Harcourt-Brown, 2002). It also covers a Harderian gland which has a small, white upper lobe and a larger, pink lower lobe. This lower lobe, also known as the deep gland of the nictitating membrane, can prolapse, similar to a “cherry eye” in a dog (Figure 8.2). Because rabbits often freeze on examination, many rabbits fail to exhibit a menace response (Vernau et al., 2007).

Rabbits have an extensive orbital venous plexus, which can make enucleation of the eye complicated. It has been suggested to perform enucleations transconjunctivally, remaining as close to the globe as possible, instead of transpalpebrally, in order to avoid this structure (Williams, 2007). In addition, a large mediastinal mass can cause compression of venous return to the heart, engorging the retrobulbar plexus and resulting in exophthalmos (Wagner et al., 2005). The rectus dorsalis muscle lies several millimeters posterior to the limbus, under the bulbar conjunctiva. Because it is visible through the dorsal conjunctiva, unlike in humans, dogs, or cats (Keil, 2010), it is possible to access this muscle during surgery and use it to stabilize the globe. Other species require dissection to expose the muscle.

The small nasolacrimal duct follows a convoluted path through the lacrimal and frontal bones, ending in a single nasolacrimal punctum on each side. The duct passes close to the molar and incisor tooth roots and can therefore be affected by dental disease (Marini et al., 1996). At the level of the proximal maxillae and the base of the upper incisor, the duct narrows and is a common place for obstruction, resulting in epiphora.

Recent work has detailed the anatomic and structural characteristics of the lacrimal duct system (Ding et al., 2010). Review of published literature has shown that the rabbit lacrimal system more closely resembles that of humans rather than that of rats or mice (Schechter et al., 2010). The smallest branches of the duct system are the intercalated ducts, composed of single-layer cuboidal cells. Several intercalated ducts join to form larger intralobular ducts, which are also cuboidal in shape. Intralobular ducts merge to form interlobular ducts, which drain several lobules and are comprised of simple cuboidal to low columnar cells. From here the interlobular ducts merge into intralobar ducts, which drain individual lobes. The cells here are low to tall columnar cells and range from simple to pseudostratified. Finally, these converge into interlobar ducts, which are of variable size depending on the surrounding tissue. These cells are composed of simple to pseudostratified and stratified columnar cells and the number of cells increases as they approach the main excretory duct (Ding et al., 2010).

Trunk

The trunk is composed of the thorax, abdomen, and back. Females have eight to ten nipples while males have similarly placed rudimentary nipples. The anal opening lies distal to the base of the tail and dorsal to the urogenital opening. The anus is surrounded on both sides by hairless inguinal spaces. The male's urogenital opening continues into a preputial fold which forms a sheath for the penis. In the female, this skin fold forms the vulva, which contains the small clitoris on the ventral wall. In males, the scrotal sacs containing the testes are located on either side of the penis.

Extremities

The forelimb is composed of the shoulder, upper arm, forearm, and hand. The hind limb is divided into the thigh, leg, and foot. The front legs have five digits and the rear legs have four, all of which extend into a long, curved claw.

OSTEOLOGY

The rabbit's skeleton is delicate in relation to its size. The skeleton makes up approximately 8% of their body weight in comparison to a cat, whose skeleton represents 12–13% of its body weight (Cruise and Brewer, 1994). Strong epaxial muscles in the presence of a relatively weak lumbar spine predisposes rabbits to fracture of their lumbar spine (Suckow and Douglas, 1997), usually at the seventh lumbar vertebrae (Queensberry and Carpenter, 2004).

Axial Skeleton

Skull

The rabbit skull has a number of bones with a spongy texture and wide medullary cavities, in contrast to the smooth, hard skull of the dog (Whitehouse and Grove, 1958). The caudal (nuchal) surface of the skull is composed of the occipital bone, which in turn is formed by the supraoccipital, paired lateral exoccipitals, and the ventral basioccipital. The foramen magnum lies within this space and with its lateral occipital condyles creates the articulation for the atlas. The external occipital protuberance creates a sharp ridge that separates the dorsal surface of the skull from the nuchal surface. The dorsal ligament of the neck and occipital muscles attach to this external occipital protuberance.

The dorsal surface of the skull is formed by the dorsal surface of the occipital, the small interparietal, the paired frontal bones, and the nasal bones. The frontal bones extend ventrally to form part of the orbital wells.

The bulla is formed by the tympanic bone and holds the large tympanic cavity and the three ossicles of the middle ear. It continues dorsally into a short wide bony tube with a large opening. This entire tube is the external auditory meatus (Cruise and Brewer, 1994). The rabbit's tympanic bullae are much larger than most mammals, with a longer and more tubular external auditory meatus (Wingerd and Stein, 1985). The tympanic bullae also appear to be rounder in shape and do not project ventrally beyond the level of the occipital bone as they do in the dog and cat (King et al., 2006).

The squamosal bone, which forms a large portion of the lateral wall of the cranium, lies anteriodorsal to the bulla. A prominent protuberance, the zygomatic process, forms the caudal end of the zygomatic arch. The zygomatic arch is flatter than that of the dog resulting in a narrower skull, which aids the rabbit in burrowing (Osofsky et al., 2007).

The mandibular fossa fits the head of the mandible, and is formed by the hollowed out ventral side of the zygomatic process. The alisphenoid is bordered caudally by the squamosal, and cranially by the orbitosphenoid, which is pierced by the optic foramen. The cephalic wall of the orbit is formed ventrally by the maxilla and dorsally by the lacrimal bone, which extends beyond the orbital rim. The maxilla extends rostrally from the orbit and its lateral zygomatic process, from the rostral end of the zygomatic or jugal bone, forms the main portion of the arch. The bilateral alveolar processes or ventral portion of the maxilla contains the roots of the incisors, and creates the rostral, ventral, and lateral boundaries of the nasal bone.

The ventral portion of the cranium comprises the medially located basioccipital, basisphenoid, and presphenoid bones rostral from the foramen magnum.

The basisphenoid is perforated by the round foramen cavernosum which leads into the interior of the bone. The hypophyseal fossa is in the floor of the cranial vault. The ventral aspect of the skull is continued by the palatine bones, where the caudal ends articulate with the two laminae of the pterygoid process of the alisphenoid bone. A thin, dorsal extension of the palatine bone can be visualized from the wall of the orbit. The palatine continues forward medial to the two alveolar processes of the maxilla where it articulates and courses medially to form the caudal portion of the hard palate. The hard palate continues rostrally from the ventral portions of the maxilla and premaxilla.

The nasal cavity is divided into the right and left fossae by the cartilaginous portion of the mesethmoid. It continues caudally with the perpendicular plate of the ethmoid bone which consists of the cribiform plate and paired lateral ethmoidal labyrinths. Caudally, the ventral portion of the cartilaginous septum is supported by the vomer bone. The turbinate bones are located on the lateral walls of the nasal cavity.

The two sides of the mandible join into a fibrous or fibrocartilaginous symphysis. The body, or the horizontal portion, contains the teeth while the caudal vertical portion comprises the ramus.

The hyoid apparatus is comprised of the median hyoid bone and the paired greater and lesser cornua. These are connected laterally by two muscles of the jugular process of the occipital bone. The entire apparatus is enveloped at the base of the tongue and lies between the angles of the mandible.

Vertebral Column

The typical vertebral formula is C7T12L7S4C16. However, the number of vertebrae can vary, with 44% of rabbits having 12T/7L, 33% having 13T/6L, and 23% with 13T/7L. The spinal cord ends within S2 in 79% of rabbits, S1 in 19%, and S3 in 2% or rabbits (Greenaway et al., 2001). All of the lumbar vertebrae have prominent mammillary processes of the cranial articular process, where the powerful lumbar muscles attach to the vertebrae (Whitehouse and Grove, 1958). Unlike other domestic animals, the dorsal aspect of the lumbar vertebral mammillary process is level with and slightly ventral to the spinous process. The first three vertebrae of the sacrum are fused, while the fourth sacral vertebra is variably fused (Whitehouse and Grove, 1958) with the third vertebra.

Ribs and Sternum

The first seven ribs are true ribs and articulate with the sternum, while the last five ribs (false ribs) do not. The heads of the ribs articulate with the corresponding thoracic vertebra and the caudal part of the body of the vertebrae cranial to it. The costal cartilage of the

seventh, eighth, and ninth ribs are attached to each other. The cartilages of the last three floating ribs are not attached to any others and therefore lie free. The sternum is composed of six sternbrae. The first is the manubrium sterni and the sixth is the xiphoid process with a distinct, thin, broad plate of cartilage protruding from the caudal end.

Appendicular Skeleton

Pectoral Girdle and Limb

The pectoral girdle is made up by the scapula and paired clavicles. The only direct attachment to the axial skeleton is the sternoclavicular ligament (Cruise and Brewer, 1994). The other major attachments are via the musculature. The humerus, radius, and ulna are typical of the mammalian family. The carpus is comprised of two rows of bones. The distal row articulates with the five metacarpal bones and there are five digits. The first digit has two phalanges while the four other digits have three.

Sesamoid bones are located on the palmar and plantar surfaces of the feet and occur in transverse pairs at the metacarpophalangeal junction and in linear pairs at the articulations of the second and third phalanges.

Pelvic Girdle and Limb

The ilium, ischium, and pubis fuse to form the pelvic girdle which is attached to the vertebral column at the iliosacral articulation (Cruise and Brewer, 1994). The os acetabuli, a small accessory bone, together with the ilium and ischium, join to form the acetabulum in the pelvic girdle. The femur attaches only to the tibia while the fibula fuses distally with the tibia for half its length. There are six tarsal bones arranged in three rows. The proximal row has two large bones, the middle row one bone, and the distal row three bones. The first metatarsal is very small, while metatarsals two through five are well-developed. The four digits of the hindlimbs each have three phalanges (Cruise and Brewer, 1994). The sesamoid bones in the pelvic limbs are the patella, the three bones located posterior to the stifle joint, and the small ones on the plantar surface of the foot by the metatarsophalangeal joints and between the second and third phalanges.

FIGURE 8.3 Peg teeth.

Rabbits have hypsodont dentition and there is a long crown in lieu of a true root. The permanent teeth grow in by 3–5 weeks old. The upper and lower incisors grow 10–13 cm a year (Jenkins, 2001). The grinding action against opposing teeth keeps the teeth worn. Dental problems are a common sequellae if there is malocclusion or dislocation. A pair of small incisors, known as peg teeth (Figure 8.3) lies caudal to the larger incisors in the upper arcade. The upper lip has a divided groove (hence the expression “harelip”) that continues curving up right and left of the nostrils. There are 25–30 tactile vibrissae, which together with the cleft lip allow rabbits to locate and eat their food. Rabbits also have a diastema, a space between the incisors and premolars, which together with the “hare-lip” and rostrally positioned incisors help to cut off short pieces of vegetation. Rabbits chew quickly and thoroughly, with jaw movements up to 120 per minute (Cruise and Brewer, 1994).

Tongue

The rabbit's tongue is large in comparison to the size of the animal. The dorsal surface is covered with small elevations called papillae, which give the tongue its roughened surface. There are four types: vallate, foliate, fungiform, and filiform. All but the last type have associated taste buds. The rabbit's large tongue and small mouth opening together make visual intubation of the trachea virtually impossible without specialized equipment.

Salivary Glands

Rabbits have four pairs of salivary glands: the parotid, the submaxillary (also called mandibular), the sublingual, and the zygomatic (Cruise and Brewer, 1994).

ORAL CAVITY

Teeth

The dental formula of the rabbit is:

$$\frac{I2}{1}, \frac{C0}{0}, \frac{PM3}{2}, \frac{M2-3}{3 \times 2} = 26 \text{ or } 28$$

The larger parotid gland extends below and in front of the ear base between the skin and masseter muscle. The associated duct runs rostrally along the lateral surface of the masseter muscle close to the branches of cranial nerve VII (the facial nerve), and enters the oral cavity opposite the last upper molar. The large size of the parotid gland and the accessibility of the duct make this system a popular research model. The submaxillary gland is oval-shaped and located at the angle of the mandible. The sublingual gland is small in the rabbit. The zygomatic salivary gland, not present in many other animals including humans, lies just below the lacrimal gland in the anteroventral angle of the orbit.

There is continuous secretion of saliva from the mandibular gland in rabbits, unlike in ruminants where saliva is produced from the parotid glands and in cats and dogs, where it is produced from the sublingual glands (Brewer and Cruise, 1994). Amylase is present in rabbit saliva while lipase and urea are only present in trace amounts (Ruckebusch et al., 1991).

Esophagus

The esophagus has three layers of semi-involuntary striated muscles that extend all the way down to the cardia of the stomach, as opposed to in humans, where striated muscle comprises the upper two-thirds of the esophagus, the middle third contains some smooth muscle and the lower third consists of only smooth muscle. There are no mucus glands in the esophagus.

Esophageal integrity can be determined by measuring the difference in electrical potential between the esophagus and the stomach. The rabbit has a relatively low gastric potential difference (-12 mV) in comparison to the esophagus (-26 to -29 mV). The opposite is true in humans (Mecheler and Ingelfinger, 1969).

ABDOMINAL VISCERA

Gastrointestinal Tract

The rabbit's stomach makes up approximately 15% of the volume of the GI tract and is never completely empty (Cruise and Brewer, 1994). In fact, for a rabbit GI tract to become completely empty it would take 9 days. The adult stomach is very acidic, with a pH of 1–2. In contrast, the suckling rabbit has a stomach pH of 5–6.5, which allows bacteria to pass through the GI tract and colonize the hindgut (Harcourt-Brown, 2002). After weaning, the stomach quickly becomes acidic. The cardia is large, thin-walled, non-glandular, and lined with stratified squamous epithelium. The fundus is the major exocrine secretory portion of the stomach. It has gastric pits lined with parietal cells which secrete

acid, and intrinsic factor and peptic cells which secrete pepsinogen. The pyloric region is heavily muscled. The duodenum lies at an acute angle and compression of the pyloric valve in response to any increased pressure, such as hepatomegaly, gas, or trichobezoar may occur. The cardia sphincter is well-developed and arranged in such a way that renders the rabbit, like rodents, unable to vomit.

The small intestine is shorter in comparison to other species and comprises about 12% of the GI tract (Suckow and Douglas, 1997). The bile duct and pancreatic duct enter the duodenum separately. The bile duct opens into the duodenum proximally while the pancreatic duct enters distally. The jejunum is less vascularized and its walls are thinner than those of the duodenum.

The ileum ends in the cecum as the rounded sacculus rotundus, which forms the junction between the ileum, cecum, and proximal colon. It is at the ileum that Peyer's patches first appear. The cecum is the most prominent organ in the abdominal cavity and typically contains 40% of the ingesta. It is a thin-walled organ that folds onto itself three times and has an internal surface made up of a long spiral fold that is continued into the ampulla coli. The distal portion of the cecum ends as a 5-inch, thick-walled, narrow, blind tube known as the vermiform appendix, and contains a large number of lymphoid aggregates. It also secretes bicarbonate ions into the cecum, acting as a buffering agent for the volatile fatty acids formed by cecal fermentation (Cheekem, 1987).

Ileoceccocolic Complex

This complicated section of the GI tract is challenging to describe due to the three-dimensional, interconnected nature of the area. It acts as the meeting point between the end of the ileum, the cecum, and the proximal colon. Simply put, the end of the ileum, which is the sacculus rotundus and the beginning of the colon, which is the ampulla coli, meet at the cecum to form this intersection (Figures 8.4 and 8.5).

The sacculus rotundus appears to have immunological properties and contains lymph follicles that give it a honeycombed appearance. It is therefore often referred to as the ileocecal tonsil and is a common site for foreign bodies (Jenkins, 2000). The ileum lies nested between the body of the cecum and the upper ascending colon in a C-shaped manner and is attached by peritoneal folds.

The colon is characterized by sacculations (haustra) and bands (taeniae). The anatomy of the colon has alternatively been described as the proximal and distal colon or as having an ascending, transverse, and descending colon. Both descriptions use the fusus coli, the "pacemaker" of the colon, as a dividing point since

FIGURE 8.4 Schematic drawing of rabbit gastrointestinal tract. 1, Stomach; 2, duodenum; 3, jejunum; 4, ileum; 5, sacculus rotundus; 6, ampulla coli; 7, cecum; 8, vermiform appendix; 9, ascending colon; 10, fusus coli; 11, transverse and descending colon; 12, rectum.

FIGURE 8.5 Photograph of GI tract in situ. 1, base of cecum; 2, colon; 3, ileum; 4, body of cecum; 5, vermiform appendix.

it is a natural anatomic and physiologic demarcation. In this reference the colon will be described as being divided into three sections. The first section, the ascending colon, has five limbs and is separated by flexures (Davies and Davies, 2003). The first limb has three taeniae that form three rows of haustra, which move food along by muscular contractions. Small, wart-like protrusions (about 0.5cm in diameter), called “warzen” (warts) populate the mucosal surface of this section. They act to increase surface area thereby increasing absorption. The three taeniae gradually taper down to one taenia and one haustrum distally in the second and third limb of the proximal colon. The rest of the colon is devoid of taenia. The transverse and descending colon is separated from the proximal colon by the fusus coli. The fusus coli has mucosa that is 4–5 times thicker than that of the descending colon and contains ganglion aggregates (Harcourt-Brown, 2002). This allows the fusus coli to act as a pacemaker to regulate

TABLE 8.1 Summary of GI Tract

Stomach	pH 1–2 Contains 15% volume of GI tract
Duodenum	Bile duct and pancreatic duct enters separately
Jejunum	Less vascularized and thinner than duodenum
Ileum	Has Peyer patches Connects to cecum as sacculus rotundus – honeycombed appearance due to lymph follicles Lies between body of cecum and upper ascending colon in C-shaped configuration Ends in a blind sac called vermiform appendix
Cecum	Typically contains 40% of ingesta
Colon	3 limbs Ascending – 3 taenia form 3 rows of haustra populated by “warzen” Transverse Descending Fusus coli – “pacemaker” of colon – separates proximal colon from transverse and descending colon

peristaltic activity, and controls excretion of the two different types of feces. In New Zealand White rabbits the colon can be a meter long (Cruise and Brewer, 1994). (Table 8.1).

Gastrointestinal Physiology

Rabbits are true herbivores. Rabbits are monogastric hindgut fermenters and require a high-fiber diet (between 14–20%). As a prey species, they rely on the rapid transit time of their unique digestive system to keep their body size and weight low, enabling them to be fast-moving and nimble. In this way, a rabbit's gastrointestinal tract has adapted to the rapid ingestion of large quantities of vegetation (Jenkins, 2001). The transit time of food through the stomach is approximately 3–6 hours and times through the jejunum and ileum are 10–20 and 30–60 minutes, respectively (Carbao and Piquer, 1998). Rabbits mostly eat at dawn and dusk (crepuscular), but eliminate continuously throughout the day. Rabbits chew quickly and thoroughly, preferentially choosing tender, succulent parts of plants as the mainstay of their diets (Queensberry and Carpenter, 2004). High-fiber materials are ingested to stimulate cecocolic motility.

Dietary fiber in rabbits is classified as “digestible” and “indigestible”. Indigestible fiber consists of fibers that are larger than 0.5mm and are quickly expelled as undigested hard, dry feces. The ascending colon separates the large indigestible fiber particles from the smaller, digestible fibers. These digestible fibers are less than 0.3mm and are retropulsed back into the cecum

where they undergo bacterial fermentation (Harcourt-Brown, 2002). The digestible portion, which ultimately becomes cecotrophs, is moved back and forth in the haustra in the cecum and colon. As the large fibers move into the center of the lumen, the digestible portion moves into the wall of the haustras. When the particles move retrograde back into the cecum, fermentation releases volatile fatty acids and produces vitamins and proteins. The constant back-and-forth movement of the cecum and upper third of the colon causes the food particles to separate. Through this motion the digestible and indigestible fiber parts are simultaneously propelled in opposite directions. This, coupled with the fast digestive time, allows the rabbit to function without having to store large amounts of food in the GI tract.

Coprophagy is an important part of the rabbit physiology. The cecotrophs (also known as “night feces”) are ingested directly from the anus and are softer and lighter in color. They are an important source of nitrogen-containing compounds such as niacin, riboflavin, pantothenic acid, and cyanocobalamin (vitamin B12). The cecotrophs have a mucoid membrane that protects the feces from the low pH of the stomach and are ingested whole (Davies and Davies, 2003). The hard waste feces are produced during the first four hours of food ingestion while the cecotrophs are produced 4–8 hours later. Access to the anus for coprophagy is an important point to keep in mind if placing an Elizabethan-collar or similar such device. The term “night feces” is a misnomer as cecotrophs can be ingested at any time of day as it is influenced by light and feeding patterns (Hornicke et al., 1984).

The GI tract of the rabbit provides an important immunologic function. In rabbits, gut-associated lymphatic tissue (GALT) is distributed along the small intestine, sacculus rotundus, and the vermiform appendix (Lanning et al., 2000). GALT is composed of follicles where diversification of the rabbit primary antibody repertoire occurs. The similarity of the rabbit GALT and chicken bursa has led investigators to hypothesize that the rabbit GALT is the functional equivalent of the bursa (Knight, 1994).

Liver and Gallbladder

The liver is comprised of four lobes. The right and left lobes are divided by a deep median cleft. These lobes are then further divided into cranial and caudal lobules (Cruise and Brewer, 1994). The quadrate lobe is a subdivision of the right lobe and lies medial to the gallbladder. The caudate lobe is small, has a narrow attachment to the dorsal hilar region of the liver, and projects dorsally toward the right kidney (Cruise and Brewer, 1994). Torsion of the caudate lobe is possible,

though rare (Queensberry and Carpenter, 2004). The gallbladder is deep within the abdominal cavity in a depression of the caudal surface of the right cranial lobule. The hepatic ducts join to form the common bile duct which receives the cystic duct from the gallbladder and enters the dorsal surface of the duodenum immediately caudal to the pylorus.

The rabbit liver is a typical mammalian liver, consisting of a cribiform sheet of hepatocytes, one cell layer thick (Cruise and Brewer, 1994). Sinusoids drain into a central vein. The perisinusoidal space is formed by the wall of the sinusoids and the wall formed by hepatocytes. In rabbits this space is very narrow so that it is difficult to observe, unlike in humans where it is wider.

Rabbits mainly secrete biliverdin rather than bilirubin in their bile, similar to most non-mammalian species; 25–50% of rabbits also produce atropinase, which can inactivate atropine, and thus it is a poor choice as an anti-cholinergic.

Rabbits secrete a large amount of bile in relation to their size. A 2-kg rabbit can secrete up to 250ml of bile a day, in contrast to the dog, which secretes seven times less on a weight basis (Brewer and Cruise, 1994). Although secretin is a potent choleretic in other mammal species, it has no effect on bile flow in the rabbit (Wheeler, 1968).

Pancreas

The rabbit pancreas is a diffuse organ that is often hidden in the surrounding mesentery. It is also close to the splenic and caudal pancreaticoduodenal vessels. The pancreatic duct empties into the duodenum approximately 35–40 cm distal to the entrance of the biliary duct and appears to be the only laboratory animal with a single, separate pancreatic duct (Brachet, 1935). This duct is actually the accessory duct, as the terminal portion of the main pancreatic duct regresses during embryonic development (Harcourt-Brown, 2002). Pancreatic surgery can be challenging in rabbits and thus must be performed with great care.

Ligation of the pancreatic duct induces atrophy and fibrotic replacement of the pancreatic acini in the rabbit (Catala et al., 1987), similar to other mammalian species. However, unlike many other species, where ligation of the pancreatic duct causes pancreatic insufficiency, rabbits continue to populate the duodenum with proteolytic enzymes. It has been hypothesized that smaller pancreatic ducts communicate directly with the duodenum to supply these enzymes (Arvanitakis and Folscroft, 1978). In fact, it appears that pancreatic duct ligation does not induce long-term visible pathologic signs except for a chronic and progressive diabetogenic state leading to irreversible pathology (Catala et al., 2001).

Spleen

The spleen lies on the left dorsolateral surface of the greater curvature of the stomach and is small compared to that of other species. The rabbit's relatively small spleen has been attributed to the fact that the gut-associated tissue contains about 50% of the total lymphoid tissue mass. At birth, the rabbit spleen lacks follicles and germinal centers and only begins to develop lymphatic follicles at 2 weeks of age (Jeklova et al., 2007).

Rabbits have been a popular model for polyclonal antibody production due to their large body size, good responsiveness to immuno-stimulation, and ease of blood collection. The most popular sites for antigen injection include the skin of the dorsum, biceps femoris, quadriceps, and popliteal lymph node. Intraperitoneal injections are generally not performed in rabbits.

Adrenals

The adrenal glands lie cranial and medial to the kidneys. The left adrenal gland is caudolateral to the origin of the superior mesenteric artery and the right adrenal gland lies close to the caudal vena cava.

UROGENITAL SYSTEM

Kidney

Unlike most other mammals, which have multipapillate kidneys, rabbits have a unipapillate kidney, similar to rodents. The anatomy of a unipapillate kidney, where one papilla and one calyx enter the ureter directly, makes the renal pelvis a direct extension of the ureter (Dwyer and Schmidt-Nielsen, 2003). As is typical in mammals, the right kidney lies more cranial than the left kidney.

The rabbit medulla has narrow ends curled around at the lower and upper poles of the kidney, similar to an orange segment (Sheehan and Davis, 1959). The structures of the medulla, which contain the loops of Henle, collecting ducts, and vasa recta, merge toward the papilla, which projects out from the center of the medulla. The medulla is divided into an outer zone, which is further divided into an outer and an inner stripe, and an inner zone, which forms the papillae (Kaissling and Kriz, 1979). The transition from the inner stripe to the outer stripe occurs at the level of the fornices. All the vascular bundles in the rabbit kidney are of uniform size and have a regular distribution throughout the inner stripe. They do not fuse to form secondary bundles, as they do in the rat and mouse (Kaissling and Kriz, 1979). The total venous system in the medulla is also simpler than in other species (Kaissling and

Kriz, 1979), where the venous vasa recta ascend with the bundles as opposed to ascending independently of the bundles. The simple structure of the rabbit medulla is considered to be a primitive one compared to other species, such as the rat and mouse, which have a more complex medullary architecture and concomitant higher functional efficiency (Kaissling and Kriz, 1979).

The pelvic tissues form two septa that surround the medullary pyramid. The pelvic cavity extends between the septa and the pyramid to the fornix. It then extends outwards to form a series of secondary pouches on the outer surface of the pelvic septa (Sheehan and Davis, 1959). The typical unipapillate pelvis is generally a simple, funnel-shaped space (Dwyer and Schmidt-Nielsen, 2003), but can, as in the rabbit kidney, have elaborate, extensive evaginations. The epithelia of the fornices, at the level of the inner medulla, are composed of a single layer of cuboidal cells, whereas in the outer medullary region the epithelium is squamous. There are two distinct layers of smooth muscle fibers found in the walls of the renal pelvis. The inner layer contains fibers that insert near where the pelvic wall joins the base of the papilla, and are continuous with the ureteral smooth muscle. The outer layer is highly innervated, more diffuse and covers only the renal pelvis. It connects with the inner layers but ends abruptly at the junction of the ureter (Dwyer and Schmidt-Nielsen, 2003). The rabbit kidney is unique in that the tubules can be separated from kidney slices with the basement membrane intact. This makes the rabbit a useful model for renal tubule physiology studies (Brewer, 2006).

Each adult kidney contains approximately 200 000 nephrons (Rytand, 1938). Unlike dogs and humans, the number of glomeruli in rabbits increases after birth (Smith, 1951), similar to rats. Ectopic glomeruli are normal in adult rabbits, about 60 in each kidney (Steinhausen et al., 1990). These ectopic glomeruli often produce small cysts in the pelvic septum and can sometimes be seen with the naked eye (Moffat and Fourman, 1964).

Differences in definition and nomenclature have resulted in a variety of terminology of renal anatomy. This text will refer heavily to the previous work done by Cruise and Brewer as stated above. As in many animals, the rabbit proximal convoluted tubule (PCT) is divided into three segments: the PCT-S1 (first two-thirds of the PCT), the PCT-S2 (last third of the PCT and first part of the pars recta), and the PCT-S3 (the terminal part of the pars recta) (Woodhall et al., 1978). Transitions between segments are gradual compared to other mammals such as the dog and rat (Kaissling and Kriz, 1979). The proximal tubule plays an important role in water reabsorption as it reabsorbs two-thirds of the glomerular filtrate. The epithelium of the proximal tubule is made up of a single layer of

cells supported by a basement membrane (Quigley et al., 2003). The proximal convoluted tubule has a net fluid absorption rate of 1 ml/mm/kg in the adult and around 0.3 ml/mm/min in juvenile rabbits (Quigley and Baum, 1990).

The rabbit loops of Henle are composed of 66% long and 34% short loops, with only 7% of the efferent arterioles from the juxtamedullary glomeruli supplying blood to the medulla (Kaissling and Kriz, 1979). In contrast, other mammals such as the rat, mouse, pig, and human have more short loops than long, while carnivores such as the cat, fox, and dog have only long loops (Cruise and Brewer, 1994). The thin descending limb of Henle's loop is different in short- and long-looped nephrons (Kaissling and Kriz, 1979). In long-looped nephrons it descends through the outer medullary zone into the inner medulla. In short loops, as well as in the thin ascending limbs of long loops, they pass over into the distal tubule. The thin descending limbs also exhibit great differences in luminal diameter and cellular thickness. The larger limbs (outer diameter up to 40 µm) are thought to give rise to the longest loops, the limbs of intermediate size (diameter range from 30 µm to 20 µm) to the intermediate-length loops, and the small thin limbs (outer diameter 20 µm) to the short loops (Kaissling and Kriz, 1979).

Superficial nephrons and upper midcortical nephrons drain separately via a connecting tubule to a cortical collecting duct (Kaissling and Kriz, 1979). Arcades are ascending tubules in the cortical labyrinth that join deep and midcortical nephrons to a collecting tube. These tubules are composed of connecting tubule cells (CNT), collecting duct (CD) cells, and intercalated (IC) cells (Kriz and Bankir, 1988). On average, six nephrons drain into one cortical collecting duct (Kaissling and Kriz, 1979). The IC cells are rich in mitochondria and have many rod-shaped particles in the membranes of cytoplasmic vesicles. The IC cells are prominent in collecting ducts and other transporting epithelia. Unlike most mammals, the rabbit's connecting ducts do not contain typical CD cells, but only CNT cells interspersed with IC cells (Kriz and Bankir, 1988). The rabbit is also unique in that the CNT has a more distinct segment in structure and in function (Knepper and Rector, 1991). The cells of the CNT appear "lighter" on light and electron microscopy and have numerous infoldings of the basal cell membrane (Kaissling and Kriz, 1979). There are IC cells in the inner stripe of the outer medullary collecting duct (OMCD), but these only occur in the outer half of the inner stripe, where they comprise 10–15% of the cell population (Ridderstrale et al., 1988). The simple, clear-cut structural and functional organization of the rabbit distal nephron makes it a useful tool to understand more complex systems in rats, mice, and humans (Loffing, 2002).

Similar to amphibians and neonatal mammals, rabbits have a wide range in the number of active glomeruli at any one time (Salako et al., 1971). Up to a 16-fold increase in water diuresis is possible without a significant change in glomerular filtration rate (Smith, 1951). Even a blood pressure increase of up to 100% will result in little or no change to the glomerular filtration rate (Smith, 1951). This autoregulation, found to some degree in other mammals, but not to the extent found in rabbits, occurs at the level of the afferent arteriole (Steinhausen et al., 1990).

The rabbit only has a limited capacity to concentrate urea, so when the urea load increases, so does the amount of urine production (Knepper and Rector, 1991). In most mammals inulin clearance is equal to the glomerular filtration rate. In rabbits, however, inulin clearance can be changed by altering blood flow of the rabbit glomeruli, specifically at the afferent arterioles (Brewer, 2006). Since the creatinine clearance and inulin clearance are equal in the rabbit, it can therefore be used to measure glomerular filtration rate (Kaplan and Smith, 1935). Rabbits are also not sensitive to the actions of loop diuretics (Ridderstrale et al., 1988), such as furosemide.

Rabbits are especially susceptible to low doses of acid administration. Unlike most mammals, a decreased plasma pH does not stimulate the deamination of glutamine, which is the major mechanism in ammonia synthesis. Only lowered bicarbonate (HCO_3^-) concentration is effective in stimulating this system (Simpson and Sharrard, 1969). The rabbit is also not as efficient in HCO_3^- reabsorption as other mammals. Most mammals avoid alkalosis by neutralizing HCO_3^- catabolism with ureagenesis. If rabbits are fed a diet low in nitrogen, they are unable to titrate enough HCO_3^- through ureagenesis. HCO_3^- is also absorbed through the gut. These two conditions make the rabbit susceptible to a greater HCO_3^- load than other mammals. In addition, carbonic anhydrase, an enzyme that catalyzes hydration of CO_2 to HCO_3^- is absent in the rabbit's thick ascending limbs of the renal tubules unlike other mammals (Ernst, 1975; Iino, 1981).

In the rabbit, the collecting duct is an important site for acid secretion, bicarbonate reabsorption, and active secretion of bicarbonate (Hamm, 1990). The transition between the convoluted part of the distal tubule to the connecting tubule is marked and clear. Here, the homogeneous epithelium of the distal tubule changes into the heterogeneous epithelium of the connecting tubule (Kaissling and Kriz, 1979). In concordance with this change in anatomy is a change in physiology, namely the absorption of NaCl. In this and all subsequent segments the sodium-potassium ATPase activity is significantly lower.

The final degradation product of purine metabolism in the human is uric acid. Different species of mammals handle this differently. Whereas humans, with 700 out of 9000 mg of urate filtered daily, have one of the lowest excretion ratios, the rabbit has one of the highest (Brewer and Cruise, 1994). Since as much as 160% of the filtered load is excreted, it is likely that much of the secreted load is also excreted. In the dog and rat less than 40% is excreted (Brewer and Cruise, 1994). The anion-exchange mechanism, located in the luminal plasma membrane in the dog and rat that affects reabsorption in the proximal tubule does not exist in the rabbit.

Rabbit urine is generally cloudy due to the high concentration of ammonium magnesium phosphate and calcium carbonate monohydrate precipitates (Suckow and Douglas, 1997). Rabbit urine can also vary in color from orange and brown to red, depending on the diet, and can be mistaken for hematuria (Harcourt-Brown, 2002). Though most mammals regulate their calcium levels through the activated metabolite of vitamin D, rabbits' absorption of calcium from the gut makes their calcium levels independent of this mechanism (DeLuca, 1974). Unlike most mammals, urine is the major route of excretion for calcium in the rabbit (Kennedy, 1965). Because of this, rabbits are unusual in that serum calcium levels vary with their diet. Rabbits fed a 10% calcium carbonate diet can excrete almost 60% of the calcium in their urine (Cheeke and Amberg, 1973). A high-calcium diet can result in thick, creamy urine, and prolonged feeding of a high-calcium diet can result in calcification of the aorta and kidney.

Urine color can vary from yellow to red due to porphyrin pigments. Though thought to be derived from the diet, the source of porphyrin has not yet been identified. Urine pH is typically around 8.2 and the rabbit produces 50–75 ml/kg of urine a day (Gillett, 1994).

Male Genital Organs

Male rabbits have two hairless scrotal sacs cranial to the penis. The testis has an elongated oval shape with a blunt cranial pole and a pointed caudal pole. The testes descend at 12 weeks and the inguinal rings do not close. Males have open inguinal canals and can retract their testicles abdominally, which they do during sexual inactivity or periods of inadequate food. Care must be taken to close the inguinal rings during castration.

The nomenclature of the accessory sex glands of the rabbit has been a source of historical confusion due to the use of terminology for other mammalian species as well as poor consensus among anatomists (Holtz and Foote, 1978). For example, in humans the terms seminal vesicle and vesicular gland are used interchangeably. In rabbits, however, they have been described as

FIGURE 8.6 Dorsal view of the male accessory sex glands. Ventral view in smaller box.

two distinct glands. In addition, different rabbit sources name the glands differently. Most references include the prostate, seminal vesicles, and bulbourethral glands. Other sources include the terms proprostate and paraprostate gland. For the sake of continuity the accessory glands here are listed (roughly cranial to caudal) as: seminal vesicles, vesicular glands, prostate, paraprostatic glands, and bulbourethral glands (Cruise and Brewer, 1994) (Figure 8.6).

The seminal vesicles are the most cranial glands located at the neck of the bladder. Depending on the amount of fluid it contains, the size of the seminal vesicles can vary greatly. The ductus deferens enters the ventral wall of the seminal vesicle dorsal to the bladder (Cruise and Brewer, 1994). The vesicular glands are caudal to the seminal vesicles, cranial to the prostate and separated by a very thin connective tissue septum (Kurtul et al., 2001). The vesicular gland ducts enter the urethra at the seminal colliculus. The prostate overlaps the caudal part of the vesicular glands and can be distinguished anatomically by its lighter color (Kurtul et al., 2001). Four to six small prostatic ducts enter the urethra on both sides and posterior to the seminal colliculus (Cruise and Brewer, 1994). The bulbourethral glands lie caudal to the prostate and are separated from it by a distinct groove. The paraprostatic glands are small, club-shaped glands that are at the ventrolateral aspect of the prostate (Holtz and Foote, 1978).

These glands cannot be visualized dorsally and are very small. All glands are bilobed, except the bulbourethral glands, which are paired.

The penis does not have an os penis, but instead has a free extremity called the pars libera. Dorsolateral to the body of the penis are the white inguinal glands and the associated brown inguinal glands, which empty their secretions into the hairless inguinal spaces. Though some references cite males as not having nipples, it appears that males have very small, rudimentary nipples under their fur.

Female Genital Organs

The female reproductive tract has a bicornuate uterus with two cervixes that open independently into the vagina. The mesometrium can be a major site of fat deposition, making ovario-hysterectomies of overweight does challenging. The urethra enters the vagina at a vestibulum known as the urogenital sinus (Cruise and Brewer, 1994), which extends out into the vulva. The bulbourethral gland, similar to that of the male, lies on the dorsal wall of the vestibulum. The clitoris is located along the ventral surface of the urogenital sinus with the glands clitoris projecting into the urogenital aperture.

Though sexual maturity depends on the breed, in general body weight is more important than age (Suckow and Douglas, 1997). Small breeds can reach sexual maturity at 4–5 months, medium breeds at 4–6 months and large breeds at 5–8 months. New Zealand White rabbit females reach maturity at around 5 months while males reach maturity at 6–7 months. Does mature earlier than bucks, with the bucks producing sperm 40–70 days after reaching puberty (Queensberry and Carpenter, 2004).

Rabbits are induced ovulators and do not have a defined estrous cycle. Ovulation occurs approximately 10 hours after copulation. Pseudopregnancy can occur if coitus does not result in pregnancy, if a doe mounts another doe, or if the rabbit is injected with luteinizing hormone (Kennelly and Foote, 1965) or human chorionic gonadotropin. Pseudopregnancy can last 15–16 days. Does are generally receptive for 14–16 days followed by 1–2 days of non-receptivity.

The placenta is hemochorial and passive immunity is endowed to the young through the yolk sac instead of through colostrum or placenta (Suckow and Douglas, 1997). Breeding life for a doe can be up to 3 years while that of a buck is around 5–6 years. Gestation is usually 31–32 days. Pregnancy can be confirmed at day 14 with palpation, day 11 with radiography and day 7 with ultrasonography.

Semen is deposited into the anterior vagina, where the sperm individually pass through the cervical mucus. During an active corpus luteal phase, such as early

pregnancy or pseudopregnancy, the cervical secretions are thick and mucoid, thereby inhibiting sperm transport.

Reproductive Behavior

Receptivity in a female is denoted by a swollen, moist dark pink to red vulva. Does do not have a defined estrous cycle, but a certain rhythm can be determined. Vaginal cytology is generally not useful. Due to territorial behavior, the doe should always be introduced to the buck's cage. Fifteen to 20 minutes (often much less than that) is usually sufficient to determine if the doe will accept the buck. Receptive females will exhibit lordosis and present the perineum to the buck. Non-receptive behavior includes running away, biting, vocalizing, or cornering. If the doe refuses the buck, the doe should be taken away. This prevents physical trauma to either animal as well as psychological trauma to the buck.

Bucks initiate copulation by sniffing, grooming, nuzzling, tail-flagging (elevation of the hindquarters with a stiff-legged gait and tail flat across the back), and enurination (urine spraying) at the female (Queensbury and Carpenter, 2004). Experienced males often initiate mating within minutes of being introduced to a receptive female. Copulation is quick, generally over after a few thrusts. The male, whose hindquarters are off the ground, falls off and emits a characteristic cry after ejaculation. Robust males will attempt to copulate almost immediately.

Parturition in rabbits is known as "kindling" and typically happens in the early morning hours. This is characterized by the rabbit pulling off fur for nest building and a decreased appetite for 2–3 days beforehand. Both anterior and breech presentations are normal. Kits are born altricial, nurse only once a day, and open their eyes around day 10. Kits can ingest up to 35% of their body weight in milk in less than 5 minutes (Hudson and Distel, 1983). Kits begin eating dry food at 21 days and are usually weaned at 8 weeks. Litter size depends on parity, with primiparous does producing smaller litters. Though textbooks describe eight mammary glands, this can be variable. A kit has total dependence on milk until day 10. Does can become pregnant during the post-partum period and can be lactating and pregnant at the same time.

THORACIC VISCERA

Cardiovascular System

Rabbits have a relatively small heart. In fact, it represents only 0.2% of the rabbit's total body weight in contrast to 0.76% in dogs (Hew and Keller, 2003). The rabbit conduction system is similar to that of other mammals and includes the sinoatrial node, internodal pathways, AV node, His bundle, and bundle branches.

The sinoatrial (SA) node is well-defined, less complex than that of other mammals, and relatively long considering its total heart size (James, 1967). The rabbit's SA node has a very large percentage of P cells, which are not distinctly organized about a central artery (Hew and Keller, 2003). This simplicity allows the exact location of the pacemaker to be delineated, and in fact the rabbit is the first mammal in which the SA node was localized (Bleeker et al., 1980).

Though the rabbit has a right and left coronary artery, most of the heart is supplied by the left coronary artery and its branches (James, 1967). The AV node and the His bundle are relatively small in the rabbit, and their only arterial circulation is supplied by the septal artery (James, 1967). Branches from the septal artery are perpendicular to its long axis and ascend across the right ventricular septal endocardium to the His bundle and the AV node. This sequence is opposite from that of humans.

Rabbits have a left and right cranial vena cava (Pariaut, 2009). The presence of a left cranial vena cava results in an extremely large coronary sinus, which in turn disrupts most of the atrial septal structures cranially. The internal carotid artery is relatively small despite being the main blood supply source to the brain. The pulmonary artery is heavily muscled compared to other species (Cruise and Brewer, 1994).

The primary return of venous blood from the head is the external jugular vein, unlike in humans, where it is the internal jugular vein. Unlike other species, there are few anastomoses between the branches of the internal and external jugular veins. Therefore, ligation of the external jugular vein can cause swelling and protrusion of the eyeball (Hoyt et al., 1994). This usually resolves itself in 24 hours. Ligation of the external carotid artery causes ipsilateral ocular necrosis.

Rabbit heart rates can range from 180–300 beats/min, with higher heart rates often seen due to the increased sympathetic tone secondary to stress (Pariaut, 2009). The right atrio-ventricular valve has two bicuspid leaflets rather than three and the aorta has a rhythmic contraction that is neurogenic in origin.

Most mammal hearts have a mixed population of connective tissue and Purkinje cells. Though this makes the conductive tissue readily distinguishable, this mixture also complicates microelectric recordings (Brewer and Cruise, 1994). Rabbits have little or no connective tissue admixture with the Purkinje cell, which makes the rabbit the species of choice for Purkinje fiber studies (Sommer and Johnson, 1968). In addition, these cells have a long cylindrical shape with wide clefts between them. These clefts, 25–50 times the width found in other species, reduce the problems with resistance and perfusion encountered in other species (Colatsky and Tsien, 1979).

The aortic nerve subserves no chemoreceptors, only baroreceptors (Kardon et al., 1974). The nerve to the carotid sinus subserves both. This nerve joins the afferent fibers from the root of the right subclavian vein to form the depressor nerve. Unlike other laboratory animals where the depressor nerve is free for only a short distance, the depressor nerve in the rabbit runs separately from the vagosympathetic trunk, making it easily accessible for electrode implantation (Cruise and Brewer, 1994). The carotid artery is more compliant than that of the dog and has a greater ratio of elastin to collagen (Cox, 1978).

Due to the fact that rabbits exhibit hypercholesterolemia within a few days of being fed a high-cholesterol diet, they are the most widely used animal in atherosclerosis research (Yanni, 2004). The Watanabe rabbit is a classic model for heritable hypercholesterolemia (Aliev and Burnstock, 1998) and plays an important role in atherosclerosis research. Rabbit lipoprotein metabolism correlates to human lipoprotein metabolism more closely than mice. Rabbit and human lipoprotein profiles are rich in low-density lipoproteins (LDL), while the mouse is rich in high-density lipoproteins (HDL) (Zhang et al., 2009). Rabbits and humans also have abundant plasma cholesteryl ester protein (CETP), whereas mice do not. Rabbits do not develop tissue plaques as humans do (Kolodgie et al., 1996). Instead, early lesions come in the form of foam cells originating from macrophages. In addition, the massive inflammation exhibited by rabbits does not reflect human physiology. Long-term studies of rabbits on a high-cholesterol diet are difficult since the high hepatotoxicity makes long-term survival in rabbits rare (Yanni, 2004). Advanced lesions can be induced in the thoracic and abdominal aorta by combining a high-cholesterol diet with a single or double balloon injury (Abela et al., 1995). These balloon lesions create plaques with lipid cores covered by a fibrous cap and a high density of smooth muscle cells (Yanni, 2004) and are more similar to human atherosclerotic lesions than those produced by solely feeding a high-cholesterol diet (Aikawa et al., 2001). Interestingly, female rabbits accumulate less cholesterol in the aorta than male rabbits when fed a high-cholesterol diet, but this protective effect is not present when the aorta is subject to balloon injury (Holm et al., 1998).

Recently, high-cholesterol-diet-fed rabbits have been used as a model for Alzheimer disease. Amyloid- β (A β), a peptide fragment of the larger membrane spanning β -APP protein containing senile plaques (SP), is found in excessive amounts in the brains of patients with Alzheimer disease (Sparks, 2008). Rabbits fed a high-cholesterol diet exhibited a high accumulation of neuronal A β compared to control rabbits (Sparks et al., 1994). The finding that increased circulating blood cholesterol levels also increases cholesterol levels in the brain (Sparks et al., 1994) has contributed to the more frequent use of the cholesterol-fed rabbit model.

Blood pressure measurements can be obtained with the Doppler method. Blood pressure and heart rate in the rabbit tend to increase during the night (Pariaut, 2009), with the most common systolic blood pressure measurement between 120 and 180 mmHg.

Respiratory System

Larynx and Pharynx

The rabbit epiglottis is a relatively large structure that lies dorsal to the soft palate, thereby allowing air directly from the nasopharynx to the larynx and trachea without entering the oral cavity. It is this anatomy that makes the rabbit an obligate nose-breather and is important to remember when attempting intubation of the trachea (Figures 8.7 and 8.8). The glottis of the rabbit is small and with the relatively large tongue, the glottis remains well covered.

Lungs

Lungs are divided into cranial, middle, and caudal lobes with the right caudal lung lobe additionally divided into the lateral and medial lobes. The thymus does not regress with age and lies in the cranial ventral thoracic cavity. The right cranial lung lobe is larger than the left cranial lung lobe due to the presence of the heart in the left pleural cavity.

The sole blood supply to the pleura is the pulmonary artery. Extensive anastomosis with the pulmonary artery occurs at the level of the hilus in the rabbit, unlike in the dog, cat, or monkey (Cruise and Brewer, 1994). In rabbits the bronchial artery extends to the third division of the bronchi. There is a lack of collateral blood supply beyond this area, which places the rabbit at serious risk if an obstruction to the pulmonary artery occurs.

The rabbit lung does not contain respiratory bronchioles, but instead terminates in vestibules which contain alveoli (Cruise and Brewer, 1994). The air flow volume of the left lung is higher than that of the right due to the lower resistance of the proximal airways per unit volume (Yokoyama, 1979).

BRAIN AND SPINAL CORD

The brain is anatomically similar to other mammals. It is enclosed by the meninges: the outer dura mater, the arachnoid, and the inner pia mater (Wingerd and Stein, 1985). The dura mater adheres to the periosteum of the skull and extends down between the cerebral hemisphere as the falx cerebri. It becomes the tentorium cerebelli (Kozma et al., 1974) at the level of the cerebellum and cerebrum.

The forebrain consists of the telencephalon and the diencephalon. The telencephalon is comprised of the

FIGURE 8.7 Sagittal view of the rabbit pharynx. Note the normal position of the epiglottis lying dorsal to the soft palate.

FIGURE 8.8 Same sagittal view with the epiglottis reflected ventrally – position for oral intubation.

cerebrum (cerebral cortices and basal nuclei), and is the largest portion of the brain. The diencephalon is comprised of the metathalamus, thalamus, hypothalamus, pineal gland, and pituitary gland. The optic chiasm lies within the diencephalon (Wingerd and Stein, 1985). The rabbit's cerebral cortex is lissencephalic, or smooth, due to the lack of gyri. The two hemispheres are divided by a longitudinal cerebral fissure (sagittal fissure) and are connected at the bottom by a white matter tract, the corpus callosum. All sensory pathways must travel through the thalamus to reach the

cerebral cortex, with the exception of olfaction (Oliver Jr and Lorenz, 1993). The olfactory bulbs are positioned at the rostral and ventral ends of the cerebral hemispheres, receive the sensory endings of the olfactory nerve, and are relatively large (Osofsky et al., 2007; Wingerd and Stein, 1985). The dorsally located pineal body originates from the corpus callosum and courses caudodorsally, nearly into the caudal end of the cerebral hemispheres.

The midbrain (mesencephalon) lies caudal to the diencephalon and is comprised of the dorsal tectum

(Latin = roof) and ventral tegmentum (Latin = covering) (Osofsky et al., 2007). The tectum consists of the rostral and caudal colliculi, which, unlike dogs and cats, are clearly visible in the rabbit (Craigie, 1951). The rostral colliculi, which are larger than the caudal colliculi (Craigie, 1951), are involved in the visual reflex while the caudal colliculi are important in the auditory reflex. Important structures in the tegmentum include the mesencephalic aqueduct, the red nucleus, and the reticular activating system (Wingerd and Stein, 1985).

The hindbrain (rhombencephalon) consists of the cerebellum, pons, and medulla. The cerebellum and pons form the metencephalon and the medulla forms the myelencephalon, the most caudal part of the brain (Wingerd and Stein, 1985). The thalamus, hypothalamus, midbrain, pons, and medulla make up the brainstem.

Similar to other mammals, the cerebellum consists of the central vermis and the right and left cerebellar hemispheres. Rabbits have prominent paraflocculi, which are ventrolateral extensions of the cerebellar hemispheres (Cruise and Brewer, 1994). The paraflocculus is often damaged when removed due to its being almost completely enclosed by the dorsal portion of the petrosal bone (Cruise and Brewer, 1994). The paraflocculus is separate from the flocculus but has connections at the pyramis and uvula. The flocculus has been extensively studied in rabbits due to its importance in the mechanism of the vestibulo-ocular reflex and in the sensory and sensorimotor integration for retinal image stabilization (Voogd and Wylie, 2004). In the midsagittal plane, the cerebellum is triangular in shape, instead of the round shape seen in other domestic animals such as the dog, cat, horse, and sheep (Osofsky et al., 2007).

The pons lies caudal to the cerebral peduncles. The ventral part of the pons contains the transverse pontine fibers that transverse across the ventral aspect of the brain into the cerebral peduncles (Osofsky et al., 2007). These thick, paired ridges, which are separated by the median interpeduncular fossa, lie just behind the mammillary body. The third cranial nerve emerges from the ventral surface of the peduncle, while the cut end of the proximal portion of cranial nerve V (trigeminal nerve) emerges from the ventral surface. The dorsal part of the pons contains the nuclei for cranial nerve V (CN V). The medulla oblongata is located caudal to the pons and connects the brain and the spinal cord. The rostral medulla contains the nuclei of CN VI (abducens nerve), CN VII (facial nerve), CN VIII (vestibulocochlear nerve), the pyramids, and the trapezoid body. The pyramids are narrow tracts that are ventrally located on each side of the midline from caudal to the pons to the anterior funiculi of the spinomedullary junction. The trapezoid body of the medulla is also located ventrally, but is dorsal and lateral to the pyramids. It is smaller and made up of transverse fibers that extend from the

ventral cochlear nucleus. It lies in between the angle formed by the lateral margin of the pyramid and the caudal margin of the pons.

The sensory and motor roots of CN V lie at the lateral border of the pons. The small abducent nerve arrives along the lateral margin of the anterior end of the pyramid via several delicate rootlets (Cruise and Brewer, 1994). CN VII and VIII arise from the lateral margin of the trapezoid body. CN IX (glossopharyngeal nerve), X (vagus nerve), and XI (accessory nerve) arise from the lateral margin of the medulla by several linearly arranged roots. CN XII (hypoglossal nerve) arises through several roots from the ventral surface of the caudal medulla at the lateral margin of the pyramid.

The cerebellum is visualized by removing the fourth ventricle and consists of the central vermis and the laterally located right and left cerebellar hemispheres (Wingerd and Stein, 1985). The posterior medullary velum supports a choroid plexus. The fourth and third ventricles are connected by the aqueduct of Silvius. The dorsal aspect of the third ventricle can be seen by spreading the caudal tips of the cerebral hemispheres and pulling away the pineal body. At the roof of the third ventricle is another choroid plexus. Small, spindle-shaped masses called habenulae form the lateral margins of the aperture. The two habenulae are united caudally by the habenulae commissure. The thalami are thick masses of nervous tissue that form the lateral walls of the ventricle. The dorsal portion of the thalamus forms an oval projection, the lateral thalamic tubercle, lateral to the habenula, and the anterior tubercle of the thalamus, a small elevation in the angle between the lateral tubercle and the cranial portion of the opening of the third ventricle. The lateral geniculate bodies lie at the most lateral parts of the dorsal surface at each side of the lateral tubercle. The medial geniculate bodies are less pronounced and lie caudomedial to the lateral bodies.

Dividing the cerebrum along the sagittal fissure exposes the midline structures. The lateral ventricle is exposed by removing the dorsal wall of one cerebral hemisphere. The corpus callosum ends rostrally in a club-shaped form and bends downward caudally, forming the splenium, which is attached to the body of the fornix. A pair of curved bands form the fornix, which fuses for a short distance in the midline until it forms the body of the fornix.

Similar to the brain, the spinal cord is enclosed by the meninges. The dura mater, the outermost layer, is a thick fibrous layer that is not firmly attached to the bone, and thereby creates an epidural space. The pia mater, the innermost layer, is a very thick membrane that is continuous with the dura mater. Fine connecting tissue resembling a spider web extends from the arachnoid mater to the pia mater (Osofsky et al., 2007).

The space between the arachnoid and the pia mater is known as the subarachnoid space, which contains the cerebrospinal fluid (King, 1987). Because the spinal cord and vertebral column have different growth rates, spinal cord segments and nerve roots are not necessarily housed in the corresponding vertebrae (Craigie, 1951). There are two enlargements of the spinal cord: the brachial and lumbar intumescences, or enlargements (Kozma et al., 1974). The brachial enlargement is located in the caudal cervical region and contains the spinal cord segments of cervical nerves 4 through 8 and thoracic nerve 1 (Osofsky et al., 2007). These nerves contribute to the brachial plexus. The lumbar enlargement contains the ventral rami of lumbar nerves 4 to 7 and sacral nerves 1 to 3 and contributes to the lumbosacral plexus. These areas contain a large number of neurons and cell bodies that innervate the muscles of the thoracic and pelvic limbs. Due to the fact that the spinal cord continues into the sacral vertebrae, it is important to remember that the chance of accidental puncture of the dura and arachnoid membranes during epidural injection is higher than in other animals (Johnston, 2005).

The formula for spinal nerves is $C_8T_{12}L_7S_4C_6$. The spinal cord contracts to a thin filament at the middle sacrum, where it is called the filum termale, and continues caudally to the base of the tail. The dorsal spinal nerves originate cranial to their exit from the vertebral column, thereby forming the cauda equina which continues down with the filum termale caudally (Cruise, 1994). Because the spinal cord extends more caudally in the rabbit, the cauda equina is less pronounced than it is in humans (Craigie, 1951).

METABOLISM

The fasting metabolic rate of a rabbit is approximately 44–55 kcal/kg/day (Gillett, 1994). The fat content of the neonate is about 16% of body weight, similar to a human infant (Cornblath and Schwartz, 1976). Neonates have a low reserve of gluconeogenic precursors in the liver. However, kits are able to remain normoglycemic without suckling until the glycogen reserves are depleted, about 6 hours postpartum (Shelley, 1961). Kits only nurse once a day during the dark phase (Jilge, 1993), and are a good model for nursing-anticipatory behavior as they show a clear locomotor anticipatory behavior in response to a nursing mother (Caba and Gonzalez-Mariscal, 2009).

Rabbits have a high intake of water compared to body size, approximately 50–150 ml/kg. Rabbits fed fresh greens ad libitum will often not drink water (Cheeke and Amberg, 1972), while high-protein diets increase water needs. When deprived of water rabbits will decrease food intake and gradually become

anorectic. Fasted rabbits also will become polydipsic, eventually ingesting almost 650% of the normal water intake by day three (Brewer and Cruise, 1994). The water source and ability of the rabbit to reach the water source should be ascertained.

Thermoregulation

The normal body temperature of an adult New Zealand White rabbit at rest is between 38.5–39.5°C (101.3–103.1°F) (Ruckebusch et al., 1991). Rabbits are uncomfortable in temperatures over 20°C (68°F) and can be significantly stressed by temperatures over 28°C (82°F). The recommended ambient temperatures (16°C–21°C/60.8–69.8°F), as outlined by the *Guide for the Care and Use of Laboratory Animals*, is significantly lower than that for other laboratory species (Jenkins, 2001).

As mentioned previously, the ears play an important role in thermoregulation due to the countercurrent heat-exchange system present there (Kawato et al., 1989). It has been shown that there is adrenergic and cholinergic innervation of the arteriovenous anastomoses (AVAs) and that the constriction of the AVA walls controls microcirculation (Iijima and Tagawa, 1976). Other examples of AVAs in nature include the pampiniform plexus, nasal mucosa, and counter-current mechanisms in the various appendages of birds, whales, and seals (Ninomiya, 2000). While these heat-exchange networks consist of arteries and corresponding veins, the rabbit ear network is composed of a major artery and a number of capillaries surrounding the vessel (Ninomiya, 2000). This anatomy allows venous blood to drain more slowly, which enhances heat exchange within the narrow skin space.

Rabbits are unable to sweat, and salivation and panting are usually insufficient to dissipate heat. Moderately heat-stressed rabbits can exhibit decreased food consumption and impaired gastrointestinal function (Jenkins, 2001). They will also lie down in a stretched or prone posture versus a resting one (Finzi et al., 1992). Unlike most mammals, the rabbit shows little increase in heart rate in response to heat. Similar to the rat, the rabbit does not have a carotid rete (Daniel et al., 1952), which normally plays an important role in blood cooling in the brain. Blood from the head drains into the external jugular vein without a pathway to keep the brain cool (Ninomiya, 2000). This unique anatomy makes rabbits highly susceptible to high temperatures (Morimoto, 2009), which can ultimately result in death.

BEHAVIOR

Rabbits are social, nocturnal animals that, despite over 2000 years of domestication, still have a highly developed prey instinct. As with most prey species,

rabbits will become immobile when scared or stressed, making them difficult to assess or examine. This defense, sometimes called “tonic immobility”, has been directly related to the proximity of the predator. When tested during the immobility phase, rabbits that are closer to a predator will right themselves more slowly, while those closer to a home cage will right themselves more quickly (Ewell and Cullen, 1981). Another defense adaptation is to run quickly towards a hiding place such as a burrow or hide box (Gunn-Dore, 1997). Rabbits that are handled in the first week of life showed less fear as adults. In fact, simply being exposed to human scent during this time period decreases fear among rabbits (Ducs et al., 2009).

Rabbits are very territorial and will use their scent glands as well as feces to mark their territory. They can also mark with urine and by “chinning” people and their environment. Rabbits can have very complex social structures. They will show dominance by mounting, barbering, and scent-marking (Baysm et al., 2006). Females are aggressive, if not lethal, towards kits not their own. Despite being timid and shy, rabbits are intelligent and cognizant of their surroundings (Jenkins, 2001). They apparently recognize not only other rabbits, but are able to identify individual humans as well (Davis, 2000).

Laboratory animal housing should take into consideration natural behaviors and preferences of the species being housed. The following recommendations do not take into account experimental, space, and budget issues that all facilities face, but rather is a summary of recommendations for optimal laboratory housing collected from the literature.

Whenever possible, rabbits should be socially housed, with compatible pairs or trios being the most effective. Group housing of immature rabbits is possible without risk to injury. Ideally however, groups should be formed soon after weaning (Gunn-Dore, 1997). Rabbits that have been single-housed for more than 6 months should not be group-housed; they may be very fearful and lack motor skills due to prolonged inactivity. Adult male rabbits should not be housed together as they will fight and can sustain serious injury.

When choosing housing it is important that vertical distance is taken into account as well as horizontal space in order to ensure that rabbits can assume a typical lookout posture (Gunn-Dore, 1997). Housing should attempt to mimic a burrow with an open front and closed top bottom and sides (Jenkins, 2001). Though wire bottom cages are common in laboratory rabbit housing, rabbits should be given an area of solid flooring. In addition, rabbits should be given a hide box, which affords them an escape route when stressed. Toys and other types of enrichment, including being fed hay, should also be provided.

Similar to other species of social animals that are frequently housed singly in the laboratory environment, stereotypical behaviors can sometimes be observed in these rabbits. These include chewing/licking/biting of the bars, the floor, the walls, and the water bottles, hair-pulling and eating, nose-sliding, head-swaying and pawing the cage walls, rearing, and self-mutilation (Gunn-Dore, 1997). Some animals will simply become lethargic and will either exhibit poor appetite or, conversely, excessive appetite. Singly housed rabbits should be in visual contact with other rabbits and extra enrichment should be provided.

Rabbits are obligate nose breathers and thus do not like to have their noses touched. This is important to keep in mind when performing oral exams or attempting to medicate or force feed. Grunts, growls, and snorts indicate anger or annoyance. They can also “thump” their back feet when upset. It is best to approach these rabbits carefully as they will scratch and bite their handlers. Fear or pain is exhibited by a high-pitched scream, as well as an extended head, flattened ears, and bulging eyes. A rabbit in pain can be inactive, dull, become hunched, attempt to hide, or excessively scratch and lick. They can also become aggressive and bite.

The most common response to pain is anorexia. Often this is the first clinical sign to be noted. Rabbits will also grind their teeth, especially in response to visceral and dental pain (Johnston, 2005). Most rabbits will sit quietly in the back of the cage with minimal movement when painful. However, some rabbits will go through periods of rapid and uncontrolled movement and will struggle when handled. Some rabbits will breathe slowly with an obvious nasal flare and deep breathing pattern, in contrast to their usual rapid, shallow respiration (Johnston, 2005). A painful rabbit will also stop grooming itself and other cagemates.

Grooming is a normal behavior and healthy rabbits will spend a lot of time grooming themselves and other rabbits. If a rabbit grooms after being handled, this usually indicates that the rabbit has recovered from the interaction. Rabbits exhibit a behavior called “tooth purring”, which is exhibited by fast, light grinding of teeth and quivering whiskers. This is usually a sign of contentment and can be distinguished from bruxism, which indicates GI pain, by the slower, louder sounds produced (Baysm et al., 2006). Rabbits can lick a person to show affection, as well as nip at them to get their attention or solicit petting.

Rabbits tend to urinate and defecate in the same location, thereby making it possible to litter-train them. However, it is best to train them when still juveniles, as adults, especially males, will defecate to mark territory.

It is possible to “hypnotize” a rabbit by placing the animal on its back with its neck stretched out and the belly gently rubbed. The breathing should decrease and

the pupils constrict (Baysm et al., 2006). However, this method appears to be dependent on the individual handler and rabbit and should never be used in place of sedatives or anesthesia.

In general, rabbits are gentle, docile animals that make them an ideal species for the research environment. Proper and careful training of laboratory workers can make the interaction calm and less stressful for both the animal and handler.

Acknowledgments

We'd like to thank Dr Ilaria Brun del Re for the drawings and Dr Tim Lawson for his invaluable support and edits.

INTRODUCTION

According to 2006 United States Department of Agriculture (USDA) statistics, there were approximately 240 000 rabbits used annually in research within the U.S. (USDA, 2006). Given that there were just under 1100 registered research facilities, this averages out to about 220 rabbits per research facility. Of course, not all USDA-registered research facilities housed rabbits that year. This is in contrast to rats and mice for which estimates put their research numbers between 17–22 million in the U.S. (U.S. Congress, Office of Technology Assessment, 2006). Thus, although rabbits are the most numerous research animals covered by the Animal Welfare Act, they represent only about 1.4% of the total number of animals used in research. Comparing this to the rabbit meat and pet industry (estimated at 9 million rabbits (USDA, 2002)), research rabbits comprise only 2.6% of all rabbits produced in this country.

The statistics on rabbit use support a common concept in “large animal research” in the U.S.: although there may be a few large research institutions using very large numbers of rabbits, there are also a significant number of research facilities which use only a few rabbits. This can present a variety of challenges for facility managers and veterinarians not accustomed to this species in a laboratory setting. The purpose of this chapter is to provide an overview of management of rabbits within a research setting.

LABORATORY MANAGEMENT

The housing of rabbits in the laboratory setting is conceptually the same as housing them for meat production, show, or pet purposes. The primary difference comes in the steps taken to preserve their health status or to contain infectious agents used within these animals for research purposes.

Most rabbits used in research today are purchased through commercial laboratory animal vendors. Many of these vendors certify their rabbits as free of many or all of the common diseases of rabbits. The integrity of the research being conducted with these animals is often contingent upon them remaining disease-free and

distress-free during the experimental period. Therefore, the housing conditions and husbandry procedures must be of sufficient design and quality so as to protect the animals from inadvertent disease exposure and environmental stress.

Equipment

The equipment used in conjunction with rabbit husbandry in the research setting must be of sufficient quality to ensure its proper function without risk to the animals. The applicable regulatory standards and guidelines prescribe vigorous sanitation methods that can damage or destroy equipment made from inferior materials very quickly. This can lead to time delays and expense of replacement, and can also create significant hazards for the animals and personnel in contact with this equipment. The following sections refer to individual or small-group housing of rabbits in conventional laboratory caging systems. Large group and non-conventional housing is addressed further below.

Caging

All caging within an animal research facility must meet the same minimum criteria: functional containment of the animal. The caging must be safe for the animal; therefore it must be without sharp edges or protrusions which may inflict injury. It must meet the minimum space requirements for the animal to be housed; and, it must have provisions for meeting the basic biological needs of the animal (feed, water, waste disposal) while maintaining a sanitary environment.

Rabbits, by nature, are curious animals that actively manipulate their environment. This can present a challenge for containment and requires that caging has sturdy lock mechanisms out of reach of the animals. Caging secured with only a slide pin or simple latch can be dislodged if the rabbit can reach the mechanism with its mouth or by vibration of the cage when hopping or “thumping” the rear feet (a communication behavior usually associated with stress or danger). Fortunately, rabbits usually tend to be fairly timid and will often remain within the cage even if the door is dislodged, especially if not immediately adjacent to the floor.

All surfaces of the cage should be free of sharp edges and rough or pointed protrusions. This should be true for both the inside of the cage (to protect the animals) and the outside of the cage (to protect personnel).

Cage and rack material must be of sufficient quality and design to ensure adequate sanitation. Surfaces must be smooth, impervious to moisture, heat- and chemical-resistant, and potentially able to withstand sterilization. Materials such as stainless steel and high-temperature plastics are recommended, although other “stainless” metals may be adequate (Figures 9.1 and 9.2). If plastics are used, they must be evaluated periodically (as should all caging) to ensure that sanitation has not been compromised due to deterioration of surfaces by chewing.

Racks may be floor-mounted, wall-mounted, or on casters. If racks are mobile, a mechanism to secure the rack should be included as the motion of the animals within the cage can cause rack motion. This is particularly important if there are drains or other floor imperfections that may result in rack instability and put the animals at risk.

Cage flooring has the potential to inflict injury upon the rabbits because they directly contact this surface more than any other and because it bears the pressure of their entire weight. Flooring must function to

support the animal in a comfortable manner while still facilitating waste removal. Animal Welfare Act Regulations (USDA, 2005) require that caging be “constructed and maintained so as to enable the rabbits to remain dry and clean.” Flooring configuration can be either slatted, tubular, wire grid, or plastic with perforations. Ulcerative pododermatitis (“sore hocks”) has long been associated with rabbits housed on wire grid flooring (Ostler, 1961; Templeton, 1962). Plastic has been advocated as providing a smoother resting surface and decreasing animal-related noise. Regardless of the configuration, slots or openings for fecal passage should be approximately 0.5–0.7 inches in at least one direction. This provides adequate space for passage of feces while providing enough support for a comfortable resting surface. Smaller openings collect fecal material and may trap the rabbit’s toes leading to injury. Floor gap width should be given special consideration when housing either very young animals or giant breed adults, and alterations may be required to prevent injury.

Consideration must also be given to the size of any other openings or gaps in the caging such as around the door, between the ventilation grates in the sides and around the water nozzle opening. This is particularly true when housing very young animals which tend to be very curious and may attempt to force their heads into small gaps, leading to injury and possibly strangulation.

Minimum space requirements for housing rabbits are provided in Table 9.1. These requirements are mandated by the Animal Welfare Act Regulations (USDA, 2005) and are similar to those in the *Guide for the Care and Use of Laboratory Animals*, except that the Guide recommends an interior cage height of 16 inches and that larger rabbits may require more cage height so that animals can sit up (ILAR, 2011). Feed and watering systems are usually incorporated into the design of the caging system. These are discussed separately in the next section.

^aThe Guide for the Care and Use of Laboratory Animals recommends 16 inches of interior cage height.

Caging Accessories

Feed and watering systems, enrichment devices, nest boxes, resting platforms, and all other cage accessories must meet the rigorous sanitation requirements of the primary cage or be disposable. If these materials are not disposable, they must be sanitized according to regulatory requirements and periodically inspected to ensure they are not damaged in such a way as to compromise sanitation or pose a hazard to the animals. Specific enrichment devices are discussed below.

FEEDING SYSTEMS

Feed distribution systems may be incorporated into the cage design or food may be provided in separate dishes on the cage floor. Most commercial caging for research use incorporates a “J” type feeder (Figure 9.3). These feeders generally attach and extend through a special slot in the front of the cage or door. This allows the provision of additional food without the need to enter the cage or disturb the animal. These feeders must attach securely to the cage and usually have a retaining clip or other mechanism to secure it to the cage. If not, some rabbits will easily dislodge the feeder as they play with it, potentially leaving an opening large enough for escape of small rabbits or possible injury.

Other caging systems may have feed bowls or troughs attached to the inside of the cage. Some of these systems have special doors or other mechanisms that allow access to the feed bowl without opening the cage. Still others may just have defined areas on the cage floor for food bowls. In any system that uses a separate food bowl, the primary consideration is that it must be secured to the cage in some manner or be heavy enough

and designed in such a way as to prevent the rabbit from tipping it over. Rabbits will play with any loose objects in the cage. Like many other species, rabbits are variable in their food intake, some eating their entire ration quickly while others nibble throughout the day. Having food left in the bowl does not preclude rabbits from playing with the dish and potentially spilling their entire daily ration through the floor grate. Although logic would indicate that the rabbit should be hungrier at the next feeding and therefore likely to finish the ration prior to playing with the bowl, this is often not the case. Rabbits may lose a significant amount of weight due to ration wasting if feed bowls are not secured.

FIGURE 9.3 Common “J-type” rabbit feeder. The feeder fits onto the front of the cage as shown in Figure 9.2.

For attached feeding systems, the food access point for the rabbit should be located 3–4 inches off the floor and the opening should be large enough to ensure that the rabbit's head does not get trapped. This is especially of concern if rabbits are limit-fed as they will force their head into the feeder to reach the last food morsels. Conversely, openings should not be so large as to allow small rabbits to enter the feeder and use the feed pellets as bedding.

WATERING SYSTEMS

Water may be provided via water bottles, automatic watering systems, or water bowls (not recommended). Selection of the appropriate system depends upon the number of animals, the type of research, and the caging design.

Water bottles are commonly used, particularly when small numbers of rabbits are being housed at one time. The bottles can be made of glass (not recommended due to safety hazards of breakage and weight) or highly resistant plastic and must be able to withstand sanitation procedures and possibly steam sterilization. The bottles may use either rubber stoppers or screw-on metal caps (usually stainless steel). Stainless steel is highly recommended for sipper tubes. Rabbits are notorious chewers and will quickly destroy any malleable materials. For this reason if rubber stoppers are used, there should be a metal guard or other device in place to prevent access by the rabbit.

For all water bottle use, the bottles must be securely attached to the cage. Many caging systems have specialized holders built-in to retain the water bottle. If not securely attached to the cage, the rabbits will play with the sipper tube and dislodge the bottle. Sipper tubes should be positioned low in the cage to ensure easy access, particularly for potentially debilitated animals.

Automatic watering systems are particularly useful in large colonies where water bottle usage would be very labor-intensive. These systems incorporate a water distribution piping system that is attached to each rack with a quick-disconnect valve connector built into the cage rack. This plenum distributes water to lick valves (Figure 9.4) which protrude into each cage, usually at the back. The plenum may terminate in a drain valve that is automatically (or manually) drained periodically into a nearby drain or sink. Alternately, the water may be recycled back into the distribution system after retreatment to ensure a sanitary supply. Most automatic watering systems for rabbits are one-pass systems where water is discharged and not recycled. The water in these systems may be treated in a variety of manners as described below.

Automatic watering systems should be used with procedures that ensure adequate sanitation and/or water purity as well as proper mechanical function on

a day-to-day basis. These systems often incorporate a water purification system, pressure reduction system, flush system, and distribution system. All of these mechanical systems are subject to failure, resulting in either widespread or individual failure to provide water. Even a single day without water can significantly affect animal health, well-being, and research results. A system for daily monitoring of automatic watering function must be developed that will ensure proper function at the individual cage level.

Although water bowls can be used with rabbits, this is highly discouraged. Aside from the animals playing with the bowls (thus requiring that they also be secured), rabbits will also quickly soil their water bowls with food slurries and possibly urine or feces. If water bowls are used, it is advisable to conduct multiple daily checks to ensure that potable water is available at all times.

RESTING BOARDS

Although not required by regulatory authority, resting boards may provide an improved environment for the animals, particularly those housed on wire grids or

FIGURE 9.4 Automatic water drinking valve.

for heavy animals. In some cases, resting boards may be incorporated into the caging system with a ramp to provide an elevated resting perch. When provided, these boards must also be chemical- and heat-resistant to withstand sanitation practices. They are usually constructed of durable plastic or metal, although disposable materials have been used to provide additional enrichment, such as autoclaved cardboard. When disposable materials are used, they should be evaluated for potential contamination and ingestion hazard as well as their potential effects on research results.

NEST BOXES

Animal Welfare Act Regulations (USDA, 2005) mandate that a “suitable nest box containing clean nesting material shall be provided in each primary enclosure housing a female with a litter less than one month of age.” Nest boxes must also be constructed of materials that are easily sanitized and durable. In this regard, stainless steel or durable plastic are recommended. Drainage holes for urine are not essential because the doe spends little time in the nest. Careful consideration should be given to the flooring material in nest boxes, as hip dysplasia has been reported in kits using boxes with slick flooring (Owiny et al., 2001). Although there are no minimum size requirements for nest boxes, they should be of adequate design to allow the doe to turn around comfortably without trampling the kits, but small enough to provide a sense of security and privacy to the doe. Bedding selection is discussed above.

ENVIRONMENTAL ENRICHMENT DEVICES

Specific approaches and effects of environmental enrichment are addressed above. As with any other equipment that enters the rabbit’s primary housing environment, enrichment materials must meet the same rigorous sanitation standards as the caging itself. If not, it must be disposable and not utilized for more than a single animal (or group if housed together). Enrichment devices that are not adequately sanitized between animals have a high potential for disease transmission as fomites because oral manipulation of the devices by the rabbit is common. Devices should also be evaluated for the potential to cause external trauma or gastrointestinal disease if ingested.

Specialized Caging

Depending on research needs, rabbits may be housed in a variety of specialized housing systems. Metabolic cages resemble standard housing cages but are equipped with a pan underneath the cage that funnels urine and feces into collection vessels for metabolic measurements. Individually-ventilated and biological-containment housing systems are just beginning to appear commercially

for rabbits. These systems provide either animal protection from the environment, containment of biological agents used within the rabbits, or some combination of both. Containment systems usually involve standardized caging housed within a containment unit, whereas ventilated caging is normally incorporated directly into the housing system. Other types of specialized caging may be encountered in the research environment depending on research protocol requirements. Housing that provides opportunities for exercise, environmental preferences, response/reward systems, and other research activities have been developed, but these are usually developed or adapted in the specific laboratory setting and are not commercially available.

Bedding

Direct bedding is not commonly utilized when housing rabbits in a research setting. Since the majority of the commercial caging systems are designed with a grate system allowing feces and urine to drop away from the animals, bedding within the cage is usually reserved for nest boxes. The exception to this is in group-housing environments which are discussed below.

There are a variety of materials that make suitable bedding for rabbits. Most commercial bedding materials for rodents are adequate, although fibrous materials such as hay, straw, or excelsior may be preferred by the rabbits, especially within nest boxes. These products more closely approximate the grass and straw that rabbits combine with their fur to make nests in the wild. Primary concerns for direct bedding should be animal comfort, low potential toxicity if ingested, and minimal dust (Kaliste et al., 2004).

Indirect bedding may be used within the pans below the cages. In this case, the absorbency of the bedding is most important as animal comfort is not a factor. Paper products, absorbent pads, wood shavings, or a variety of other materials may be suitable. Some products contain odor-absorbing chemicals or antibiotics to break down or decrease ammonia production to help decrease room odor. Another concern with indirect bedding should be that the products not emit volatile odors that may affect research either naturally or when in contact with urine, although this may be of less concern in rabbits than rodents (Ruben et al., 2007).

Physical Environment

Indoor environmental requirements for housing rabbits can be found in both the Animal Welfare Act Regulations (USDA, 2005) and the *Guide for the Care and Use of Laboratory Animals (Guide)* (ILAR, 2011). Requirements are similar to most other species housed in a research setting, with specific exceptions noted below.

Lighting

Light levels are generally set at 30-foot candles 1 meter above the floor as per *Guide* recommendations for all species. This has been shown to be adequate for general husbandry purposes without detrimental effects on the animals (Bellhorn, 1980). Levels above this may cause significant optic alterations which may affect research results, especially for albino rabbits which already have an altered visual threshold compared with pigmented animals (Balkema and Drager, 1991). Bi-level lighting with increased illumination during husbandry duties may allow for more subdued lighting overall. Care must be taken to ensure the high-light override automatically reverts back to low-light levels to prevent accidental overexposure.

The photoperiod should be controlled and is normally set at 12 hours light and 12 hours dark for typical research applications. If breeding or reproductive studies are being conducted, a 16-hour light:8-hour dark cycle has been recommended (Cheeke, 1987). The light cycle should be monitored, preferably continuously, to ensure proper functioning. Alterations in light cycle can have profound effects on research and reproductive parameters (Colasanti and Trotter, 1976; Hasan et al., 1981).

Light fixtures should provide even light throughout the housing environment; should be sealed to the ceiling to prevent the entrance of vermin; and should allow for external sanitation. Although external windows may provide natural lighting and viewing enrichment for the animals, they are not recommended. External windows make photoperiod control challenging; can cause temperature variations within the room; and may pose a security and vermin risk. Although viewing windows indoors may be beneficial in allowing animal monitoring without disturbance, care must be given to prevent room photoperiod disturbance with continuous hallway lighting.

Noise

Excessive noise to the point of potential auditory damage (>85db) is rarely encountered in the normal laboratory housing environment, but sound can be a significant stressor for laboratory animals (Nayfield and Besch, 1981; Sales et al., 1999). Rabbits are keenly aware of noise in their environment and this should be taken into consideration when designing facilities for rabbit housing. Housing rabbits adjacent to other species that are very vocal (e.g., non-human primates, dogs) can provide a source of stress and therefore, potential experimental variation. Constant background noise appears to be less disturbing than intermittent noise and providing a low level of constant noise (white noise) may help mask noises of intermittent interruption.

Rabbits can be a significant source of noise as well. Thumping in metal cages or rattling enrichment devices or cage doors can cause quite a disturbance when numerous rabbits are housed in the same room. This may be a consideration for sensitive species in surrounding housing areas.

Heating, Ventilation, and Air Conditioning (HVAC)

Although the *Guide* (ILAR, 2011) sets temperature recommendations for rabbits at 61–72°F, they appear to be most comfortable at the low end of this range. Temperatures above this range can lead to panting, anxiety, and hair loss. Room temperature selection should take into consideration the type of caging, whether bedding is provided, and whether animals are housed singly or in a group. Room temperatures need to be monitored, preferably continuously, to ensure proper functioning and to maintain animal health and welfare.

Humidity ranges per *Guide* recommendations are set at 30–70% relative humidity. Rabbits appear to be most comfortable at the lower end of this recommended range.

Standard ventilation rates of 10–15 air changes per hour (ILAR, 2011) appear adequate for laboratory-housed rabbits. Rabbit housing rooms are generally set at a negative air pressure differential to adjacent spaces to help contain allergens and the relatively large amount of hair these animals shed. Multiple factors should be considered in determining the appropriate pressure differential. These include the requirements of adjacent spaces, types of research, and health status of the animals.

It is generally recommended that room air supply be 100% fresh air with no recirculation. Although recirculation is allowed with HEPA-filtration (ILAR, 2011) and may offer significant heating or cooling efficiency, this practice should be evaluated carefully. Not only might recirculation of contaminated air expose animals to pathogens, but rabbits release significant amounts of hair and dander which may make filter maintenance challenging. Ooms et al. (2008) demonstrated airborne contaminants within rabbit holding areas to be substantial.

Secondary Enclosure

The secondary enclosure is defined as the space within which the primary enclosure resides; i.e. the room in most laboratory settings. Even though in many housing situations the animal never comes in direct contact with the secondary enclosure, stringent sanitation requirements necessitate careful consideration in design of the space. Surfaces must be smooth, impervious, and able to withstand heat and chemical exposure. Wall and ceiling penetrations should be sealed to prevent vermin entrance. Fixtures, outlets, and switches

must be water-resistant to allow safe room sanitation. Wall fixtures should be protected if heavy, mobile rack systems are used for housing. Floors should be impact-resistant to withstand heavy stationary and mobile racks and dropped equipment (such as cage pans). Access panels, ventilation grates, and other permanent fixtures should be constructed of materials (such as stainless steel) that can withstand physical and chemical abuse without breaking or rusting.

Husbandry

Husbandry in the research environment is more than just meeting the biological needs of the animals. Research is a sophisticated endeavor where inter- and intra-animal variations must be minimized. Experimental results may be affected by changes in diet, chemical exposure, light levels, temperature, and many other environmental factors. It is the challenging responsibility of the husbandry program to provide the most appropriate setting for the animals while maintaining tight control over environmental variables that may affect research.

Food

Specific nutritional requirements of rabbits are discussed elsewhere in this chapter. In most laboratory settings, rabbits are fed a limited ration once or twice per day. Rabbits, particularly the New Zealand White breed, tend to get very obese if fed *ad libitum*. Feed is usually provided without further treatment or processing in the laboratory setting. The appropriate amount to feed depends on the quality of the food, the metabolic state of the animal, and specific research requirements. In general a once-daily feeding of 90–120 g of a high-quality, pelleted rabbit feed will be adequate for a medium-sized adult rabbit (Harkness and Wagner, 1989). An alternative method to prevent obesity is to feed a higher-fiber, lower-energy diet *ad libitum* (Cheeke, 1994), although this will be associated with increased fecal output. A liquid rabbit diet with comparable results to pelleted diets has been described (Latour et al., 1998) and this may be useful for studies requiring oral dosing. Changing diets can have significant impact on gut flora and should be done slowly over several days by gradually increasing the new diet mixed with the old.

Food should be purchased from a reputable dealer where it is stored in an area with appropriate environmental and vermin control. Many animal feeds produced for commercial use contain additives and/or antibiotics which may have significant impact on research studies. Certified, laboratory-grade feeds are recommended and producers should be able to certify not only the ingredients used to make the feed, but also that there has been no contamination of the feed from

products left over from other food production runs. Feed should be transported to the facility in dedicated vehicles which prevent contamination and/or vermin infestation. Feed bags that arrive damaged in any way should not be used as they constitute a contamination risk.

Within the facility, feed should be stored off the floor and away from the walls to facilitate sanitation of the feed holding area. Refrigeration is preferable, but any clean, dry, cool area is adequate. Regardless of storage conditions, feed should not be used beyond 6 months past the mill date (usually stamped on the bag) and perhaps sooner if storage conditions are less than ideal. Within the storage area feed should be rotated so that the oldest feed is used first.

Open feed in use may be stored within the animal room, but should be kept in a clean, sealed container. The mill date (or expiration date) should be clearly visible. Feed storage containers and feeding implements should be sanitized between fillings on a regular basis.

Water

Unless restricted by research protocol, rabbits should have *ad libitum* access to clean, potable water. This is most easily accomplished via an automatic watering system, but bottles are adequate if checked frequently. Poor water quality may impact animal health and research results. Water treatments vary by institution and research requirements and run the spectrum from untreated well water to reverse osmosis and irradiation. The level of water treatment is often dictated by other projects and species being housed. Regardless of source and treatment, water quality should be periodically evaluated to ensure the absence of impurities and infectious agents.

Bedding

Specific bedding selection was discussed above. Selection of a bedding supplier should follow the same criteria as for a feed supplier. A reputable supplier should store and transport bedding materials under very similar conditions as outlined for feed suppliers.

Within the facility, bedding should be stored off the floor and away from the walls to facilitate sanitation. Storage areas should be maintained clean, dry, and monitored for vermin. Although bedding rotation is not critical, it may be appropriate, especially under storage conditions with higher humidity.

Open bedding in use may be stored within the animal room, but should be kept in a clean, sealed container. Bedding storage containers and implements should be sanitized on a regular basis.

Health Monitoring

Monitoring the health and well-being of animals in the research setting is the responsibility of all who enter that setting. A good health-monitoring system ensures

that any abnormalities are promptly reported to the responsible veterinary care staff, up to and including the institutional veterinarian. An alert system (such as a health check notification card (Figure 9.5)) is a good way to ensure prompt veterinary assessment of abnormal conditions. Although there is no federal mandate in the United States for individual health records for rabbits, the *Guide* (ILAR, 2011) highly recommends such records to appropriately document health concerns and treatments, especially for animals on surgical protocols. Even if individual records are not kept, documentation must be sufficient to convey this information for any given animal within the facility.

Sanitation

Sanitation standards are one of the few places where the Animal Welfare Act Regulations (USDA, 2005) and the *Guide* (ILAR, 2011) differ. The Animal Welfare Act Regulations require monthly sanitation of primary enclosures for rabbits whereas the *Guide* generally suggests biweekly sanitation (although there is some latitude for professional judgment). Sanitation protocols to be utilized should be compared to any and all applicable standards and the most stringent standards should be followed to ensure compliance. In all cases, sanitation is generally defined as cleaning followed by either chemical disinfection and/or hot water rinse (typically at least 180°F). If chemical disinfectants are utilized,

there must be adequate contact time for disinfection and they must be thoroughly rinsed to prevent animal exposure. Regardless of the methods utilized, sanitation efficacy should be periodically tested to ensure adequate and consistent results. Rabbit cages and pans present a difficult sanitation challenge because rabbits on standard laboratory diets excrete significant amounts of calcium in their urine which forms calcium carbonate scale on cages and pans. Acid wash cycles or pre-soaks may be necessary to remove this scale prior to sanitation because normal alkaline wash cycles inadequately remove the scale. In addition to calcium deposition, rabbit urine may normally be pigmented red or orange and this must be distinguished from hematuria (Cheeke, 1987).

PRIMARY ENCLOSURES

The *Guide* (ILAR, 2011) suggests sanitizing enclosures and accessories, at least once every 2 weeks, although allowance is granted for professional discretion based upon the individual situation. The Animal Welfare Act Regulations (USDA, 2005) require sanitation of the primary enclosure at least every 30 days. Whether individually housed in a caging system or group-housed in pens, the primary enclosure must be emptied and appropriately disinfected at least once per month. Many facilities just default to biweekly cage sanitation to ensure that integrated equipment (such

as feeders) is being sanitized according to regulatory requirements. For directly bedded animals, soiled litter must be removed and replaced with clean litter weekly and collection pans/troughs under grid-type caging must be “cleaned” weekly (USDA, 2005).

SECONDARY ENCLOSURES

There are neither regulatory requirements nor specific recommendations concerning how often secondary enclosures (i.e., rooms) must be sanitized. Though left to professional discretion, the general expectation is that secondary enclosures will be cleaned regularly and disinfected as appropriate to the circumstances. In most facilities the housing room is completely disinfected either between groups of animals or periodically anywhere from monthly to biannually.

ANCILLARY EQUIPMENT

Although the *Guide* (ILAR, 2011) generally leaves sanitation, frequency of feeding and watering equipment up to professional judgment, it does recommend that solid-bottom caging, bottles, and sipper tubes be sanitized at least weekly. The Animal Welfare Act Regulations (USDA, 2005) strictly require that these implements be sanitized at least every 2 weeks. This standard is generally applied to any other equipment directly within the primary enclosure (such as manipulation devices), although the sanitation requirements for these implements are vague.

Animal Procurement

Suppliers

In many areas there are “backyard breeders” and/or agricultural auctions where inexpensive rabbits may be purchased for research use. The procurement of rabbits from these sources should be undertaken with caution because the health status of such rabbits is often substandard or, at best, undefined. Numerous studies have documented untoward effects of rabbit pathogens on research (Baker, 2003). High-quality, pathogen-defined animals purposely bred for research are highly recommended. Although the expense of purchasing and shipping these animals may be significantly higher than local breeders, this is often offset by the time and effort saved in having to repeat studies due to unforeseen variables or even animal loss due to illness. In addition, the need to repeat studies due to animal health-related complications may be considered wasteful from an ethical perspective of animal use. Numerous natural pathogens, such as *Pasteurella multocida* and *Clostridium piliforme*, have been shown to alter a variety of organ system functions and could significantly impact research results (Baker, 2003). Although cost cannot be

discounted in times of limited research funding, the quality of the research produced must always remain a high priority to ensure scientific progress and, thereby, justify animal use.

Quarantine and Stabilization

Animals may arrive in reusable transport cages that need to be returned to the supplier or in disposable transport boxes. Entrance procedures into the facility are dependent upon the health status of the animals, housing conditions, and research needs. These may vary from direct placement into the caging environment where the research will be conducted to strict isolation and quarantine procedures.

At a minimum, animals should be inspected upon arrival to ensure they are free from overt clinical signs of disease or trauma. If acceptable, the animals should ideally be placed in a quarantine holding area. This may not be required if animals are received from a single vendor with high and consistent health standards. The length of quarantine is highly variable and depends upon the expected health status, time requirements for any diagnostic procedures, likely cross-contamination with other colony animals, and incubation times for diseases of concern. If quarantine procedures are utilized, they should be at least as long as the acclimation period.

Even if quarantine is deemed unnecessary due to high health quality, newly arrived animals need a period of acclimation to regain a consistent physiological plane prior to initiation of any research project (Conour et al., 2006; Obernier and Baldwin, 2006). Again, recommendations for the length of the acclimation period are variable, but most institutions adhere to a minimum of 48–72 hours which has been shown to correlate with stress hormone stabilization after shipping (Toth and January, 1990). Acclimation periods may also be varied within a facility depending upon the intended use of the animals; i.e. a survival surgery research protocol may require a longer acclimation period than a non-survival teaching protocol.

Identification

Although there are no specific legal requirements for rabbits in a research facility to be individually identified, it is highly recommended for research recording and clinical health record maintenance. The cage card alone may be sufficient identification for individually housed animals, but other methods that are integral to the animal should be considered and would likely be advantageous when animals are pair- or group-housed. Although small numbers of animals may allow individual animal feature recognition; this may not be adequate when staff are unfamiliar with the rabbits. Feature recognition may also be insufficient when

large numbers of similar animals (such as New Zealand White rabbits) are being housed.

Animal-specific methods of identification include ear tattoos, ear clips or tags, fur dyes, and implantable telemetry devices. Ear tattoos are usually very permanent, but may require anesthesia to place depending upon institutional policy. This may be true for ear clips or tags as well. In addition, clips or tags may tear out causing trauma to the pinna and loss of identification. Non-toxic fur dyes (Figure 9.6) are usually innocuous, but may require repeat application. Subcutaneous transponders (microchips) are being used more commonly as they are relatively easily placed and can provide significantly more information, including telemetry data such as body temperature. The disadvantages are that they require specialized equipment for detection, may require anesthesia for placement, and have been associated with tumor induction in rodents (Blanchard et al., 1999; Blanchard et al., 1997; Elcock et al., 2001; Tillman et al., 1997).

Environmental Enrichment

The *Guide* (ILAR, 2011) stresses the importance of meeting all environmental requirements of laboratory animals, including physical, social, and behavioral requirements. Stereotypic behaviors (Hansen and Bethelsen, 2000), self-injurious behaviors, and even metabolic abnormalities (Potter and Borkowski, 1998)

can result from maintaining rabbits in a mundane environment. Obviously the normal environment of wild rabbits cannot adequately be replicated within the research environment, so one must make approximations of environments and activities that might substitute for normal experiences and promote normal species-specific behaviors (Baumans, 2005; RSPCA, 1993).

For all laboratory species, environmental enrichment must be approached with several important factors in mind: (1) there is animal-to-animal variation in what is considered enriching, what is considered stressful, and what makes no difference at all; (2) food rewards change the nutritional status of the recipient; and (3) enrichment devices are a potential source of disease transmission or other health risk. Although it is desirable for rabbits to live as comfortably as possible, enrichment choices must be evaluated to ensure that they do not detrimentally alter research results. This has been of particular concern in toxicology research facilities, but at least one study (Johnson et al., 2003) has demonstrated that manipulation enrichment can be provided without untoward effects on toxicology studies in rabbits.

Environmental enrichment for rabbits commonly involves the addition of either food supplements (Figure 9.7A,B) and/or a variety of manipulation devices (Figure 9.8A–D) to provide variety and activity to the sterile cage environment. Few studies examining the interaction of rabbits with enrichment devices had

FIGURE 9.6 Non-permanent identification mark on inner surface of rabbit ear.

FIGURE 9.7 Common food-enrichment devices, alfalfa cubes (A) and fruit-flavored gnawing treats (B). Photographs courtesy of Bio-Serv, Inc. (Frenchtown, NJ).

been conducted prior to publication of this text (Hansen and Bethelsen, 2000; Harris et al., 2001; Huls et al., 1991; Johnson et al., 2003; Lidfors, 1997).

Food supplements and/or diet variations are common methods of enriching the environment for research rabbits. One study (Harris et al., 2001) found that the total interaction time was higher for food supplement-type enrichments than for non-food enrichment devices. Berthelsen (1999) found that bar gnawing and fur chewing were decreased in rabbits supplied hay in the cage environment. The nutritional quality of the supplement should be evaluated to ensure purity and

to determine potential research impact. In addition, some popular supplements may greatly increase caloric intake, leading to obesity or decreased ration intake and potentially resulting in nutritional deficiencies.

Manipulation devices are the other common means of enriching the environment for laboratory rabbits. There are many commercially available products advocated for rabbit enrichment (Figure 9.8A–D) and many laboratories have devised their own homemade devices for this purpose. Such products usually involve something the rabbit can pick up and move about or something attached to the cage that can be rattled to

make noise. Manipulation devices should be carefully evaluated to make sure they do not pose a hazard to the animal either inherently or after damage by the rabbit (Shomer, 2001).

The impact of human social interaction must not be discounted when it comes to rabbit enrichment. Rabbits have been demonstrated to recognize and respond to particular individuals (Davis and Gibson, 2000), particularly when those individuals were associated with positive interactions (food rewards).

Group Housing

Group housing of rabbits in various configurations has been recommended as a preferred alternative to the traditionally single-housed rabbit in stainless steel caging (BVAAWF et al., 1993). Although most rabbits (especially in the United States) are still housed individually or in pairs within standard commercial rabbit caging, group housing in pens on contact bedding is increasing in popularity (Quinn, 2009). Cage housing is perceptually easier from a research control, sanitation, animal-monitoring, and health standpoint. Mixing animals in a pen environment allows for aggression, can make food intake monitoring difficult, and brings up concerns about meeting stringent sanitation requirements. These perceptions aside, as concerns over the social environments of research animals rise, group housing of rabbits will likely become an increasingly selected option or may even become the standard as regulations are revised.

Group housing is normally accomplished by creating a pen arrangement on the room floor (Figure 9.9). Walls may be constructed of plastics or laminates and may incorporate the room walls. Materials must be non-toxic and able to withstand chewing and sanitation

procedures. Pens are usually bedded with straw, shavings, or paper; and hay (often autoclaved) may be provided as forage. Various containers or huts may be provided to allow animals privacy and escape from aggression. Sanitation is accomplished by spot-cleaning daily and complete bedding removal and sanitation at least biweekly.

Stereotypical behavioral disorders, which may occur in single-caged rabbits, have been shown to greatly diminish in group-housed rabbits (Held et al., 2001; Krohn et al., 1999; Love, 1994; Poderscek et al., 1991) and female rabbits have displayed preference to be housed together (Brooks et al., 1993; Held, 1995), although this depended on the configuration of the solitary housing choice.

Some investigators have expressed concern over the influence that group housing may have on research results or control in social animals where dominance hierarchies are likely to develop. As rabbits are commonly used for antibody production, Turner et al. (1997) examined immunological responses between dominant and submissive rabbits in a group-housing environment and found no differences. Another group (Whary et al., 1993) compared humoral and delayed hypersensitivity response, feed intake, growth rate, and selected physiological parameters and found no differences between group-housed and individually caged rabbits. Not only have studies shown that there may be no significant research differences between housing types (Fuentes and Newgren, 2008), Nevalainen et al. (2007) demonstrated that biological parameters can actually be more stable in group-housed animals. Even if group housing is not feasible during research studies, some have advocated keeping rabbits in groups until the research begins (Stauffacher, 1992).

Aggression between male rabbits (and occasionally females) after puberty makes group housing of intact male groups essentially impossible without significant risk of injury. Castrated males have been successfully group-housed with only minor conflicts (Raje and Stewart, 1997).

BREEDING

The age of reproductive maturity is variable by rabbit breed, but usually occurs between 4–8 months with smaller breeds maturing faster than larger breeds (Harkness, 1987). The adult male rabbit is referred to as a buck, the female as a doe, and the young as kits (plural). Does should be bred as soon after maturity as possible as they will become less receptive the longer they go without breeding; especially if they become obese.

Although breeding is a natural activity of rabbits, the laboratory setting is not a natural environment for

FIGURE 9.9 Group housing of rabbits in floor pens. Photograph courtesy of J. Kincer.

this activity. Environmental factors can have significant impact on the willingness to breed and the overall success of a breeding program. Both sexes of rabbits have very specific behaviors in association with sexual activity and understanding these behaviors is crucial to ensuring the successful production of offspring from mating through weaning.

Sexual Behavior in Bucks

Pre-copulation

In the wild, male rabbits display a range of behaviors to attract females and dissuade male competitors. Chasing of both sexes is commonplace in the wild, but usually physically limited in the laboratory environment, therefore other behaviors may be intensified as a replacement. These other activities include tail-flagging, urine spraying (enurination), stiff-legged walking, and intensive cage circling (Patton, 1994).

Tail-flagging is a display behavior commonly seen in males when exposed to receptive females. The tail is held straight up or laid over the back and may be flicked repeatedly with the hindquarters pointed towards the female. Besides display purposes, this behavior may also be associated with the release of olfactory stimuli.

Enurination is the purposeful ejection or spraying of urine. This is a common behavior of bucks in non-breeding situations believed to primarily be a means of olfactory marking. This behavior can intensify in bucks exposed to breeding does and may be directed toward the doe or a competitor buck.

Ambulation within the cage may increase when bucks are exposed to breeding does. They may appear agitated, “thump” the bottom of the cage with the hind feet, circle the cage, increase interaction with enrichment devices, assume specific postures (e.g., elevating the hindquarters), and walk with a stiff-legged gait.

Copulation

Does should always be brought to the buck’s cage for breeding. Rabbits can be very territorial and does will often attack bucks that enter their environment. In the wild, receptive does seek out bucks for breeding and therefore are away from their marked nesting area. In addition, bucks may be more interested in marking the female’s territory than in copulation.

If the doe is receptive, breeding should occur very rapidly. The buck mounts from behind the doe and makes quick, jerky pelvic thrusts. Once intromission occurs, the buck ejaculates quickly and then may fall backwards and cry out. This may appear unnatural and cause concern for observers, but it is perfectly normal and the buck recovers very quickly.

The ejaculate is usually of a gelatinous consistency and the normal volume is approximately 1 ml. Details of normal rabbit ejaculate composition have been published elsewhere (Hammer, 1970).

If copulation does not occur very soon after placing the doe in the buck’s cage, the doe should be removed. This indicates either a disinterested buck or an unreceptive doe and can present an unsafe environment for both.

Post-Copulation

Bucks tend to be aggressive breeders and will often quickly attempt to mount the doe again after copulation. Although this second attempt may be successful, the doe may aggressively reject the buck leading to injury; therefore the doe should be removed shortly after the first successful copulation.

Individual bucks may be used to breed several does in the same day without a decrease in fertility. Commercial breeders will often keep one buck for every 10–25 breeding does, with the buck used to breed several does in a single day and with a day of rest in between sets (Patton, 1994).

Sexual Behavior in Does

Pre-Copulation

Although rabbits do not appear to have a regular estrous cycle, they do display periods of increased receptivity that occur every 4–6 days in domestic does (Meyers and Poole, 1962). In the wild they are much more seasonal with specific periods of receptivity mixed with periods of anestrus. Although there appear to be some cyclic vaginal changes, cytology may be unreliable due to variability associated with environmental cues. Vaginal smears from normal adult rabbits showed no distinct pattern of cellular type in does isolated from males, but showed increased numbers of superficial epithelial cells in does with auditory, olfactory, and visual contact with bucks (Ola and Oyegbade, 2008). Studies on follicular development and estrogen levels indicated a 14–16-day cycle with 12–14 days of higher estrogen (receptive period) followed by 1–2 days of low estrogen (refusal period) (Cheeke et al., 1987). The reproductive cycle of the doe is difficult to define because it is so highly influenced by environmental factors such as buck exposure, nutrition, light, and temperature.

If the doe is receptive, she usually will present her hindquarters to the buck with her tail elevated. Aggressive, confrontational activity should be a clear indicator to remove the doe quickly to prevent injury (see below). Both sexes may display a “preference” for partners. Although one breeding may not be successful, presenting a new partner for either or both may result in successful copulation.

Vaginal examination may give an indication if a doe is ready to breed. Receptive does usually have a dark pink to red, moist vulva. Unreceptive does usually have a light pink to almost white, dry vulva. Because this evaluation is quite subjective, it is probably more productive to simply pair prospective breeders and observe behavioral cues.

Copulation

Receptive does will readily accept the buck mounting and will remain passive during the copulation period. Copulation tends to be very brief; therefore there is little time for distinct behavioral variation in the doe.

Post-Copulation

Once the buck has dismounted, the doe may potentially become aggressive towards the buck, particularly if the buck attempts a second copulation. Once a successful copulation has occurred, the doe should be removed from the buck's cage.

Rabbits are induced ovulators with ovulation usually occurring 10–13 hours after copulation (Patton, 1994). A variety of methods have been developed for inducing ovulation in does for artificial insemination, a common practice in commercial production colonies (Bruni et al., 1982; Michelmann and Paufler, 1973; Staples and Holtkamp, 1966). Artificial insemination of rabbits will not be discussed in this chapter. For a complete review, see Theau-Clément (2008).

Gestation

Pregnancy Determination

Pregnancy is usually determined by gentle palpation of the abdomen. Fetuses can generally be detected between 12–14 days of pregnancy (Cheeke et al., 1987). Radiography can be used after day 11 (Hafez, 1970) and ultrasound can be used reliably as early as 7 days post-breeding (Chavatte-Palmer et al., 2008).

Pseudopregnancy may also occur, although this is not common. This is essentially an unfertile ovulation which can be caused by a sterile mating; mounting activity by other does; or any other environmental stimulant which may replicate copulation. Pseudopregnancy generally lasts 16–22 days and the doe may begin nest-building at the end of this period (Templeton, 1940). After about 18 days the corpora lutea begin involution and the condition resolves.

Gestation Length

Gestation length is generally between 29–35 days, with an average length of 31–32 days (Harkness and Wagner, 1989). Environmental factors, especially in housing situations permitting seasonal cues, may

influence total gestation length (Asdell, 1946). Larger litters tend to have longer gestations than smaller ones.

Physical Changes

Rabbits do not show overt signs of pregnancy until very late in gestation. This is particularly true for longer-haired breeds or obese individuals. New Zealand White rabbits are often overfed in the laboratory setting, which can make the detection of an unexpected pregnancy quite challenging. It is not uncommon for husbandry staff to miss a late pregnancy in a newly arrived animal only to find kits in the cage the next morning. With careful observation, conformational changes can be observed. The caudal abdomen will assume a bulkier shape giving the animal a much more prominent pear-shape when observed from above. As parturition nears, the mammary glands will thicken and should become noticeable on palpation, although milk is unlikely to be expressed prior to birth.

As parturition approaches, the doe will normally begin building a nest. If available, substrates such as hay, straw, paper, or excelsior will be incorporated, but the nest almost always includes copious amounts of hair plucked from the doe's body as a liner. The hair loosens as parturition approaches (Sawin et al., 1960) and this hair loss/plucking can give the doe an unthrifty appearance prompting concern from unfamiliar husbandry staff.

Parturition

Parturition (kindling) generally occurs in the morning (Sawin, 1950) and usually occurs very rapidly (within about 30 minutes). Both anterior and breech presentations may occur and occasionally kits may be born hours or even days apart (Patton, 1994). Natural parturition is accompanied by a sudden release of oxytocin and parenteral administration of oxytocin (1–2 IU) may be used to induce parturition or assist if parturition is prolonged (Hagen, 1974).

Pups are generally born in the nest. Immediately after birth the doe will eat the placental membranes, bite through the umbilical cords, and clean the kits.

Litter Composition

In the research setting, the average number of live New Zealand White kits born in a litter is approximately eight (Patton, 1992). Average litter sizes measured in other settings have been variable (Templeton, 1962) depending on methods of counting; environmental variables such as season; and genetics of the rabbit population being measured (Piles et al., 2006; Rollins et al., 1963; Sittman et al., 1964).

The information available on sex ratios within litters is as variable as it is for average litter size. Some studies

have indicated a slight male bias (Hafez, 1970) while others have demonstrated a small preference toward females (Brambell, 1942). Once again environmental factors may play a significant role in sex determination and this could explain the discrepancies in the published data.

Postpartum Breeding

Does will often be receptive to mating immediately following parturition and this receptivity may last up to 35 days if young are removed (Patton, 1994). If the kits remain with the doe, this receptivity drops off within 1–2 weeks and remains low until after weaning (Hammond and Marshall, 1925). When postpartum breeding is utilized, pregnancy success rates appear to be inversely proportional to current litter size and lowest during peak lactation (at approximately 3 weeks) (Cheeke et al., 1987).

Postpartum Care

Nest Building and Behavior

Pregnant does should be provided a nest box approximately 1 week prior to parturition. The design and selection criteria for use in a laboratory setting were discussed earlier. The nest box should include an appropriate direct bedding material such as hay, straw, paper, excelsior, or other non-toxic product. Several days prior to parturition, the doe will begin plucking loose hair from her body to mix with the bedding substrate to make a nest. The nest will be hollow in the middle and usually lined with her hair.

Kits will be born directly into the nest where they will remain until they are physically able to leave the nest on their own. Maternal retrieval is not typical for rabbit does (Ross et al., 1959), therefore any kits that are displaced from the nest will be left to die of malnutrition and/or hypothermia.

Nursing

Does usually have eight mammary glands distributed evenly along the ventral abdomen and thorax, four on each side. Although the glands will thicken and develop several days prior to parturition, milk is not released until after the doe gives birth. Milk production increases to a maximum at approximately 3 weeks postpartum (Hafez, 1970), then declines until lactation ceases at 5–9 weeks.

Rabbit milk is quite rich, containing 12–13% protein, 10–18% fat, 1–2% lactose, and 2.3% minerals (Coates et al., 1964). This richness allows for the normal rabbit maternal behavior of only nursing the litter once per day, regardless of access to the nest (Zarrow et al., 1965). The nursing behavior is probably instinctual, held over from wild rabbits which spend most of the

day away from the nest foraging. Nursing generally occurs in the morning, but this is variable and usually only lasts from 3–5 minutes.

Orphaned rabbits may be fostered or hand-reared using commercially available rabbit or kitten milk replacers. They are generally fed 2–4 times per day allowing them to consume as much as they will take.

Weaning generally occurs between 4–8 weeks of age, depending on availability of access to solid food for the kits. When compared in commercial production, weaning at 4 weeks was not associated with any increased mortality over those weaned at 6 or 8 weeks (Chen et al., 1978).

NUTRITION

Gastrointestinal System

Anatomy and Physiology

Rabbits are herbivores and are considered “concentrate selectors” which means they tend to choose soft, nutrient-rich vegetative growth over those that are higher in fiber and roughage (Irlbeck, 2001; McNitt et al., 1996). This means that their diets are usually higher in protein and soluble carbohydrate and lowest in fiber compared to other types of herbivores (Cheeke, 1994).

Anatomically, the rabbit is a hind-gut fermenter. Similar to many small herbivorous rodents, guinea pigs, and horses, the rabbit’s gastrointestinal tract is dilated towards the end (in this case the cecum) to create a fermentation vat. Symbiotic microbes (primarily *Bacteroides* spp.) populate the cecum and provide the rabbit with the means of breaking down digestible fiber (Irlbeck, 2001).

Ruminants have the advantage of being able to hold food materials in their rumen for prolonged periods of time. This allows prolonged digestion and enables them to subsist on high-roughage, low-quality feed-stuff. The rabbit cecum does not provide this prolonged storage capacity and functions more like a continuous pass-through organ similar to other parts of the gastrointestinal tract. This would potentially allow for a significant loss of digestible materials if it were not for the unique anatomy of the proximal colon. Immediately past the ileoceccocolic junction the colon has distinct haustrae and a specific peristaltic pattern that separates out large, indigestible particles from smaller, nutrient-rich ones (Bjornhag, 1981). The larger particles are sent distally to become fecal pellets and the smaller particles are pushed retrograde back into the cecum for further fermentation.

CECOTROPHY

Another unique aspect of the rabbit’s digestive process is the production and consumption of cecotrophs.

Since rabbits normally consume highly digestible plant products, much of the nutrients are derived directly via normal gastric digestion and absorption in the small intestine. Indigestible dietary portions are fermented in the cecum. As the majority of nutrient absorption occurs prior to the cecum, the rabbit needs a method for getting these nutrients to the absorptive parts of the gastrointestinal tract. To accomplish this, a special form of feces called a cecotroph is created. Sometimes referred to as “night feces,” cecotrophs are only expelled 1–2 times per day and are comprised of material directly from the cecum coated with mucus. The rabbit ingests the cecotrophs directly from the anus and this allows for further digestion and absorption of these nutrients in the upper gastrointestinal tract. These cecotrophs are excreted in glistening, grape-like clusters and are often mistaken for a clinical indication of disease, such as diarrhea, since they are rarely observed in normal animals. This, in fact, may be a true indication of disease since the rabbit normally will consume all the cecotrophs produced and, thus, lack of consumption may indicate an abnormal state, although this may be influenced by diet quality as well. As a general rule of thumb, high-quality diets are associated with less cecotrophy (Fekete and Bokori, 1985). This also applies to the animal’s metabolic state, but in a direct manner; high metabolic demand is associated with greater cecotrophy (Lorente et al., 1988).

As stated previously, the proximal colon separates out the rough, indigestible feedstuffs and passes them along to be expelled as feces. These would be the usual fecal pellets commonly associated with rabbits. Cecotrophs are expelled in discrete clusters completely separate from fecal pellet expulsion. The control of this separation occurs at another unique anatomical feature known as the *fusus coli*; a muscular constriction separating the proximal colon (with haustrae) from the distal colon (without).

Cecotrophy is a very important aspect of rabbit nutrition as a significant portion of the rabbit’s diet is not digestible via normal monogastric digestion. The fermentation process in the cecum provides significant amounts of protein and B-vitamins, and nutritional deficiencies may occur if animals are prevented from ingesting cecotrophs (Robinson et al., 1985).

Nutritional Requirements

There have been surprisingly few studies on the specific nutrient requirements of rabbits and many specific nutrient requirements are still unknown, especially for rabbits in various metabolic states such as gestation. Lebas (1980) remains as one of the most comprehensive reviews of rabbit nutrition available. Fortunately, research rabbit diets have been available commercially for many years and reports of nutritional deficiency or

toxicity in the laboratory setting are rare (Ringler and Abrams, 1970; St. Claire et al., 2004; Stevenson et al., 1976). These reports usually involve inadvertent miscalculations in the formulation of special research diets.

Although it is common in commercial rabbit production to have several diet formulations for different stages of growth, this is usually unnecessary in the laboratory setting as most animals can be maintained on a generic maintenance diet from weaning through senescence. Obesity is much more of a concern than specific nutrient requirements as the metabolic demands on rabbits in the research setting are often small while being fed excessive amounts of high quality, easily digestible feeds. See above for specific feeding guidelines.

Feeding Patterns

Rabbits primarily eat at night and in the early morning when fed *ad libitum*, but often eat immediately after feeding if limit-fed. They usually eat well, hence the obesity concerns noted above, but occasionally go “off feed” for brief periods of time (1–2 days) without recognizable indications of disease or distress (Poderscek et al., 1991). These animals will usually resume eating without treatment and with no apparent physiological impairment, but should be monitored closely as prolonged anorexia may lead to hepatic lipidosis if untreated (Bergdall and Dysko, 1994). Providing molasses on the feed or supplementing with sweetened breakfast cereals may entice consumption, but care must be observed not to train the rabbit to reject its normal ration in favor of these sweet treats. Fresh fruits and vegetables with higher fiber content may be an effective alternative to induce consumption without the potential enteritis complications associated with sweet feeds.

Environmental factors can affect feed intake as well, particularly temperature. Rabbits have a lower thermal neutral zone than most other laboratory species. At higher temperatures, even those normal for other species, food consumption will often be decreased in rabbits. In cooler temperatures they will consume more to meet metabolic demands to regulate body temperature (Cheeke, 1994).

Food Preferences

Rabbits seem to perform better when fed pellets than when they are fed mixed grains, meal diets, or textured feeds (Cheeke, 1994). Rabbits will preferentially eat pelleted, dehydrated alfalfa (Figure 9.10) over alfalfa in its natural form (Irlbeck, 2001). This may be due to their general dislike of fines and stems. The optimum pellet size for rabbits has been suggested to be 0.63 cm long and 0.47 cm in diameter (McNitt et al., 1996). Small-diameter pellets (<0.25 cm) lower intake while

FIGURE 9.10 Standard pelleted alfalfa-based feed.

larger-diameter pellets ($>0.5\text{cm}$) result in greater food wastage (Maertens and Villamide, 1998).

Rabbits appear to have a distinct preference for sweet feeds, but will also preferentially eat foods laced with bitter compounds like saponins (Cheeke et al., 1977) or specific flavors like thyme (Fekete and Lebas, 1983). Although this may be exploited to entice rabbits to accept test compounds orally, these animals can be particularly fastidious about any dietary changes.

Diet Composition

Unless nutritional studies are being conducted or special diet formulations are required for research purposes, a standard, laboratory-grade commercial rabbit feed is recommended. These diets provide balanced nutrition, detailed compositional analysis, and standardized production methods critical to the controlled research environment.

Most commercial rabbit diets are alfalfa-based, although other types of grasses may be suitable. Dehydrated alfalfa is usually the primary ingredient, but this is usually supplemented with grains and grain byproducts (hulls, middlings, etc.), sugars (molasses), vitamins, and minerals.

Grain-based diets, although often accepted by rabbits in the pelleted form, are usually too high in carbohydrates and too low in fiber to sustain a healthy gastrointestinal system. If such diets are utilized, they should be supplemented with a source of indigestible fiber to promote gastrointestinal mobility.

Fresh greens and other succulent feeds may be consumed by rabbits and may serve as enrichment treats; they should not constitute a significant portion of the diet for laboratory rabbits as their nutritional content and quality are generally unknown or inadequate.

Protein and Amino Acids

Optimal crude protein levels have been studied primarily for commercial rabbit production and recommendations range from 15–19% depending on metabolic demands, lower (15–17%) for growth, higher (17–19%) for reproduction (Omole, 1982; Sanchez et al., 1985). Feeding of diets high in protein ($>20\%$) has been associated with increased cecal ammonia, pH, and enteritis (Morisse et al., 1985).

Rabbits have a better ability to digest forage proteins (such as in alfalfa) than other non-ruminant species such as chickens or swine. This is primarily due to their hindgut fermentation and cecotrophy (Robinson et al., 1985). Forages with high tannin content appear to have much lower protein digestibility than those with lower levels of phenolic compounds (Raharjo et al., 1990).

Microbial protein from fermentation contributes to the overall protein intake for rabbits, particularly supplying the amino acids, lysine, threonine, and the sulfur amino acids (Carabano and Piquer, 1998). Unlike ruminants, microbial protein only plays a minor role in meeting the rabbit's protein and amino acid needs (McNitt et al., 1996). Dietary protein intake influences cecotroph consumption; low dietary protein increases consumption, high dietary protein decreases consumption (Cheeke, 1994). Cecotrophs contain approximately 28% crude protein (Stevens and Hume, 1995), but may be low in certain amino acids (such as methionine) and synthetic amino acids are often added to alfalfa–corn diets due to amino acid deficiencies (McNitt et al., 1996).

Absolute requirements for specific amino acids are still not well delineated for rabbits. Recommendations range from 0.2–1.2%, depending on the specific amino acid and the metabolic stage of the rabbit (Lebas, 1980). Most of this work was conducted in the 1970s and involved determination of maximum weight gains while consuming diets with varying levels of specific amino acids (Adamson and Fisher, 1973). Cheeke (1987) conducted a review of this literature. When formulating diets it is probably most important to understand that amino acid levels should be based on unit of digestible energy instead of percentage of diet since rabbits consume diet based on caloric density of the feed (Colin and Allain, 1978).

ENERGY

Maintenance energy requirements have been estimated at 96 kcal metabolizable energy (ME) per kilogram body weight^{0.75} ($\text{BW}^{0.75}$) for lactating New Zealand White does (Partridge et al., 1983). Further studies estimated pregnant doe requirements to be 79 kcal/kg $\text{BW}^{0.75}$ and 114 kcal/kg $\text{BW}^{0.75}$ for lactating does (Partridge et al., 1986a). Lactation requires the highest energy demands of any normal metabolic state (Lang, 1981) and lactating

does at peak lactation are in a negative energy balance and must mobilize reserves to meet their requirements (Partridge et al., 1983). If lactating does are to be used in the research environment, a higher-energy lactating diet should be considered to maintain body condition. Care must be taken to ensure that this diet is not fed to non-lactating animals as obesity will result.

The two major sources of energy for rabbits are sugars absorbed in the small intestine and volatile fatty acids (VFA) produced during cecal fermentation (Cheeke, 1994). Rabbits do not appear to digest starch as readily in the small intestine as other non-ruminants such as swine (Wolter et al., 1980). High-starch, low-fiber diets increase cecal fermentation and production of VFA presumably due to increased substrate (starch) and cecal hypomotility (low fiber) (Cheeke, 1994).

Fermentation in the rabbit gut produces higher levels of butyrate instead of propionate as seen in ruminants. This is due to the microbial flora which is primarily *Bacteroides* spp. (which are often butyrate producers) compared with *Lactobacillus* spp. which commonly populate the rumen and typically produce propionate (Vernay and Marty, 1984).

Dietary fats can also provide for the energy requirements of rabbits. Vegetable fats contain higher levels of digestible energy for rabbits than animal fats (Maertens et al., 1986), and good sources include soybeans and other oilseeds (Johnston and Berrio, 1985).

Fiber

Rabbit growth is optimal with a dietary crude fiber range of 10–15% (de Blas et al., 1986), but dietary recommendations range from 10–25% (Jenkins, 1999). Given the physiological basis for rabbit digestion described earlier, one would logically presume that feeding a high-nutrition, low-fiber diet would be the most beneficial for rabbits, but this is not the case. Insoluble fiber is a very important regulator of gastrointestinal motility in rabbits and low-fiber diets may lead to hindgut hypomotility, fur chewing, and enteritis (Brooks, 1997; McNitt et al., 1996). In addition, low-fiber diets are less palatable to rabbits and may decrease food intake (Cheeke, 1994).

Crude fibers high in cellulose and lignin (such as in alfalfa and other forages) are poorly digested in rabbits. Non-lignified material (such as citrus or beet pulp) has much higher digestibility, but does not contribute to hindgut motility and therefore may be counterproductive for nutrition and increase the incidence of enteritis (Cheeke, 1987). Fine grinding of lignified fiber increases digestibility, but also leads to hypomotility and potential enteritis. Cecotrophy does not significantly increase fiber digestion since the fiber is separated out of the cecotrophs and passes out as normal fecal pellets (Robinson et al., 1985; Stephens, 1976).

Dietary fiber is very important in the digestive health of rabbits (Stein and Walshaw, 1996). The incidence of enteritis (see below) is increased in animals on low-fiber diets and these diets can also predispose them to fur-chewing and the development of trichobezoars (hairballs) (Brooks, 1997; McNitt et al., 1996).

Minerals

Most mineral requirements are easily met by the normal dietary ingredients with the addition of a trace mineralized salt (Cheeke, 1994). A review of recommended mineral levels can be found in Lebas (1980). Calcium and phosphorus metabolism are the most significant mineral concerns for rabbits, and these will be discussed in detail here.

Calcium levels of 0.4–0.5% of the diet have been recommended for non-lactating rabbits (Cheeke, 1994). Alfalfa meal has a high calcium concentration, therefore alfalfa-based diets are usually sufficient to meet the rabbit's needs. In fact, long-term maintenance on alfalfa-based diets may be associated with excessive calcium intake and may lead to health concerns.

Rabbits are unique in that they have high circulating serum calcium levels (12–13 mg/dl compared to 10 mg/dl for other animals) (Brommage et al., 1988). This is the result of calcium absorption not being vitamin-D-dependent and not relying on activation of calcium binding proteins in the gut (Jenkins, 1999; McNitt et al., 1996). In addition, the excretion of excess calcium occurs primarily through the urine instead of the bile as in most other species. The renal fractional excretion for calcium is higher (2.5 mM) for rabbits than in most other species (1.5 mM) (Buss and Bordeau, 1984). This urinary excretion is commonly observed as a white deposit (calcium carbonate) in the pans of animals kept on commercial alfalfa-based diets.

Rabbits are able to respond to low dietary calcium levels with the release of parathyroid hormone leading to calcium reabsorption and hypocalciuria (Bordeau et al., 1988). During lactation, this response mechanism may be exceeded leading to a calcium-deficient state (milk fever) (Bartlett, 1980). Aside from the increased absorption and urinary excretion of calcium, other mechanisms of calcium/phosphorus control appear to be very similar to most other species, although their homeostatic mechanisms do not appear to be as effective (Cheeke, 1994).

Phosphorus metabolism is vitamin-D-dependent with deficiencies in vitamin D leading to phosphorus malabsorption and impairment of skeletal mineralization (Brommage et al., 1988).

Vitamins

Specific requirements for most vitamins have not been adequately determined, but recommendations can

be found in Lebas (1980). Meeting the dietary vitamin requirements for laboratory rabbits is relatively easy as their normal feed ingredients are usually more than adequate; and rabbits produce additional B-complex and vitamin K by cecal microbes. Water-soluble vitamins are rarely associated with disease in rabbits, and most reported concerns have been related to the fat-soluble vitamins A, D, and E; 10000 IU vitamin A per kg diet appears to be adequate. The minimum level for vitamin D has not been determined since the rabbit's calcium/phosphorus regulation is not dependent on this vitamin as in other species. Toxicity has been the only reported concern with vitamin D. Minimum levels for vitamin E are also unknown, but deficiency has been reported (Ringler and Abrams, 1970) with a level of 16.7 mg α -tocopherol per kg diet.

Vitamin deficiencies or toxicities are rare in the laboratory setting (Besch-Williford et al., 1985; Brommage et al., 1988; Ringler and Abrams, 1971; Stevenson et al., 1976) and are almost always associated with errors in diet formulation.

Water

Water intake in the rabbit is greater than in most other species. Rabbits consume approximately 120 ml of water per kg BW per day (Cheeke, 1994). Potable water should be available ad libitum.

Water consumption is influenced by feed intake, environmental factors, and feed composition. High-fiber diets require more water intake to maintain a fluid mixture in the gut, as many types of fiber absorb water. High-protein diets will result in increased water intake, as well, to promote urea excretion. Rabbits will compensate for food deprivation with increased water consumption, potentially leading to electrolyte imbalances (Cizek, 1961).

NUTRITIONALLY RELATED DISEASES

Enteritis

Enterotoxemia refers to a specific type of enteritis resulting from the release of toxins by infectious organisms such as *Clostridium spiroforme* (Carman and Borriello, 1982), and *Escherichia coli* (Peeters et al., 1985, 1986), but the disease is frequently diagnosed clinically without culture verification, so the term is often used synonymously with generic enteritis in rabbits. It may be used synonymously here as well since the dietary factors predisposing to enterotoxemia may predispose to other types of enteritis not specifically caused by the release of toxins, such as mucoid enteropathy. The primary etiology in nearly all cases is the alteration of the hindgut flora in a manner that changes gut

homeostasis, fluid balance, and/or provides an environment for the proliferation of pathogenic organisms. In fact, a limited model of mucoid enteropathy can be created simply by ligation of the cecum (Hotchkiss and Merritt, 1996). Nursing rabbits appear to be protected and Gallois et al. (2007) demonstrated that maternal milk contained factors that protect kits from enteropathogenic *E. coli* infection. Newly weaned rabbits may develop enteritis spontaneously (Carman and Borriello, 1983), but older animals usually require some additional predisposing condition for the disease to develop. The specific diagnosis is somewhat irrelevant to the discussion of these dietary influences.

Improvement in rabbit health standards, dietary standardization, limit-feeding, and gradual diet transition protocols can greatly decrease the incidence of enteritis in laboratory rabbits. Enteritis may still be seen in newly acquired animals if immediately given full access to a diet formulation significantly different from what they were previously fed. In commercial production colonies enteritis may still account for losses of up to 20% of rabbits born (Cheeke, 1994).

One of the most common dietary factors leading to enteritis is an excessive amount of fermentable carbohydrate (Lelkes, 1986), leading to hyperfermentation which increases the concentration of volatile fatty acids, decreases cecal pH, and inhibits the normal cecal flora (Bradley, 2004; Harcourt-Brown, 2002; Irlbeck, 2001; Reusch, 2005). The lowered cecal pH leads to excretion of mucus to neutralize this change and the common clinical presentation of a mucoid diarrhea. In addition, hyperfermentation leads to increased glucose production in the cecum and it has been determined that *C. spiroforme* requires glucose to produce toxin (Carman and Evan, 1984).

Dietary fiber, particularly indigestible fiber, is extremely important in the prevention of rabbit enteritis. This is presumably due to its ability to stimulate hindgut mobility and cecal emptying. Increasing dietary fiber may help prevent further occurrences of disease during outbreaks.

Dietary protein levels can also affect the incidence of enteritis. When dietary protein levels are elevated, ammonia production is increased in the cecum causing an increase in cecal pH. This pH change may also cause a dysbiosis and allow pathogenic organisms to flourish (Morisse et al., 1985).

Another dietary factor in the development of enteritis is antibiotic administration, particularly if administered orally. Morris (1995) conducted an extensive review of this subject. Certain antibiotics have been associated with induction of enteritis in rabbits, including lincomycin, ampicillin, amoxicillin, procaine, penicillin, cephalixin, erythromycin, clindamycin, tylosin, and metronidazole (Katz et al., 1978; Loliger et al.,

1984). The actual effect from each of the drugs will differ between animals, but it is generally agreed that these compounds may cause deleterious shifts in the intestinal microbial flora (Stein and Walshaw, 1996). In contrast, some antibiotics do not typically cause this microbial shift, including oxytetracycline, virginiamycin, and tetracycline which have been used as growth promoters (Brooks, 1997; Cheeke, 1994); and sulfaquinoxaline which has been used to control coccidia (Brooks, 1997). Although antibiotics are sometimes used as additives in commercial rabbit meat production, extreme care is usually taken to ensure that laboratory-grade diets are antibiotic-free.

The addition of probiotic cultures of yeast and bacteria (such as *Lactobacillus acidophilus*) to the diet may be beneficial in the prevention and/or treatment of rabbit enteritis (Hollister et al., 1989, 1990).

Obesity

Obesity is a common problem in laboratory-reared rabbits, particularly if fed *ad libitum*. Laboratory diets are highly digestible and often high in carbohydrate content. Combined with the limited physical activity of most rabbits within the laboratory environment, it is not surprising that they may become obese. Obesity is easily prevented in the laboratory environment by following the manufacturer's feeding recommendations and limit feeding to maintain the desired body condition.

Obesity has been linked to lower reproductive performance in does. Obese does may have decreased interest in mating and, if they do mate, kit mortality is increased. This mortality has been associated with increased fetal weight combined with fat deposits in the doe's abdomen resulting in dystocia (Partridge et al., 1986b).

Gastrointestinal Hypomotility/Trichobezoars

Fur chewing has been associated with low-fiber diets and may result in the accumulation of hair within the stomach (trichobezoars) (Cheeke, 1987). The association with low-fiber diets indicates that it is unlikely just an excess ingestion of hair, but more likely decreased gastric motility. Indigestible fiber is important for motility of the rabbit gastrointestinal tract, so the low-fiber diet probably allows the normally ingested hair to accumulate. Although this is commonly seen in long-haired breeds (such as Angora), it is not uncommon in laboratory breeds as well. The hair can become matted with mucoproteins within the stomach and form a mass that can neither pass nor be digested, even if the dietary conditions improve. Severe trichobezoars can result in decreased food intake leading to malnutrition and are easily diagnosed by palpation.

Early diagnosis and treatment of gastrointestinal hypomotility are key to a successful outcome (Bergdall and Dysko, 1994). Historically, recommended treatments included oral administration of proteolytic enzymes such as papain, bromelain, or pineapple juice. Although these may be helpful in breaking down the mucoproteins and softening up the trichobezoar for passage, they do not address the primary problem. The most important factor in treatment and future progression is to get the animal well-hydrated and eating a high-fiber, low-carbohydrate diet. This may require extensive supportive care such as nasogastric feeding and/or parenteral fluid and analgesic administration (for gastric distention pain) (Reusch, 2005). In worst cases the trichobezoar may need to be removed surgically if it becomes too large to pass, although the prognosis for recovery is guarded.

Calcium Imbalances

As discussed earlier, rabbits normally have higher serum calcium levels than other species and their calcium absorption is not under the influence of vitamin D. Combined with their rather inefficient serum calcium control mechanisms, hypercalcemia can easily occur in rabbits consuming diets high in calcium (4%) (Kamphues et al., 1986); and this is intensified by high vitamin D levels. In addition, since the majority of calcium excretion occurs through the kidneys in rabbits, renal disease can also result in a hypercalcemic state (Garibaldi and Pecquet-Goad, 1988).

Prolonged hypercalcemia results in calcium deposition in soft tissues within the urinary, nervous, and gastrointestinal systems (Garibaldi and Pecquet-Goad, 1988) or result in formation of urinary calculi. Prolonged hypercalcinuria can lead to kidney damage.

Lactating does may develop a calcium deficit (milk fever) just after parturition. Symptoms include muscle tremors, jerking of the hind limbs, and ear flapping (Bartlett, 1980). Rabbits may become hypocalcemic (5.8mg/dl) and hypophosphatemic (2.9mg/dl) and may clinically improve following intravenous calcium gluconate administration.

Vitamin D Imbalances

Vitamin D deficiency is very unlikely in the laboratory setting due to high-quality diets combined with the microbial production of vitamins and intake via coprophagy. Prolonged deficiency has been reported (Brommage et al., 1988) and the primary effects were impaired bone mineralization and osteomalacia. This deficiency was associated with impaired phosphorus absorption and hypophosphatemia.

Vitamin D toxicity has been reported in rabbits due to dietary formulation errors or contamination (Besch-Williford et al., 1985; Ringler and Abrams, 1970; Stevenson et al., 1976). Clinical signs included emaciation, weakness, decreased appetite, diarrhea, intense thirst, ataxia, paralysis, and death. Calcification occurred in soft tissues similar to primary hypercalcemia.

Vitamin A Imbalances

Both vitamin A deficiency and toxicity (DiGiacomo et al., 1992; St. Claire et al., 2004) have been reported in rabbits. This literature has been extensively reviewed by Cheeke (1987). Both conditions produce similar signs affecting reproduction with low conception rates, fetal resorption, abortion, low kit survival, and hydrocephalus in neonates. Paresis and muscular dystrophy have also been reported in juveniles with vitamin A toxicity and the animals responded to vitamin E therapy (St. Claire et al., 2004). Lorente and Miller (1977) reported that placental transfer of vitamin A is lower than in the rat, and, although this may protect the fetus from toxicity, this may contribute to their sensitivity to deficiency.

Vitamin-A-deficient rabbits may be more susceptible to infectious diseases as well, since vitamin A plays an important role in the integrity of epithelial tissues including mucous membranes.

Vitamin E Deficiency

Several reports of vitamin E deficiency have been documented. Principal signs have included muscular dystrophy with paralysis of the hind legs. In one report (Ringler and Abrams, 1970), rabbits died at 3–10 days of age with marked degeneration of skeletal muscle. Reproductive failure has also been reported (Yamini and Stain, 1989) and can mimic vitamin A imbalances, although muscular dystrophy was also reported and this is not characteristic of vitamin-A-related disease. Vitamin E deficiency has been reported in association with vitamin A toxicosis (St. Claire et al., 2004).

Dietary Toxins

Dietary toxins are generally of low concern in the laboratory setting when high-quality, laboratory-grade feeds are provided. Fungal toxicosis has been reported in commercial rabbitries due to feed contamination (Krishna et al., 1991). Mycotoxins, particularly aflatoxin and the trichothecenes, are the most common concern. These toxins can cause liver damage, gastritis, nephritis, and enteritis (Fekete et al., 1989; Orsi et al., 2007). Teratogenic effects have also been reported (Wangikar et al., 2005).

INTRODUCTION

This chapter describes humane methods for handling and restraining laboratory rabbits, as well as techniques for obtaining biological samples; for administering substances; and for specialized procedures. Rabbits have individual temperaments, and a gentle, calm, confident

restraint method and demeanor in working with each animal will decrease stress for both the rabbit and the researcher. Rabbits can easily be injured, and can inflict injury on the handler if proper considerations are not followed to keep the animals secure and to minimize stress. Acclimating the animals in advance to procedure areas and restraint methods can be helpful. Whenever

possible, use of anesthesia or tranquilizing medication can facilitate procedures. Analgesia is provided after procedures that may cause pain or discomfort after the anesthetic has worn off. Finally, each researcher must be willing to acknowledge when a particular method or procedure does not succeed, and seek assistance or an alternative method.

HANDLING AND RESTRAINT

Physical Methods

Rabbits evolved under pressure as a prey species, which may account for their light skeleton paired with large muscles, to facilitate speed in fleeing from predators. This fragile bone structure predisposes these animals to injury from improper handling, in particular fracture or subluxation of vertebrae, or a broken back. Handling and restraint techniques therefore require that the rabbit's front and rear ends be supported, and that the animal not be allowed to kick or struggle. Handler injury may result from scratches; long-sleeved cloth lab coats with knit cuffs reduce the chances of sustaining a scratch from rabbit toenails.

To remove a rabbit from a cage or pen, the loose skin over the shoulders (scruff) is grasped from above in one hand. The rabbit is turned to face the handler so it is less likely to try to leap back into its housing. With the other hand supporting the rabbit's hind-quarters from behind or beneath, the animal may be lifted. To carry short distances, the animal is brought in close to the handler's body, and the head is tucked under the handler's arm (Figure 10.1). The ears are not included in the grip. Most rabbits are somewhat timid, but an

occasional individual may be aggressive, as evidenced by stamping, growling, and boxing at the approach of the handler. These bold individuals may be easily subdued by placing a towel over the entire animal. The animal may be firmly bunched in the towel and removed from the cage, and then placed on a secure surface, where it may then be grasped by the scruff. Animals are again faced toward the handler when returned to housing, so they will not attempt to leap back into the cage or pen.

Animals held snugly tucked under the arm of the handler as described may be safely carried short distances, but if an animal begins to struggle, the handler should gently release the rabbit on a secure surface; struggling animals can injure themselves and the handler. For moving longer distances, use of a plastic transport box is recommended. Boxes that open from the top, rather than from a door on one end, facilitate entry and removal of the animals. Plastic may be easily sanitized between animals.

Restraint of rabbits by the immobility reflex, or hypnosis, is induced by maintaining traction on the spine with the rabbit held in dorsal recumbency in a stretched position until it relaxes. The head is held flexed toward the chest and the hind legs are held in the other hand as the rabbit is stretched. Once the rabbit relaxes, the rear legs may be released but the head must continue to be held in a flexed position. Once the head is released, the rabbit returns to its normal state of awareness. Restraint boards have been designed to hold animals in this position. However, hypnosis is a method with considerable variation in effect and duration in individual animals. Therefore, it is not recommended for routine use, and never for procedures that could cause pain if the animal suddenly emerges from the hypnotic state.

FIGURE 10.1 Restraint for cage removal and carrying. (A) The scruff is grasped and the rear end is supported to keep the spine flexed as the animal is lifted. (B) The rabbit's head is tucked between the handler's arm and body. The animal's hind quarters are held snugly to prevent kicking.

Restraint Devices

A number of commercially available restraint devices are designed for rabbits. Most are designed to give access to the head and ears. Rigid metal and plastic devices are most common (Figure 10.2). Caution is needed to be certain yokes or neck openings are not secured too tightly in models that have an adjustable neck gate or band. Cloth “cat-bags” with Velcro closures can also be used with rabbits, with the advantage of permitting easy access to limbs via zippered side openings in the bags (Figure 10.3). Rabbits can injure their spines or limbs if they struggle in a restraint device. Accustoming them to the device is recommended. Covering the animal’s eyes with a soft drape can help to calm an animal in a restraint device. Absorbent padding may increase comfort if animals are expected to remain in the restraint device for more than a few minutes, and also serve to provide the security of traction for the animals on the slick flooring of

the boxes. Animals should never be left unattended in a restraint device; if the animal panics and struggles, a handler must be nearby to release the restraint and calm the animal.

A simple and effective method of restraint can be achieved with the use of a terry-towel cloth or cloth drape. The animal is snugly wrapped, much in the manner of swaddling a baby, with the final wrap held in place under the rabbit by the rabbit’s own weight (Figure 10.4). In livestock, restraint devices have a calming effect if they provide sufficient even pressure so that the animal feels securely held without pinching or pressure points (Grandin et al., 1989), which may explain why many rabbits are calmed when snugly wrapped (Grandin, 1992). For skittish animals, the handler may sit on a drape on the floor with his legs extended, with the rabbit placed on its abdomen facing the handler with the rabbit’s head at the level of the handler’s knees. A towel or drape is placed over the rabbit’s back, and

FIGURE 10.2 Restraint devices. Rigid metal (A) and plastic (B) restrainers are designed to permit access to the ears. The rear support should be pressed gently against the animal’s rump. In models with a neck restraint, the neck yoke is fastened last, leaving several cm of space between the yoke and the neck. Floor padding is recommended.

FIGURE 10.3 Cloth cat-bag restraint.

FIGURE 10.4 Restraint in a cloth wrap.

held securely tucked on either side under the handler's lower legs; if the animal struggles, it cannot fall. This restraint position gives ready access to the rabbit's ears. Similarly, the handler may kneel on a towel spread on the floor and place the rabbit between his knees; positioning the rabbit facing the handler allows access to the rear end for placing a rectal thermometer or for administering an intramuscular injection in the lumbar muscles.

Stereotaxic Methods

Rigid fixation for stereotaxic work is accomplished in the anesthetized rabbit. Several atlases of the rabbit brain are published (Fikova and Marsala, 1967; Lavond and Steinmetz, 2003; Monnier, 1961; Shek et al., 1986; Girgis and Wang, 1981; Urban and Phillippe, 1972) that use bregma and lambda coordinates to establish the horizontal and vertical planes. Unlike rodents, where ear-bars are used to secure the head in the sagittal axis, the rabbit ear canals (external auditory meati) are at an oblique angle, requiring specialized adaptation of the stereotaxic frame. Commercial devices are available that adapt stereotaxic frames to fit rabbit skulls, using a tooth bar, nose clamp, and u-shaped clamp that secures the head by clamping at the zygomatic bones (Girgis, 1980; Lavond and Steinmetz, 2003), with additional modifications to permit use of gas anesthesia (Cegavske and Biela, 1980). A stereotaxic frame has been developed that uses the contact plane of the rabbit's mandible as a spatial reference (Kockro et al., 2008). This frame is accurate for operations which require approximate stereotactic guidance, such as the puncture of CSF spaces, but its use in other applications like tumor seeding, biopsy sampling, or lesion generation is dependent on individual accuracy requirements.

SAMPLING TECHNIQUES

Blood Sampling

Blood volume is generally estimated based on body weight. To avoid causing distress and abnormal physiology, a general rule is not to exceed removal of 1% of body weight (10% of blood volume) in any given 2-week interval (Diehl et al., 2001; Joint Working Group on Refinement, 1993; McGuill and Rowan, 1989). This would be the equivalent of 30 ml from a 3-kg rabbit. If larger blood volumes are needed, fluid and cell replacement is necessary. Exsanguination should only be performed as a terminal procedure on an animal that is in a surgical plane of anesthesia; approximately half the animal's blood volume, or about 90–120 ml, can be obtained from a 3-kg rabbit.

Blood samples may be readily obtained from the arteries, veins, and from cardiac puncture. The rabbit ear

provides easy access to a lateral vein or central artery. The ear artery is preferred to the vein for removal of blood volumes of several ml or more. Cardiac puncture is most often a terminal procedure, and allows rapid collection of large volumes of blood. There are a number of methods to accomplish restraint for blood sampling in conscious animals, as described above.

Refinements for blood sampling technique include numbing the ears with local anesthesia, such as a lidocaine and prilocaine cream, applied to the site of vessel puncture about 15 minutes prior to sampling (Figure 10.5) (Flecknell et al., 1990). Gently warming the animal or the ears can produce vasodilation. Use of a tranquilizer that promotes relaxation and vasodilation is also recommended. Approximately 15 minutes prior to sampling, a dose can be given of a phenothiazine tranquilizer such as acepromazine maleate at 0.8 mg/kg subcutaneously, or an opioid combination, fentanyl/fluanisone (Hypnorm) at 0.2 ml/kg intramuscularly. Other traditional methods of inducing vasodilation include topical application to the ear of agents such as xylene (highly irritating, not recommended), d-limonene, 2% nitroglycerin ointment, or oil of wintergreen (irritant). All of these fast-acting agents must be thoroughly washed from the ear after the blood sample has been obtained, using 70% ethanol.

Aural Vessels

For sampling from the ear vessels, a size 25–23-gauge butterfly needle, or a catheter with tubing and syringe adaptor can be used. Butterfly needles have the advantage of flexible tubing, which permits movement of the animal with decreased likelihood of dislodging the needle once it is seated in a blood vessel. Alternatively, a 22-gauge double-headed needle can be used with vacuum collection tubes for sampling from the ear

FIGURE 10.5 Application of topical anesthetic cream to numb the ear for vessel puncture. Note that the cream slicks the hair so that the vessel can readily be seen.

artery (Barrera and Young, 1997). Sampling from the ear vessels does not require that hair be plucked or shaved though this is often done, but the site should be gently cleaned with warm antiseptic solution and dried. Topical anesthetic cream or a lubricant jelly can be used to slick the hair to allow visualization of the vessels. Both the artery and vein are superficial, and are accessed from the dorsal surface of the ear. The needle is placed at a very flat angle, almost parallel to the ear surface, and advanced about half its length (or about 0.5cm), in a direction toward the head (Figure 10.6). For the vein, holding off the vessel at the base of the ear helps to raise the vessel for puncture. Blood flow into the needle hub or tubing is observed with gentle aspiration. When the needle is correctly seated in the artery, blood will be seen pulsing into the syringe or tubing (Figure 10.7). Catheters or butterfly needles may be capped and flushed, and then secured in place with tape, suture, or glue, for repeat sampling. Upon removal of the needle or catheter, hemostasis is achieved by applying gentle pressure with a gauze sponge; pressure may need to be applied for a minute or longer after arteriopuncture to prevent a hematoma.

Jugular Vein

For collecting blood from the jugular vein, the rabbit may be wrapped snugly in a towel, or held securely with one hand on the scruff and one hand on the abdomen. The rabbit is placed in dorsal recumbency by an assistant, who holds the rabbit's neck extended and applies gentle pressure at the base of the neck to distend the vessel. The fur may need to be clipped to facilitate visualization. The blood is then collected via a needle directed in a caudal direction. (Crow and Walshaw, 1997; Nelson et al., 2010). Tranquilization of the animal is recommended for this collection method if the animal is wrapped in a towel for restraint.

Cardiac Puncture

The rabbit must be in a plane of surgical anesthesia prior to cardiac puncture or carotid artery cannulation. Cardiac puncture may result in lethal damage to the heart, lungs, and surrounding tissues, or lead to cardiac tamponade, and so is most commonly used as a terminal procedure; once the blood is withdrawn, the animal is euthanized before it regains consciousness from the anesthesia. The anesthetized rabbit is placed in dorsal recumbency. The location of the heart can be ascertained by palpating the heartbeats at the point of maximum intensity. The heart is pierced with a large 16–18-gauge, 1.5-inch needle, attached to flexible tubing. The approach may be from the side, entering between the ribs at the level of the elbow, or entering from beneath the sternum. The heart is pierced with a single firm thrust, and correct placement into the heart is confirmed by the appearance of blood pulsing into the tubing. If blood does not flow well, the needle may be turned but the tip should not be moved other than in the same line of insertion; repeated probing within the chest may result in death of the animal. If there is no initial blood flow, a fresh start with a clean needle may be attempted. Blood can be drawn into large syringes for collection. A method of euthanasia should be at hand for use once the blood has been collected.

Carotid Artery

Carotid artery cannulation is done under direct visualization. If the animal is to be recovered from the procedure, sterile technique is used. Carotid cannulation may allow for more complete removal of the maximum blood volume for exsanguination than cardiac stick. In the anesthetized rabbit, a cut-down incision is made midline on the ventral neck, to expose the carotid artery running parallel to the trachea. A small segment of the artery is carefully dissected from

FIGURE 10.6 Sampling from the ear vein with a 25-gauge butterfly needle.

FIGURE 10.7 Sampling from the ear artery with a 23-gauge butterfly needle.

the surrounding connective tissue. A single ligation of the carotid is made cranially, and a temporary clamp is placed caudally on the vessel. A loose ligature is placed around the vessel ready to secure the catheter once it is placed. A small snip is made in the vessel, and a catheter is inserted toward the heart. The catheter is secured in place with the ligature, and the clamp is removed. For exsanguination, if the contralateral neck vessels are exposed and the jugular is cannulated, high flow rate of saline into the jugular vein during the blood collection may help maintain blood pressure and allow increased volume of blood collection.

Indwelling Catheters

For chronic blood sampling over days or weeks, indwelling catheters may be surgically placed into the carotid, jugular, or heart (Cleva et al., 1995; Dennis et al., 1989; Karnabatidis et al., 2006; Nishijima, 2009). Tubing from the catheters can be tunneled under the skin to exit at a site such as the nape of the neck, or tubing is connected to vascular access ports that are completely concealed beneath the skin (Kunta et al., 2001; Swindle et al., 2005). Anticoagulant solutions must be maintained in the tubing to prevent clotting. A technique has been described for using polyethylene tubing to create arterio- or venous catheters that remain patent in the ear vessels for over 3 weeks, and can be used for sampling or infusion (Hungate et al., 1996).

Cerebrospinal Fluid Collection

Performance of cerebrospinal fluid (CSF) collection requires skill and steady hands. During penetration,

damage to the dura mater and atlanto-occipital membrane may cause the sample to become contaminated with blood. For repeated sampling or sampling in the conscious animal, placement of a catheter is needed; a number of approaches to surgical catheter placement have been described (Arkan et al., 1996; Tissot et al., 1995; Vistelle et al., 1994).

For a single tap, the atlanto-occipital (cisterna magna) approach allows harvest of volumes of CSF of 0.5cc, or up to 1.0–2.0cc in larger animals (Wildlife Information Network, 2009). This approach can also be used for measuring intracranial pressure, or for myelography. Equipment needed includes a 22-gauge 1.5-inch spinal needle with stylet (or a hypodermic needle from 25 gauge 5/8 inch to 23 gauge 1.25 inch) and sterile plastic collection vial. Plastic is preferred to glass to minimize adhesion of leukocytes. Aseptic technique is essential during collection, including shaving and antiseptic scrub of the puncture site. A surgical plane of anesthesia is necessary for the rabbit. Ideally, an endotracheal tube is placed to aid in maintaining an open airway as the neck is flexed for the procedure, which may cause airway obstruction.

The animal is placed in lateral recumbency along the edge of a table, with the head flexed toward the chest no more than 90°. Flexion can be accomplished by grasping the ears with the thumb placed on the occipital protuberance (Figure 10.8). Landmarks for needle insertion are the occipital protuberance and the wings of the atlas. The spinal needle with stylet in place is placed midway between these two points, at a 90° angle to the vertebral column, parallel to the table surface. The needle is advanced just a few millimeters

FIGURE 10.8 Cerebrospinal (CSF) fluid collection technique.

at a time in a cranial direction toward the rabbit's nose. Penetration of the dura and subarachnoid membranes may be felt as a "pop", and appearance of CSF in the needle hub when the stylet is removed confirms placement in the 4th ventricle. If the needle hits bone, it may be redirected cranially or caudally, or removed and replaced after reassessing the site location.

A manometer may be attached to the needle to assess intracranial pressure. Care should be taken not to move the needle during this manipulation. To collect CSF, fluid may be allowed to drip into a collection tube. Application of negative pressure with a syringe can cause damage; a 1-ml syringe may be used to collect CSF at no more than 1 ml per 30 seconds.

A lumbar approach may also be used to collect a small volume of CSF, and this is the preferred site to administer contrast agents for myelography. The anesthetized animal is shaved and scrubbed with an antiseptic over the lumbar spine, and placed in either lateral or ventral recumbency. If the rabbit is in lateral recumbency, the spine is flexed and padding is placed under the animal to support the spine so that it is straight and parallel to the table. The needle is directed cranially and inserted between a 45–90° angle to the spine at the cranial edge of the dorsal spinous process of vertebra L6. It is important not to apply negative pressure with a syringe to harvest CSF at this site.

Urine Collection

Metabolic cages designed to collect urine separately from feces are commercially available. If urine samples free from cage contamination are needed, then urine can be collected by manual expression of the bladder, cystocentesis, or urethral catheterization.

Manual urine expression may be best accomplished in an anesthetized rabbit. The full bladder can be palpated and pressure applied in a firm, steady manner. Excessive pressure can cause bladder rupture. Cystocentesis is performed on an anesthetized rabbit, placed in dorsal recumbency. The full bladder is palpated and pressed between the fingers and thumb, up against the abdominal wall. A 20-gauge needle is inserted directly through the skin into the bladder. A 30–60-ml syringe is used to aspirate the urine.

Catheterization of the urethra can be accomplished most readily in male rabbits. A subcutaneous dose of acepromazine at 0.8mg/kg will tranquilize the animal and encourage protrusion of the penis. The buck is supported in a sitting position, tilted slightly back; a seated handler can restrain the animal held in the handler's lap with one hand holding the scruff and the other restraining the rear legs. A sterile, flexible, lubricated catheter, size 9 French is passed into the urethra in a downward direction for about 2cm. The catheter

and penis are manually depressed, and the catheter tip is then gently advanced into the bladder. To catheterize a doe, the sedated rabbit is placed in ventral recumbency. The catheter is first directed vertically in the caudal part of the vagina. The catheter is then brought to a horizontal position to enter the urethral opening in the ventral vagina. A cupped hand can be used to apply abdominal pressure to express urine through the catheter.

Urine collection in neonatal (12-hour- to 10-day-old) rabbits can be accomplished by stroking the abdomen. The kit is held gently but firmly on its back in one hand, while the other hand strokes from the stomach area to just beyond the bladder, with most pressure in the bladder area. After 10 days of age, muscular control of the bladder and increased size of the kit makes it more difficult to use this method, and a longer period of stroking is needed. Up to 5ml of urine can be collected in this manner (Kurien et al., 2004).

Milk Collection

Transgenic rabbits have been produced to secrete into their milk specific proteins which are harvested for medical and research use. A doe can produce 250ml of milk per day of lactation, but only 100–150ml is collected each day, for a yield of 10–15 liters of milk per year. Milking machines for transgenic rabbits have been developed, but the designs remain proprietary (Bioprotein Technologies, 2009). Does typically nurse their young for about 5 weeks. Milk is collected from the females from days 5 through 25 post-partum, to correspond with the peak milk production time.

Rabbit does typically nurse their litters once per day, most commonly in the early morning. Milk collection is done prior to allowing the kits to nurse (Maertens et al., 2006). A milking machine can be devised from a small suction pump (such as a Gomco portable pump). A T-connector is attached to the port of the suction machine. Commercially available DeLee suction catheters with mucus traps are used to collect the milk. The DeLee catheter tip is cut at a 30° angle and inserted into the narrow half of a cleft-palate nipple. This nipple serves as the funnel for milk collection and is cut to fit the size of the rabbit's nipples (Figure 10.9).

A sedated doe can be treated with an intramuscular dose of oxytocin (6IU/kg) to stimulate milk letdown. The doe is restrained in lateral recumbency, and the nipples gently cleansed. Each nipple is inserted into the rubber nipple on the DeLee catheter and rhythmically squeezed gently at the base to express milk in a steady stream, which is collected in the mucus trap by 12.5cm of continuous vacuum. An average of 43.5ml (range 23–114ml) of milk can be collected from each rabbit with this technique (Marcus et al., 1990).

FIGURE 10.9 Milking machine. (A) T-connector, (B) suction trap, (C) tubing to suction pump, (D) DeLee catheters, (E) mucus trap where milk is collected, (F) nipple.

Bone Marrow Collection

Marrow samples are obtained only from anesthetized rabbits. To collect an aspirate for cytology, the proximal humerus or proximal femur can be accessed using a spinal needle with stylet or 18-gauge Rosenthal pediatric biopsy needle (Wildlife Information Network, 2009). The site is shaved and prepped for a sterile procedure. The subcutaneous tissue and periosteum to be penetrated are infiltrated with 2% lidocaine or 0.25% bupivacaine. In the humerus, the needle is inserted at an angle to follow a line between the elbow and the greater trochanter of the humerus. For the femur, the needle penetrates via the trochanteric fossa between the first and third trochanter, at a 45° angle to the femur's long axis. The needle is pushed through the skin, and then into the marrow cavity using a drilling motion. As the needle enters the marrow cavity there is typically a loss of resistance. The stylet is removed and a sterile syringe attached. Negative pressure is applied until about 0.5ml of marrow has been aspirated. The negative pressure is released, and the syringe detached from the needle before the needle is pulled from the bone. Post-procedure analgesia may be necessary, as bone marrow collection can be a painful procedure. If a biopsy is needed for histopathology, a 1.5-inch 18-gauge needle without stylet is used to collect the sample, and no syringe is needed. If samples are needed for both cytology and histopathology, the aspirate is collected first.

COMPOUND ADMINISTRATION

There is great variation in the literature on recommended maximum volumes of substances for administration to rabbits (Diehl et al., 2001; Hawk et al., 2005;

Morton et al., 2001). Paramount consideration goes to avoiding volumes that would cause pain or distress, as well as changes in physiology or pathology that would compromise the goal of the research. Maximum volumes of administration are listed in the sections describing each route, but the reader is cautioned that while these maximal volumes may be tolerated, *the smallest volume that can be given is considered best practice for animal welfare.*

Considerations for substance administration include: warming the substance so as not to chill the animal, particularly when large volumes are to be administered; avoiding substances with extreme pH (<4.5, >8.0) which cause tissue damage; use of isotonic solutions such as 0.9% saline, or giving hypertonic solutions intravenously in a large vessel to promote rapid dilution and decrease chance for irritating the vessel wall; using the smallest needle that will allow ease of administration for the volume to be given, viscosity of the substance, shear-damage to cells passing through the needle, and toughness of the tissue to be penetrated; and using sterile solutions, needles, and syringes and following aseptic technique, including gentle yet thorough disinfection of the tissue at the site of skin penetration.

Oral Route

Feed

Mixing compounds into rabbits' food or water is the simplest method of oral substance administration, when exact quantity and timing of ingestion are not of concern. Several commercial producers of laboratory animal diets will create custom compound diet formulations for rabbits. Rabbits will refuse food or water that has disagreeable odor or flavor. To administer small quantities of liquid, the rabbit is restrained wrapped in a towel, and a syringe is introduced into the corner of the mouth. The liquid is slowly dispensed as the rabbit is observed to ingest it (Figure 10.10). Mixing a substance with honey or sweetened yogurt may increase its palatability.

Gavage

To directly administer precise quantities of liquid, a flexible tube (oral gavage tube) is passed directly to the stomach. Rabbits should not be anesthetized for this procedure, because of the risk of inadvertently passing the tube into the respiratory tract. A size 8–10 red French rubber urinary catheter or infant feeding tube works well. The tube length is measured from the tip of the rabbit's nose along its side to the level of the last rib; when passed this distance, the tube should have entered the stomach. A mark is put on the tube so the correct distance can be readily gauged. A mouth speculum is needed to prevent the animal from chewing on the tube. A speculum can be readily fashioned from a

FIGURE 10.10 Oral administration using a syringe.

plastic syringe barrel; holes big enough for the tube to pass through are cut on opposite sides of the center of the barrel, and the cut edges are smoothed with a file or flame. The rabbit may be restrained in a towel or cat bag, and held in an upright or tipped-back position. A special restrainer has been developed to facilitate oral dosing without an assistant (Abell et al., 1995).

The mouth gag is placed behind the incisor teeth at the diastema, above the tongue. A small amount of lubricant may be placed at the end of the tube. The tube is passed through the mouth gag, and should easily pass the entire pre-marked distance into the esophagus, meeting no resistance. Correct tube placement into the stomach must be assured before any liquids are instilled; liquid placed into the respiratory tract will most often prove fatal to the rabbit. To assure correct placement, the chest may be auscultated for normal breathing, or one can place the open end of the stomach tube into a small beaker of water and observe for bubbles that would be seen if the tube is mistakenly placed in the respiratory tract (Ogden, 2007). A syringe is used to administer the liquid, followed by several ml of water or carrier vehicle to clear the tube. The syringe is kept in place on the tube, or the end of the tube is clamped to stop fluid from exiting the tube as it is withdrawn, to prevent possible fluid inhalation.

Substances in an aqueous base are better tolerated by gavage in large volume than substances in an oil base. Maximum volume recommendations for oral gavage vary from 10–15 ml total, to 10–15 ml/kg (Diehl et al., 2001; Hawk et al., 2005; Morton et al., 2001). A smaller volume generally means a safer and less potentially distressful procedure.

Pharyngotomy Tube

For frequent or chronic dosing, a tube can be surgically placed via a pharyngotomy (Figure 10.11). In an anesthetized rabbit, a 1-cm skin incision is made on

the left side anterior to the larynx. A stomach tube is passed through the mouth into the stomach. Forceps are introduced through the mouth and the tube is grasped and pushed against the pharynx so that externally it can be seen bulging at the site of the skin incision. A cut is made to allow the oral end of the tube to pass through the pharynx. The tube is anchored at this site, and then passed subcutaneously and exteriorized at the base of the ear, where it is again anchored. Pharyngotomy tubes have remained in place and patent for 6–12 months (Harcourt-Brown, 2004; Rogers et al., 1988).

Nasogastric Tube

Nasogastric tubes can also be placed (Brown, 2010; Harcourt-Brown, 2004) but may be stressful to rabbits, and run the risks of nasal cavity irritation and bleeding. The nasal mucosa is first numbed with a few drops of topical anesthetic such as proparacaine or 2% viscous lidocaine, and the rabbit's head is tipped up to allow the drops to coat the nasal passages. If the rabbit struggles during tube placement, use of a sedative may be necessary as well. A size 5–8 French flexible feeding tube is premeasured for the distance from the nose to the last rib, and the length is marked. To pass the tube, the animal's head is held in ventral flexion, taking care not to compress the trachea. The end of the tube is lightly lubricated, and the tube is inserted into a nostril, aimed ventrally and medially. The tube should pass with no or minimal resistance all the way to the premeasured mark. Correct placement should be confirmed as described for a gavage tube. A tape tab is placed on the tube where it exits the nostril, and is glued or sutured in place. The remaining length of tube is secured behind the neck with a light wrap. An Elizabethan collar or padded collar is used to prevent the rabbit from removing the tube. Tubes can remain in place for weeks.

Capsule

Oral dosing with capsules or small pills is difficult in rabbits, but may be accomplished with a small animal balling gun or pill gun. The rabbit is restrained as for oral liquid dosing, and the pill or capsule is placed as far back on the tongue as possible. A pill gun can be fashioned from a plastic 3-cc syringe. A razor is used to cut off the end of the syringe barrel at the 0-ml mark, and the surface is then smoothed with a file or flame. A size 00 gel capsule may be used to hold medication. Once placed into the gun, the pill or capsule may be lubricated with a small amount of mineral oil immediately prior to being placed into the oral cavity. Alternatively the substance may be crushed and mixed with a palatable substance such as honey or flavored yogurt and administered via a syringe placed into the mouth.

FIGURE 10.11 Pharyngotomy.

Subcutaneous Route

Subcutaneous injections can be accomplished without removing the rabbit from its housing. The animal may be gently pushed up against a cage or pen wall, and the scruff grasped and raised. The needle is held parallel to and pointed away from the hand holding the scruff, and inserted into the loose skin; one should not point the syringe at the hand holding the scruff, to decrease the chance for self-injury if the rabbit should move suddenly. If irritating substances are being injected, such as adjuvants for antibody production, the scruff is not the ideal site, as this area must be grasped for restraint. Alternative restraint methods include wrapping the animal in cloth, or placing it into a cat bag or an open-top plastic carrier or restraint box. The skin at the scruff may be thick, and a 23–25-gauge needle may be needed to penetrate the skin. Maximum volume recommendations are up to 5 ml/kg. If large volumes are being given, such as fluid for rehydration, the fluids should first be warmed.

Intravenous Route

The marginal ear vein is the most readily accessible site for intravenous injection in the conscious animal. In larger rabbits (3 kg or more), cephalic and saphenous veins may be used, but are more easily accessed in an anesthetized or sedated animal. The puncture site should be gently cleaned with warm disinfectant

solution. A refinement for venipuncture technique is to numb the site with a local anesthetic, such as a lidocaine and prilocaine cream, applied to the site of vessel puncture about 15 minutes prior to sampling. Hair may need to be clipped from the cephalic or saphenous sites, but the lateral ear vein can be visualized without clipping or plucking the hair, simply by slicking down the hair with petrolatum or anesthetic cream. A butterfly needle is easiest to use, as the flexible tubing is forgiving of animal movement once the needle is seated in the vessel (Figure 10.6). A 23–25-gauge needle or over-the-needle catheter can also be used. Needles and catheters can be secured in place with tape or glue or a single suture for repeat administration. A drop of surgical glue works well to temporarily secure a wing of a butterfly needle to the hair on the ear (Harcourt-Brown, 2004). The rabbit is restrained in a cloth wrap or cat bag or rigid restrainer. The vessel is held off near the base of the ear to promote distention, and the needle is advanced in the direction of the head for at least 1 cm. A flash of blood into the needle hub or tubing when gentle aspiration is applied confirms placement in the vessel.

For long-term venous access, a catheter can be surgically implanted, as previously described for sampling techniques. For constant intravenous infusion, rabbits can be maintained on a swivel-tether system, which permits the animal to remain unrestrained and mobile within its cage unit (Yu et al., 1995). Swivel-tether systems for rabbits are commercially available from several

sources, as are jackets or harnesses to secure the system to the animal. These systems may be used with catheters in the ear vessels, or with implanted catheters.

Recommended maximum volumes run to 5ml/kg given as a bolus over several minutes, or 10–20ml/kg for slow infusion over 10 minutes or longer. Lower volumes are given of substances with pH or tonicity that could cause damage. Fluids should be warmed.

Intramuscular Route

Sites for intramuscular injection include the large dorsal muscles of the anterior thigh (quadriceps) and the dorsal lumbar muscles. For quadriceps injection, with the rabbit resting on a table, the handler's forearm holds the rabbit snugly against the handler's body with the rabbit's head toward the elbow, and the hand holding the rear leg to be injected. The large quadriceps muscle group can be easily palpated dorsal to the femur. A short (5/8-inch), 25-gauge or smaller needle is placed parallel to the table surface, perpendicular to the side of the rabbit's thigh.

The lumbar muscles are accessed lateral to the spine, between the readily palpated landmarks of the last rib and the point of the hip (wing of the ileum). The handler's forearm holds the rabbit snugly against the handler's body with the rabbit's head toward the elbow and the hand cupped around the rabbit's rump. The needle is placed parallel to the spinal column, at about a 45° angle to the animal's back.

Volume of injection should be minimized to avoid the pain of muscle fiber separation. If a dose is split into more than one site, consider that multiple injections in a single limb may cause lameness. Recommendations for maximum volume are up to 1.0ml per site, or 0.05ml/kg (Diehl et al., 2001; Hawk et al., 2005; Morton et al., 2001).

Intraperitoneal Route

Intraperitoneal injection carries the risk of causing internal injury or of misplaced injection into a blood vessel or an organ, particularly the large thin-walled cecum or urinary bladder. The injection should be made in the lower (caudal) left quadrant of the abdomen, to avoid the more cranially located organs such as the liver, and the cecum, which tends to be on the right. The rabbit can be restrained, head downward, with its back toward the handler and with its body clasped between the handler's knees while the rear legs are held upward to expose the ventral abdomen. Alternatively, the animal may be held in a sitting position with one hand on the scruff and one hand holding the rear legs. A short (5/8- to 3/4-inch) needle is placed at a 45° angle to the body wall. Gentle aspiration on the syringe prior to

injection may help to confirm that the needle is not in a blood vessel or organ; caution must be used not to change the angle or location of the needle during the aspiration and subsequent injection.

A 23–25-gauge needle is generally used. Maximum volume limits range from 10–20ml/kg (Diehl et al., 2001; Hawk et al., 2005; Morton et al., 2001).

Intradermal Route

The injection site selected is most often along the flanks or loin area where a rabbit cannot readily scratch with its rear feet. The area is clipped, treated with a depilatory cream to remove remaining hair, and finally cleansed gently with an antiseptic scrub solution. The skin is stretched taut, and a tuberculin syringe with a 25–30-gauge needle is inserted, bevel up, into the dermis at a very shallow angle, almost parallel to the skin surface, just until the bevel disappears. Injection of a maximum volume of 0.1ml should produce a bleb. If seepage occurs when the needle is removed, then the needle may be inserted somewhat further on subsequent injections, and held in place for several seconds after injecting the substance.

Endotracheal Route

Endotracheal or transtracheal instillation of substances is used to create experimental models and to treat pathology of the lungs and respiratory tract. Endotracheal intubation techniques are discussed in greater detail in Chapter 2. The animals must be anesthetized or heavily sedated prior to intubation. Rabbits are prone to laryngospasm, and an application of topical anesthetic to the laryngeal membranes is necessary prior to intubation. Rabbits have a small oral cavity, and visualization of the laryngeal openings for placement of an endotracheal tube is possible but challenging.

A number of "blind" intubation techniques may be used, in which the person placing the endotracheal tube listens for breath sounds or observes moist air pulsing in the tube to determine when to advance the tube through the laryngeal opening; stethoscopes with adaptors can be attached to end of the tube (Figure 10.12) (Conlon et al., 1990). Correct placement of the endotracheal tube can be confirmed by auscultation. Substances can readily be introduced to the lungs via the endotracheal tube, by passing a small catheter through the tube lumen, and can be targeted to specific lung lobes (Frevert et al., 2000). Another option is to place a naso-tracheal tube. This technique is performed in an anesthetized rabbit, using an uncuffed, lubricated, endotracheal tube measuring 14.5cm in length and 2.0–2.5mm in inner diameter. (Stephens De Valk, 2009).

FIGURE 10.12 Endotracheal tube placement in an anesthetized rabbit, assisted by an attached stethoscope. The tube is advanced to the larynx, and breath sounds are readily heard through the stethoscope. The tube is advanced into the trachea when the laryngeal openings are widened, as detected by the sound of inhalation. Though not visible in this figure, note that the stethoscope tubing has a 3/4-cm hole cut just past the attachment to the endotracheal tube, to permit air to enter and exit the tube as the rabbit breathes.

Tracheostomy may also be accomplished in an anesthetized rabbit (Irazuzta et al., 1997). Pediatric transtracheal airway catheters are commercially available that are inserted much like over-the-needle catheters used in blood vessel cannulation. Simplest to perform is a transtracheal injection. The anesthetized rabbit is placed in dorsal recumbency. The head is extended and the cricoid prominence is palpated in the midline of the neck. The ventral neck is clipped and scrubbed with disinfectant. A hypodermic needle is placed through the skin 1–2 mm caudal to the cricoid prominence, and through the cricoid membrane, then directed caudally into the trachea. Aspiration of air confirms correct placement (Venkatesh et al., 1988). This technique may be more challenging in females with large dewlaps.

Intra-Articular Route

The anatomy of the joint selected should be reviewed prior to the procedure. The animal is anesthetized. The joint is palpated to determine the site of entry. The site is shaved and scrubbed for this aseptic procedure. A local anesthetic such as 1% lidocaine or 0.25% bupivacaine is infiltrated subcutaneously over the site of penetration. The joint is held steady. Stifle joints are held in a flexed position and entered from either side of the patellar tendon. A 22–25-gauge 3/4- to 5/8-inch needle with attached syringe is inserted carefully into the joint space. Aspiration of synovial fluid can confirm proper placement. Injection volumes of up to 0.5 ml can be made, depending on the size of the joint. If aspiration is done, negative pressure on the syringe is released

before pulling the needle from the joint. Complications include hemorrhage into the joint, trauma to the cartilage, and infection (Crow and Walshaw, 1987; Washington State University, 2009).

Administration to Neonates

Newborns present challenges in substance administration due to their size and fragility. Intravenous administration can be accomplished in the jugular vein, using a 30-gauge 5/8-inch needle. Maximum suggested volume to administer is 0.001 ml/g of body weight. Intraperitoneal injections are given in the lower left quadrant of the abdomen about 3 mm off the midline, using a 27-gauge 5/8-inch needle. Maximum suggested volume of injection is 0.01 ml/g of body weight. Subcutaneous injections may be made in the dorsal neck area with a 27-gauge needle, with a maximum volume of 0.01 ml/g of body weight. Oral gavage is accomplished with an 18-gauge feeding needle, using extra care to prevent traumatic injury. Intratracheal administration of up to 0.3 ml may be tolerated (Venkatesh et al., 1988). Maintaining warmth and hydration are essential when newborns are removed from the nest. Neonates should be handled with gloves and returned to the nest as soon as possible.

SPECIALIZED RESEARCH TECHNIQUES

Telemetry

Telemetry for remote data collection from freely moving animals is a refinement in experimental technique, freeing animals from the stress of repeated restraint and procedures. Small biocompatible transponders surgically implanted in animals can transmit biological data to receivers located outside the cage or pen. Telemetry devices for research animals, and associated computer software, are available from several commercial sources. Rabbits, like any small mammal, can be implanted with telemetry devices to monitor heart rate, blood pressure, body temperature, and electrocardiogram. Implantation of the device subcutaneously in the neck with cannulation of the carotid artery with complete occlusion of the artery is recommended as minimally invasive, with rapid recovery and device longevity of a year or more. (D'Aubioul et al., 2008). Telemetry has also been used to remotely follow intraocular pressure in the rabbit (Vogel, 2002).

Artificial Insemination

Semen can be collected about four times per week from a buck without reducing sperm count or libido. Most bucks can be readily trained to ejaculate into an

artificial vagina. A simple device can be made from 3" T-connector polyvinyl chloride (PVC) pipe with $3/4" \times 3/4" \times 1/2"$ openings, two rubber chair leg tips (25mm and 32mm inner diameters respectively), a rubber band, and a silicone condom (Naughton et al., 2003). The $1/2"$ opening of the PVC pipe is covered with the 25-mm chair tip. The condom is placed straight through both $3/4"$ openings in the PVC pipe. The open end of the condom is folded around one opening and secured in place with the rubber band, to create the vaginal entrance. The closed end of the condom is pulled through the other $3/4"$ opening, and is folded over outside the open $3/4"$ end and held in place while warm water is introduced into the pipe to fill the space between the condom and inside of the pipe. Once filled, the remaining chair tip is put over the opening including the folded-over closed end of the condom, to contain the water and to keep the condom stretched within the length of the pipe. A non-spermicidal lubricant jelly can be placed into the condom opening.

The artificial vagina is held under a dummy made from female rabbit hide that is placed over the handler's arm; the buck mounts the handler's arm. Alternatively, the artificial vagina can be held beneath a sedated female rabbit. The dummy or the doe is brought to the buck's cage. Bucks will generally mount and ejaculate quickly. Recommendations on the ideal temperature of the water vary from 98–113°F (Morrell, 1995; Naughton et al., 2003). If the water temperature is too hot, the buck may contaminate the sample with urine, but if it is too low, the buck will not ejaculate. Rinsing the condom ahead of time with 2–4ml of the extender that will be used to preserve or dilute the semen will help avoid loss of sperm that may adhere to the liner.

Ejaculate volumes range from 0.2–2ml, varying with breed. A quick subjective assessment of sperm motility can be made on a warm slide viewed under a microscope. Samples with less than 70% of sperm showing forward motility are not likely to be fertile (Morrell, 1995). If the semen is to be used immediately, a diluent such as physiological saline can be used. The semen should be maintained at 37°C if it is to be used right away, and should be used within 30 minutes of collection. Cryoprotectants must be added if the semen is to be frozen. The reader is advised to consult assisted reproduction references for discussion of semen extenders and preservation (Daader and Zeidan, 2008).

Does have an irregular estrous cycle with seasonal variation in receptivity. Females should be housed separately for at least 19 days prior to artificial insemination, to assure that they are not pseudo-pregnant. Swelling and color of the vulva can be used to gauge the likelihood of female receptivity, though this method is not always accurate; a swollen, dark pink or purple color is generally indicative of estrus. Lordosis response, an

elevation of the hindquarters to expose the perineum to facilitate mating, is also an indicator of estrus. A doe can be placed into a restrainer with a non-skid floor surface, and pressure gently and firmly applied to her rump with the palm of a hand, to gauge lordosis response (Contreras et al., 2008). An unreceptive doe will clamp her tail firmly against the perineum and remain seated.

Does are induced ovulators, but the mechanical stimulation from artificial insemination is not sufficient to induce ovulation in most females. To induce ovulation, the doe can be mated with a vasectomized buck, or treated with hormones. If a vasectomized buck is used, the artificial insemination should occur 1–4 hours prior to the mating so that the ejaculate does not mix with the artificially placed semen; occasionally vasectomized males develop anti-sperm antibodies in the seminal plasma, which could interfere with the sperm placed via artificial insemination. Does generally ovulate 9–13 hours after coitus. To induce ovulation with hormones, the doe can be given an injection of human chorionic gonadotropin (hCG) at 20 micrograms intramuscularly, or a gonadotropin releasing hormone (GnRH) analog such as Buserelin at 0.8 microgram, subcutaneously (Morrell, 1995). The GnRH analog can be given at the time of insemination, to induce ovulation some 10–12 hours later. hCG is not recommended for repeated use in a doe as antibodies may develop to the hormone (International Rabbit Reproduction Group, 2005). Some studies suggest that the same dose of GnRH analog may be mixed directly with the sperm given for artificial insemination, eliminating the need to provide it by injection (Quintela et al., 2004).

Insemination is accomplished with approximately 0.25ml of dilute semen, containing at least 5 million motile spermatozoa. The aliquot must be placed in the cranial aspect of the vagina, which requires an insertion angle of about 45° upward to negotiate the rim of the pelvis. A 1-ml glass laboratory pipette may be heated and then bent 45° about 8cm from the end, to fashion an easy-to-use delivery pipette (Morrell, 1995). The pipette is warmed to 37°C in a water bath just prior to use. Pregnancy detection via commercial ELISA progesterone tests designed for use in other species can be used with rabbits at about days 17–18 of gestation (Morrell, 1995).

Ovariohysterectomy

Ovariohysterectomy in the doe is performed like the standard veterinary procedure for a cat, with several key differences. Extra care is taken while making a ventral midline incision from cranial to the pelvis to the umbilicus, as the bladder and the cecum may lie directly beneath the body wall. Each ovary is located and ligated twice at the pedicle, and the pedicle is transected. Does have unusual anatomy in having separate uterine horns, each with its own cervix, that open into

a single vagina. Each horn should be ligated separately just cranial to its cervix. A circumferential and transfixation suture is recommended to ligate each horn. Uterine vessels running beside each horn should also be ligated. The horns are transected and removed. Closure of the incision occurs in three layers: muscle wall, subcutaneous space, and skin. Subcuticular closure of the skin may be used, assisted with superglue, or staples may be used (Mitchell and Tully, 2009; Wildlife Information Network, 2009). Laparoscopic ovariectomy has been described in the rabbit (Al-Badrany, 2009).

Orchiectomy

Orchiectomy in the buck is performed like the standard veterinary procedure, with several key differences. One should not pluck hair from the site as this may cause the skin to tear. The inguinal canal is open in bucks, and the testes can move between the scrotum and abdomen. Any of three surgical approaches can be taken: Scrotal (incision in each side of the scrotum); prescrotal (a single midline incision anterior to the scrotum); or abdominal (ventral midline incision). The procedure may be done with either an open or closed tunica albuginea. If an open castration is done, the tunica must be closed separately to assure closure of the canal. Scrotal incisions may be closed with a subcuticular pattern and/or with surgical glue (Mitchell and Tully, 2009, Wildlife Information Network, 2009).

Bile Collection

Long-term bile collection can be accomplished in the unrestrained rabbit (West et al., 2002). Bile flow is diverted via an implanted, exteriorized polyethylene Tygon tube that returns the bile to the enterohepatic circulation. In a sterile surgical procedure using an abdominal midline approach, the gallbladder is removed, and one end of a 40-cm length of tubing inserted into the cystic duct to collect the bile. The distal end of the same tubing is inserted into the common bile duct, to return the collected bile to the gut. The large loop of tubing exits the body wall, is tunneled under the skin, and exteriorized at the shoulder region. The exteriorized loop of the tubing is then cut and the bile can be directed to a collecting bag, or the ends can be reconnected to return bile to the duodenum. The rabbit is fitted with a small commercially available jacket to protect the tubing and hold the collection bag.

Decerebration

Decerebration is elimination of cerebral brain signal integration by separation of connection with the

hind brain (brain stem) and spinal cord. Depending on where the separation is made, specific reflexes are abolished that require integration in the brain. Decerebrate models have been created in rabbits to study control of movement, righting reflexes and proprioception, as well as physiology and pharmacology in the absence of stimulatory effects. Decerebration can be achieved in the anesthetized animal by physically cutting through the brain at a specific site, or running an electric current between probes inserted at specific sites in the brain (coagulation). Depending on the procedure and the anatomic site of the separation, animals may be able to survive the procedure for long periods, or may need to be euthanized in the course of the procedure. For specifics on the procedures, readers are referred to literature describing surgical methodology (Musienki et al., 2008) and coagulation methodology (Koller, 1969).

INTRODUCTION

Prepared antibodies are critical reagents in a wide variety of research methodologies. The antibodies used may be either polyclonal or monoclonal, with each having distinct advantages and disadvantages. The exquisite specificity of a homogeneous monoclonal antibody limits non-specific reactions but also may limit the usefulness of the antibody for a variety of different research procedures. Polyclonal antibodies are heterogeneous and bind to several different antigen epitopes. While decreasing the specificity and potentially increasing non-specific reactions, the polyclonal antibody is also more likely to successfully bind to the specific antigen in a variety of different test conditions. The production of polyclonal antibodies remains and will likely

continue to remain, a common research procedure involving vertebrate animal use.

Rabbits are the most commonly used laboratory animal for the production of polyclonal antibodies. The rabbit offers many advantages over other species. The adequate body size of the rabbit and the ready accessibility of the marginal ear vein and central auricular artery affords a technically easy procedure for the collection of large blood samples. The availability of specific-pathogen-free animals ensures a healthy animal that will focus its immune response upon the presented antigen. The excellent responsiveness of the rabbit to a wide variety of antigens, the presence of a single primary Immunoglobulin G isotype, the vast amount of information available on the production and purification of rabbit immunoglobulins, and the ready

FIGURE 11.1 Intradermal injection of Freund's complete adjuvant. The viscous water-in-oil emulsion requires the use of larger-gauge needles than is typical for intradermal injections. The needle is passed with the bevel up through the skin into the subcutaneous tissues and then advanced back into the dermis.

availability of secondary reagents further enhance the reputation of the rabbit in polyclonal antibody production.

The response to an immunogen is a complex and dynamic phenomenon involving the interaction of different cell populations, cytokines, and chemokines potentially resulting in the production of antibodies, the activation of a CD4 cell-mediated response, and in many cases a CD8 cytotoxic lymphocyte response. Factors impacting the immune response are extremely varied and include the immunogen itself, the immunogen dose, the route of exposure, the host species, the immune status of the host species, and the use of adjuvants.

THE IMMUNOGEN

An immunogen is any molecule capable of generating an immune response when injected into an animal. Polypeptides, polysaccharides, glycoproteins, glycolipids, and lipoproteins with molecular weights above 10000 are typical immunogens since these are the types of molecules generally presented on the surface of pathogens. Immunogens contain one or typically more molecular sites (antigenic determinants or epitopes) to which antibodies are produced and bind. Antigens, in subtle contrast to immunogens, are molecules that contain a site (epitope) that can be recognized and bound by an immunoglobulin or T-cell receptor. While all immunogens are antigens, smaller compounds such as peptides with molecular weights <10000 may contain an epitope but not be capable of inducing an antibody response when injected alone (haptens). These haptens may become immunogenic when bound to carrier compounds, either in the laboratory or in vivo.

Thymus-Independent Antigens

Some antigens are capable of directly activating B cells and inducing a humoral antibody response without the involvement of helper CD4 T cells. These T-independent antigens are generally large molecules associated with bacterial infections including lipopolysaccharides, polymerized flagellin, and pneumococcal polysaccharides or closely related analogs such as dextrans, polyvinylpyrrolidone, and Ficoll (Clark, 1986). These antigens either bind to the B-cell receptor and other receptors on B cells (TI-1 antigens such as lipopolysaccharides of Gram-negative bacteria) or they cross-link multiple B-cell receptors resulting in activation of the B cell (TI-2 antigens such as pneumococcal polysaccharide or polymerized flagellin). Many of these T-independent antigens are potential non-specific mitogens for B cells and are referred to as polyclonal B-cell activators.

The humoral immune response to T-independent antigens is not dependent upon antigen processing and presentation by helper CD4 T cells and is thus a more rapid response. The T-independent response, however, is limited, as primarily IgM is produced and there is no potential for increasing antibody affinity through this mechanism. It has been suggested that this response evolved and persisted to permit a rapid humoral response to the initial bacterial invasion while the specific immune response, normally requiring helper CD4 T cells, is developing. While potentially beneficial for immune protection, the humoral immune response to T-independent antigens is not a significant factor in the experimental production of polyclonal antibodies.

Thymus-Dependent Antigens

The production of antibodies to thymus-dependent antigens involves the interaction of specific antigen, B-cells, professional antigen-presenting cells, and CD4 T cells in the secondary lymphoid tissues. Antigen is either transported to the lymphoid tissues via dendritic cells or the antigen arrives via either the draining lymphatics or direct contact and is phagocytosed by macrophages. In both cases the antigen is processed by the professional antigen-presenting cells and is presented to antigen-specific CD4 T-cells along with MHC class II molecules. This interaction results in the activation of antigen-specific helper T-cells. As B-cells pass through the secondary lymphoid tissue T-cell areas, those recognizing their specific antigen are bound and then activated through specific interactions with antigen-specific helper T-cells. The result is the formation of a primary focus of rapidly multiplying B lymphoblasts in the T-cell area of the lymphoid tissue. Some of the rapidly

multiplying B lymphoblasts relocate to the medullary cords and mature into antibody-producing plasma cells. Other B lymphoblasts relocate to the primary follicles attached to their respective helper T-cells, forming the germinal center. These B lymphoblasts, now referred to as centroblasts, are large metabolically active cells with a rapid mitotic rate. The centrocyte, a group of B-cells expressing an altered surface immunoglobulin with a range of affinities to the antigen, is the end product of the rapid division and somatic hypermutation of the centroblasts. The centrocyte competes with other centrocytes for antigen access and antigen-specific helper T-cells thus selecting for cells with increasing affinity to the antigen. This maturation of the antibody results in the selection of centrocytes with the highest antigen affinity for continued differentiation into antibody-producing plasma cells and long-lived memory B-cells.

The use of a rabbit to produce antibody to a single immunogen has been the typical approach for polyclonal antibody production. The rabbit is capable of mounting an antibody response to multiple immunogens simultaneously, producing a final product reactive with multiple antigens. In specific cases, immunizing a rabbit with multiple immunogens provides an opportunity to conserve resources and improve efficiency. Care must be taken to ensure that the antibodies produced to the respective immunogens will not interfere with the end-use of each antibody or affinity purification techniques can be used to isolate monospecific antibodies. The expansion of antibody-based proteomics is an example of a field where the immunization of rabbits with multiple immunogens followed by affinity purification to obtain monospecific antibodies is well documented (Larsson et al., 2006).

IMMUNOGEN DOSE

The immunogen dose may affect both the level of the antibody response (quantity) and the affinity of the antibody produced (quality). Very low immunogen doses may be inadequate to stimulate antibody production though the low doses may result in the production of memory B-cells that can be stimulated by a secondary exposure to the immunogen. Excessive immunogen doses may result in the production of low-affinity antibodies or the development of tolerance with no antibody production.

A number of studies have compared the antibody response to varying immunogen doses and detailed the dramatic variations. Siskind et al. (1968) compared the antibody response to doses of dinitrophenylated bovine γ -globulin (DNP- γ G) ranging from 0.05–50mg emulsified in Freund's Complete Adjuvant (FCA) in rabbits and had the optimum antibody response with the

FIGURE 11.2 Typical intradermal injection of Freund's complete adjuvant with distention of the dermis and a pale central region (0.05 ml inoculation volume).

0.5-mg doses. Immunizing doses of 5 and 50mg resulted in an initially greater antibody response at 13 days post-immunization but by 41 days post-immunization the antibody response to the 0.05-mg immunizing dose was three times greater. Goidl et al. (1968) immunizing guinea pigs with either 50 μ g or 1mg of DNP-bovine serum albumin (DNP-BSA) showed both an increased quantitative antibody response at 2 weeks and an increased antibody affinity at 2 months post-immunization in the animals immunized with 50 μ g of DNP-BSA. In developing antibodies to viomycin for enzyme immunoassay development, Hu et al. (Hu et al., 1989a, 1989b; Hu and Kitagawa, 1990) determined that the optimal initial immunization dose was 10 μ g with FCA as the adjuvant, 200 μ g with Freund's Incomplete Adjuvant (FIA), and 10 μ g with aluminum hydroxide (alum).

Determining the optimal immunogen dose is not a simple matter. The specific immunogen (immunogenicity, purity, pH, contaminants, etc.), the adjuvant used, the frequency and number of immunizations, and the route of immunization are all variables that directly affect the optimal immunogen dose. The optimal dose of highly immunogenic proteins with robust adjuvants may be as low as 10 μ g while less immunogenic proteins, small peptides, or polysaccharides along with less robust adjuvants may require greater doses to generate an optimal immune response. Since the primary goal is generally to produce a functional polyclonal antibody for other purposes and not to determine the optimal dose, the immunogen dose is generally estimated based upon the experience of the investigator, references in the literature with similar compounds, and the anticipated immunogenicity of the compound. Generally, 100–250 μ g quantities of proteins in adjuvant are adequate to produce a high-titer antibody response in rabbits (Cooper and Paterson, 2009; Harlow, 1988).

FIGURE 11.3 Freund's complete adjuvant intradermal injection sites (25 μ l/injection site) at 4 weeks post-immunization. Injection sites are enlarged, firm, and raised from the surface with central ulceration of the overlying epidermis. There is no indication of local hyperemia, tenderness, or pain upon palpation of the masses.

ROUTE OF IMMUNIZATION

The route of immunization, in large part, determines the distribution and presentation of the immunogen and has a profound effect on the immune response. The ideal immunization route should result in the exposure of the antigen to a large number of professional antigen-presenting cells (APCs) with secondary exposure of a large proportion of lymphoid tissues via the draining lymphatics and blood circulation. Additionally, the immunization site should be chosen such that the inflammatory reaction to the immunogen/adjuvant results in minimal functional impairment or pain and distress to the host animal. A wide variety of immunization sites have been described in polyclonal antibody production. Intra-articular, intrasplenic, and intralymph node injections have been described but these routes provide little advantage over the more routinely used routes of immunization (Holborow and International Association of Microbiological Societies, Permanent Section of Microbiological Standardization, 1970; Horne and White, 1968; Horne et al., 1970). Rabbits lack true foot pads, and coupled with the large body weight supported by the feet, the use of the foot pad as an immunization site is unacceptable in rabbits (Amyx, 1987). Intraperitoneal immunizations, extensively used in rodents, have been associated with pain and distress in mice when FCA is used (Toth et al., 1989; Leenaars et al., 1998; Wanstrup and Christensen, 1965) and are rarely used in rabbits. The intravenous route of immunization can be used with particulate immunogens and for booster injections of soluble immunogens in saline though anaphylaxis is a potential complication (Herbert, 1973). The intravenous injection of water-in-oil emulsions is associated with significant lesions in multiple organs (Brooks et al., 1978; Edwards and Slauson, 1983; McIntosh et al., 1974) and should not be used for polyclonal antibody production. The primary routes of immunization in the rabbit are

subcutaneous, intradermal, transdermal, and intramuscular. Each route has potential advantages and disadvantages and the choice of immunization route is heavily dependent upon the immunogen, the adjuvant, and the immunization schedule.

Intramuscular and subcutaneous injections are both technically quite easy to perform in the rabbit and permit the injection of greater volumes of immunogen/adjuvant per site than the intradermal route. Subcutaneous injections of immunogen-adjuvant mixtures are generally made on the dorsal back of the rabbit with a maximum volume for water-in-oil emulsions of 0.25 ml per site and 1 ml total volume (Canadian Council on Animal Care, 1991, 2002) though multiple injections of smaller volumes per site (e.g. 0.1 ml) may result in a reduction of potential complications. Subcutaneously injected immunogen/adjuvant mixtures tend to diffuse and may result in fistulous tracts that eventually open and drain distant from the initial injection site (Broderson, 1989). Intramuscular injected immunogen/adjuvant is generally placed in a single site within the quadriceps muscle group or the biceps femoris of the thigh. The maximum recommended volume in the rabbit is 0.5 ml with a 0.25-ml recommended single-site limit (Canadian Council on Animal Care, 1991, 2002). Intramuscular immunizations with robust adjuvants have been associated with granuloma formation that extends through both the muscle and fascial planes with possible nerve involvement (Leenaars et al., 1998; Stills and Bailey, 1991).

The intradermal route of immunization, while technically more challenging, offers some distinct advantages (Figures 11.1 and 11.2). The injected immunogen is localized with minimal diffusion, providing some protection from rapid antigen destruction and potentially enhancing the depot effect. The exposure of the Langerhans cells, professional antigen-presenting dendritic cells in high density within the epidermis, ensures efficient immunogen processing and an extensive distribution of activated immune cell populations in the draining lymph nodes. The intradermal route also has drawbacks including the limited recommended injection volume at any single site, the potential for pain with any injection into a closed space (Canadian Council on Animal Care, 2002), and the tendency for oil adjuvants to produce localized ulcerative lesions (Figure 11.3). Maximum single-site intradermal injection volumes are 50 μ l for saline-based immunogens and 25 μ l for water-in-oil adjuvant mixtures (Canadian Council on Animal Care, 2002; Halliday et al., 2000).

Transdermal immunization using Particle Mediated Epidermal Delivery, the commercial name for the current gene gun technology, delivers gold beads coated with DNA vaccine plasmids encoding for the specific immunogen into the epidermis of the skin (Wang et al.,

2008; Williams et al., 1991). Low-volume jet injection similarly targets the epidermal layer but without the particle component (gold beads) (Cartier et al., 2000; Furth et al., 1995; Ren et al., 2002). Both methodologies rely upon the ability of the vaccine plasmids to penetrate the cytoplasm of the targeted dendritic cells of the epidermis and dermis resulting in the DNA being processed and the resulting proteins being presented to T-cells (Donnelly et al., 1997). Both the gene gun and the low-volume jet injection methods are reported superior to the routine intradermal injection procedure in producing an immune response to DNA immunogens (Ren et al., 2002). In both cases, adjuvants can be added to the immunogen to enhance the immune response (Donnelly et al., 1997).

DNA immunization is an attractive alternative to the traditional protein immunization because plasmid DNA is relatively easy and inexpensive to generate and avoids the need to generate specific peptides or purify proteins for immunization. Transdermal DNA vaccination methodologies are still evolving and significant differences in behavior between species and injection sites on the same species have complicated development (Scheerlinck and Greenwood, 2006). While the DNA vaccination strategies have great promise for both therapeutic vaccinations and polyclonal antibody production, they presently have only limited application in routine polyclonal antibody production.

IMMUNIZATION SCHEDULE

The frequency of re-immunization or boosters is a significant variable in the production of polyclonal antibodies. The goal of the booster immunization is to re-stimulate the immune system and increase the circulating antibody level. To be most effective, the booster immunization should be administered after the initial immunogen level has decreased (i.e. where antibody titers have measurably waned), allowing selection for B-cells producing antibody of a higher affinity for the antigen. Appropriately timed booster injections stimulate the expansion of high-affinity memory B-cells resulting in the production of high levels of high-affinity antibody. Boosters administered too quickly after the initial immunization maintain high immunogen exposure levels, delay the selection of high-affinity B-cells, and fail to induce the desired secondary antibody response.

As with other aspects of polyclonal antibody production, the determination of an optimal interval for booster injections is complicated by the variations introduced by immunogen type, immunogen dose, route of immunization, and the adjuvant used. Without a "depot"-forming adjuvant the antibody titers tend to peak at 2–3 weeks following immunization and rapidly

FIGURE 11.4 Freund's complete adjuvant intradermal injection sites (25µl/site) at 15 weeks post-immunization. The skin has been reflected to show the confinement of the granulomatous inflammation to the dermis (arrows).

decline. With "depot"-forming adjuvants antibody titers frequently peak 3–4 weeks or later following immunization and, dependent upon the adjuvant and immunogen, often remain elevated for many weeks.

ADJUVANTS

Adjuvants are best described as compounds that augment the immunological response to an immunogen. Purified proteins are poor immunogens and seldom result in a robust immune response when injected without an adjuvant. One of the prerequisites for a good immune response to an antigen is an inflammatory response. Inflammation results in recruitment of inflammatory cells and the activation of macrophages and dendritic cells, an essential component in the development of an immune response. The inflammation is not without consequence, resulting in variable degrees of tissue damage and pain, in large part dependent upon the characteristics and extent of the inflammatory response. Of all the components of the production of polyclonal antibodies, the choice of adjuvant is one of the most important and frequently the most contentious.

In choosing an adjuvant the overall goal is a critical component. Prophylactic or therapeutic vaccines are designed to produce a protective immune response with a minimum of side-effects. The desired response is one that will protect the recipient from developing serious disease following exposure to the agent and may require a humoral antibody response, an activated CD4-cell-mediated response, or a CD8 cytotoxic lymphocyte response. Experimental antibody production, however, is primarily directed towards the efficient and economical production of a high-titer and high-affinity antibody to the specific immunogen. While minimizing the side-effects is a consideration it is not nearly as critical

FIGURE 11.5 Freund's complete adjuvant subcutaneous injection sites (100 μ l/site) at 15 weeks post-immunization. Granulomas extend ventrally from each injection site along the dorsal back (arrows).

as with prophylactic vaccines while the production of CD4-cell-mediated responses or CD8 cytotoxic lymphocyte responses, often a critical component in prophylactic vaccine development, is of minimal concern.

The mechanism of adjuvant stimulation of the immune response is becoming better defined as the aspects of antigen recognition and immune response are more fully understood. Adjuvants may have up to five specific mechanisms of action including the "depot" effect, an antigen presentation effect, an antigen distribution effect, an immune modulation effect, and a cytotoxic lymphocyte induction effect (Cox and Coulter, 1997). Of these effects, the depot activity and the immunomodulatory effects are critical for the induction of a robust humoral immune response to a specific immunogen.

An adjuvant with "depot" effect protects the immunogen from both dilution and degradation by the host. "Depot" adjuvants localize and slowly release the immunogen resulting in a prolonged exposure of the immune system to a low level of the immunogen. The significance of the "depot" effect was demonstrated by Herbert in several studies. First, he immunized animals daily for 50 days with either antigen in saline or antigen in a water-in-oil emulsion. While both groups developed a high antibody titer, the titer remained elevated in the animals injected with the emulsion but it rapidly dropped in the animals injected with the antigen in saline (Herbert, 1967). In another experiment he inoculated mice with a single subcutaneous injection of ovalbumin in either saline or a water-in-oil emulsion. The water-in-oil emulsion produced antibody titers nearly 500 times that of the saline-injected ovalbumin and they remained at peak levels for approximately 1 year following the single injection (Herbert, 1968).

Emulsions are the most commonly used type of "depot" adjuvants in experimental immunizations for

the production of polyclonal antibodies. The most common emulsions are either water-in-oil or oil-in-water emulsions although more complex emulsions do exist. A number of emulsifiers have been used with either highly purified non-biodegradable mineral oils or biodegradable oils such as squalene and squalane. Other compounds that may serve as adjuvant "depot" agents include aluminum compounds (alum), microparticles, liposomes, and nitrocellulose.

In addition to protecting and slowly releasing the immunogen, a "depot" adjuvant should also preserve the conformational integrity of the immunogen so as to present the antigenic site to the effector cells. Water-in-oil emulsions maintain the immunogen in the aqueous phase while oil-in-water emulsions tend to localize the immunogen in the oil phase. Oil-in-water emulsions tend to work better with hydrophobic or amphipathic immunogens while water-in-oil emulsions tend to be more effective with hydrophilic or amphipathic immunogens (Hanly et al., 1995). Aluminum salt adjuvants bind immunogens via electrostatic forces and ligand exchange, an interaction that is dependent upon the appropriate pH, the buffer used, the type of aluminum salt, and the ratio of aluminum salt to immunogen. Optimizing this binding for the maximum presentation of the immunogen to effector cells requires reaction conditions specific for each immunogen-aluminum adjuvant mixture (Baylor et al., 2002; Hansen et al., 2007, 2009; Lindblad, 2004).

While protecting and slowly releasing an immunogen, an adjuvant must also ensure that the immunogen is processed and distributed widely throughout the immune system to maximize immune response. Many adjuvants form large multimolecular aggregates with the immunogen encouraging uptake and processing of the immunogen and any associated immunomodulators by macrophages and professional antigen-presenting cells (dendritic cells). Adjuvants may incorporate carbohydrate moieties or molecular configurations specific for macrophage or dendritic cell receptors to increase uptake and processing (Abel et al., 1989; Bonifaz et al., 2004; Chinnah et al., 1992; Jiang et al., 1995; Ribí et al., 1984). Following initial processing of the immunogen, the dendritic cells and macrophages relocate to the regional lymph nodes and spleen where further processing results in the production of antigen-specific B-cells and plasma cells. This processing and transport to the regional lymphoid tissues occurs quite quickly with both emulsion and aluminum salt adjuvants and surgical removal of the initial injection sites within days of the immunization has little effect on the animal's immune response even though antigen is still present in the excised injection site (Freund, 1951; Holt, 1950).

Immunomodulators are used in many adjuvants to stimulate and often alter the immune response of the

host. Immunomodulators have historically consisted of microbial cells (i.e., killed mycobacteria and *diphtheria pertussis*), microbial cell components (i.e., mycobacterial cord factor, cell wall skeleton, muramyl dipeptide, lipopolysaccharide, and N-acetyl-glucosaminyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (a soluble glycopeptide from *Lactobacillus bulgaricus*)), and modified microbial products (i.e., monophosphoryl lipid A and t-muramyl dipeptide). These immunomodulators are recognized by the innate immune system as associated with infection and are referred to as pathogen-associated molecular patterns (PAMPs). Pattern recognition receptors (PRRs) such as the toll-like receptors (TLR), the nucleotide-binding oligomerization domain receptors (Nod-like receptors or NLRs), and Dectin-1 specifically bind to these PAMPs stimulating and directing the adaptive immune system. Immunomodulators may also be included as contaminants in proteins used as carriers for small peptides such as keyhole limpet hemocyanin (KLH), bovine serum albumin (BSA), ovalbumin, etc. (Palm and Medzhitov, 2009) or the immunogen can be conjugated with a PAMP such as flagellin (Cuadros et al., 2004). To be effective, the immunomodulator and the immunogen must be delivered together and preferably to the same phagolysosome (Blander and Medzhitov, 2006).

The recruitment and activation of the dendritic cells and macrophages by adjuvants that is essential for immunogen processing also results in a number of other inflammatory sequelae. Activated macrophages secrete a number of proinflammatory cytokines including interleukin (IL)-1 β , tumor necrosis factor (TNF)- α , IL-6, IL-8, and IL-12. These cytokines recruit additional inflammatory cells, increase vascular permeability, cause local tissue destruction, and result in systemic effects including pyrexia and the production of acute-phase proteins by the hepatocytes. These local and systemic effects are potentially undesirable effects that may result in pain and distress to the host. Balancing the requirement for immune activation for antibody production against the resultant inflammatory reactions and potential pain and distress to the host is a critical consideration in adjuvant selection for experimental polyclonal antibody production.

Water-In-Oil Emulsion Adjuvants

Freund's Adjuvants

Since the original descriptions of its formulation and efficacy (Freund, 1951, 1956; Freund and McDermott, 1942; Freund et al., 1937, 1948), Freund's complete adjuvant (FCA) has remained the most widely used and most effective adjuvant for polyclonal antibody production. The immunostimulatory capabilities of FCA are generally unsurpassed (Altman and

FIGURE 11.6 Transverse sections of the biceps femoris and adjacent muscles 15 weeks following an intramuscular injection of Freund's complete adjuvant. Multifocal areas of hemorrhage and granulomatous inflammation extend the entire length of the biceps femoris.

Dixon, 1989; Munoz, 1964; Smith et al., 1992; Warren et al., 1986) and FCA remains the "gold standard" to which newly formulated adjuvants are compared. The use of FCA has also been associated with a variety of lesions including localized injection site granulomas (Broderston, 1989; Johnston et al., 1991; Kleinman et al., 1993; Leenaars et al., 1994, 1998a, 1998b; Leskowitz and Waksman, 1960; Steiner et al., 1960; Stills, 1994, 2004; Stills and Bailey, 1991; Toth et al., 1989; Warren et al., 1986); granulomas in a variety of organs distant from the injection site (Broderston, 1989; Steiner et al., 1960); necrotizing dermatitis (Leenaars et al., 1998a; Steiner et al., 1960); and spinal cord damage from granuloma formation (Hill et al., 2006; Kleinman et al., 1993). The serious lesions produced by FCA prevent the licensure of this adjuvant in either human or veterinary medicine for prophylactic vaccinations and have resulted in numerous regulatory guidelines (Canadian Council on Animal Care, 1991, 2002; United States Department of Agriculture, 1997) and recommendations (Grumstrup-Scott and Greenhouse, 1988; Jackson and Fox, 1995; Leenaars et al., 1999; Stills, 2000, 2007) regarding its use in experimental polyclonal antibody production in animals.

FCA is composed of a light mineral oil, mannide monooleate (a surfactant), and heat-killed and dried mycobacterial cells. Freund's incomplete adjuvant (FIA) lacks the heat-killed and dried mycobacterial cells but is otherwise identical. The present FCA and FIA adjuvants are far more refined and vastly less toxic than the original formulations. The original Freund's adjuvants used a crude mannide monooleate (Arlacel A[®]) surfactant and an oil that contained a variety of organic hydrocarbons and contaminants, including paraffins, olefins, aromatic hydrocarbons, and cycloparaffins, many of

FIGURE 11.7 Chronic granulomatous inflammation in the biceps femoris 15 weeks following the intramuscular injection of Freund's complete adjuvant. Multifocal areas of macrophage infiltration (*) with necrosis of the adjacent muscle fibers (X). Residual mineral oil appears as clear vacuoles. Hematoxylin and eosin; bar = 100 μ m.

which were cytotoxic and inflammatory. Contaminating short-chain hydrocarbons were both immunosuppressive and responsible for the acute toxicity associated with the adjuvants (Shaw et al., 1964; Stewart-Tull et al., 1976; Wilner et al., 1963). The development of mineral oil-based influenza and poliomyelitis vaccines for human use in the 1940s and 1950s resulted in specific and more stringent requirements for both the oil and the surfactants to minimize adverse reactions (Berlin, 1962; Friedewald, 1944; Henle and Henle, 1945; Salk, 1953; Salk and Laurent, 1952; Salk et al., 1951, 1952). Changes in oil-refining procedures after 1970 and improved purification techniques have removed most of the contaminants from the light mineral oil presently used (Stewart-Tull, 1998). The type and amount of killed and dried mycobacterial cells in FCA has also been changed from 10mg/ml of virulent *Mycobacterium tuberculosis* in the original formulation (Freund and McDermott, 1942; Freund et al., 1937) to 0.1mg/ml to 1mg/ml of relatively avirulent *Mycobacterium tuberculosis* H37Ra or *Mycobacterium butyricum* (Stewart-Tull, 1995).

Both FCA and FIA are very efficient and effective adjuvants, generally producing high-affinity and high-avidity antibody to a wide range of immunogens. The mycobacterial components of FCA tend to produce a strong delayed-type hypersensitivity with a bias towards a Th1 profile (Lindblad, 2000). The delayed-type hypersensitivity reaction generally prevents reimmunization with FCA due to the severe resultant reaction. Both FCA and FIA are water-in-oil emulsions that when properly prepared, slowly release their immunogens over many weeks (Halbert et al., 1946). Glass Luer-lock syringes are used with double-hubbed needles or three-way stopcocks to emulsify the water-in-oil emulsion by repeatedly passing the

mixture through a small orifice. Properly prepared, the thick and viscous water-in-oil emulsion does not diffuse when a drop is placed on the surface of cold water (Garvey et al., 1977; Herbert, 1973). Improperly prepared emulsions and oil-in-water emulsions of Freund's adjuvants are much less effective in producing a robust immune response.

There are numerous reports characterizing the lesions associated with the use of Freund's adjuvants. The typical lesion is focal necrosis with a granulomatous inflammatory response with oil-filled "foamy" macrophages (Broderson, 1989; Leenaars et al., 1994, 1998b; Stills, 1994; Stills and Bailey, 1991; Wiedemann et al., 1991). Intradermal injections are associated with large palpable granulomas that frequently ulcerate (Broderson, 1989; Leenaars et al., 1994; Stills, 1994; Stills and Bailey, 1991) (Figures 11.3 and 11.4). Subcutaneous injections frequently migrate from the injection, forming granulomatous fistulous tracts that may open and drain remotely from the initial injection site (Broderson, 1989) (Figure 11.5). Intramuscular injections result in granuloma formation that extends through the fascial planes of the muscle with possible secondary nerve involvement (Altman and Dixon, 1989; Leenaars et al., 1998a; Stills, 1994; Stills and Bailey, 1991) (Figures 11.6 and 11.7). Beyond the reactions associated with the injection site, granulomatous lesions are often detected in the draining lymph node, spleen, lung, kidney, and other organs where microdroplets of the emulsion are distributed by the circulatory and lymphatic systems (Waksman and Bullington, 1960).

While there is an extensive literature on the associated lesions, there are few studies evaluating pain and distress associated with the use of FCA or FIA in rabbits. Amyx (1987) first addressed the issue and concluded that under some conditions the local inflammatory lesions likely resulted in pain or distress. A few reports of the pathological lesions associated with the use of FCA and FIA in rabbits have included some information on the clinical assessment of pain or distress (Johnston et al., 1991; Leenaars et al., 1994; Stills and Bailey, 1991) while others have presumed the presence of pain or distress based entirely on the observed lesions without any clinical or behavioral evaluation (Jennings, 1995; Mallon et al., 1991). The few prospective studies to evaluate both physiologic and behavioral changes in rabbits injected with FCA or FIA via the subcutaneous or intramuscular route have failed to detect any changes directly attributable to the adjuvant-immunogen injection (Halliday et al., 2000, 2004; Leenaars et al., 1994, 1998a). In contrast there are a number of studies indicating that pain or distress is associated with the intraperitoneal injection of FCA-immunogen in rodents (Leenaars et al., 1998b; Toth et al., 1989; Wanstrup and Christensen, 1965) and high dosages of intraperitoneal FCA in rats reliably

produce acute inflammation (Geisterfer and Gauldie, 1996; Geisterfer et al., 1993; Giffen et al., 2003; Olivier et al., 1999), indicating that Freund's adjuvants have the potential for inducing pain and distress in animals under specific circumstances.

An additional approach to evaluating the potential of pain and distress associated with the injection of Freund's adjuvants comes from reports of human injections. Water-in-oil adjuvants similar to FIA were used in human influenza vaccines in the early 1960s prior to discontinuance due to safety concerns. Reports of injection site pain were uncommon and generally mild (Alving, 2002; Lindblad, 2000; Salk, 1953; Salk and Salk, 1977; Salk et al., 1952) but rare side effects (Cutler et al., 1962; Stuart-Harris, 1969) included cystic swellings and muscle indurations which persisted for up to 1 year and histologically consisted of oil granulomas. Long-term follow-up studies on United States military personnel vaccinated with FIA-influenza failed to identify any additional risk associated with the vaccination (Beebe et al., 1964, 1972). In spite of FIA's low incidence of adverse reactions and its proven effectiveness, attempts to reintroduce FIA in human vaccines in the late 1960s were unsuccessful (Davenport, 1968). Reports of human administration of FCA are far fewer than with FIA. Hughes and colleagues (Hughes et al., 1970) used repeated injections of FCA in early human cancer immunotherapy studies and reported that severe reactions were only seen after repeated injections, after the patients developed sensitivity to the tuberculin antigen. Chapel and August (1976) reported severe pain in five of nine cases of accidental FCA injection in humans and only in those that were tuberculin-sensitive prior to the injection. These reports, coupled with the fact that many human diseases characterized by chronic granulomatous inflammation, including tuberculosis, leprosy, sporotrichosis, and "Buruli" (*Mycobacterium ulcerans*) cutaneous ulcers are relatively painless until quite advanced (Kumar et al., 2005; Pfyffer et al., 2003), suggests that the initial granuloma produced by FCA is not necessarily associated with significant pain.

Specol

Specol (ID-DLO, Lelystad, The Netherlands) is a water-in-oil adjuvant composed of a purified light mineral oil (Markol 52) with the emulsifiers Span 85 and Tween 85 (Bokhout et al., 1981) developed as a less toxic alternative to Freund's adjuvants. All of the ingredients in Specol are individually FDA approved for veterinary use and can be purchased individually (Vogel and Powell, 1995). Studies comparing the antibody responses to different immunogens emulsified in either Specol or FCA/FIA have generally reported similar results in rabbits (Leenaars et al., 1994, 1998b), pigs (Oonk et al., 1998), and mice (Leenaars et al., 1995,

1998b) although there are a few reports with self-antigens (Leenaars et al., 1995) and small peptides (Ferber et al., 1999) where FCA/FIA was shown to be more effective. Studies comparing the histologic lesions following the use of Specol or FCA/FIA are limited, inconclusive, and have been primarily conducted in mice. Leenaars et al. (1994, 1998a, 1998b) reported fewer histologic lesions associated with the use of Specol than FCA/FIA while Ferber (Ferber et al., 1999) reported more severe lesions with Specol. Studies comparing pain and distress are very limited but it is likely that the pain and distress are similar with the use of either Specol or FCA/FIA.

Montanide ISA Adjuvants®

The Montanide Incomplete Seppic Adjuvants (ISAs) (Seppic, Paris, France) consists of a series of adjuvants composed of a variety of oils, emulsions characteristics, emulsifiers, and immunomodulators. The Montanide ISA50V, ISA51, and ISA70 adjuvants are water-in-oil emulsions based on a purified mineral oil and are very similar to FIA. The few studies comparing these adjuvants and FCA/FIA report a similar antibody response with equal or less inflammation (Johnston et al., 1991; Leenaars et al., 1994, 1995, 1998b). The other Montanide adjuvants are primarily prophylactic adjuvants composed of a variety of mineral and metabolizable oils designed for use in human and veterinary vaccines (Stewart-Tull, 2003).

TiterMax® and TiterMax Gold®

TiterMax and TiterMax Gold (CytRx, Norcross, GA) are water-in-oil emulsion adjuvants consisting of the metabolizable oil squalene, an emulsifier (sorbitan monooleate 80), a patented block copolymer (CRL8941 or CRL8300, respectively), and microparticulate silica. The high-molecular-weight non-ionic block copolymers consist of linear chains of hydrophilic polyoxyethylene flanking linear chains of hydrophobic polyoxypropylene (Hunter and Bennett, 1986) producing an adjuvant effect presumably through enhanced antigen presentation, complement activation, chemotaxis, and macrophage activation (Howerton et al., 1990; Hunter and Bennett, 1984; Hunter et al., 1994). The immunomodulatory effects of block copolymers have made them very promising candidates in the development of human prophylactic vaccines (Hunter, 2002).

TiterMax and TiterMax Gold adjuvants were developed as alternatives to the use of FCA/FIA in polyclonal antibody production capable of equal or better antibody production with less reported tissue toxicity (Bennett et al., 1992; Jennings, 1995). Since their introduction, numerous studies have compared the TiterMax adjuvants with other adjuvants using a variety of species, immunogens, and routes of administration.

Bennett et al. (1992) reported comparable antibody responses with TiterMax and FCA in rabbits, mice, and goats with reduced lesions. Other reports, however, have indicated reduced inflammatory lesions in comparison to FCA but also reduced antibody production in rabbits (Leenaars et al., 1994, 1998b; Smith et al., 1992) and guinea pigs (Robuccio et al., 1995). Studies in mice have indicated comparable antibody production to FCA following intraperitoneal administration but severe lesions were also produced while subcutaneous administration resulted in minimal lesions but also poor antibody production (Leenaars et al., 1998b).

Oil-In-Water Emulsion Adjuvants

Oil-in-water adjuvants differ from the water-in-oil adjuvants in that they are typically formulated with only a small amount of oil dispersed in an aqueous phase in contrast to the water-in-oil emulsions that typically have $\geq 50\%$ oil. Oil-in-water emulsions tend not to form a localized depot like the water-in-oil adjuvants but rather are rapidly transported from the injection site to the draining lymphatics, reducing the potential for localized chronic inflammation at the injection site. The reduction in potential injection site complications has made the oil-in-water emulsion adjuvants much more likely candidates than the water-in-oil emulsion adjuvants for the development of human prophylactic vaccines (Allison, 1999; Alving, 2002).

RIBI Adjuvant System[®]

The RIBI Adjuvant System[®] (RAS[®]) (Corixa Corporation, Seattle, WA) is a commercial adjuvant system first available for experimental antibody production in 1985. The system is based upon the use of a small quantity of metabolizable squalene oil and Tween 80 surfactant into which the antigen is incorporated prior to emulsification with the aqueous phase (Ribi et al., 1975). The resulting emulsion is much less viscous than typical water-in-oil emulsions and can be sterilized by filtration and administered easily by injection (Saha and Mondal, 2000; Stills, 1994). Immunostimulants must be added to the emulsion as alone, the emulsion is a poor adjuvant (Altman and Dixon, 1989). Three different immunostimulants are used to produce the three different research formulations of the RAS[®].

Trehalose 6,6'-dimycolate (TDM) is the non-immunogenic lipid component of the mycobacterial cord factor that is found in virulent strains of the mycobacteria (Altman and Dixon, 1989). TDM is included in all RAS[®] formulations and augments both the humoral and the cell-mediated immune responses (Azuma et al., 1974; Ribi et al., 1975, 1982) though it is reportedly less effective in the rabbit than in rodents (Altman and Dixon, 1989). Monophosphoryl lipid A (MPL[®]) is a

chemically modified form of lipid a, the component of bacterial lipopolysaccharide that mediates endotoxic shock. MPL[®] serves as an agonist for TLR-4, retaining the immunostimulatory effect, but has greatly reduced toxicity (Ribi et al., 1984). MPL[®] is a component of two of the RAS[®] formulations, only absent in the formulation recommended for use in mice with strong antigens. A second mycobacterial-derived compound, cell wall skeleton (CWS), is present in the RAS[®] formulation recommended for use in rabbits, goats, and primates. The immunostimulatory activity of CWS is primarily due to muramyl dipeptide (MDP), which is responsible for much of the adjuvant activity attributable to whole mycobacterial cells (Ellouz et al., 1974).

Studies comparing the antibody response to specific immunogens with RAS[®] formulations and FCA/FIA have, with one exception in mice (Lipman et al., 1992), generally indicated substantially higher antibody production with the FCA/FIA adjuvant regimen (Johnston et al., 1991; Leenaars et al., 1995, 1998a). Studies comparing the pathological lesions produced by RAS[®] have yielded widely varying results from lesions similar to those seen with FCA/FIA (Johnston et al., 1991; Leenaars et al., 1994, 1998a) to only minimal lesions with the RAS[®] adjuvant compared with FCA/FIA (Deeb et al., 1992; Leenaars et al., 1998b).

Syntex Adjuvant Formulation (SAF)[®]

The Syntex Adjuvant Formulation (SAF, SAF-1, SAF-m)[®] (Chiron Corporation, Emeryville, CA) is a microfluidized oil-in-water emulsion consisting of 5% squalane, 2.5% Pluronic[®] L121, 0.2% polysorbate 80 (Tween 80), and phosphate-buffered saline with threonyl muramyl dipeptide (t-MDP) (Vogel and Powell, 1995). The synthetic block copolymer Pluronic[®] L121 and t-MDP, a synthetic analog of muramyl dipeptide (MDP), serves as the immunostimulants (Allison and Byars, 1986; Howerton et al., 1990; Allison, 1999; Hunter and Bennett, 1984).

The Syntex Adjuvant Formulation was developed as a prophylactic vaccine adjuvant and has been evaluated in humans and a number of other species for efficacy and safety as a prophylactic vaccine adjuvant. Adjuvant-related complications in a human cancer immunotherapy trial consisted of injection site erythema, tenderness, induration, myalgia, arthralgia, and pyrexia (Hsu et al., 1997). As with other adjuvants, studies comparing the effectiveness of SAF with FCA and other adjuvants in antibody production have reported mixed results. A study comparing influenza immunization with SAF or FCA as the adjuvant in mice (Hjorth et al., 1997) reported SAF to be equal or superior to FCA. A similar influenza immunization study in guinea pigs, however, found SAF to be inferior to FCA, TiterMax[®], RIBI[®], and aluminum phosphate for antibody production (Robuccio et al., 1995).

Particulate Adjuvants

Aluminum Salt Adjuvants

Absorption of immunogens onto aluminum phosphate or aluminum hydroxide (Alhydrogel) is the most common method of producing prophylactic vaccines for both human and veterinary use (Galloway et al., 2004; Gupta et al., 1993, 1995). Aluminum salt adjuvants bind immunogens via electrostatic forces and ligand exchange providing a relatively short-lived depot effect with peak antibody titers at 3–4 weeks post-injection (Altman and Dixon, 1989). Aluminum adjuvants also exhibit some immunomodulatory properties, inducing secretion of CCL3, CCL4, and CXCL8 by human monocytes and macrophages (Seubert et al., 2008), CCL2, CXCL1, CCL11 (Kool et al., 2008), and IL-1 β (Kool et al., 2008) in mice. Aluminum adjuvants tend to promote a nearly exclusive Th2 type of immune response (Lindblad, 2004) with little or no cell-mediated Th1 or CD8 cytotoxic lymphocyte response (Reed et al., 2009).

Aluminum adjuvants have been extensively used in human vaccines and have a proven safety record. They do rarely result in side effects, primarily localized erythema and granuloma formation at the injection site (Baylor et al., 2002; Gupta et al., 1993) and this appears to be more commonly seen with subcutaneous administration (Pittman, 2002). While they will continue to be used extensively in prophylactic vaccines, aluminum salt adjuvants are not extensively used for primary immunizations for experimental polyclonal antibody production purposes. Aluminum adjuvants do, however, have a number of characteristics that warrant their consideration as adjuvants for both primary and booster injections in polyclonal antibody production (Stills, 1994).

Immune-Stimulating Complexes

Immune-stimulating complexes (ISCOMs) are 40–100-nm honeycomb complexes composed of immunogen, cholesterol, phospholipids, and a saponin from the South American soap tree (*Quillaja saponaria*) (Dalsgaard et al., 1995; Liang et al., 2006; Morein and Bengtsson, 1999; Morein et al., 1984; Sun et al., 2009). The saponin is a heterogeneous mixture of glycosides that is essential in the formation of the ISCOM and serves as a potent adjuvant, presumably increasing uptake of the ISCOMs by dendritic cells (Liang et al., 2006). There are a number of commercial semipurified or purified *Quillaja* saponin preparations including Quil A (Superfos AS), Spikoside (AdVet), and Iscoprep 703 (Isotec AB). Quil A has been extensively used in veterinary vaccines but the hemolytic activity of Quil A on parenteral administration has prevented its use in human vaccines (Vogel and Powell, 1995). ISCOMs are classically formed by reacting the saponin, cholesterol,

and phospholipids with a hydrophobic or amphipathic antigen in the presence of a suitable detergent. Hydrophilic immunogens such as small peptides must be modified by incorporating hydrophobic regions to be effectively used in ISCOMs. The preparation of the ISCOM matrix is dependent upon the ratio of saponin to immunogen, the hydrophobicity of the immunogen, the phospholipid component, and the preparation method, making proper formulation of the immunogen-adjuvant mixture problematic and evaluation of the final product difficult (Myschik et al., 2006; Sun et al., 2009). Many difficulties associated with the use of ISCOMs for experimental polyclonal antibody production were addressed by the development of the preformed ISCOMs (ISCOM-matrix) that could be readily associated with the chosen immunogen (ISCOMATRIX[®], CSL Behring, King of Prussia, PA). While developed primarily for use in prophylactic vaccines, the ISCOM-matrix provides an easy-to-use adjuvant for the development of experimental polyclonal antibodies.

ISCOMs and ISCOM-matrix adjuvants have been used extensively in veterinary vaccines (Morein et al., 2004; Scheerlinck and Greenwood, 2006) and in a number of experimental vaccines in a variety of species (Sun et al., 2009). The ability of ISCOMs to induce a CD8 cytotoxic lymphocyte (CTL) response has made them a valuable adjuvant, especially for prophylactic vaccines against viral diseases (Scheerlinck and Greenwood, 2006). ISCOMs are efficiently endocytosed by antigen-presenting cells with processing for both MHC class I and class II presentation (Reed et al., 2009; van Binnendijk et al., 1992). While ISCOMs have an excellent safety record as veterinary vaccines, studies evaluating the inflammatory response to ISCOMs in mice immunized by intraperitoneal injection (Smith et al., 1999) have documented a rapid influx of neutrophils and mast cells followed by macrophages, dendritic cells, and lymphocytes with an increase in the levels of IL-1, IL-6, IL-12, and interferon- γ peaking at 24–72 hours post-injection.

Studies comparing ISCOMs or ISCOM-matrix adjuvants with other adjuvants for experimental polyclonal antibody production have been quite limited and reached varying conclusions from the production of significantly greater antibody (Browning et al., 1992), being comparable to FCA (Leenaars et al., 1995; Sjolander et al., 1993), to producing a significantly lower antibody response (Levi et al., 1993; Lockyer et al., 1993; Sjolander et al., 1993). In all cases where the histologic lesions were compared, significant histologic lesions were minimal with the ISCOM adjuvants except in the case of intraperitoneal injections (Leenaars et al., 1995). The use of ISCOMs in experimental polyclonal antibody production suffers from the complicated adjuvant preparation

and the necessity of immunogen modification to ensure binding with the ISCOM-matrix or incorporation in the ISCOM. As stated by Leenaars et al. (1995), the complicated preparation is a significant disadvantage.

Gerbu® Adjuvants

The Gerbu® adjuvants (GERBU Biochemicals GmbH, Am Kirchwald 6, 69251 Gaiberg, Germany) are based on the use of the immunomodulator N-acetyl-glucosaminyl-N-acetylmuramyl-L-alanyl-D-isoglutamine (GMDP), a soluble glycopeptide from the cell wall of *Lactobacillus bulgaricus*. All Gerbu® adjuvants contain cimetidine as an immune enhancer and most also contain saponin, another immunomodulating compound. A Gerbu® adjuvant specifically designed for monoclonal antibody immunizations in mice (Gerbu Adjuvant MM®) additionally contains poly(adenylic)-poly(uridylic) acid heteroduplex (poly A:U) and theophylline as additional immunomodulators. Gerbu® adjuvants are aqueous adjuvants with suspended ultrafilterable particles composed of a paraffin mixture containing dimethyldi(stearoylhydroxyethyl)ammonium chloride (Esterquat 1) in conjunction with mannide monooleate, glycerol, L-proline, and ciprofloxacin.

Developed primarily as adjuvants for prophylactic vaccines, the Gerbu® adjuvants have evolved and changed in an effort to improve response and minimize complications. Evaluations and comparisons of studies using the Gerbu® adjuvants are complicated by the many variations of the adjuvant and the tendency to refer to all products as "Gerbu adjuvant." Studies that have evaluated and compared Gerbu® adjuvants to others have consistently shown Gerbu® to be well tolerated with few lesions but generally failing to produce antibody titers equivalent to those produced using other adjuvants. Studies in sheep and avians have shown Gerbu® adjuvants to be effective for prophylactic immunization but deficient in antibody production compared to FCA, FIA, and others (Beck et al., 2003; Shu et al., 2001). Ferber et al. (1999) reported the antibody response to immunization with small synthetic peptides in Gerbu adjuvants to be equivalent to the response using FCA/FIA and superior to that using PolyA:PolyU, TiterMax®, and RIBI while other reports indicate superior responses using FCA, FIA, and TiterMax® (Seetharamaiah et al., 1996).

SUMMARY

Polyclonal antibody production will remain an essential research activity and rabbits will continue to serve as one of the primary species used in polyclonal antibody production. The schedules and methodologies used to immunize rabbits and produce polyclonal antibodies will continue to vary dependent upon the

immunogen, the adjuvant, and the end purpose of the antibody. The choice of adjuvant and immunization schedules are critical components of the polyclonal antibody production process that are frequently overlooked as researchers resort to standard published methodologies (Cooper and Paterson, 2008, 2009; Harlow, 1988) that may or may not be applicable to their needs. While FCA remains overall the most effective adjuvant for polyclonal antibody production, the extensive histologic lesions it produces will continue to stimulate the development of alternative adjuvants producing less tissue destruction and potential pain and distress.

INTRODUCTION

This chapter discusses the use of domestic rabbits in toxicity and safety testing of substances such as drugs, chemicals, and medical devices that can impact human safety. While non-clinical testing also benefits animals as with development of veterinary drugs, the examples and procedures described in this chapter represent those commonly used in research and regulated non-clinical safety testing settings. Toxicity and safety studies should always be conducted in compliance with

applicable regulations, laws, policies, and guidelines as well as the requirements specified by the facility's Institutional Animal Care and Use Committee (IACUC).

Domestic rabbits, *Oryctolagus cuniculus*, belonging to the order *Lagomorpha* and the family *Leporidae*, are easily housed and handled. Rabbits are small relative to other species (minipigs, dogs, and monkeys) evaluated in toxicity and safety studies, but large enough to easily conduct ocular and dermal irritation and embryo-fetal evaluations. Breeds frequently used in non-clinical studies include New Zealand White (NZW) and Japanese

albino rabbits (3–5 kg or 6.6–11 lbs) and the smaller, pigmented Dutch Belted (0.9–1.8 kg; 2–4 lbs). Dutch Belted rabbits provide an advantage with respect to the amount of test material required (approximately 40% less compared with albino rabbits). They also provide the ability to test for potential effects of drugs and chemicals on melanocyte development and for potential sequela of drugs that have a propensity to bind melanin in pigmented retinal epithelium and skin (Spence, 2003). Himalayan rabbits have been used in developmental toxicity studies, primarily in Europe, and several decades of information exists demonstrating consistent inter- and intra-laboratory reproductive data with no relevant differences compared with reproductive data in other rabbit breeds (Viertel and Trieb, 2002). Other breeds of rabbit are sometimes used such as the Flemish Giant, Polish, and Red Burgundy to name a few (Gratwohl et al., 1986; Salamon et al., 2007).

Housing and food requirements for rabbits are well-known (Salamon et al., 2007). Several characteristics should be considered when designing toxicity and safety studies and establishing criteria for appropriate supportive care and endpoints. Gastrointestinal flora of rabbits are easily disrupted, leading to diarrhea and poor health, and common laboratory procedures include step-wise acclimation to a specified (e.g., 120 grams) once-daily limited feeding regimen. Coprophagia (ingestion of feces) is normal behavior in rabbits. Ingestion of soft fecal pellets excreted in the early morning is essential because bacterial syntheses of certain B vitamins in the cecum are excreted at this time. Decreases in activity and food consumption are important indicators of intolerance and toxicity. In contrast, decreased food consumption and increased activity, including pulling hair from their ruff to make a nest, are normal changes observed in pregnant rabbits prior to delivery. Normal rabbit urine can resemble purulent discharge; it is often cloudy, even paste-like, ranging from light yellow to deep orange or red brown in color because of the diet. Modifications to housing conditions and habituation to humans have been shown to result in normal circadian body temperature profiles and less variability in the behavioral response of rabbits to experimental procedures such as handling for dosing and blood collection (Verwer et al., 2009).

Test materials can be administered to rabbits by a variety of routes including dermal, ocular, oral, inhalation, intranasal, intramuscular (IM), intraperitoneal, intravenous (IV, including continuous IV infusion), subcutaneous (SC), sublingual, and vaginal. Best practice techniques for administration and dose volume limits as well as vehicle considerations have been described in several publications (Dali et al., 2006; Diehl et al., 2001; Gad, 1994; Morton et al., 2001; Salamon et al., 2007). Blood is relatively easy to obtain from rabbits, and procedures for collection from various sampling sites,

limits for blood sampling volumes, and recovery periods between sampling have been described (Diehl et al., 2001; Salamon et al., 2007). Techniques have been established for collection of urine (Salamon et al., 2007) and semen (Christian, 2008; Foote and Carney, 2000). The larger spleen of rabbits, compared with rodents, has expanded the capacity for screening highly specific monoclonal antibodies. Rabbits recognize more antigens and epitopes than mice or rats making rabbits a good choice for production of monoclonal antibodies against site-specific histone modifications (Guo et al., 2006).

Rabbit anatomy and physiology, including reproductive physiology, have been characterized (Christian, 2008; Foote and Carney, 2000; Salamon et al., 2007). Rabbits are induced ovulators requiring stimulation of the cervix which occurs when a buck copulates with the female. Artificial insemination, less frequently used than natural mating, requires ear vein injection of human chorionic gonadotropin (hCG) to compensate for reduced natural cervical stimulation. Rabbits have a short gestation period and are sensitive to teratogens. In some cases, rabbits respond to test agents in a manner closely approximating those of humans as with thalidomide, which causes similar birth defects in rabbits and primates (including humans), but not in other commonly used laboratory species such as rats (Neubert and Neubert, 1997; Palmer, 1968). Much is known about rabbit placenta and embryo-fetal and postnatal development and comparisons have been made with other species, including humans (Beaudoin et al., 2003; Christian, 2008; Leiser and Kaufmann, 1994; Pentšuk and van der Laan, 2009).

TOXICITY TESTING

Exposure to drugs and chemicals can result in toxicity manifest in specific organs, known as target organs of toxicity. Factors contributing to the susceptibility of an organ to toxicity include pharmacokinetics, metabolism of the drug or chemical, and the ability of the organ to respond to toxic insult (Pfaller and Gstraunthaler, 1998). Typically, mechanistic toxicity testing is conducted retrospectively to understand mechanisms of action and relevance to human safety. These studies provide information applicable to early diagnosis or prevention of target toxicity in humans and may contribute to development of metabolites or analogs of the drug or chemical with the same or better efficacy but with reduced side-effects.

Hepatotoxicity

Tuberculosis (TB) remains an unmet medical need due, in part, to complicating factors such as HIV

co-infection, drug resistance, and variable efficacy of the bacille Calmette-Guerin vaccine (McMurray, 2001). Rabbits, one of the animal models for TB are also animal models to investigate liver toxicity produced by drugs used in the chemoprophylaxis and treatment of TB in humans. The widely used TB treatment isoniazid (INH), the hydrazide of isonicotinic acid, causes hepatotoxicity ranging from elevated liver enzymes in up to 20% of individuals to liver damage (predominantly hepatic necrosis) in 1–2% of individuals (Sarich et al., 1999). Subcutaneous injections of INH in NZW rabbits produces hepatotoxicity similar to that observed in humans, characterized by hepatic necrosis, hepatic steatosis (hepatic fat accumulation), hypertriglyceridemia (elevated plasma triglycerides), and elevated liver enzyme activity (Sarich et al., 1995, 1996, 1998, 1999). Initial studies in rabbits implicated acetylhydrazine and hydrazine, INH metabolites, as the causative hepatotoxins. Further investigation demonstrated hydrazine, and not INH or acetylhydrazine, is most likely involved in the pathogenic mechanism of INH-induced hepatic necrosis. Treatment of TB with the antibiotic rifampicin, an inducer of mixed-function oxidase, also causes hepatotoxicity. The incidence of hepatotoxicity is higher with INH and rifampicin in combination compared with INH alone (Kalra et al., 2007). In albino rabbits, rifampicin potentiates INH-induced hepatotoxicity, and high doses of cimetidine, an inhibitor of the cytochrome (CYP) 450 enzyme system, ameliorated elevations in liver enzyme activity and histopathologic changes (Kalra et al., 2007). Co-administration of silymarin, a polyphenolic flavonoid derived from milk thistle, antagonized INH-induced hepatotoxicity in rabbits suggesting a role for pre-treatment with an anti-oxidative agent in the process of hepatoprotection (Maryam et al., 2010).

As reviewed by Ulrich et al. (2001), idiosyncratic toxicities, defined as those not predicted by dose, duration of exposure, or mechanism of action, are difficult to predict due to their low incidence and differences in species sensitivity. Panadiplon, an experimental non-benzodiazepine anxiolytic, was withdrawn from development due to hepatic toxicity indicated by elevations of serum transaminases in a few Phase 1 clinical trial volunteers not predicted in non-clinical toxicity studies in rats, dogs, or monkeys. Development of a second-generation compound required a suitable animal model to understand the mechanism of panadiplon-induced hepatic toxicity. The Dutch Belted rabbit was selected based on hepatic changes of lipid accumulation observed in a developmental toxicity study (Ulrich et al., 1995). The mechanism of panadiplon-induced hepatic toxicity was investigated by comparing results from in vitro studies in hepatocytes from the sensitive species (rabbits) to those from insensitive species (rats and monkeys) and results from in vivo studies in the

sensitive species (rabbit) to those from an insensitive species (rat). Hepatic toxicity observed in rabbits resembled Reye's syndrome-like changes produced by a variety of mitochondrial fatty acid oxidation inhibitors. However, not all rabbits showed evidence of hepatic toxicity, suggesting other factors such as individual differences in metabolism or nutritional status were necessary to produce the complete toxicological profile including cell death and subsequent liver pathology.

Immunotoxicity

A variety of medical (e.g., latex gloves, condoms, and catheters) and everyday items (e.g., balloons, tires) derived from natural rubber can induce immediate type I or delayed type IV, IgE-mediated hypersensitivity allergic reactions of local contact urticaria, asthma-like symptoms, and systemic anaphylactic reactions (Gad and McCord, 2008a; Rodgers et al., 1997). The source and processing of latex protein in the finished product have been identified as two factors contributing to the high frequency of type I allergic reactions to latex gloves. Studies conducted with rabbit anti-latex sera indicate fresh, unprocessed latex sap contains the most complete presentation of all potential allergenic proteins in comparison to raw latex containing ammonia and finished latex products (Rodgers et al., 1997).

Tampons were known to cause mild and transitory vaginal infection but not severe medical issues until 1978 when toxic shock syndrome (TSS), an acute-onset multi-organ illness, was described (Gad and McCord, 2008d). This occurred a few years after a super-absorbent tampon was test-marketed and subsequently withdrawn from the market. Causes of menstrual TSS are the *Staphylococcus aureus* superantigen toxic shock syndrome toxin-1 (TSST-1) and staphylococcal enterotoxin B or C (Brosnahan et al., 2008). In general, superantigen-secreting *S. aureus* localized at the vaginal surface must penetrate the vaginal mucosa and interact with underlying immune cells to cause TSS. As reviewed by de Azavedo (1989), establishing a suitable animal model to study TSS was difficult and had to take into account: (i) the ability to induce infection with a suitable strain of *S. aureus*, (ii) the ability of the host to mount a specific antibody response to TSST-1, and (iii) the presence of a foreign body to increase the potential to contract TSS. Only rabbits and baboons have been shown to exhibit TSS- or TSST-1-like symptoms following infection with *S. aureus* (Reeves et al., 1986). The response appears dependent upon the age and strain of rabbit with the NZW strain more susceptible to TSST-1 than the Dutch Belted strain (de Azavedo, 1989). Methods employed to induce TSS-like changes in rabbits, and provide an animal model for studying the

pathogenesis of TSS, include: (i) direct administration of TSST-1 via SC infusion over 7 days (Parsonnet et al., 1987), (ii) implantation of micropore diffusion chambers into the uterine horns to permit passage of host proteins into and bacterial products out of the chambers (de Azavedo, 1989), (iii) implantation of flattened polyethylene whiffle balls into the dorsolumbar region for 4–8 weeks to allow leukocyte infiltration prior to inoculation with a *S. aureus* strain (Scott et al., 1983), and (iv) a vaginal tampon model to evaluate the interaction of host, bacteria, and tampon composition on production of TSST-1 and TSS (Melish et al., 1989).

Fungal contamination of feed and feedstuffs reduces nutritional value and causes mycotoxicosis associated with acute and chronic toxicity and death in livestock and humans. Mycotoxins have immunosuppressive properties that lead to increased susceptibility to infection, and several mycotoxins including ochratoxin A (OTA) and citrinin (CIT), both found in improperly stored foods, also cause nephrotoxicity in animals (Kumar et al., 2008). An investigation of OTA- and CIT-related immunotoxicity in NZW rabbits, a species susceptible to mycotoxicosis, revealed significantly lower humoral and cellular immune responses in OTA- and OTA plus CIT-treated animals compared with CIT-treated animals. Based on results of skin hypersensitivity tests and lymphocyte proliferation assays indicated the interaction between these two mycotoxins was severe and additive (Kumar et al., 2008).

Nephrotoxicity

Rabbit in vitro and in vivo models are used to investigate nephrotoxicity. In vitro methods allow mechanistic studies of epithelial transport and alterations brought about by metabolism, hormones, drugs, and chemicals (Blais et al., 1993). Isolated perfused kidney, isolated perfused tubules, isolated glomeruli, renal cortical slices, and proximal tubule cell culture models developed in rabbits have been used to study mechanisms of action of a variety of nephrotoxins such as anticancer drugs (e.g., cisplatin and other platinum analogs) and antibiotics (e.g., gentamicin and cephalosporin) (Aleo et al., 1989; Blais et al., 1993; Pfaller and Gstraunthaler, 1998; Phelps et al., 1987; Romero et al., 1992; Rush et al., 1992; Williams et al., 1990b).

The rabbit renal system is sensitive to contrast agents; thus, in vivo rabbit studies can be used to evaluate toxicity of contrast agents being developed for use in radiographic, ultrasound, or computed tomographic imaging procedures (Pettersson et al., 2002).

Rabbits have been used to study nephrotoxicity induced by administration of the antibiotic cephalosporin. Due to differences in renal accumulation, rabbits are more sensitive to the nephrotoxic effects of

cephalosporins compared with mice and rats (Halligan et al., 1995). Single IV injections of one of three cephalosporins to NZW rabbits produced changes in urine (e.g., glycosuria, lactic aciduria, and aminoaciduria) and bilateral necrosis of the proximal convoluted tubules in cephaloridine-treated rabbits (Halligan et al., 1995). No urinalysis or histopathologic changes were observed in rabbits given cefoperazone or cephalothin. Nephrotoxic effects of cephaloridine were confirmed and minimal effects of cefoperazone and cephalothin were identified using ^1H NMR spectroscopy urinalysis. This study demonstrates the importance of the analytical methods used in conjunction with the appropriate animal model.

Nephrotoxicity is a dose-limiting toxicity associated with administration of cyclosporin (CsA), an immunosuppressant agent that inhibits proliferation of T cells. Rabbits are an established animal model of immunosuppressant-induced nephrotoxicity, although initial toxicity studies of chronic CsA-induced toxicity was challenging in this species. As an example, SC administration of CsA for 60 days to NZW and Red Burgundy rabbits produced clinical toxicity (e.g., weight loss, reduced movement, death) and increased serum creatinine but no histologic changes in kidneys (Gratwohl et al., 1986). The outcome was unrelated to the route of administration or the strain. In contrast, IV administration of CsA at doses in the upper level of the human therapeutic range given to NZW rabbits for 30 days produced histopathologic and ultrastructural changes in the proximal and distal tubules, but not glomeruli, consistent with changes observed in renal biopsies of patients with chronic CsA nephrotoxicity (Thliveris et al., 1991, 1994). In addition to the morphological similarities between CsA-induced renal toxicity in rabbits and human, concentrations and profiles of the major CsA metabolite were similar in NZW rabbits and humans (Venkataramanan et al., 1988). In a modification of the animal model, heterotopic cardiac transplanted NZW rabbits given rapamycin IV for 60 days had significantly less renal toxicity than rabbits given CsA under the same conditions (Thliveris et al., 1995). Because CsA also is used for short periods, a model of acute CsA-induced toxicity was developed in rabbits (Prevot et al., 2000). In this model, SC administration of CsA for 5 days induced vasomotor-related acute renal failure characterized by decreased glomerular filtration rate, decreased renal blood flow, and increased renal vascular resistance; effects partially reversed after discontinuation of treatment.

Neurotoxicity

The pathogenesis of Alzheimer disease (AD) is characterized by extracellular deposition of amyloid beta,

formation of neurofibrillary tangles, selective neuronal loss, and cognitive impairment including loss of memory for recent events. Of the animal models developed to study the AD disease process and potential drug therapies, rabbits are considered relevant because the mammalian order (*Lagomorpha*) closely resembles primates and shows consistent production of neurofibrillary pathology and associated cognitive changes (Bharathi et al., 2006). The role of aluminum (Al) in AD is controversial, and not all animal models (e.g., transgenic mice) are sensitive to Al-induced neurotoxicity. In contrast, rabbits are sensitive to Al-induced neurotoxicity, developing AD-like histopathologic and cognitive changes dependent upon age, dose, route of administration, and specific aluminum complex administered (Bharathi et al., 2006; Savory et al., 2006). Behavioral studies in rabbits using a water maze or a classic conditioning paradigm of nictitating membrane extension (Yokel, 1983, 1985, 1987) determined that changes in learning and memory were not observed after SC administration of Al lactate to neonatal and immature rabbits. A biphasic effect in which learning was facilitated by a low dose and learning and memory impaired by a high dose was seen in pregnant rabbits exposed during gestation and learning deficits alone were seen in adult (6–8-month-old) rabbits (Yokel, 1983, 1985, 1987, 1989). Al-maltolate was shown as the more effective aluminum compound in producing AD-like neuropathology, with effects more pronounced in aged rabbits (Bharathi et al., 2006, 2008).

A cholesterol-fed NZW rabbit model for AD was developed to evaluate disease mechanisms and test potential disease-modifying treatments (Woodruff-Pak et al., 2007). In this model, modification of the rabbit diet by addition of 2% cholesterol alone or with trace amount of copper (0.12 mg/L water) for 10 weeks produced neuropathologic changes in the frontal cortex, hippocampus, and cerebellum resembling those in human AD. Eyeblink conditioning, a form of learning impaired in AD, was also impaired in this rabbit model. Galantamine, a drug approved for treatment of mild to moderate AD, given SC (3 mg/kg) for 15 days ameliorated eyeblink conditioning. This rabbit model of AD provides a means to investigate new drug therapies from both a neuropathological and cognitive perspective.

Embryo-fetal Toxicity

Methotrexate (MTX), a structural analog of folic acid, is indicated for treatment of certain types of cancer, rheumatoid arthritis, and other rheumatic conditions, including systemic lupus erythematosus and juvenile arthritis (Lloyd et al., 1999). Through a well-defined mechanism, MTX depletes the pool of tetrahydrofolate

which limits the availability of one-carbon fragments necessary for the synthesis of purines, ultimately disrupting deoxyribonucleic acid (DNA) synthesis causing rapidly dividing cells to arrest and die (Wolfgang, 2007). Thus, MTX toxicity forms the basis of both its therapeutic and teratogenic effects in humans. A rabbit model has been developed to understand the mechanism of teratogenicity and test protective strategies. Embryo-fetal effects are dependent upon the period of maternal administration of MTX. Administration on gestation days (GD) 8 and 9 leads to litter resorption; administration on GD 10, 11, or 12 causes anomalies (e.g., limb and digit, micrognathia, cleft palate, hydrocephalus, microphthalmia); and administration on GD 12–15 causes distal limb dysplasias (Jordan et al., 1977; Lloyd et al., 1999). A model of MTX-induced teratogenicity was established in NZW rabbits where a single IV dose (19.2 mg/kg) of MTX on GD 12 consistently produces malformations of the head, limbs, and trunk in nearly all surviving fetuses (DeSesso and Jordan, 1976). Focusing on changes in limb-bud structures, a series of experiments indicated these anomalies were caused by transient inhibition of cell division, rather than by cell death, and administration of compounds capable of transferring one-carbon units, whether structurally related to folate or not, provided some protection against formation of the anomalies (DeSesso and Goeringer, 1991, 1992; Lloyd et al., 1999).

Acetazolamide, a carbonic anhydrase inhibitor, and hydroxyurea (HU), an antineoplastic drug that reduces DNA synthesis, are mammalian teratogens. The MTX rabbit model was adapted to investigate embryo-fetal limb-bud development subsequent to maternal SC administration of acetazolamide (1500 mg/kg) or HU (650 or 750 mg HU/kg) on GD 12 (DeSesso, 1981; DeSesso and Jordan, 1976). External and histologic evaluation of fetuses obtained 2–32 hours postdose and on GD 29 demonstrated these drugs did not produce limb anomalies by the same mechanism. Acetazolamide produced bilateral retarded ossification or possible aplasia of the first metacarpal of the forelimb and talus of the hindlimb without apparent alterations in limb-bud morphology. For HU, a series of events led to extensive mesenchymal cellular death resulting in increased intercellular space among remaining viable cells in fetal limb buds. Compared to the sequence of changes induced by MTX, it was concluded that HU and MTX both disrupt intercellular contacts and breakdown of intercellular communication by different mechanisms of action: HU through cytolethality and MTX via disruption of intercellular junctions.

Co-administration of the phenolic antioxidant propyl gallate, the structurally different anti-oxidants ethoxyquin and nordihydroguaiaretic acid, and D-mannitol, a scavenger of hydroxy free radicals, all delay onset of

necrosis and ameliorate the teratogenic effects seen in term rabbit fetuses (DeSesso, 1981; DeSesso and Goeringer, 1990a, 1990b; DeSesso et al., 1994). In a series of studies, vehicle, propyl gallate, or D-mannitol were injected into implantation sites followed by injection of the maternal animal with HU and examination of embryos and fetuses at various times. Amelioration of HU-induced embryotoxicity was reflected in delayed onset of necrosis due to interactions between HU and propyl gallate or D-mannitol within the embryo, results consistent with the hypothesis that hydroxyl free radicals are the proximate reactive species in HU-induced early embryonic cell death.

SAFETY TESTING

Non-clinical studies are conducted to provide information relative to human safety when exposed to a variety of substances including drugs, industrial and agricultural chemicals, specific medical devices, residues of veterinary drugs in human food, and food and color additives. Non-clinical safety tests are conducted (i) in accordance with requirements and guidelines developed and adopted by global regulatory agencies specific to type of test or test material with rationale provided for when these strategies are not followed; (ii) in adherence with the International Organization for Standardization (ISO; <http://www.iso.org/iso/home.html>) and/or Good Laboratory Practices (GLP) specific to the region (e.g., Japan GLP 2008, US GLP 2001) to ensure quality and reliability, although screening, pilot, and dose range-finding studies may be conducted in a non-GLP manner, and (iii) in compliance with United States Department of Agriculture (USDA) requirements specified by the IACUC.

Regulatory agencies recognize the need to reduce duplication of studies and unnecessary use of animals in order to meet regional specific marketing requirements. Guidelines issued by the International Conference on Harmonisation (ICH) addressing safety tests for pharmaceutical drugs have been adopted by the United States Food and Drug Administration (FDA), European Union, and Japan (<http://www.ich.org>). The Organisation for Co-operation and Development (OECD) issues methods for assessing the safety of chemical products that have been adopted for use by government, industry, and independent laboratories (<http://www.OECD.org>). ISO has published standards for testing strategies for medical devices (<http://www.iso.org>). The Office of Prevention, Pesticides and Toxic Substances (OPPTS; <http://www.epa.gov/ocsp>) has harmonized testing guidelines in order to minimize variations among testing procedures required by the United States Environmental Protection Agency (EPA) and replace guidelines issued under the

EPA Toxic Substances Control Act (TSCA) and Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Regulatory agencies also recognize the value of refining animal testing strategies. Some of these approaches include (i) testing only one species for potential embryofetal toxicity if there is more than one relevant species and it can be shown the selected species is a relevant model for the human as outlined in the 2005 ICH S5(R2) guideline; (ii) delaying conduct of some in vivo tests until late in development as described in the 2010 ICH S9 Guidance for Nonclinical Evaluation for Anticancer Pharmaceuticals; (iii) using a tiered approach to toxicity testing (Cooper et al., 2006; Hurrt et al., 2003); and (iv) using step-wise testing strategies such as those in the OECD and EPA OPPTS guidelines for ocular and dermal irritation tests.

Efforts have been made to introduce meaningful, validated alternatives to non-clinical safety testing. In some cases, humans can be ethically tested, eliminating the need for animal studies as with comedogenicity testing (Nigam, 2009). Use of computer models such as LabHEART, a computer model of rabbit ventricular myocytes, simulates conditions such as ventricular tachycardia (Puglisis and Bers, 2001). Information from validated structure-activity relationships (SAR) models can be used to predict toxicity (e.g., ocular, dermal, and reproductive) of some test substances, eliminating the need to test in vivo. In vitro models may be used to screen drugs and chemicals, contributing to go/no go development decisions and providing perspective on the relevance of animal data to human safety. Per OECD and EPA OPPTS guidelines, no in vivo testing is required for substances with predictable corrosive properties such as strongly acid or alkaline substances. The European Centre for Validation of Alternative Methods (ECVAM; <http://ecvam.jrc.ec.europa.eu>), created in 1991, and the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM; <http://iccvam.niehs.nih.gov>), formally established in 2000, work to support development, validation, and acceptance of testing methods that could reduce, refine, or replace use of laboratory animals. However, as detailed in comprehensive reviews on this topic, the complexity of safety and risk assessment for toxicity, reproduction, sensitization, and toxicokinetics, to list a few areas, present considerable scientific and regulatory hurdles (Debbasch et al., 2005; Genschow et al., 2002, 2004; Lilienblum et al., 2008; McNamee et al., 2009; Spielmann and Liebsch, 2001).

A detailed review of all regulations and guidelines applicable to safety tests discussed in the following sections is beyond the scope of this chapter; several will be discussed to provide examples of types of safety tests conducted in rabbits. The timing of non-clinical safety tests relative to clinical studies should be appropriate to

support exposure of humans to the test material. This topic is discussed in various documents such as the ICH M3(R2) Guidance for Nonclinical Safety Studies for the Conduct of Human Clinical Trials and Marketing Authorization for Pharmaceuticals.

Cardiovascular

Safety pharmacology studies evaluate potential undesirable pharmacodynamic effects of a drug or chemical on physiological function, including cardiovascular, in relation to exposure at or above the intended therapeutic range. It is important to identify drugs and chemicals that produce drug-induced, or drug-aggravated cardiac arrhythmias or that prolong the QT interval of the electrocardiograph. Prolongation of the QT interval can lead to ventricular tachyarrhythmia, particularly torsade de pointes which can degenerate into ventricular fibrillation, a life-threatening event that can be caused by administration of anti-arrhythmic and non-cardiovascular drugs. The 2005 ICH S7B guidance proposes an integrated risk assessment based on conduct of *in vitro* and *in vivo* non-clinical tests in conjunction with follow-up mechanistic studies, as necessary. Types of tests include those measuring (i) ionic currents in heterologous expression systems for cloned human ion channels or in isolated cardiac cells, (ii) action potential duration (APD) parameters in isolated cardiac preparations or anesthetized animals, (iii) electrocardiograph (ECG) parameters in conscious or anesthetized animals, and (iv) proarrhythmic effects in isolated cardiac preparations or animals. Rabbits are recognized as an appropriate species for many of these testing strategies, and the following paragraphs provide a broad overview of rabbits models used to assess cardiovascular risk.

In Vitro

Action potential (AP) models use rabbit cardiac ventricular myocytes to investigate the ionic basis of electrophysiological properties linked to arrhythmic risk (Romero et al., 2009) and to replicate cardiac dynamics at rapid heart rate, as would be relevant to tachyarrhythmias (Mahajan et al., 2008).

The rabbit Purkinje fiber model is a multicellular preparation comprised of a single cellular population homogeneously expressing the major ionic channels (Roche et al., 2010). As a surrogate assay for the *in vivo* ECG, this *in vitro* model (i) profiles a drug or chemical candidate's effect on ion channels contributing to the genesis of the AP, (ii) predicts the potential for drugs and chemicals to induce QT prolongation, and (iii) is used to refine assessments of proarrhythmic risk (Aubert et al., 2006; Lu et al., 2002; Roche et al., 2010).

The arterially perfused rabbit ventricular wedge preparation, which preserves cell coupling and is characterized by long viability, is used to assess electrophysiological properties of drugs and chemicals and as a model for testing induced proarrhythmias including ventricular fibrillation, ventricular tachycardia, and torsade de pointes (Roche et al., 2010; Wang et al., 2008). Rabbit ventricular wedge preparations are considered better models compared with guinea pig or dog because rabbit hearts are more prone to early afterdepolarizations, a characteristic likely related to the unique fast recovery of the calcium channel from inactivation (Wang et al., 2008).

The isolated whole-heart rabbit model exhibits characteristics of class III (potassium channel blockers) drug-induced ventricular arrhythmia associated with QT prolongation and increased monophasic AP during late repolarization (Johna et al., 1998). This model allows manipulation of ionic and pharmacologic conditions while preserving the functional anatomy of the heart without interference of cardiovascular reflexes. SCREENIT, a rabbit isolated perfused heart model that records parameters such as monophasic AP, is used to identify drugs and chemicals that induce APD prolongation and proarrhythmia (Hondeghem and Hoffmann, 2003; Lawrence et al., 2006). This model is considered useful for screening drugs and chemicals intended for life-threatening diseases where a tolerance for cardiovascular risk is less of a concern and for defining safety margins above which adverse effects may appear in humans and as added value to an integrated QT risk assessment (Lawrence et al., 2006).

In Vivo

Cardiovascular risk may be assessed prior to initiation of clinical studies based on results from an *in vitro* hERG (human ether-a-go-go related gene) study in combination with *in vivo* ECG and blood pressure measurements from conscious dogs or monkeys, typically the non-rodent species tested in repeat-dose toxicity studies. Rabbits can also be used for these *in vivo* assessments because the ion channels controlling ventricular repolarization are similar in rabbits and humans (Bynum et al., 2009) and prolongation of the QT interval leads to torsades de pointes (Farkas et al., 2004), with females more sensitive to drug-induced prolonged QT than males (Lu et al., 2001). Telemetry-instrumented rabbits have been validated for use in safety pharmacology electrophysiology studies (Bynum et al., 2009). An anesthetized rabbit model using three surface ECG leads has been developed to measure QT and JT interval dispersion, proposed markers of heterogeneous ventricular repolarization and electrical instability (Lu et al., 2004). The advantage of this model is that it provides valuable information in a simplified

manner compared with the technically challenging 6 and 12 surface lead approach. Because several factors, including a high heart rate and short cycle length, contribute to variable ECGs and difficulty measuring the QT(U) interval, guidelines have been proposed to support reliable and reproducible measurements from anesthetized rabbits (Farkas et al., 2004).

Development and Reproductive Toxicity Testing

Assessment of the potential for developmental and reproductive toxicity (DART) is critical in evaluating the safety of drugs, industrial and agricultural chemicals, specific medical devices, residues of veterinary drugs in human food, and food and color additives. As reviewed by Barrow (2009), the US FDA published guidelines in 1966 for teratology testing of medicinal products in response to the high incidence of a severe, recognizable pattern of birth defects in children exposed in utero to thalidomide, a drug used by pregnant women in Europe and Canada as a sedative to treat morning sickness. Other countries also issued reproductive toxicity guidance; however, differences in testing requirements and methodology meant separate reproductive toxicity studies were necessary to meet marketing submission requirements in each of the three major regions: US, Europe, and Japan. Discussions on harmonization of regulatory requirements during the 1980s led to formation of the ICH in 1990 followed by issuance of the S5A guideline for Detection of Toxicity to Reproduction for Medicinal Products in 1994. Last revised in 2005, the ICH S5(R2) guideline (Detection of Toxicity to Reproduction for Medicinal Products and Toxicity to Male Fertility) outlines a three-segment strategy covering six stages of reproduction that should be addressed to fully evaluate effects on maternal reproductive function and on viability, growth, morphogenesis, and function of the developing offspring. At the time the ICH S5A guideline was written, rats were acknowledged as appropriate for all three segments with rabbits an accepted second mammalian species in the conduct of embryo-fetal toxicity studies. Although not often selected, rabbits can be evaluated in fertility and pre-postnatal studies (Teo et al., 2004a, 2004b). Rabbits may also be a relevant species for testing biopharmaceuticals (e.g. monoclonal antibodies) because IgG crosses the yolk sac by a neonatal Fc receptor (FcRn) transport mechanism during late organogenesis similar to non-human primates and humans and in contrast to rodents where transfer occurs earlier in pregnancy (Martin et al., 2009; Pentšuk and van der Laan, 2009).

Currently, regulatory guidelines addressing tests for reproductive toxicity have been issued by ICH, FDA, EPA OPPTS, and OECD. The various guidances

are intended as starting points for investigators who are encouraged to design testing strategies in accordance with knowledge of the drug, chemical, device, etc., and state of the art. The discussion in this section refers to the 2005 ICH S6(R2) guideline as the study designs and concepts are similar with those in the other guidance documents. The ICH S6(R2) guideline emphasizes all endpoints of developmental toxicity (e.g., embryo-lethality, reduced weight, functional or behavioral changes), not just malformations, as important outcomes. Sixteen to 20 adult animals/group are an acceptable minimum number using the mating pair, when both sexes are treated, and the litter, not individual conceptuses, as the unit of comparison when employing inferential statistics. Dose levels should be selected to provide no adverse developmental effects at the low- and mid-dose levels, and minimal maternal toxicity at the highest dose, avoiding increases or decreases in body weight compared with concurrent controls, body weight loss, exaggerated pharmacology, and marked lethality of the pre- and postnatal offspring. Administration of 1 g/kg/day is an adequate limit dose. The statistical power of DART tests to discriminate random from treatment-related effects is poor, and the presence or absence of a dose-related trend can be a critical means of determining the probability of a treatment effect. Four groups, a control and three drug-treated groups usually suffice to define the relationship of findings to dose; however, in the presence of a steep dose-response, a fourth dose group may be necessary to avoid excessive dosage intervals. Selected dose levels should provide data that can be used to determine a no observed adverse effect level (NOAEL) for maternal toxicity, reproductive function, and embryo-fetal development. While statistical significance should be used to support interpretation of results, findings may be biologically relevant in the absence of statistical significance. The guideline discusses data presentation and consistent conventions for reporting data have evolved over time.

The convention of data presentation has evolved to presentation of maternal data on discrete days and over intervals such as organogenesis, postdosing, and overall for the study with calculations for evaluation of body weight change, corrected body weight and corrected body weight change. Cesarean-section parameters are used to calculate values such as mean number ($\pm$ standard deviation) of corpora lutea, implantations, live fetuses per pregnant female, mean percent ($\pm$ standard deviation) pre- and postimplantation loss per pregnant female, and mean percent ($\pm$ standard deviation) early and late resorptions, and dead fetuses per litter. Fetal evaluations can be presented by region (e.g., torso, limb, head) and selected findings combined (e.g. cervical vertebral variations).

Generally, positive control groups are not included in DART studies. Interpretation is made by comparison to the concurrent controls, supplemented with the testing facility's historical control data in the same species and strain used as necessary. Efforts to compile historical control data across facilities have provided databases intermittently supported by various organizations.

In vitro alternatives to animal testing for developmental toxicology have been proposed, ranging in complexity from cell and organ cultures to embryo cultures, the latter approach closely representing embryogenesis from cellular proliferation and differentiation to pattern formation. The possibilities for their application as toxicity screens have been investigated in various validation studies, with rat whole embryo culture (WEC) validated by ECVAM as a screening and prioritization tool for pharmaceutical, agricultural, and industrial chemicals (Genschow et al., 2002, 2004; Piersma, 2004). Use of rabbit WEC is discussed below.

Fertility

Assessment of effects on fertility and general reproductive performance encompasses ICH stages A and B: premating to conception (adult male and female reproductive functions, development and maturation of gametes, mating behavior, and fertilization), and conception to implantation (adult female reproductive functions, pre-implantation development, and implantation). This study also is referred to as a Segment I study or a fertility and early embryonic development study.

Reproductive function in male rabbits can be monitored by analysis of ejaculated semen. Evaluation of ejaculated versus epididymal sperm allows for assessment of alterations in accessory sex gland secretions and measurement of drug or chemical levels in seminal fluid (Perreault et al., 2008). Serial semen samples obtained from bucks allows longitudinal assessment of morphologic, biochemical, and fertility parameters (Morton, 1988; Perreault et al., 2008; Williams et al., 1990a). Using ejaculated semen and inducing ovulation in females, male fertility can be assessed by artificial insemination (AI) of females with known numbers of sperm and effects on embryo-fetal development studied in relation to the paternal animal. Intra- and inter-individual variability of sperm number and concentration is reduced by collecting ejaculates at regular intervals from the same male buck (Perreault et al., 2008) and when measured in four ejaculates collected within a short period of time rather than a single ejaculate (Williams et al., 1990a). Use of automated computer-assisted sperm analysis (CASA) allows for high-speed, objective analysis of many characteristics of rabbit sperm (Farrell et al., 1995) such as motility patterns of spermatozoa obtained from testes, vas deferens, and various sections of epididymis (Pérez-Sánchez et al., 1996).

Segment I fertility studies, generally conducted in rodents or non-human primates, can be conducted in rabbits. As an example, a Segment I study of thalidomide has been conducted in NZW rabbits (Teo et al., 2004a). Therapeutic use of thalidomide is increasing yet little is known about the effect of this drug on human reproductive function and early embryonic development. NZW rabbits were selected for the study because this species is more sensitive than rodents to thalidomide-induced developmental effects. Following conduct of a dose range-finding study that included determination of plasma concentrations of thalidomide in male and female rabbits, a pivotal study was conducted in which four groups of female NZW rabbits (25/group) were given up to 100mg/kg of thalidomide via oral gavage for 14 days prior to mating with untreated males and through GD 7, with cesarean sections conducted on presumed GD 29. Following the initial mating with treated females, male NZW rabbits (25/group) were given up to 500mg/kg/day of thalidomide, 15 times the average human exposure, via oral gavage for 14 days and mated with untreated female NZW rabbits that were cesarean-sectioned 29 days after the last attempted mating. Dosing of the males continued during the mating period and until the day before euthanasia, for a minimum of 56 days. In addition to standard evaluations for viability, clinical observations, body weight, food consumption, cesarean section parameters, and gross evaluation of viscera at necropsy, evaluations in treated males included histopathology of reproductive organs and CASA analysis of sperm motility and count. Administration of thalidomide had no effects on mating and fertility in males or females, pregnancy parameters in females. No thalidomide-related external fetal anomalies occurred in treated or untreated female rabbits. Litter averages for corpora lutea, implantations, litter sizes and viable fetuses decreased mainly in the high-dose female group. It was postulated that the resorptions could be due to thalidomide's anti-angiogenic activity on fetal neovascularization or to thalidomide's immunomodulatory properties. Bilateral small testis in the mid- and high-dose male groups and histopathologic changes (e.g., increased incidence of multinucleated cells in the lumen of the seminiferous tubule and loss of round, elongated spermatids) in the high-dose male group were not associated with effects on sperm motility, count, or concentration at Day 56.

Embryo-fetal Development

Assessment of embryo-fetal development encompasses ICH Stages C and D: implantation to closure of the hard palate (adult female reproductive functions, embryonic development, and major organ formation). This study is also referred to as a Segment II, developmental toxicity, or teratogenicity study.

IN VITRO

As previously stated, *in vitro* techniques enable screening of new drug or chemical candidates and provide a means to investigate mechanisms of action. *In vitro* techniques in rabbits include limb bud cell micro-mass and palatal organ culture systems, in which undifferentiated cells transition to differentiated cells in culture, and postimplantation WEC (Foote and Carney, 2000). Advantages to WEC are (i) use of intact embryos of the same species tested *in vivo*, (ii) testing over a defined period (i.e., 48 hours) during embryogenesis, (iii) control of the environment (e.g., hyperthermia), and (iv) exclusion or introduction of variables (e.g., metabolites) into the culture medium (Chapin et al., 2008).

This section focuses on rabbit WEC, and comprehensive reviews have been published by Chapin et al. (2008) and Ellis-Hutchings and Carney (2010). Briefly, methods first developed in chicks during the early 1900s were applied to mammalian embryo cultures, and, by 1966, techniques were available to explant rat embryos on GD 9.5 or 10 and maintain them up to 48 hours in an *in vitro* environment supporting normal growth and development from the presomite to limb bud stages of organogenesis. Reliable methods for explanting and culturing rabbit embryos during the same early gestation timeframe were developed in the late 1990s. Subsequently, refinements by Carney and Tornesi (2003) demonstrated that chorionic tissue could be completely removed and rabbit embryo, amnion, and attached visceral yolk sac cultured as in rodent WEC. This became the standard method for rabbit WEC and enabled direct comparison of rat and rabbit embryo responses under identical culture conditions. Quantitative endpoints for evaluating effects of treatment on development in cultured embryos include (i) viability, assessed by the presence of a heart beat and by visualization of blood cells circulating through the vitelline vessels, (ii) growth, measured by somite count, (iii) crown-rump length, and (iv) biochemical measures such as total protein. A quantitative morphological scoring system was established in rodents in which developmental landmarks were assigned numerical scores reflecting progression of development. This was followed by a morphological scoring system for rabbit postimplantation embryos (Pitt and Carney, 1999a, 1999b) later modified to align with the system for rats (Carney et al., 2007).

Compared to rodents, rabbit extraembryonic membranes more closely resemble humans and differences in maternal-embryonic exchange contribute to understanding mechanisms of action for developmental toxicants. Rat and rabbit WEC often are studied in conjunction to investigate mechanisms that might explain discordant responses between *in vivo* rat and rabbit developmental toxicity studies and provide a framework for determining the relevance of animal data

to human safety (Ellis-Hutchings and Carney, 2010). Ninomiya et al. (1993) used WEC to study the mechanism of trypan blue-induced teratogenesis, hypothesizing a role for the visceral yolk sac. In culture, trypan blue induced neural tube anomalies, suppression of growth in rat embryos, and concentration-dependent accumulation of trypan blue in the yolk sac. In contrast, no effects on cultured rabbit embryos or yolk sac were observed, suggesting that the species-specific response to trypan blue was related to yolk sac, not maternal factors.

Hansen et al. (1999) investigated the hypothesis that thalidomide alters the amount of reducing and oxidizing equivalents in cells (redox status) inducing oxidative stress resulting in teratogenesis. Using rat and rabbit WEC, species resistant and sensitive, respectively, to thalidomide-induced malformations, Hansen et al. evaluated alterations in levels of glutathione (GSH), a tripeptide with a central role in detoxification processes, and cysteine, the rate-limiting precursor amino acid in GSH formation. Rabbit conceptuses displayed lower baseline GSH and cysteine levels and less ability to recover following *in vitro* exposure to thalidomide compared to rat conceptuses. Limb buds appeared normal on gross examination, but *in situ* hybridization demonstrated severe downregulation of limb differentiation factor FGF-10 in rabbit but not rat embryos exposed to equivalent concentrations of thalidomide. Hansen et al. concluded that rat visceral yolk sac more efficiently handled the toxic insult of thalidomide, and the sensitivity of rabbit embryos to thalidomide-induced GSH depletion resulted from lower visceral yolk sac detoxication capacity allowing more toxicant/oxidant to reach the embryos. Additional support for the validity of these WEC findings in the mechanism of thalidomide-induced teratogenicity comes from the growing body of information supporting the role of redox-sensitive processes in developmental programming (Hansen, 2006) and identification of a thalidomide-GSH conjugate in human liver microsomes (Chowdhury et al., 2010; Ellis-Hutchings and Carney, 2010).

IN VIVO

Numerous *in vivo* developmental toxicity studies have been conducted in rabbits, an accepted, commonly tested species for this evaluation based on accumulated knowledge, availability, and practicality. This section discusses considerations for study designs and evaluation of endpoints important in assessing developmental toxicity.

Conduct of a preliminary, or dose range-finding, developmental study is necessary if (i) no or not sufficient data are available from other non-clinical studies to select dose levels for the pivotal study or (ii) preliminary development toxicity data from two

species will be used to support inclusion of women of child-bearing potential using adequate birth control into a clinical trial of short duration. In the absence of prior data in rabbits, it is prudent to first conduct a tolerability study in a few non-pregnant rabbits, using clinical signs and food consumption as indicators of tolerance. An up-down scheme can be used wherein a leader dose is evaluated to ensure tolerance, followed by a higher dose or a lower dose, depending upon initial results. This approach minimizes the numbers of animals tested and precludes testing too high of a dose.

In a preliminary developmental study, seven or eight presumed pregnant animals/group are dosed and evaluated to achieve the recommended minimum six pregnant rabbits/group. Duration of dosing varies across laboratories ranging from GD 6 or 7 through 18, 19, or 20 to encompass the period from implantation to closure of the hard palate. Initiation and completion of implantation has been shown to range from GD 6.5 to 9 in NZW, Japanese White, and Harlan Porcellus Dutch rabbits (Garside et al., 1996; Nishimura, 2001; Sivaraman et al., 2008), and closure of the hard palate is complete by GD 19 with soft palate closure also complete in many fetuses (Sivaraman et al., 2008). Dosing may extend to GD 28 to ensure inclusion of organogenesis of genitalia (Wise et al., 2009). Dosing over the entire gestational period, GD 0 through 29, is acceptable under the EPA OPPTS 870.3700 guideline (1998). Evaluations are the same as for a pivotal study with the exception that maternal body weight and food consumption may be obtained daily, fetal skeletal examinations are not conducted, and developmental toxicity is assessed based on fetal body weight, numbers of resorptions, and fetal external and visceral examinations. Fetal morphology may not be evaluated in groups where unexpected, severe maternal toxicity occurred in the study, particularly if this leads to death, early euthanasia, or maternal body weight loss lasting more than a couple of days. In this scenario, embryo-fetal findings may be confounded by excessive maternal toxicity, and the dose level that produced the severe toxicity would not be tested in the definitive study.

For the pivotal study, dose levels are selected to evaluate a dose-response. The numbers of presumed pregnant animals assigned to each group should ensure evaluation of 16–20 litters/group. Average litter sizes range from 6.5–8.5 (Wise et al., 2009), although larger litters occur. Studies with one control and three drug-treated groups are typical, with initiation of dosing staggered across groups to control the number of cesarean sections and same-day fetal evaluations. Dosing and study termination are as described above. All animals are observed for mortality and clinical signs. Maternal body weights should be obtained on GD 0 (day of observed mating or artificial insemination) and

every 2 or 3 days to monitor health and adjust the dose. A final body weight at the time of the cesarean section is necessary to calculate adjusted (corrected) maternal body weight (maternal body weight minus gravid uterine weight). Food consumption generally is recorded weekly (four times) by measuring food consumed over a 24-hour period or multiple days and then calculating grams consumed per day for each pregnant female. Optional parameters are maternal clinical pathology, toxicokinetics, and organ weights and embryo-fetal toxicokinetics. Some laboratories add a subgroup of animals to obtain blood samples; however, techniques such as dried blood spot on paper, which requires only 20 µl blood, may eliminate use of additional animals in the future (Wise et al., 2009).

The focus of the cesarean section is to conduct a gross examination of the maternal thoracic and abdominal organs and initiate embryo-fetal evaluations. The gravid uterus is removed, weighed, and opened. The number of corpora lutea, early and late resorptions, live and dead fetuses, fetal sex and weights, and placental observations are recorded. Fetuses are individually identified so all findings ascertained in each fetus by different techniques (e.g., body weight, external, visceral, and skeletal examinations) can be correlated to detect patterns of anomalies. Methodology for fetal evaluations has been reviewed (Christian, 2008; Wise et al., 2009). Each live fetus is maintained in a warm environment during the time, weight, sex, and external observations are recorded, followed by humane euthanasia. Visceral examinations are conducted in each fetus on the day of cesarean sectioning using a free-hand technique, with special attention to the head and heart to ensure evaluation of the brain, hard palate, and cardiac ventricular septum. Skeletal examinations require decalcification and application of stain, alizarin red for bone and, in the case of double staining, alcian blue for cartilage. An alternative to staining, X-ray micro-computed tomography (micro-CT), has been shown to produce high-resolution, 3D images of skeletal structures (Guldberg et al., 2004; Winkelmann and Wise, 2009; Wise and Winkelmann, 2009; Wise et al., 2010). Some attributes of micro-CT are reduction in time and hazardous wastes associated with staining. Regardless of the technique, evaluations of low- and mid-dose group fetuses may not be necessary if there are no relevant differences between the control and high-dose groups.

Efforts to harmonize terminology for fetal anomalies have been underway since the 1980s. The second revision (update to the 1997 version) of Internationally Harmonized Terminology of Developmental Abnormalities (Makris et al., 2009) addressing findings in mice, rats, and rabbits is available on-line at <http://www.devtox.org>. The document's focus is to provide flexibility in application of terminology balanced with

consistency in the approach to describe, rather than interpret or diagnose, fetal observations. The lists of fetal observations are organized as external, visceral, and skeletal abnormalities with the finding designated as a structural or ossification term. Categorization of observations as malformations, variations, or incomplete or delayed skeletal ossification is left to the discretion of each testing facility. Typically, malformations are a permanent structural change likely to adversely affect survival or health of the animal and variations are changes unlikely to adversely affect survival or health of the animal (Wise et al., 2009). Incomplete ossification is a partial ossification, typically assessed by reduced alizarin red uptake at a given site compared with concurrent controls at the same site, and does not imply any change to the bone precursor. Makris et al. (2009) also discussed use of descriptive (e.g., long/large, short/small) terms, alternative terms, combined terms and syndromes, and maternal–fetal anomalies frequently observed for amniotic fluid, umbilical cord, and placenta.

Pre- and Postnatal Development

Assessment of effects on pre- and postnatal development examines fetal development, maternal parturition and lactation, and offspring development and maturity. This study, also referred to as a Segment III study, encompasses ICH stages D through F: closure of the hard palate to the end of pregnancy (adult female reproductive functions, fetal development and growth, and organ development and growth), birth to weaning (adult female reproductive functions, neonate adaptation to extrauterine life, and preweaning development and growth), and weaning to sexual maturity (postweaning development and growth, adaption to independent life, and attainment of full sexual function).

Rabbits have not been considered an appropriate species for this type of study based on their tendency for maternal rejection of neonates and lack of an established behavioral testing battery (Bailey et al., 2009). However, the Segment III study can be modified to ensure evaluation of appropriate endpoints in this species as done by Teo et al. (2004b) in a pre-postnatal assessment of thalidomide following a design similar to that outlined in ICH S5(R2) with the exception that behavioral testing was not conducted in offspring of treated does. Briefly, four groups of rabbits (25 time-mated first generation (F_0) rabbits/group plus an additional six rabbits per group for assessment of concentrations of drug in plasma and milk) were given up to 500 mg/kg of thalidomide, 15 times the average human exposure, via oral gavage from GD 19 through lactation day 28. The F_0 rabbits were allowed to litter, and the offspring (F_1 generation) observed through sexual maturity at which time they were mated (12/sex/group) and cesarean sections conducted on GD 29 to allow external evaluation of

the second-generation (F_2) fetuses. Key findings in this study were increased abortion, changes in some natural delivery and litter parameters (e.g., increased numbers of does with stillborn pups, decreased pup survival on postnatal days 1–4), and limb splay in F_1 -generation pups. The ability of the F_1 generation to reproduce was unaffected by maternal (F_0) administration of thalidomide; and no external observations were seen in F_1 - or F_2 -generation offspring.

Vaccines

Vaccines encompass a range of biological products designed for prophylaxis or treatment of infectious disease, chronic viral disease, cancer, allergy, contraception, addiction, obesity, AD, and bioterrorism. Categories of vaccines include live attenuated or whole killed microorganisms that introduce the pathogen to elicit an immune response, protein subunit vaccines containing purified antigens, and DNA vaccines introducing genes coding for antigens into the hosts' cells (Ramachandra, 2009), vaccines deliver or generate antigens that confer protective (active) immunity by stimulating the immune system to produce antibodies or B cells (humoral immunity) or T cells (cell-mediated immunity). Adjuvants may be added to or used in conjunction with vaccine antigens, particularly with subunit vaccines, to augment or potentiate the specific immune response to the antigen.

Vaccines are given to large numbers of healthy people, including women of child-bearing potential, pregnant women, and children, typically as a limited number of doses separated by months or years. Regulatory and safety issues related to vaccine development, safety testing, and consistency in product regulation have been reviewed by Verdier (2002, 2005), Brennan and Dougan (2005), Ramachandra (2009), and Klinman et al. (2010). Numerous regulatory guidelines either address specific categories of vaccines or are general in nature. Guidance documents have been issued in Europe by the World Health Organization (WHO; <http://www.who.int/en>), European Medicines Agency (EMA; <http://www.ema.europa.eu/ema>), specifically the Committee for Medicinal Products for Human Use (CHMP) and its Vaccine Expert Group; and in the US by the FDA Center for Biologics Evaluation and Research (CBER; <http://www.fda.gov/BiologicsBloodVaccines/default.htm>), specifically the Office of Vaccines Research and Review (OVR) organization.

Non-clinical vaccine studies characterize the nature and duration of the immune response by evaluating local reactogenicity (e.g., irritation, granuloma, abscess, necrosis, and regional lymphadenopathy) and systemic changes (e.g., anaphylaxis, pyrogenicity, organ toxicity, and immune-mediated toxicity, teratology, and

carcinogenicity). Criteria for selecting the appropriate test species include (i) sensitivity to the pathogen, (ii) induction of antibodies and development of an immune response similar to that expected in humans, (iii) ability to develop exacerbation reactions, and (iv) ability to assess local and systemic responses. Rabbits are an accepted species for evaluating vaccines, particularly those designed to stimulate antibody responses, because most human vaccines are immunogenic in this species, a full human dose can be easily administered by a variety of routes, and a large body of background data exists (Brennan and Dougan, 2005; FDA, 2006; Klinman et al., 2010; Verdier et al., 2003). Rabbits are suitable for assessing reproductive toxicity of vaccines because, as with humans, most of the antibody is transferred prenatally versus rodents in which most antibody is transferred postnatally in milk (Brennan and Dougan, 2005; Martin et al., 2009; Verdier et al., 2003). Rabbits are also used to demonstrate drug efficacy as with evaluation of different amounts of the antigen of pertussis whole-cell vaccines because the weight and sensitivity of rabbits to endotoxins are comparable with that of infants (Verwer et al., 2009) and as an inhalation model for testing vaccines against *Bacillus anthracis* (Phipps et al., 2004).

Non-clinical safety study designs should be prepared following appropriate guidance, modified on a case-by-case basis, and reviewed by the applicable regulatory group (e.g., CBER) prior to initiation of animal studies. In general, a non-clinical repeat-dose vaccine study should mimic the clinical plan with respect to dose level, dosing regimen, route of administration, and study duration. Where possible, one full human dose (i.e., the highest dose planned for human use) or the most immunogenic dose level, if this differs from the human dose, should be administered, not scaled to body weight, using the same or comparable lot as intended for use in the clinical trial. The number of doses should be one more ($n + 1$) than the clinical dose schedule. Additional groups could include a placebo control; each valence in the case of multivalent vaccines; and, if the vaccine is formulated with adjuvant, a group that receives adjuvant alone. Three to five rabbits are the minimum number tested per group. Study duration includes time between vaccinations to allow a host immune response to develop (e.g., 2 weeks between doses), and effects of short-term and persistent toxicity should be evaluated in separate cohorts 2–3 days and 2–3 weeks after the final inoculation, respectively. Assessments include routine in-life analysis (e.g., clinical observations, body weight, and food consumption), local reactogenicity (e.g., visual inspection of injection sites or mucosa following oral or nasal administration), impairment of limb use after each injection, immunotoxicology via clinical pathology, immunology

assessments after the first vaccination and at scheduled necropsies, and pharmacokinetics. Postmortem evaluations include histopathology of injection sites and a comprehensive gross and microscopic evaluation of immune organs (e.g., thymus, spleen, and lymph nodes) or, for novel adjuvants, a full tissue list. On a case-by-case basis, it may be necessary to evaluate other immunological parameters such as anti-drug antibodies, cytokines, and cytotoxic T cells. For parenteral vaccines, separate studies in rabbits may be required to examine the presence and persistence of the vaccine antigen or adjuvant at the injection site and draining lymph nodes (Brennan and Dougan, 2005).

Developmental toxicity studies are conducted for many vaccines because prophylactic and therapeutic vaccination programs often include women of child-bearing potential and pregnant women leading to concern for immunomodulatory effects on gestation and development of the fetal immune system (Brennan and Dougan, 2005; Martin et al., 2009). Additionally, use of some vaccines has increased as with the US military anthrax vaccination program which has widened the scope of population receiving BioThrax® to include women of child-bearing age and, inadvertently, pregnant women (Franco et al., 2009). As described in the 2006 FDA guidance for Considerations for Developmental Toxicity Studies for Prevention and Therapeutic Vaccines for Infectious Disease Indications, non-clinical vaccine developmental toxicity studies evaluate effects induced or manifested in the embryo-fetal and postnatal periods. The guidance does not address male reproductive toxicity or male and female fertility, and acknowledges there are times when developmental toxicity studies are not required, such as when a vaccine in development is similar to or of the same product class as an investigational or already licensed product or when tests were previously conducted on individual components in a combination vaccines. When developmental toxicity studies are required, one species, including the rabbit, is acceptable. No suitable species for assessment of appropriate endpoints shows an immunogenic response, studies would be conducted in a non-reactive species. The 2006 FDA guidance on developmental toxicity studies of vaccines refers to the ICH S5(R2) guideline as a point of reference with additional, relevant features added (e.g., the vaccine-induced immune response). Information about the onset and duration of antibody response can be obtained from literature and previously conducted single- and repeat-dose studies in non-pregnant animals. If antibody formation is expected to differ in pregnant versus non-pregnant females, a pilot study in a small number of pregnant animals may be necessary to evaluate antibody formation in relation to exposure and placental antibody transfer to the fetus.

As in a non-clinical repeat-dose study, vaccine developmental toxicity studies assesses a single full human dose or the most immunogenic dose level, not scaled to body weight, administered by the intended clinical route using the same or comparable lot as intended for use in the clinical trial. Additional groups are added as necessary (e.g., placebo and/or adjuvant controls). Forty animals are recommended for each group allocating 20 animals each to cesarean-section and littering subgroups. Additional animals may be necessary if the study design includes dosing prior to implantation or if effects on pregnancy are anticipated. The dosing period should provide exposure to the antigen during organogenesis and at later stages of pregnancy (cesarean subgroup) with growth and development observed in offspring until weaning (littering subgroup). A longer (e.g., 6–8-week) postnatal assessment period may be necessary to evaluate potential long-lasting or permanent changes. Daily dosing may result in immune tolerance; the exact number of doses administered depends on the onset and duration of the expected response. Based on the short, 29-day gestational period of rabbits, it may be necessary to administer priming doses to the doe prior to conception to elicit a peak antibody response during the period of organogenesis. Additional doses may be necessary (e.g., around the time of implantation) to maintain high levels of antibody throughout gestation. Evaluations include maternal, cesarean-section, fetal, and postnatal assessments, plus endpoints demonstrating an immune response in the pregnant female and verification of exposure of the fetuses to maternal antibodies. This latter can be accomplished by collecting serum from maternal animals prior to administration of the vaccine and on the day of the cesarean sectioning to assess development of antibodies. Umbilical cord blood samples are recommended to assess placental transfer of maternal antibodies. On a case-by-case basis, it may be necessary to evaluate other immunological parameters such as anti-drug antibodies, cytokines, and cytotoxic T cells.

Rabbits are also used to support release of vaccine and adjuvanted vaccine formulations through tests contributing to characterization of each lot's potency, pyrogenicity, immunogenicity, and real-time stability (FDA 21CFR610). Dose titration studies are used to confirm the immune response is proportional to the antigen delivered at all doses and to determine the optimal vaccine dose conferring 100% protection. Stability tests consider antibody generation and toxin neutralization. In this type of study, rabbits are inoculated with production vaccine or reference vaccine and serum samples evaluated by enzyme-linked immunosorbent assay (ELISA) and compared for their ability to generate protective antibodies and for toxin neutralization. The

number of rabbits required for release testing depends upon the scope of the project.

Biological Reactivity Tests

Biological reactivity tests evaluate responses to elastomers, plastics, and other polymeric material with direct or indirect contact, or by injection of specific extracts prepared from the material under the skin (United States Pharmacopeia (USP) <88>, 2009). Typically, the systemic injection test is conducted in albino mice, and the intracutaneous and implantation tests are conducted in healthy, young albino rabbit. General procedures in studies in rabbits include clipping fur from the testing site avoiding mechanical injury or trauma, removing loose hairs by vacuum, applying, injecting, or implanting material, and scoring observations at prescribed times according to a weighted scale from 0 (none) to 4 (severe) as described by Draize et al. (1944).

Intracutaneous Test

The USP intracutaneous test (USP <88>, 2009) evaluates local responses to extracts of materials following intracutaneous injection into thin-skinned, albino rabbits. Test material (Samples) and Blanks are diluted in a prescribed manner. On the day of study, fur is clipped closely on both sides of the spinal column and each Sample tested in two rabbits with intracutaneous injection of a Blank on the opposite side of the spinal cord. If results will not be affected, more than one extract from a material can be tested in each rabbit. Up to five test sites/rabbit can be tested, dosing 200 µl/site. Animals are observed 24, 48, and 72 hours after injection. The injection sites should not be touched between observation periods except to discriminate between edema and oil residue. Fur can be re-clipped and test sites lightly swabbed with diluted alcohol to facilitate the examination. Each injection site is examined and scored for evidence of tissue reactions including erythema and eschar formation, edema, and necrosis. After the 72-hour observation, all scores for each Sample and Blank are separately totalled and divided by 12 (2 animals × 3 scoring periods × 2 scoring categories) to determine the overall mean score for each Sample versus each corresponding Blank. The test requirements are met if the difference is 1.0 or less. The test is repeated in three additional animals if the average reaction to the Sample is questionably greater than the average reaction to the Blank at any scoring interval.

Implantation Test

Details of various implantation tests used to evaluate local and systemic responses to plastics and other

polymeric materials in direct contact with living tissue are found in the USP (USP <88>, 2009) and ISO 10993, Part 6 (2007), and have been reviewed by Gad and McCord (2008b).

The USP implantation test is conducted in two rabbits with paravertebral muscles sufficiently large enough to allow implantation. The fur is clipped up to 20 hours prior to the test, and the rabbits anesthetized to prevent muscle movement, including twitching. Proper preparation and placement of the implant strips are critical to the study design. In each rabbit, four Sample strips are implanted on one side of the spine 2.5–5 cm from the midline, parallel to the spinal column, and approximately 2.5 cm apart from each other. Two Blanks are implanted in a similar manner in the opposite paravertebral muscle of each animal. A duplicate strip is implanted at another site if excessive bleeding is observed. Animals are euthanized after 120 hours, and the tissue around the implants grossly examined and scored for hemorrhage, necrosis, discoloration, infections, and encapsulation, the width of which is scored on a scale from 0 (none) to 4 (greater than 2 mm). Histopathology, while not required, is generally conducted. Test requirements are met if the difference between average scores for the Sample and Blank sites does not exceed 1.0, or if the difference between Sample and Blank mean scores for more than one of the four implant sites does not exceed 1.0 for any implanted animal.

The 2007 ISO 10993-6 standard applies to materials that are solid and non-biodegradable; degradable and/or resorbable; non-solid, such as porous materials, liquids, pastes, and particulates. This ISO standard may be applied to medical devices intended for topical use in clinical conditions where the surface or lining may have been breached, in order to evaluate local tissue response. Implantation tests evaluate local short-term (up to 12 weeks) or long-term (up to 104 weeks) effects in the selected species; however, rabbits are generally not tested beyond 52 weeks. The ISO standard contains details applicable to each type of implantation test. In general, the test Sample is implanted into the tissues most relevant to the intended clinical use of the material (e.g., dorsal subcutaneous tissue, paravertebral muscle, or bone). The test period and interim necropsies are selected to evaluate the steady-state biological response in the selected implantation site and based on the nature of the test material (e.g., degradable/resorbable or non-resorbable solid). The biological response is determined via macroscopic and histopathological responses as a function of time comparing responses of the test Sample to those obtained at the control sample or sham-operated sites. A description of the degree of degradation, including material characteristics (e.g., free particles, fiber

formation, amorphous gel, and crystallinity) is provided for degradable materials.

Local Tolerance

These short-term studies evaluate effects of a test substance (e.g., drug, chemicals, or medical devices) in the immediate region of tissue contact. In general, the objectives of the tests are to determine whether the test substance causes irritation (i.e., changes shown to be fully reversible during the defined time period) or corrosion (i.e., tissue damage not fully reversible during the defined time period). Comprehensive discussion and details of local tissue tolerance testing, including differences across regulatory agencies, have been reviewed by Salamon et al. (2007), Blazka and Hayes (2008), and Gad and McCord (2008c). While this test can be conducted in rats or guinea pigs, healthy, young adult albino rabbits from a single strain, generally weighing not less than 2 kg, are preferred based on their size, ease of handling, skin permeability, and extensive data base.

The OECD and EPA OPPTS guidelines employ a sequential testing strategy. For example, no testing is required for material (i) with an extremely acid or basic pH, (ii) an acid/alkaline reserve (i.e., buffering capacity) that suggests corrosivity, or (iii) deemed corrosive or a severe irritant based on prior information. When tests are conducted, a set amount of test substance or a known, moderately toxic dose determined based on a review of all available information is evaluated in a step-wise manner. Initially, one animal is tested and further testing discontinued if a corrosive or severely irritating effect is observed. A negative or irritant response is confirmed in up to two animals, tested simultaneously or one at a time based on the results of the initial test. Additional animals may be needed to confirm weak or moderate irritant responses. Control animals usually are not necessary for tissue tolerance testing; opposite or adjacent tissues of each animal serve as the control. The duration of the study is sufficient to evaluate the reversibility or irreversibility of effects. Effects of the test substance are evaluated at specific intervals and scored according to a weighted scale (e.g., 0 (none) to 4 (severe)) based on set criteria. As reviewed by Hackett and McDonald (1996), the concept of testing a specified amount of material and use of a weighted scale was proposed in the 1940s by Freidenwald et al., Carpenter and Smyth, and Draize et al. and modified over time (e.g., Draize, 1959) to a scoring system that accounted for ocular and dermal irritation and production of reversible inflammatory changes or irreversible tissue damage following application of the test material. The Hackett and McDonald scoring system, a modification

of the McDonald-Shadduck system, was developed for recording findings of slit lamp (biomicroscopic) examinations in studies evaluating topical ophthalmic medications because the Draize Test was considered poorly suited for evaluating medications and devices intended for use in the eye (Hackett and McDonald, 1996; Munger, 2002). Regardless of the scoring system used, personnel performing the observations need to be adequately trained in the scoring system to support appropriate interpretation of observations and promote harmonization across testing laboratories. Also, individual scores do not represent absolute standards for irritant properties of a test substance. The scores should be viewed as reference values evaluated in combination with all other observations from the study, such as the nature and severity of lesions and reversibility or lack of reversibility.

Ocular Irritation and Toxicity

Ocular irritation testing is required by regulatory agencies for hazard assessment of test substances (e.g., drugs, chemicals, medical devices, and cosmetics) applied into or around the eye or which may come in contact with the eye from the environment or in the workplace. Results from ocular irritation tests contribute to hazard classification in accordance with various international regulatory schemes (reviewed by Blazka and Hayes, 2008). Non-clinical test guidelines vary with respect to the number of animals tested, the observation times, and whether or not local anesthetic and irrigation are used (Blazka and Hayes, 2008; Gad and McCord, 2008c). For example, ocular testing of cosmetics that follow Draize et al. (1944) use six to nine rabbits observed for 72 hours after application of the test material, with some tests lasting 7–18 days to assess reversibility (Nigam, 2009) whereas OECD and EPA OPPTS test paradigms use three rabbits followed by observations through 72 hours and out to 21 days to assess reversibility.

The OECD 405 guideline (2002) is commonly used to evaluate drugs, chemicals, and medical devices. Testing for pump sprays and aerosols, not detailed in this section, are described in this guideline. Liquids are tested at a dose of 0.1 ml. Solids, pastes, and particulate substances are tested at a volume of 0.1 ml or a weight of not more than 100 mg with test material ground to a fine dust and the volume of the solid measured after gentle compacting. The test substance is placed into the conjunctival sac of one eye of each animal after gently pulling the lower lid away from the eyeball, instilling the test material, holding the lids together gently for 1 second to prevent loss of material, and evaluating the absence or presence of lesions at specific intervals up to 21 days to assess the reversibility or irreversibility of effects. A local anesthetic may be used prior to

instillation of the test substance; the control eye is similarly treated. Irrigation (washing) of the eyes should not be done for at least 24 hours following instillation of the test substance. Exceptions are solids where the eye can be rinsed 1 hour post-instillation if material has not been removed by physiological means and in case of immediate corrosive or irritating effects. If scientifically justified, the influence of washing is evaluated in two rabbits. Eyes are examined 1, 24, 48, and 72 hours after instillation and 7, 14, and/or 21 days in order to determine reversibility or irreversibility. Ocular reactions are scored according to a weighted scale for changes in the cornea (opacity on a scale from 0 to 4), iris (hemorrhage/gross destruction/no reaction to light on a scale from 0 to 2), and conjunctiva (redness on a scale from 0 to 3), and for chemosis (conjunctival swelling on a scale from 0 to 4). Other effects in the eye and adverse systemic effects are described to provide a complete evaluation. Examination of reactions can be facilitated by use of a binocular loupe, hand slit-lamp, or other suitable device. After recording the observations at 24 hours, the eyes may be further examined with the aid of fluorescein, a stain that highlights corneal changes. The test is terminated sooner than 21 days if animals have no lesions, show continuing signs of severe pain or distress without expectation of reversibility, or if reversibility is observed before 21 days.

A 21-day irritancy test in rabbits is conducted to evaluate potential local irritancy and systemic effects of contact lenses and disinfecting and cleansing solutions (reviewed by Gad and McCord, 2008d). Sixteen rabbits are allocated to two groups to evaluate effects of test and control lenses, or lenses soaked in test and control disinfectants. The lenses are inserted into the right eyes up to 8 hours daily for 21 days. Eyes are examined prior to testing, before each daily application and 24 hours after the last application. Responses are graded on a weighted scale for changes in the cornea (opacity), iris (congestion), and conjunctiva (redness, chemosis, discharge).

Although not discussed in detail in this section, rabbits are commonly used to test novel delivery techniques for drugs in development or medications intended for use in the eye (e.g., treatments for glaucoma) because the rabbit eye is large enough to perform accurate ocular injections or delivery by other methods (Short, 2008). Non-pigmented rabbits (e.g., NZW) are acceptable when combined with studies in a pigmented species (dog, primate). Pigmented rabbits such as Dutch Belted or New Zealand Red are recommended, especially by European regulatory agencies, if the drug binds to ocular melanin. Repeat topical dose application studies may be necessary with ocular tolerance studies conducted first in one to three rabbits.

A basic approach is to start with a single application (20–30 µl) with hourly observations and weighted scoring, followed by an increase in concentration or frequency over several days and evaluation by slit-lamp biomicroscopy. Typical parameters in a pivotal study include ophthalmic examinations, including biomicroscopy to examine the anterior segment, indirect ophthalmoscopy to examine the posterior segment, tonometry to measure intraocular pressure measurement, corneal thickness measurement, electroretinograms (ERG) if the drug reaches the retina, and histopathology. Systemic, not ocular, toxicokinetics is determined. Specialized procedures including fluorescein angiography, ocular computed tomography, or vitreal pharmacokinetics may be required.

Dermal Irritation and Toxicity

Dermal irritation tests evaluate local tissue reactions initiated or aggravated by substances in contact with skin. The OECD 404 (2002), OECD Draft 434 (2004), EPA OPPTS 870.1200 (1998), and EPA OPPTS 870.2500 (1998) guidelines apply to drugs and chemicals. Per EPA OPPTS 870.2500, data on primary dermal irritation are required to support the registration of each manufacturing-use product and end-use product. For medical devices, testing is in accordance with the regulations of the Consumer Product Safety Commission (<http://www.cpsc.gov>) or ISO 10933 – 10 (2002) and American Society for Testing and Materials (ASTM; <http://www.astm.org>) standards to evaluate potential dermal irritation to intact and abraded skin (to simulate wound tissue) of rabbits.

Several procedures are common to the guidelines. Fur is removed from the dorsal area or the trunk approximately 24 hours prior to administration of the test substance. Unless specified otherwise by the specific test, rabbits with abraded skin are not used as this alters permeability. The test substance is applied uniformly to a defined area of skin covering as much area as possible with a thin uniform film. Solids may be pulverized if appropriate, and moistened with the smallest amount of water or, where necessary, a suitable vehicle to ensure good contact with the skin. When a vehicle is used, the influence of the vehicle on penetration of skin by the test substance should be taken into account. Test substances are held in contact with the skin with a porous gauze dressing and non-irritating tape throughout the exposure period. As directed by the specific guideline, the test site may be further covered in a suitable manner to retain the gauze dressing. A collar may be used to prevent ingestion of the test substance, but complete immobilization is not recommended. At the end of the exposure period, residual test substance should be removed, using water or an appropriate solvent.

Acute dermal toxicity studies assess short-term, 24-hour exposure to a solid or liquid test substance. The OECD Draft Guideline 434 (2004) proposes a limit test design to provide information on hazardous properties and rank and classify substances in accordance with the Globally Harmonised System. Under this guideline, one or more fixed, moderately toxic doses ranging from 50–2000 mg/kg is tested in one sex, usually females. Higher doses (e.g., 2000–5000 mg/kg) may be evaluated if the results are directly relevant for protecting human or animal health or the environment or if prior information indicates the test substance is not likely toxic. A stepwise testing paradigm includes an initial, sighting test of one dose followed, if necessary, by a main, pivotal study. A lethal dose in the sighting study is not retested in the main study. Based on results after the first dose in the main study, the test may terminate and the appropriate hazard classification category may be assigned or a higher or lower fixed dose tested. In the main study, each dose level is tested in five animals of one sex; doses can include the one tested in the sighting study. Animals are observed immediately after dosing (at least once during the first 30 minutes), periodically during the first 24 hours with special attention given during the first 4 hours, and daily thereafter for a total of 14 days. Administrations are separated by 3 or 4 days to observe delayed toxicity. Observations should characterize the nature, time of onset, and duration of clinical signs. Other endpoints include body weights and a gross necropsy in all animals. Microscopic examination of organs showing evidence of gross pathology in animals surviving 24 or more hours after the initial dosing may also be conducted.

The primary dermal irritation test per EPA OPPTS 870.2500 (1998) and OECD No. 404 (2002) also evaluates the potential for a test substance to produce irritant and corrosive effects, reversible and irreversible inflammatory changes, respectively, on mammalian skin. This test typically is conducted in three or four rabbits in two phases using a decision-tree approach to guide the next step. Initially, up to three test patches are sequentially applied to one rabbit. The first patch is removed after 3 minutes. If no serious skin reaction is observed, a second patch is applied and removed after 1 hour. If the observations indicate exposure can be humanely extended, a third patch is applied and removed after 4 hours. The test terminates immediately if corrosive effects are observed after any of the three sequential exposures. In the absence of a corrosive effect after removal of the last patch, the animal is observed for 14 days unless corrosion develops at an earlier time point. If the test substance is not expected to produce corrosion but may be irritating, a single patch is applied to one animal for 4 hours. If a corrosive effect is not observed in the initial test, the irritant or negative

response is confirmed in up to two additional animals, each with one patch, for an exposure period of 4 hours. If an irritant effect is observed in the initial test, the confirmatory test may be conducted in a sequential manner, or by exposing two additional animals simultaneously. In the exceptional case, in which the initial test is not conducted, two or three animals may be treated with a single patch, which is removed after 4 hours. When two animals are used, no further testing is needed if both exhibit the same response. Otherwise, the third animal is tested. Equivocal responses may need to be evaluated using additional animals. In each test, the material is administered as an undiluted 0.5ml liquid or as a 0.5-g solid or paste applied to a small area (approximately 6cm²) of skin which is covered with a gauze patch. If direct application is not possible (e.g., liquids or some pastes), the test substance is applied to the gauze patch which is then applied to the skin, ensuring good contact and uniform distribution of the substance on the skin. At the end of the exposure period, normally 4 hours, residual test substance is removed, where practicable, using water or an appropriate solvent without altering the existing response or the integrity of the epidermis. All animals are examined 30–60 minutes and 24, 48, and 72 hours after patch removal, and dermal responses for erythema and eschar formation and edema formation are scored according to a weighted scale from none (0) to maximum (4). In addition, local toxic effects, such as defatting of the skin, and systemic effects (e.g., effects on clinical signs and body weight) are described and recorded. Histopathological examination should be considered to clarify equivocal responses. The study duration is sufficient to evaluate fully the reversibility of the effects observed, typically up to 14 days after removal of the patches. The test is terminated sooner if animals show continuing signs of severe pain or distress or if reversibility is seen before 14 days.

Assessment of skin irritation resulting from chemicals released from medical devices is detailed in ISO 10933 – 10 (2002). Single or repeated exposures (up to 21 days) are tested in healthy young adult albino rabbits of either sex. One animal is tested first if irritation is anticipated. As with the primary dermal irritation test, unless a well-defined positive response is observed, testing is repeated in a minimum of two additional animals. If no response is expected, testing is conducted in three animals. Additional rabbits are tested based on an equivocal response in the three rabbits. Unlike the primary dermal irritation test, negative and positive control groups are included to demonstrate sensitivity of the assay, and a maximum of two test materials may be applied together with the control materials if the same vehicle is used. In preparation for testing, fur on the animals' backs is clipped a sufficient distance (approximately 10cm × 15cm) on both sides of the spine for

application and observation of all test sites. Depilatories may be used if the process has been validated at the testing facility. Four patches are applied in pairs (one control and one test substance) on each side of the spine. Solids, powders, or liquids are applied directly to the skin, and application sites covered with a non-occlusive dressing (e.g., absorbent gauze patch). Extracts and extract vehicles are applied to absorbent gauze patches. In all cases, the application sites are wrapped with a semi-occlusive or occlusive bandage. After a minimum of 4 hours, the dressings are removed and the site positions marked with permanent ink. Tests are scored at 1, 24, 48, and 72 hours following removal of patches. Extended observations for reversibility or irreversibility may be necessary for up to 14 days. Dermal responses include erythema and eschar formation and edema formation graded on a weighted scale. The means of the single- and repeat-dose dermal response scores are correlated with a response category to derive a Primary Irritation Index and Cumulative Irritation Index, respectively.

Mucosal Irritation

Rabbits are used to test for potential irritation of mucosal tissues including vaginal, rectal, and penile (ISO 10993-10:2002). No tests are conducted with material shown to be a skin or eye irritant or with an extremely acid or basic pH. When conducted, tests use six rabbits: three controls and three treated. Additional testing may be necessary if the initial test is equivocal. Animals are evaluated for discharge, swelling, and other evidence of infection, irritation, and injury prior to each treatment. The test solution or suspension, typically 1.0ml, is gradually introduced into the specified orifice or onto a 1-cm area of the penis, sheath retracted. For vaginal and rectal tests, the solution or suspension is introduced into the orifice via a soft catheter or blunt-tipped cannula attached to a syringe moistened with the control or a suitable lubricant; an inert bung may be installed immediately after introduction of the test material. Animals should be prevented from licking the test site and confounding the primary irritation by secondary factors.

The period of exposure typically mimics the projected human duration. Test and control materials are introduced at 24-hour intervals for a minimum of five consecutive days in the vaginal and rectal irritation tests, and every hour for 4 hours in the penile irritation test. Tissues and surrounding areas are evaluated for appearance and signs of discharge, erythema, eschar, edema, and irritation 1 hour (penis) or 24 hours (vagina, rectum) after the initial application and immediately prior to each treatment. In the acute penile irritation test, observations also occur 1, 24, and 48 hours after the last application. Twenty-four hours after the last dose,

animals are euthanized and applicable tissues examined macroscopically. Histologic evaluations are conducted and irritant effects graded by a pathologist for evidence of changes in epithelium, leukocyte infiltration, vascular congestion, and edema. The microscopic grades for all animals in the test group are averaged to derive an Irritation Index ranging from none to severe.

Parenteral Irritation

Parenteral routes are those by which material can be injected or infused. Safety concerns for parenterally administered drugs and chemicals and, in some cases, medical devices, include tissue and muscle irritation, pyrogenicity, blood compatibility, and sterility. Per the 2010 ICH M3(R2) guidance, local tolerance can be confirmed by clinical signs and macroscopic and histopathologic evaluations of injection sites in animals tested in the toxicology studies. However, a single-dose local tolerance study in a single species is considered appropriate to support limited human administration by non-therapeutic routes (e.g., a single IV dose to assist in the determination of absolute bioavailability of an oral drug). The formulation delivered for local tolerance need not be identical but should be similar to the clinical formulation.

As reviewed by Gad and McCord (2008c), three tests conducted in male albino rabbits evaluate parenteral irritation or tolerance to medical devices. In the acute IM irritation study, test material and vehicle are injected once into the left and right vastus lateralis muscle, respectively, of nine male rabbits (1.0ml/site). Euthanasia and evaluation of lesions are performed in three rabbits each at 24, 48, and 72 hours post-treatment. The left and right vastus lateralis muscles from each rabbit are excised, and lesions scored for muscle irritation on a numerical scale from 0 to 5 in accordance with Shintani et al. (1967). The average score for all nine rabbits is calculated and an irritancy category determined over a range of none (0) to severe (5).

Acute vascular irritation studies are conducted in six male rabbits per study. Test material and vehicle are injected into the left and right veins, respectively, of the vastus lateralis muscle at 1.0ml when testing via the IM route (four rabbits), the cervicodorsal subcutis at 1.0ml when testing via the SC route (same four rabbits), and the auricular vein at 0.5ml when testing via the IV route (two other rabbits). Gross observations of injection sites are scored 24 and 72 hours post-treatment for all routes. Euthanasia and scoring of lesions occurs 24 and 72 hours post-treatment (two rabbits/time point) for the IM and SC tests and 72 hours post-treatment for the IV test. Reactions are scored over a range of none (0) to severe (5) following IM and SC administration and from none (0) to severe (3) following IV administration.

An intracutaneous irritation test evaluates local responses to extracts of a biomaterial. As in a dermal

irritation test, fur is clipped from the skin of albino rabbits on both sides of the spinal column and loose hair removed; only rabbits without evidence of trauma from the clipping or other causes are used. The test material (Sample) and control (Blank) are diluted in an appropriate vehicle. More than one extract from a given material can be given to each rabbit if it has been determined test results will not be affected. Up to five sites per animal can be injected in a grid pattern injecting the Sample and Blank into the left and right side of the spinal column, respectively, at 200µl per site. Injection sites are observed 24, 48 and 72 hours post-treatment. The skin may be swabbed lightly with diluted alcohol and the fur clipped to facilitate examination of the injection sites. Observations are scored according to weighted scale from none (0) to severe (4) for evidence of erythema and edema, and necrosis and eschar are noted, if present. The test is repeated in three additional animals if the average reaction to the Sample is questionably greater than the average reaction to the Blank at any scoring interval.

Comedogenicity Test

Comedogenicity is the ability of certain drugs or agents, such as anabolic steroids, to produce comedones (acne), dried sebum and keratin plugging sebaceous follicular openings. Comedogenicity testing in rabbit ears is considered more sensitive than human skin because agents mildly comedogenic in rabbit ears were often negative in humans (Puhvel, 1985). The test in rabbits is conducted in two stages. In the first stage, comedones are induced in the inner surface of both ears of three rabbits (e.g., 0.5–1 ml of 1% coal tar, 50% oleic acid, or 50% tetradecane). This generally takes 2 weeks followed by the second stage, which is application of the test substance to one ear daily for 2 weeks; the other ear serves as a control. At the end of the treatment period, full-thickness biopsies of the treated and control ears are examined histologically, and sections are graded for the amount of reduction of intrafollicular keratin (Kligman and Kwong, 1979; Puhvel, 1985).

Pyrogen Test

A pyrogen is a substance causing induction of a febrile response (elevation of body temperature, fever) which can be fatal in humans and animals. The causal substance is usually a bacterial endotoxin, the lipopolysaccharide complex associated with the outer membrane of Gram-negative pathogens including, but not limited to, *Escherichia coli*, *Salmonella*, and *Shigella*. Pyrogenicity is associated with microbiological contamination of parenteral products, including those that have been sterilized, biosynthetically produced materials, vaccines and adjuvants, and medical devices

introduced into the fluid path. Regulatory agencies require evaluation of these products for pyrogenic potential, either by in vitro methods or the in vivo rabbit test, as a means to limit acceptable risk of febrile reaction in humans to administration, by injection, of the specified product.

The in vitro Limulus Amebocyte Lysate (LAL) test is a clotting reaction produced by a small amount of endotoxin in aqueous extracts of circulating amebocytes of the horseshoe crab (*Limulus polyphemus*). Because the LAL test cannot detect pyrogens except endotoxin, the USP (USP <85>, 2009) only recognizes the LAL method for assaying lipopolysaccharides produced by Gram-negative micro-organisms. Other in vitro alternatives to the rabbit pyrogenicity test have been proposed (Hartung et al., 2001), and ECVAM and ICCVAM consider five in vitro methods based on cytokine release from human blood cells to be validated replacements for the evaluation of materials or products where the objective is to identify and evaluate pyrogenicity produced by Gram-negative bacterial endotoxins but, as with the LAL method, not for other pyrogens.

The in vivo pyrogenicity test is conducted in healthy, adult rabbits by evaluating the rise in rectal temperature after IV injection of a test solution (test product reconstituted, if necessary) into the ear vein (European Pharmacopeia (EP), 2009; Gad and McCord 2008c; USP <151>, 2009). The test is designed for products that can be tolerated by rabbits at a dose not to exceed 10 ml/kg injected IV for 4 minutes (EP) or 10 minutes (USP). No rabbit should be used for pyrogen testing more frequently than once every 48 hours or prior to 2 weeks following a rise in temperature of 0.6°C or more or following its having been given a test specimen judged pyrogenic. Up to 1 week ahead of the test, rabbits are conditioned to all study procedures including injection per EP, and except injection per USP. The pyrogen test is conducted in three rabbits, injecting a sterile, warmed solution that may be dissolved or diluted with acceptable liquids (e.g., sodium chloride). Temperatures are recorded at baseline (30 minutes prior to injection) and at 30-minute intervals up to 3 hours post-injection, although EP and USP differ slightly in the exact times. The UPS and EP also differ with respect to criteria for absence of pyrogenicity. The test material is not pyrogenic if no rabbit shows an individual rise in temperature of $\geq 0.5^\circ\text{C}$ above its respective control temperature. If any rabbit's temperature increases $\geq 0.5^\circ\text{C}$, five other rabbits are tested. Requirements for the absence of pyrogenicity are met if not more than three of eight rabbits have an individual rise in temperature of $\geq 0.5^\circ\text{C}$ and if the sum of the maximum rise in temperature of the eight rabbits does not exceed 3.3°C.

Per the EP, the test material passes if the summed response (i.e., difference between the highest

temperature 3 hours post-injection and baseline temperature for the three rabbits) does not exceed 1.15°C, and fails if the summed response exceeds 2.65°C. If the test fails, it is repeated in three additional rabbits and their response plus the responses of the first three rabbits (i.e., summed responses of the six rabbits) determines if the product passes (summed response does not exceed 2.80°C) or fails (summed response exceeds 4.30°C). Up to 12 rabbits may be tested with pass/fail criteria based on whether or not the summed temperatures are less than or greater than 6.60°C.

Other findings in the rabbit resulting from smaller injection amounts can include increased capillary permeability, increased numbers of white blood cells, hemorrhages, and changes in venous pressure. In some cases, the response to the pyrogen is a severe hemorrhagic reaction with localized necrosis, known as the Schwartzman's phenomenon or reaction. This response is demonstrated in rabbits by SC administration of a bacterial pyrogen followed 24 hours later with IV of the same pyrogen and noting if the site of the later injection turns blue at the center and red at the periphery. Pyrogen tolerance develops when the animals are given repeated injections of a pyrogen. A reduced sensitivity to the same and other pyrogens develops and the febrile response diminishes.

In some cases, a blended testing approach is recommended. For example, the US Center for Veterinary Medicine requires testing the first three batches manufactured using both the LAL and rabbit pyrogen tests to determine whether other types of pyrogenic substances are present (PPM 1240.4122, 2000). This approach takes into account the possibility that pyrogenic materials present in the product are not lipopolysaccharides. Testing the first three commercial batches demonstrates if pyrogen contamination other than lipopolysaccharides is present in the final drug product. If rabbit pyrogen testing in the first three commercial lots is negative, the LAL test can be utilized for release testing.

METABOLISM AND TOXICOKINETICS

Metabolism

The term metabolism, often used synonymously with biotransformation, describes the total fate of a drug or chemical. Rabbit metabolism, primarily studied in the latter half of the 1990s, has been summarized by Calabrese (1988) and Salamon et al. (2007).

Percutaneous absorption and distribution studies in rabbits contribute to developing topical formulations for therapeutic use (Lu et al., 1997; Wu et al., 1996). Rabbits approximate humans with respect to absorption of aspirin (Kergueris et al., 1988). The full range of

hepatic CYP450 isoenzyme activity is present in rabbits (Salamon et al., 2007), and rabbit microsomes have been shown to metabolize diverse agents including retinoids, arachidonic acid, prostaglandins, alcohols, imidazole, trichloroethylene, acetone, prazole, and isoniazid (Anderson and Henck, 1994). Rabbits and humans display N-acetyltransferase activity for isoniazid and several other arylamine drugs, including sulfapyridine, hydralazine, and procainamide, and both display genetic polymorphism with respect to the activity of this enzyme (Calabrese, 1988). In a study of arylamine carcinogens, Glowinski et al. (1978) determined that, in general, acetylation activity levels of rabbits were in the range displayed by fast and slow acetylators humans, making the rabbit a viable animal model for this pharmacogenetic phenomenon. Rabbits are similar to humans in hydroxylation of the antidepressant vinoxazine (Thomare et al., 1992). As reviewed by Calabrese (1988), hepatic aryl hydrocarbon hydroxylase activity is similar and hepatic levels of epoxide hydrolase activity is lower in rabbits compared with humans. Activity of β -glucuronidase in rabbits is slightly higher in liver, lower in kidney, and comparable in the gastrointestinal tract compared with humans (Calabrese, 1988). N-dealkylating, UDP-glucuronyltransferase, and glutathione transferase activities are variable depending upon the substrate, and N-hydroxylase activity is mediated predominantly via the polycyclic hydrocarbon-induced CYP450; and sulfate conjugation is low to medium in rabbits (Salamon et al., 2007).

Toxicity is influenced by factors other than metabolism. For example, dose-dependent disposition of prednisolone in humans is due, in part, to nonlinear serum protein binding, and the binding profile in rabbits is more similar to humans compared with rats and dogs (Rocci et al., 1980). Tesserommatis et al. (2003) investigated the binding of clonidine to rabbit liver protein in the presence and absence of the non-steroidal anti-inflammatory drugs (NSAIDs) flurbiprofen, ketoprofen, ibuprofen, and acetylsalicylic acid. The NSAIDs significantly decreased protein binding of clonidine in homogenized and intact liver slices except for ibuprofen which has a different affinity for liver protein compared to the other NSAIDs.

Metabolism in Pregnant Rabbits

During pregnancy, maternal metabolic adjustments provide an increased supply of nutrients to the fetus. Serial sampling from catheterized NZW rabbits before and during pregnancy show glucose concentration decreases and lactate concentration increases during pregnancy with no significant changes in free fatty acids and ketoacid levels (Gilbert et al., 1984a, 1984b) and the term gravid uterus is a site of high glucose consumption (Gilbert et al., 1984b). Late pregnancy is

characterized by hyperinsulinemia and euglycemia, during which time hepatic glucose production is partially suppressed and peripheral glucose utilization impaired relative to the non-pregnant state (Pere et al., 1992). Using NZW rabbits, Pere et al. investigated the influence of pregnancy on hepatic handling of nutrients after food ingestion in pregnant (GD 30) and non-pregnant rabbits implanted with catheters in the right hepatic vein, portal vein, and femoral artery. The magnitude and duration of arterial hyperglycemia and hyperinsulinemia was greater in pregnant versus non-pregnant animals. The increased glucose levels were attributed to higher gut glucose production and insulin resistance. Higher levels of free fatty acids in pregnant rabbits also contributed to the hyperglycemia. The investigators proposed the glucose was diverted to other sites such as uterus.

Metabolism studies in pregnant rabbits contribute to understanding mechanisms of teratogenicity. Retinoids, used as a chemopreventive and to treat dermatological disorders and induce embryotoxicity and teratogenicity in animals and humans, with two geometric isomers of vitamin A acid, all-*trans*-retinoic acid (RA) and 13-*cis*-RA (isotretinoin) displaying similar effects in laboratory animals (Tzimas et al., 1994). Rabbits have been shown more susceptible to the teratogenic action of 13-*cis*-RA than mouse or rat with teratogenicity of all-*trans*-RA comparable in these three species. In a study to investigate these species- and structure-related differences, Tzimas et al. (1994) administered the two isomers to pregnant Swiss hare rabbits from GD 7–12 and evaluated transplacental pharmacokinetics from the maternal plasma samples and embryos collected at various intervals after the final dose. The primary metabolites of all-*trans*-RA and 13-*cis*-RA were identified as all-*trans*- β -glucuronide, and 13-*cis*-4-*oxo*-RA, respectively. Key findings were slower elimination of 13-*cis*-RA and its metabolites from maternal plasma with accumulation of 13-*cis*-RA in maternal plasma, and more efficient placental transfer of all-*trans*-RA and all-*trans*-4-*oxo*-RA to rabbit embryos reaching concentrations similar to that in plasma. Based on these results, the sensitivity of rabbits to the teratogenic effects of 13-*cis*-RA was attributed to prolonged exposure to the drug and its metabolite and not to isomerization to all-*trans*-RA.

Toxicokinetics

Metabolism and Toxicokinetics

Toxicokinetics describes what an animal's body does with a drug or chemical or its metabolites following administration of the parent drug, typically at a high dose relative to the therapeutic or effective dose. The 1994 ICH S3A guideline identifies toxicokinetics as an

integral part of a non-clinical testing program because it supports species selection and the treatment regimen, enhances the toxicity data, and provides comparisons with clinical data, which is important in assessing risk and safety in humans. The guidance also notes the role for toxicokinetics in interpretation of similarities and differences across species, which may result from differences in protein binding, tissue uptake, receptor properties, and metabolic profiles. Both ICH S3A and the ICH S5(R2) guidelines suggests toxicokinetic data be obtained prior to initiating reproductive studies, and ICH S5(R2) notes information on kinetics in pregnant or lactating animals may also be required.

Toxicokinetics from in vitro studies contributes to understanding mechanisms of action and species differences. For example, Carney et al. (2008) used WEC to investigate why high-dose gavage exposure to ethylene glycol (EG) is teratogenic in rats but not rabbits. Maximal levels of unchanged EG in rabbits were comparable to those reported for pregnant rats while maximal levels of the teratogenic metabolite, glycolic acid, in rabbit maternal blood and embryo were 46% and 10% of the respective levels in rats. The toxicokinetic profile in rabbits indicated the lower levels of glycolic acid was due to a slower rate of maternal metabolism of EG to glycolic acid, slow uptake of the metabolite into the yolk sac cavity fluid surrounding the embryo, and little transfer to the embryo via the visceral yolk sac placenta. Based on a comparison of these data to that known for humans, the authors concluded rabbit is a relevant model for human EG exposure based on the negligible role of the visceral yolk sac (which humans lack) in placental transfer and similar rates of EG metabolism and extraembryonic fluid turnover.

Acknowledgments

The authors thank Ms. Mary Ballweg, Librarian, for her valuable advice and assistance in response to our many questions and requests. Thanks also to our veterinarian colleagues who have enriched our scientific approach to conducting toxicity and safety studies.

INTRODUCTION

Bacteria are responsible for an important group of naturally occurring diseases of rabbits. These diseases cause substantial morbidity and mortality, and thus interfere with the use of rabbits for many purposes. Even when subclinical, bacterial infections may render rabbits unsuitable for certain types of research. Bacterial diseases of rabbits most often involve the respiratory and gastrointestinal systems. This review emphasizes spontaneous diseases affecting these systems, including pasteurellosis, enterotoxemia, Tyzzer's disease, and colibacillosis. Experimentally induced bacterial diseases are discussed in detail elsewhere in this text, and will be addressed here only to the extent that they shed light on naturally occurring diseases.

PASTEURERLOSIS

Background

Pasteurella multocida is the most common bacterial pathogen of laboratory rabbits. The term pasteurellosis can be used to refer to several conditions caused by this organism. Most often, *P. multocida* is harbored in the nasal cavity of rabbits, resulting either in rhinitis or an asymptomatic chronic infection. Occasionally, infection extends from the nasal cavity to other parts of the body. This can result in a variety of clinical manifestations, including pneumonia, otitis media, conjunctivitis, abscesses, genital tract infections, and septicemia. The importance of pasteurellosis in rabbits is underscored by the fact that many of the clinical syndromes are refractory to antibiotic therapy, and there is no reported vaccination strategy that can prevent all the manifestations of the disease.

The earliest descriptions of rabbit pasteurellosis are those of Davis (1913, 1917), who described a *Haemophilus*-like bacillus associated with rabbit abscesses, septicemia, and respiratory disease. These descriptions formed a basis for the most definitive work on rabbit pasteurellosis, a series of ten papers by Webster (1924a–e, 1926a–b, 1927), Smith and Webster (1925), and Smith (1927). These are classic studies in which the etiologic agent, the clinical and pathologic forms of the disease, and factors important in pathogenesis were identified. Many papers on pasteurellosis have been published since this work, but none has contributed as much toward a basic understanding of the disease.

The cause of rhinitis, the most common form of pasteurellosis, was not known until the publication of Webster's studies. Earlier reports suggested that most cases were caused by *Bordetella bronchiseptica*, with *P. multocida* (then called *Bacterium leprosepticum*) and

Staphylococcus aureus contributing occasionally (Ferry and Hoskins, 1920). McCartney and Olitsky (1923) tried to reproduce the condition by challenging rabbits with these organisms, but their attempts were unsuccessful and the etiologic agent remained unclear. Eventually, Webster (1924c) studied the nasal flora of rabbits and proposed that *P. multocida* was the causative organism. This was based on culturing *P. multocida* from virtually all rabbits with rhinitis, while recovering *B. bronchiseptica* from only 30–40%. Webster (1924e) then reproduced the disease by intranasal inoculation of *P. multocida* in *Pasteurella*-free rabbits.

Webster also recognized that *P. multocida* was a principal cause of pneumonia, otitis media, abscesses, and septicemia. He isolated the organism from clinical cases of pneumonia and reproduced the disease by intranasal, intratracheal, and intravenous inoculation (Webster 1926a, 1926b). Otitis media was observed by Smith and Webster (1925) during necropsy of 100 rabbits, few of which had clinical signs suggestive of otitis. Many rabbits had rhinitis and otitis media concurrently, thus implicating *P. multocida* as the cause of otitis media. This was confirmed when intranasal inoculation with *P. multocida*, but not *Bordetella bronchiseptica*, resulted in otitis media. Abscesses and septicemia were also recognized by Webster (1924a) as manifestations of pasteurellosis. He proposed that septicemia was a potentially fatal sequel to other forms of pasteurellosis, especially rhinitis and pneumonia.

Smith and Webster (1925) stated a basic principle governing the pathogenesis of pasteurellosis: the disease usually begins in the nasal cavity following a carrier state, then spreads to other parts of the respiratory system by direct extension, or to other parts of the body by the blood (Figure 13.1). Smith and Webster also

FIGURE 13.1 Possible routes of spread of *Pasteurella multocida* in the rabbit.

realized that development of clinical signs and spread of infection within the rabbit depended on interactions between the host and the organism. They suggested that host resistance was a function of genetic and environmental factors, whereas microbial virulence was strain-dependent.

Etiologic Agent

Pasteurella multocida is a Gram-negative, non-spore-forming, non-motile coccobacillus or short rod that shows bipolar staining. *Pasteurella multocida* is the type species of the genus *Pasteurella*. *P. multocida* includes three subspecies designated *P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, and *P. multocida* subsp. *gallicida* (Mutters et al., 1989, 2005). Approximately 80% of rabbit isolates are *P. multocida* subsp. *multocida* (Stahel et al., 2009). *Pasteurella multocida* is a member of the family *Pasteurellaceae* and closely related to the genera *Actinobacillus* and *Haemophilus*. The three genera are heterogeneous, and the exact relationships among the various species are not clear. Many of the species in the family have been reclassified on the basis of genomic relatedness, especially 16S rRNA sequences, rather than phenotypic characteristics.

Pasteurella multocida grows well on blood or dextrose-starch agar but not on MacConkey's agar. After aerobic incubation for 24 h at 37°C, colonies are circular, convex, smooth, and non-hemolytic. Most isolates have large capsules, which imparts a viscous or mucoid appearance to the colonies. Less often, isolates have small or absent capsules, which gives the colonies an iridescent or blue appearance. Encapsulated isolates produce colonies 2–2.5 mm in diameter, whereas non-encapsulated isolates produce colonies about half as large (Brogden, 1980). Rarely, isolates with unusual growth requirements have been reported. In one instance, a strain with an increased carbon dioxide requirement was isolated from a rabbit abscess (Targowski and Targowski, 1979a).

Biochemical characteristics of *P. multocida* have been described by Heddleston (1976) and summarized for rabbit isolates by Manning et al. (1989). Virtually all isolates are positive for catalase, oxidase, indole, hydrogen sulfide, and hexose fermentation and are negative for urease production.

Serological typing has long been used for identification of strains of *P. multocida*. A capsular typing scheme based on hemagglutination was developed by Carter (1955) and later refined by Sawada et al. (1982). Five capsular serotypes have been identified (A, B, D, E, and F). Serotypes A and D are often associated with pasteurellosis in rabbits (DeLong and Manning, 1994; Dziva et al., 2000). Serotype F has also been reported (Jaglic et al., 2004, 2008).

A somatic antigen typing scheme based on a gel diffusion precipitin test identifies 16 somatic antigens designated 1–16 (Heddleston et al., 1972). These antigens are presumed to be lipopolysaccharide (LPS) molecules. These molecules are of low molecular weight with at least two types of antigenic determinants: non-serospecific determinants that may represent partially conserved core LPS components, and serospecific determinants that represent more variable regions (Carey et al., 1984; Manning, 1982, 1984; Manning et al., 1986).

DNA-based methods of typing *P. multocida* provide alternative methods of characterization that overcome the classic phenotypic methods described above. Methods used in characterizing rabbit isolates of *P. multocida* include (i) restriction endonuclease analysis, (ii) ribotyping: restriction endonuclease digestion with subsequent hybridization with a standard probe, (iii) RAPD: random amplification of polymorphic DNA, and (iv) multiplex capsular polymerase chain reaction (PCR) typing (Dziva et al., 2008).

Restriction endonuclease analysis was used to characterize isolates obtained from rabbits in Ohio. The enzyme *Hpa*II was used and 12 distinct DNA profiles were observed (El Tayeb et al., 2004).

Ribotyping involves hybridizing restriction enzyme digested genomic DNA with a 16S or 23S rRNA-based probe. RAPD (random amplification of polymorphic DNA) involves PCR amplified fragments that are resolved by agarose gel electrophoresis; in some cases this method may offer more discriminatory power than ribotyping. The two methods of typing were compared in a study by Chaslus-Dancia et al. (1996). Both methods were used as tools for epidemiologic investigations of patterns of *P. multocida* infection in rabbits in France. Results of the RAPD assays were in general agreement with those of ribotyping.

The multiplex PCR typing method of Townsend et al. (2001) has largely replaced the traditional indirect hemagglutination assays for capsular serotyping.

Single primer PCR fingerprinting with minisatellite and microsatellite primers has also been used to characterize rabbit isolates. This has been described as a technique that can be performed on boiled bacterial extracts as well as genomic DNA and can reliably differentiate among *P. multocida* isolates from rabbits with pasteurellosis (Dabo et al., 1999, 2000).

Epizootiology

Infection with *P. multocida* can occur at a very young age; organisms may be transmitted from infected dams to their offspring during birth or lactation. Perhaps because of maternally acquired antibody, many rabbits remain uncolonized for the first several weeks of

life, but the prevalence of infection increases rapidly with age (Glass and Beasley, 1989). Soon after weaning over 75% of rabbits nursing infected dams are positive by pharyngeal culture (Holmes et al., 1984; Nakagawa et al., 1986). Interestingly, nasal cultures performed at the same age are less likely to be positive (Deeb et al., 1990; DiGiacomo et al., 1983a). This suggests that the pharynx is the earliest site of colonization, with spread to the nasal passages occurring later.

The proportion of rabbits infected with *P. multocida* increases as rabbits mature, and up to 90% of adult rabbits from endemically infected colonies may harbor the organism in the nasal passages (DiGiacomo et al., 1983a; Deeb et al., 1990; Duclos et al., 1986; Garlinghouse et al., 1981; Hagen, 1967; Holmes et al., 1983a, 1983b, 1986; Kawamoto et al., 1990a; Lu et al., 1978; Lukas et al., 1987; Mraz et al., 1980; Nakagawa et al., 1986; Weisbroth and Scher, 1969a). Additional animals may be free of *P. multocida* in the nasal passages, yet still harbor the organism in the pharynx (Holmes et al., 1986). Many infected animals develop clinical pasteurellosis, but the majority remain asymptomatic carriers.

Transmission of *P. multocida* usually occurs by the oral or respiratory route. The organism is passed most readily from animals with acute infections (DiGiacomo et al., 1987a). Direct contact between infected and uninfected animals is the most rapid means of spread, resulting in transmission in as little as 8 days. Aerosol transmission can also occur but it is considerably slower, taking up to 12 weeks when uninfected and infected animals are housed in separate cages in the same room (DiGiacomo et al., 1987a; Lelkes and Corbett, 1983). This slow rate of spread suggests that transmission might be avoided by housing infected and non-infected rabbits in separate rooms, but long-term studies have shown that housing rabbits this way may still result in transmission within 3–6 months (DiGiacomo et al., 1983a; Scharf et al., 1981). It is unclear what mediates spread of infection under these conditions, but fomites could be involved. Rabbits with rhinitis frequently contaminate watering devices with *P. multocida*, and other objects may act as fomites as well, but the length of survival of the organism on inanimate objects is not known (Holmes et al., 1983b; Kawamoto et al., 1990a).

Transmission of *P. multocida* can also occur by way of the reproductive system. Venereal transmission of *P. multocida* was first reported by McKennedy and Shillinger (1938), who observed genital tract infections in does bred to a buck with a testicular abscess. Does frequently carry the organism in the vagina, and thus may act as a source of infection for other rabbits during mating and parturition (Holmes et al., 1983a, 1984).

Studies of *P. multocida* transmission and epizootiology can be facilitated by use of the serologic and DNA-based typing methods described above.

Clinical Manifestations

Background

There are many clinical manifestations of *P. multocida* infection, including rhinitis, pneumonia, otitis media and interna, conjunctivitis, subcutaneous abscesses, genital infections, and septicemia. Many rabbits have several syndromes concurrently. On the other hand, it is common for infected animals to remain carriers for long periods and show no clinical signs. Whether or not overt disease occurs depends on the resistance of the host and the virulence of the organism.

Rhinitis

Rhinitis (“snuffles”) is the most common manifestation of rabbit pasteurellosis. The primary sign of rhinitis is nasal discharge, which may be serous, mucoid, or mucopurulent. The discharge may cause the rabbit to rub the nares with the medial aspect of the forepaw, which results in dampness, matting, and yellowish discoloration of the fur. Occasionally, the external nares have no apparent discharge, and matting is the only evidence that exudate is present. Rabbits with rhinitis may breathe audibly and sneeze or cough, but unless infection has extended beyond the nasal passages there are no other signs of respiratory distress.

Rhinitis is usually a chronic condition with high prevalence in conventionally managed rabbit colonies. The percentage of rabbits affected may be as high as 60%, with the incidence peaking in the spring and fall months (DiGiacomo et al., 1983; Webster, 1924a, 1924c). It is most common for clinical signs to wax and wane while infection persists, but recovery from rhinitis and elimination of *P. multocida* has been claimed to occur (Webster, 1924d). Progression to one of the clinical entities listed below occurs occasionally, with conjunctivitis, abscesses, and otitis media occurring in decreasing frequency (DiGiacomo et al., 1983a).

About 50% of rabbits harboring *P. multocida* in the nares show no clinical signs of rhinitis (DiGiacomo et al., 1983a; Webster, 1924d). In part, this may be a reflection of differences in bacterial virulence. However, the same serotypes are isolated from asymptomatic rabbits and those with rhinitis (DiGiacomo et al., 1983a). Host factors probably also influence the response to infection. Although there has been little experimental investigation of host factors, there is extensive anecdotal evidence that clinical signs can be precipitated by stressful conditions such as shipping, inclement weather, and experimentation. There is also evidence that the incidence of rhinitis is higher in some breeds of rabbits than others (Webster, 1927).

Pneumonia

Pneumonia occurs frequently in rabbit colonies and is sometimes accompanied by pulmonary abscesses,

pleuritis, and pyothorax. Webster (1926) showed that *P. multocida* is the most common etiologic agent. Later investigators supported this finding by isolating *P. multocida* in pure culture from lungs of rabbits with acute pneumonia (Alexander et al., 1952). Flatt and Dungworth (1971b) also concluded that *P. multocida* was responsible for pneumonia. Although they isolated *P. multocida*, *B. bronchiseptica*, and *S. aureus* from pneumonic lungs, they noted that the latter two organisms were also present in normal lungs and were therefore probably not the primary cause of pneumonia. Under experimental conditions, however, *B. bronchiseptica* can induce pneumonia, and it may occasionally act as a copathogen with *P. multocida* (Glavits and Magyar, 1990; Watson et al., 1975).

Although acute cases and epizootics sometimes occur, pneumonia is usually chronic and asymptomatic. In severe cases rabbits are anorectic and depressed, but respiratory distress is seldom observed. Because of the lack of specific clinical signs, the diagnosis of pneumonia is usually made at necropsy. In apparently healthy 8–10-week-old animals, approximately 20% had macroscopic lesions of pneumonia (Flatt and Dungworth, 1971a).

Otitis Media and Interna

Clinical signs are usually absent in rabbits with otitis media. If the inflammatory process extends to the inner ear, torticollis can occur (Figure 13.2) (Fox et al., 1971; Smith and Webster, 1925; Snyder et al., 1973). The prevalence of otitis media at necropsy in conventionally managed rabbit colonies can approach 33%, whereas the number of animals with torticollis is usually under 5% (Smith and Webster, 1925; Snyder et al., 1973). In both clinical and subclinical cases, *P. multocida* is usually isolated in pure culture, but *B. bronchiseptica*, and staphylococci may also be found in 5–10% of cases (Fox et al., 1971).

Sometimes rabbits with torticollis are free of lesions of otitis media/interna, and *P. multocida* is not recovered by culture. In these cases the torticollis may be due to granulomatous encephalitis caused by *Encephalitozoon cuniculi* (Kunstyr and Naumann, 1985). There is no evidence to indicate that ear mites cause otitis media, but affected rabbits may have torticollis due to concurrent infection with *P. multocida*.

Conjunctivitis

Conjunctivitis is a common manifestation of *P. multocida* infection, but it has been rarely mentioned in the literature (Figure 13.3). DiGiacomo et al. (1983) reported that the incidence of conjunctivitis in one rabbitry was second only to rhinitis. While experimental studies are lacking, cultures obtained from rabbits with conjunctivitis usually yield *P. multocida* (Flatt, 1974).

FIGURE 13.2 Pasteurellosis: torticollis secondary to otitis media/interna.

FIGURE 13.3 Pasteurellosis: mucopurulent conjunctivitis.

Signs of conjunctivitis include ocular discharge, chemosis, and conjunctival hyperemia. Extension from the nose via the nasolacrimal duct is the probable route of access to the conjunctiva. Occasionally, the only sign is epiphora; in this instance infection may be restricted to the nasolacrimal duct (Jones and Carrington, 1988).

Abscesses

Webster (1924a) and Griffin (1952) recognized that abscesses are often caused by *P. multocida*. Subcutaneous abscesses are the most common type, and can be recognized by the presence of a firm swelling which may have a soft center. Aspiration of the swelling reveals thick tan-to-creamy-white exudate. Common sites for

FIGURE 13.4 Pasteurellosis: cerebellar abscess occurring as a result of extension of otitis media.

FIGURE 13.5 Pasteurellosis: heart with abscess in right ventricle.

the development of subcutaneous abscesses are the areas around the head, neck, and shoulders. Abscesses may also occur in internal organs, including the lungs, reproductive tract, brain, and heart (Figures 13.4 and 13.5). Specific clinical signs are rarely present and the diagnosis is usually made at necropsy. As in other species, abscesses in rabbits develop by bacteria gaining access to the site by one of several routes: direct extension, hematogenous spread, and wound contamination.

Genital Tract Infections

Infections of the reproductive tract can occur in both bucks and does. Any part of the tract may be affected, but metritis, orchitis, and epididymitis are most common. These infections are usually acquired by venereal transmission, but hematogenous spread from other sites may occur as well (Flatt, 1974). Many genital infections are chronic and asymptomatic, but in breeding animals low conception rates can be seen. Does may have vaginal discharge, especially in acute infections. In

chronic infections, pyometra and massive uterine dilatation are common, sometimes resulting in rupture of the distended uterus (Bjotvedt et al., 1979). Pyometra must be distinguished from uterine adenocarcinoma, which also causes uterine enlargement. Bucks with orchitis or epididymitis may have swelling of the testicles or epididymis in the acute phase of the disease; in later stages abscessation may occur (Flatt, 1974).

Septicemia

Septicemia was recognized by Webster (1924a) as a potentially fatal sequel to other forms of pasteurellosis, especially rhinitis and pneumonia. Clinical signs are not usually observed because death occurs rapidly, but other clinical forms of pasteurellosis may be present concurrently. Diagnosis depends on recovery of *P. multocida* from the blood or parenchymal organs.

Miscellaneous Infections

P. multocida can be associated with infection of any system or organ. Examples of unusual infections include osteomyelitis and meningoencephalomyelitis without coexisting otitis media (Chaffee et al., 1975; Liebenberg and Badger, 1984; Murray et al., 1985). Clinical signs depend on the organ or tissue involved, plus the extent of involvement.

Pathology

Gross and microscopic lesions of pasteurellosis are typical of acute or chronic suppurative inflammation. Grossly, exudate is usually present. The exudate is most often purulent, but may be serous or mucoid depending on the duration of infection. Microscopically, there are large numbers of neutrophils in affected tissues.

Rhinitis is characterized grossly by edema and hyperemia of the upper respiratory mucosa, sometimes accompanied by mucosal erosions. Mucopurulent exudate is present in the nasal cavity and sinuses, and the nasal turbinates may be eroded or atrophic (Figure 13.6). Microscopically, there is vascular congestion, edema, focal mucosal erosion, and an inflammatory cell infiltrate composed primarily of neutrophils. Turbinate bones may be abnormally small and irregular, with increased numbers of osteoblasts and osteoclasts (DiGiacomo et al., 1989, 1991b; Webster, 1924b).

In cases of pneumonia, affected areas of the lungs are dark red and consolidated (Figure 13.7). The cranioventral lobes are most often affected, and there is frequently a sharp line of demarcation from the adjacent normal tissue. Sometimes there are accompanying areas of atelectasis or abscesses (Flatt and Dungworth, 1971a, 1971b; Hagen, 1958). Histologically, the most typical acute lesion is fibrinopurulent necrotizing bronchopneumonia (Figure 13.8). Fibrinopurulent exudate

FIGURE 13.6 Pasteurellosis: purulent rhinitis, nasal cavity, sagittal section.

FIGURE 13.7 Pasteurellosis: consolidation of cranioventral lung lobes.

is present in airways and alveoli; neutrophils are the primary inflammatory cell but there are also abundant macrophages and erythrocytes. In chronic cases abscesses surrounded by fibrous tissue are common, as are dense accumulations of lymphoid cells around blood vessels. Airway epithelium is necrotic and necrosis may extend into adjacent lung parenchyma. Frequently, there is accompanying fibrinopurulent pleuritis, pericarditis, and pyothorax (Flatt and Dungworth, 1971a, 1971b).

Early gross lesions of otitis media include reddening of the tympanic membrane and accumulation of

FIGURE 13.8 Pasteurellosis: acute bronchopneumonia.

serosanguineous fluid in the middle ear. Later, the middle ear becomes filled with thick, creamy exudate, which becomes inspissated in chronic cases. Exudate in the middle ear is the most common lesion and occurs in up to 30% of rabbits with no clinical signs of ear disease (Smith and Webster, 1925; Snyder et al., 1973). Histologic lesions of otitis media consist of suppurative inflammation of the tympanic bullae with massive accumulations of neutrophils and necrotic cell debris in the tympanic cavity. In the submucosal tissue of the bulla there is a mixed cell infiltrate of neutrophils and lymphocytes (Snyder et al., 1973). Occasionally, infection of the middle ear extends to the inner ear and brain, resulting in suppurative meningoencephalitis (Figure 13.7).

Other forms of pasteurellosis (except septicemic) are characterized by accumulations of purulent exudate in the affected tissue or organ. The amount and consistency of exudate vary with the severity and duration of the infection. Abscesses may become large and encapsulated; genital tract infections may progress to abscesses of the testicles or pyometra (Figure 13.6). Microscopic lesions are characterized by suppurative inflammation. In organs lined by epithelium there may be neutrophils and cell debris in the lumen, ulceration of the epithelial layer, and infiltration of the underlying tissue by inflammatory cells. In subcutaneous tissue the area of inflammation may be surrounded by a thick fibrous capsule (Flatt, 1974).

In septicemic pasteurellosis lesions are seldom seen, although other forms of the disease are often evident. Grossly and microscopically, there may be congestion of visceral organs and focal serosal or subcutaneous hemorrhages.

Ultrastructural pathology of the respiratory tract of rabbits infected with *P. multocida* serotypes A:3 and D:1 has been reported by Al-Haddawi et al. (1999, 2000,

2000a, 2001). Serotype A:3 attached to cells of the upper respiratory tract and caused damage to ciliated epithelium and goblet cell hyperplasia. In the lungs, thickening of alveolar septa due to hyperplasia of type II pneumocytes was observed. In both locations, coccobacilli were present in membrane-bound vacuoles in the cytoplasm of epithelial and endothelial cells, suggesting that *P. multocida* can invade host cells and cause degenerative ultrastructural changes. Serotype D:1 was associated with similar lesions, but intracellular bacteria were not reported. Another difference was more extensive vascular involvement, with congested subepithelial capillaries, intravascular fibrin deposition, platelet aggregation, and adherence of organisms to endothelial cells. Serotype D:1 proved more pathogenic than serotype A:3. The pronounced vascular lesions were indicative of septicemia and may be due to release of bacterial endotoxin. Dermonecrotic exotoxin, which is often produced by serotype D:1, apparently exacerbated the lesions and facilitated colonization.

Pathogenesis

Dissemination of Infection

Smith and Webster (1925) and Webster (1926a) proposed that pasteurellosis usually begins in the nasal cavity, and then spreads to contiguous tissues by direct extension or to distant sites via the blood (Figure 13.1). They observed that intranasally infected rabbits developed otitis media, and concluded that direct extension through the auditory tube was responsible. They also noted that intravenous, intratesticular, and subcutaneous inoculations of *P. multocida* resulted in pneumonia, and interpreted this as evidence for hematogenous spread.

Studies have confirmed that dissemination within the host is by direct extension and hematogenous spread. When rabbits are inoculated nasally or orally with *P. multocida*, the result is often pneumonia or otitis media (Chengappa et al., 1980; Lu and Pakes, 1981; Lu et al., 1982; Sokkar et al., 1987; Watson et al., 1975). Intravenous or intratracheal challenge also results in pneumonia (Flatt and Dungworth, 1971b; Percy et al., 1986).

Host-parasite Interactions

As in most infectious diseases, the outcome of infection with *P. multocida* depends on interactions between the host and organism. A subclinical state precedes but does not necessarily progress to overt disease. The extent of progression is governed in part by host response, which is in turn related to the genetic background of the host and environmental factors. The most resistant rabbits tend to remain carriers, while less resistant animals are prone to rhinitis or pneumonia.

Progression is also influenced by bacterial virulence. Strains of *P. multocida* vary in their ability to produce disease; some are primarily associated with rhinitis, others with septicemia and pneumonia. Therefore, the ultimate expression of clinical disease is “an index, if perhaps only a rough one, to the resistance of the rabbits and the virulence of the microbe” (Webster, 1924e).

HOST RESPONSE

Both genetic and environmental factors affect host susceptibility. Webster (1927) first reported the influence of genetic factors, noting that the incidence of rhinitis and the mortality rate from pasteurellosis were three times higher for the Chinchilla breed than the Blue Beveren breed. He attributed wide variation of individual response within a breed to “variables inherent in each individual concerned.” Webster and Burn (1927) investigated environmental influences on host response by studying the effects of temperature fluctuation and dietary supplementation. Daily fluctuations between 55 and 90°F caused significant increases in mortality and incidence of rhinitis. Dietary supplementation with fresh vegetables resulted in fewer asymptomatic carriers of *P. multocida*, but there was no reduction in rhinitis or mortality in the supplemented group.

The effects reported by Webster and Burn are examples of how stress can influence the course of pasteurellosis; recent studies confirm and extend these findings. Ammonia in ambient air (50 ppm) or hydrocortisone treatment increase the susceptibility of rabbits to intranasal challenge with *P. multocida* (Lu et al., 1982; Patton et al., 1980). Similarly, the incidence of spontaneous pasteurellosis increases when immunosuppression is induced by intradermal challenge with a malignant variant of Shope fibroma virus (Corbeil et al., 1983).

Humoral immunity is one mechanism of host resistance to pasteurellosis. Infection with *P. multocida* is followed within 2–3 weeks by development of specific IgM and IgG antibodies (DeLong et al., 1992; DiGiacomo et al., 1990). There is evidence that these antibodies can prevent lethality and the development of severe clinical signs. For example, hyperimmune serum from either mice or rabbits protects mice against challenge with homologous organisms (Collins, 1977). Similarly, hyperimmune rabbit serum prepared against extracts of *P. multocida* protects rabbits against intranasal challenge (Lu et al., 1987).

Protection appears to be mediated largely by antibodies against the outer membrane proteins of *P. multocida*. This is suggested by two lines of evidence. First, a monoclonal antibody against the 38.5-kDa outer membrane protein of *P. multocida* protects rabbits against intranasal challenge with homologous organisms (Lu et al., 1991b). Second, affinity-purified rabbit antibodies against outer membrane proteins, but not

antibodies against lipopolysaccharide, inhibit pulmonary proliferation of *P. multocida* in mice (Lu et al., 1991a).

The mechanism by which humoral immunity protects against pasteurellosis is unknown. Immune serum is not directly bactericidal for rabbit isolates in vitro and it is not significantly better than non-immune serum at bacterial opsonization (Hofing et al., 1979; Rush et al., 1981). It is possible that the bactericidal or opsonic activities of specific antibodies are enhanced in vivo, perhaps by interaction with cell-mediated immunity and non-specific immune mechanisms.

The protective effects of antibody appear to be limited to pneumonia and other severe manifestations of pasteurellosis. Neither passively nor actively acquired antibody protect against the carrier state or rhinitis; the organism can persist in the presence of significant levels of serum IgG and secretory IgA (DeLong et al., 1992; Lu et al., 1987). It seems likely that *P. multocida* has developed mechanisms to circumvent the host antibody response, at least at the mucosal level.

The importance of cell-mediated immunity in protection against pasteurellosis is unclear. Rabbits infected with a malignant variant of Shope fibroma virus have depressed T cell activity and are susceptible to severe pasteurellosis, but B cell function is depressed as well (Corbeil et al., 1983). In mice, cell-mediated immunity seems to have a minor role, since immune lymphocytes do not protect non-immune recipients (Collins, 1977). On the other hand, in avian pasteurellosis cell-mediated immunity appears important for protection (Baba, 1984).

Non-specific host responses such as fever and neutrophil response may be important defenses against *P. multocida* infection. A febrile response is correlated with increased survival when rabbits are challenged intravenously with *P. multocida*. When febrile rabbits infected with *P. multocida* are given antipyretics, there is increased mortality, decreased blood leukocyte counts, and greater numbers of bacteria isolated from the spleen and liver (Kluger and Vaughn, 1978; Vaughn et al., 1981). It appears that fever enhances bacterial clearance, perhaps by activation of granulocytes or the monocyte-macrophage system.

Neutrophil function appears to be unaffected by immunization or infection with *P. multocida*. It is therefore unlikely that altered neutrophil function is important in the pathogenesis of pasteurellosis. Granulocytes from immunized, infected, and uninfected rabbits are equally effective in phagocytosing and killing *P. multocida* in vitro (Hofing et al., 1979). Similarly, in infections induced experimentally in subcutaneous chambers, there is no difference in neutrophil response between immunized and non-immunized rabbits (Petkus et al., 1979).

Other non-specific host responses associated with *Pasteurella multocida* include increased expression of

vascular cell adhesion molecule-1 (VCAM-1) by aortic endothelium (Richardson et al., 1997). Interestingly, increased expression can occur even when infection is apparently restricted to a remote site such as the lungs. Another non-specific response is reactive thrombocytosis, which can occur in response to a variety of bacterial infections including pasteurellosis. In a study of experimental *P. multocida* infection, reactive thrombocytosis was a consistent finding but there was no correlation between the magnitude of thrombocytosis and the severity of disease (Ruble et al., 1999b).

BACTERIAL VIRULENCE

The importance of bacterial virulence in pasteurellosis was recognized by Webster (1926b) when he inoculated rabbits intranasally with strains designated as either mucoid or type D. The mucoid strains usually produced an asymptomatic carrier state. In contrast, the D strains tended to be cleared from the nasal passages, although they sometimes caused marked clinical disease. Webster concluded that mucoid strains are better able to colonize the nasal passages than non-mucoid strains; other studies support this finding (DeLong et al., 1992).

The capsular serotypes of rabbit isolates are usually A, D, or non-typeable, and somatic serotypes are usually 3 or 12 (Brogden, 1980; Chengappa et al., 1982; DiGiacomo et al., 1983a, 1991a; Kawamoto et al., 1990b; Lu et al., 1978, 1983; Lukas et al., 1987; Mushin and Schoenbaum, 1980; Percy et al., 1984; Pestana de Castro et al., 1980). Recently, capsular type F has been shown to occur in rabbits. It is unknown whether some isolates previously reported as non-typeable may actually be serotype F. In general, capsular type A and somatic type 12 cause less severe disease than capsular type D and somatic type 3. Serotype F can also be highly pathogenic for rabbits, and is associated with pneumonia and septicemia under conditions of experimental infection (Jaglitz et al., 2008). The predominance of these strains suggests that they produce products such as toxin(s), antiphagocytic substances, or adhesins, which promote infection and enhance virulence (Carter, 1967).

P. multocida virulence factors that have been the subject of research in various species include the bacterial capsule, lipopolysaccharide (also referred to as endotoxin), adhesins, toxins, iron-regulated and iron-acquisition proteins, and sialidases (Harper et al., 2006). These are discussed in detail below.

Capsular composition and structure is governed by one or, at most, two areas on the genome. Capsule is believed to play a significant role in resistance to phagocytosis. In rabbit pasteurellosis, this is suggested by persistence of the organism in infected tissues, despite the presence of large numbers of neutrophils. Studies have shown that some rabbit isolates of *P. multocida*

can in fact resist phagocytosis and killing, but there is no clear correlation between resistance and virulence (Anderson et al., 1984; Rush et al., 1981). This is probably a reflection of the multifactorial nature of virulence and the possible loss of some virulence factors caused by in vitro cultivation.

Lipopolysaccharide (endotoxin) from *P. multocida* can cause fever, central nervous system depression, and shock. In septicemic rabbits, free endotoxin is present in plasma, but it is unclear whether endotoxin plays a significant role in clinical disease, especially in the most common syndromes (Anderson et al., 1984). Lipopolysaccharide stimulates humoral immunity, and antibodies to it convey some level of protection. Since lipopolysaccharide is presumed to be responsible for somatic serotype, the predominance of somatic serotypes 3 and 12 suggests that certain properties of lipopolysaccharide are important in pathogenesis. Attempts to reproduce clinical syndromes of pasteurellosis in birds and ruminants with intravenous injection of lipopolysaccharide from various serotypes have not been consistently successful (Harper et al., 2006).

Another bacterial property that may be important in pasteurellosis is the production of adhesins. Rabbit pasteurellosis usually begins with colonization of the upper respiratory tract, which could be facilitated by production of bacterial adhesins. As might be expected, isolates of *P. multocida* obtained from rabbits adhere better to rabbit cells – especially buccal and pharyngeal cells – than do isolates obtained from other species (Bonilla-Ruz and Garcia-Delgado, 1993). Differences in adhesiveness may explain the predominance of specific serotypes in this disease. Type A strains adhere better to pharyngeal epithelium than types B, D, or E; this observation correlates with a higher rate of isolation of type A organisms from the upper respiratory tract (Glorioso et al., 1982). Type D strains appear to adhere well to tracheal epithelium and aorta endothelium (Al-Haddawi et al., 2000, 2000a). This pattern is in contrast to the pattern seen with type A strains and may explain the ability of type D strains to cause septicemia.

Exotoxin production is uncommon in *P. multocida* with the exception of capsular type D strains. Type D isolates are sometimes highly virulent and capable of causing septicemia or severe pneumonia (Okerman et al., 1979). The virulence of these strains is in part mediated by exotoxin, which is recognized as an important cause of atrophic rhinitis in pigs. In rabbits, purified toxin can induce pneumonia, pleuritis, hepatic necrosis, lymphoid atrophy, and possibly nasal turbinate atrophy (Chrisp and Foged, 1991). Nasal turbinate atrophy in rabbits may not be as closely associated with toxin production as it is in swine; in one study, serotype A:12 isolates appeared to cause turbinate atrophy in rabbits, but evidence of toxin production was equivocal

(DiGiacomo et al., 1993). The toxin produced by type D strains has a molecular weight of 145 kDa and acts by activation of alpha-subunits of heterotrimeric G proteins. G protein activation occurs via deamidation of a specific glutamine residue present on alpha subunits of the proteins (Orth et al., 2009).

Iron acquisition proteins are produced by most bacteria, including *P. multocida*. Analyses of the complete genome sequence of an avian isolate revealed more than 50 genes with a potential role in iron acquisition and metabolism (May et al., 2001). The presence of iron in the environment determines the level of expression of these proteins, so they are referred to as iron-regulated outer membrane proteins. Inactivation of these proteins has been shown to attenuate virulence in mice (Harper et al., 2006). The exact role in virulence is not certain, but may simply relate to the ability of bacteria to survive in the host environment. Bacteria grown in iron-poor conditions express these proteins at a relatively high level and induce a better immune response than bacteria grown in iron-replete conditions. Therefore, strains grown under these conditions may be useful for developing immunization strategies (Confer et al., 2001).

In many species of bacteria, production of virulence factors is regulated by plasmids, but this does not appear to be true for *P. multocida*. Isolates may possess a single small plasmid, but there is no apparent correlation between presence of the plasmid and bacterial virulence (Gunther et al., 1991).

Diagnosis

Isolation

Pasteurellosis may be diagnosed by the observation of clinical signs, coupled with isolation of the organism from infected tissues. If control of pasteurellosis in a colony is desired, it is also necessary to detect subclinically infected animals. This can usually be done by nasal culture. A calcium alginate urethral swab is inserted 1 cm into both nares, then plated onto blood agar with clindamycin (2 µg/ml). Clindamycin inhibits the growth of most rabbit nasopharyngeal flora, but allows growth of *P. multocida*. Identification can then be made on the basis of colony morphology, without additional biochemical tests (Garlinghouse et al., 1981). Samples should also be plated on plain blood agar, to ensure detection of the few strains of *P. multocida* that are inhibited by clindamycin. As an alternative to nasal culture, nasopharyngeal cultures may be obtained by passing the swab 4–5 cm through the nares. Since colonization of the pharynx sometimes occurs before colonization of the nasal cavity, this method may detect infected animals that are negative by nasal culture (Holmes et al., 1987).

If nasal cultures require storage or transport, Cary-Blair medium or Leibovitz medium no. 15 (L-15) have been shown to allow 80–90% recovery after 4 days (Kawamoto et al., 1997).

Cultures of the nares are inexpensive and easy to perform, but may not detect organisms which are few in number or localized to other parts of the body. Studies evaluating the reliability of nasal cultures suggest that approximately 30% of infected animals may not be detected by a single culture (Holmes et al., 1986; Manning et al., 1987). It would be prudent to perform three sequential cultures before accepting an animal as *Pasteurella*-free.

Serodiagnosis and Polymerase Chain Reaction

The limited sensitivity of culture for detection of carriers of *P. multocida* has prompted the development of several serologic tests, including agar gel diffusion precipitin tests (GDPT) (Heddlestone et al., 1972), enzyme-linked immunosorbent assays (ELISA) (Holmes et al., 1986; Klaasen et al., 1985; Lukas et al., 1987; Sanchez et al., 2004; Zaoutis et al., 1991), a capture ELISA assay (Peterson et al., 1997) and ELISA-based immunoblot assays (Manning et al., 1987; Zimmerman et al., 1992). The GDPT technique is more labor intensive than ELISA and slightly less sensitive. ELISA can detect antibody in up to 98% of nasal culture-positive animals, as opposed to 86% for GDPT. Both approaches detect antibody in about 10% of rabbits that are negative by nasal culture, suggesting false-negative culture results for these animals (Kawamoto et al., 1994).

ELISA and immunoblot assays can detect antibody to *P. multocida* in infected rabbits that are nasal culture-negative, but careful selection of bacterial antigen preparations is important for adequate sensitivity and specificity. Boiled cell extracts (Klaasen et al., 1985), potassium thiocyanate extracts (Lukas et al., 1987), polypeptides isolated from whole cell preparations (Zimmerman et al., 1992) and lipopolysaccharide mixtures (Manning et al., 1987) have been reported to provide adequate results. Specificity can be enhanced by using well-defined antigens, such as the 37-kDa protein employed in the capture ELISA described by Zimmerman et al. (1992). However, this approach may result in loss of sensitivity; prevalent serotypes of *P. multocida* such as A:3 and A:12 express this protein, but less common ones may not.

An approach to serodiagnosis that is designed to maximize sensitivity and specificity involves a recombinant antigen ELISA designed to detect antibody to sialidase encoded by the bacterial gene *NanH* (Sanchez et al., 2004). Sialidases are extracellular bacterial enzymes that have glycolytic activity on mucin, thereby providing a carbon source and facilitating mucosal colonization. The host typically produces detectable IgM and

IgG responses, even in the absence of clinical signs. The sialidase produced by *P. multocida* is believed to be ubiquitous in *P. multocida* isolates and lack homology with sialidases from other organisms. Therefore, this technique may minimize problems of sensitivity and specificity that can occur with other serologic diagnostic techniques.

Any serologic assay used in screening for *P. multocida* infection can result in false negatives in the early stages of infection. Therefore, tests several weeks apart are necessary to ensure *Pasteurella*-free status. Seroconversion is usually detectable 2–4 weeks after infection (DiGiacomo et al., 1990; Lukas et al., 1987; Manning et al., 1987).

Another consideration in using serologic screening is that false-positive results can occur when passively acquired antibody is present in juvenile animals. The disappearance of passively acquired antibody to *P. multocida* has not been studied in rabbits, but data from other infections suggest that up to 8 weeks may be required (DiGiacomo and Thouless, 1986). Thus, serologic tests may be unreliable in animals under 2 months of age.

A *P. multocida*-specific polymerase chain reaction (PCR) assay has been described (Kumar et al., 2004). The amplified product is approximately 460 base pairs in size and is present in all confirmed *P. multocida* isolates, regardless of host species. In rabbits as in other species, the assay has been shown to perform satisfactorily with a variety of substrates, including bacterial colonies, bacterial cell lysates, and purified genomic DNA.

Prevention and Therapy

Prevention

Control of pasteurellosis depends mainly on prevention, since therapy is only marginally effective. Several strategies for prevention have been tried, including barrier housing, vaccination, and antimicrobial prophylaxis. Barrier housing is the most reliable strategy.

BARRIER HOUSING

Barrier housing is used to ensure that *Pasteurella*-free rabbits do not become infected. The rabbits should be maintained using barrier facilities and procedures, the specifics of which range from semi-isolation to strict isolation, depending on the needs of the facility and availability of equipment and personnel (Scharf et al., 1981).

Pasteurella-free rabbits are readily available commercially, but other methods can also be used to obtain a *Pasteurella*-free colony. The simplest approach is to cull infected animals. All rabbits with clinical signs of pasteurellosis or positive nasal cultures should be removed (Webster and Burn, 1927). The prospect of success is improved if rabbits that are either related to infected animals or housed nearby are also culled (Griffin, 1952).

Since some rabbits harboring *P. multocida* may be consistently negative by nasal culture (Holmes et al., 1986), culling may be more effective if culture is combined with other screening tests, such as PCR or serologic assays.

Methods besides culling have also been used to select *Pasteurella*-free stock. These methods include cesarian derivation (Baba et al., 1987; Scher et al., 1969; Weisbroth and Scher, 1969), and transfer of fertilized ova to *Pasteurella*-free does (Ward, 1973). Another method is addition of either furazolidone or sulfaquinoxaline to the diet of does prior to kindling until weaning (Hagen, 1966). Treatment of infected does with enrofloxacin prior to and up to a week after kindling may be sufficient to derive *Pasteurella*-free offspring, although the treatment is unlikely to eliminate the organism from the does. Intramuscular and oral routes of administration appear equally effective (Suckow et al., 1996b).

It is possible that early weaning, even without use of antimicrobials, helps select for *Pasteurella*-free stock. Preweanling rabbits have a relatively low rate of infection, possibly because of resistance conveyed by passively acquired maternal antibodies (DiGiacomo et al., 1983a, 1987a; Nakagawa et al., 1986).

VACCINATION

At present there is no commercially available vaccine that is fully effective against pasteurellosis. Many approaches to vaccination have been evaluated, including the use of killed whole bacteria, live avirulent streptomycin-dependent strains, potassium thiocyanate bacterial extracts, and inactivated exotoxin. Strategies have also been employed to enhance the immune response, such as administering antigens encapsulated in alginate microspheres or delivered in conjunction with cholera toxin. Other novel approaches to vaccination include preparations containing iron-regulated outer membrane proteins and preparations designed to evoke antibodies to core antigens of Gram-negative bacteria. In general, regardless of the route of administration, these strategies provide incomplete protection against disease and do not prevent colonization of the upper respiratory tract. While immunity may be enhanced in comparison with more traditional approaches, colonization still occurs.

Early attempts to control pasteurellosis by vaccination used killed whole bacteria (Alexander et al., 1952; Bapat and Sawhney, 1972; Okerman and Spanoghe, 1981; Torres-Anjel and Cotrino-Badillo, 1977). These vaccines provided protection against mortality, particularly when rabbits were challenged with homologous organisms, but they did not prevent clinical illness or colonization. To overcome this, live vaccines using avirulent streptomycin-dependent *P. multocida* were tried

(Chengappa et al., 1980; Deeb et al., 1989; DiGiacomo et al., 1987b; Lu and Pakes, 1981; Percy et al., 1985; Wei and Carter, 1978). These vaccines proved relatively effective against clinical disease and colonization caused by homologous strains, but they were less effective against heterologous strains (DiGiacomo et al., 1987b; Percy et al., 1985). In addition, they provided no control of pasteurellosis under field conditions (Deeb et al., 1989).

Bacterial derivatives, including potassium thiocyanate extracts, purified outer membranes, and inactivated toxin have also been evaluated for their ability to protect against pasteurellosis (Lu et al., 1987b, 1991c; Ringler et al., 1985; Suckow, 2000; Suckow et al., 1995). Several of these trials involved intranasal administration in an attempt to stimulate mucosal immunity and inhibit bacterial colonization. In most cases, intranasal administration provided only partial protection against disease and colonization, even when animals were challenged with homologous organisms. Interestingly, a field trial of potassium thiocyanate extract vaccine compared intranasal and subcutaneous routes of administration and found that subcutaneous administration provided better protection (Suckow et al., 2008). Intranasal administration can be more effective when antigens are combined or administered with adjuvants such as cholera toxin. For example, intranasal administration of potassium thiocyanate extract combined with inactivated toxin conveys better protection than potassium thiocyanate extract or toxin alone (Jarvinen et al., 1998). The level of protection provided by potassium thiocyanate extract or inactivated toxin vaccines may be improved by including cholera toxin, which strengthens the mucosal immune response, or by alginate encapsulation, which may enhance antigen presentation to macrophages (Jarvinen et al., 2000; Suckow et al., 1996, 1996a, 2002). However, cholera toxin combined with alginate encapsulation offers little advantage over alginate alone (Suckow et al., 1996a).

Another approach to vaccination was designed to elicit antibody against antigens that are non-serospecific, and thereby shared by most, if not all, serotypes. A commercially available *E. coli* J5 bacterin was evaluated, in the hope that antibodies elicited Gram-negative core antigens would be cross protective, thereby reducing the severity of pasteurellosis in infected rabbits. This strategy was not successful, however (Ruble et al., 1999a).

Iron-regulated outer membrane proteins expressed by bacteria may be important in virulence and tend to induce a strong immune response (Gu and Lu, 2006). Therefore, outer membrane proteins containing iron-regulated proteins might be good vaccine candidates. In fact, such a preparation, administered intranasally and combined with cholera toxin, provided protection

against experimental challenge and reduced the number of *P. multocida* organisms that could be recovered from the nasal cavity (Confer et al., 2001).

Future directions in *P. multocida* vaccine research will attempt to identify individual candidate vaccine antigens by cloning various surface proteins and assessing their role in virulence. Some promising candidates include the outer membrane protein designated Oma87, the fimbrial subunit protein designated PtfA, iron-regulated transferrin binding protein, and several enzymes involved in capsule biosynthesis (Adler et al., 1999). A different approach, which attempts to immunize with a broad cross-section of antigens, involves production of bacterial “ghosts” by phage-mediated bacterial lysis. The bacterial ghosts are devoid of cytoplasmic and genomic material, yet retain all surface antigens in their native conformation (Marchart et al., 2003).

PROPHYLAXIS WITH ANTIMICROBIALS

Antimicrobials have been used prophylactically to prevent pasteurellosis, primarily by adding them to the feed or drinking water of pregnant or lactating does. Although antimicrobials may reduce the incidence of pasteurellosis in does and their offspring, they are probably not capable of eliminating the infection. Antimicrobial agents that have been used include furazolidone, sulfaquinoxaline, sulfamethazine, and chlor-tetracycline (Hagen, 1966, 1967; Plant, 1974). Treatment of does with enrofloxacin may be more effective than other antibiotics in producing *Pasteurella*-free offspring (Suckow et al., 1996a). Does remain infected, however, perhaps because the organism colonizes sites where effective concentrations of antibiotics cannot be achieved (Mähler et al., 1995).

Treatment

Treatment of pasteurellosis is difficult. Clinical signs may subside, but the organism is rarely eliminated from the host and recurrences of disease are common (Jaslow et al., 1981). The clinical forms of pasteurellosis most likely to respond to therapy are rhinitis, conjunctivitis, and subcutaneous abscesses. Rhinitis can be treated with systemic antibiotics alone, whereas conjunctivitis should be treated with antibiotic ophthalmic ointments as well as systemic antibiotics. Abscesses should be drained, flushed, and antibiotics should be administered. Other forms of pasteurellosis respond poorly to treatment, probably because the diagnosis is only made when the disease is far advanced.

Historically, penicillin has been the most widely used antibiotic for treatment of pasteurellosis. Nearly all *P. multocida* isolates are sensitive to penicillin. One problem with penicillin therapy, which may partially explain why treatment of pasteurellosis is often unsuccessful, is that it is difficult to maintain therapeutic

blood levels. Procaine penicillin must be administered at 8-hour intervals to ensure adequate levels in blood and nasal secretions (Welch et al., 1987). If once-a-day dosage is desired, combined preparations of procaine and benzathine penicillin should be used (Gaertner, 1991). Aerosol preparations of penicillin have been suggested for treatment of rhinitis, but they offer no advantage over systemic administration (Jaslow et al., 1981).

Pasteurella multocida is sensitive to many antibiotics, and a variety have been used for treatment, including tetracyclines, chloramphenicol, gentamicin, tilmicosin, and fluoroquinolones, including enrofloxacin and related compounds (Hanan et al., 2000; Marangos et al., 1997; McKay et al., 1996; Okewole and Olubunmi, 2008; Rougier et al., 2006). Most of these antibiotics offer few advantages over penicillin; for example, one study showed that penicillin is preferable to gentamicin for treatment of rhinitis (Gaertner, 1991). Enrofloxacin and other fluoroquinones, however, may sometimes be more effective than penicillin. Enrofloxacin has been suggested as the drug of choice for treatment of *Pasteurella*-associated rhinitis or conjunctivitis, since there is a high rate of response when the drug is administered either orally or by injection (Broome and Brooks, 1991). Enrofloxacin is also effective in an experimental model of septicemic pasteurellosis (Okerman et al., 1990). A pharmacokinetic evaluation of this drug showed that two or three times a day dosing is required, depending on the route of administration (Broome et al., 1991). As is the case with most antibiotics, although enrofloxacin treatment can result in improvement of clinical signs, it does not appear to eliminate the carrier state (Mähler et al., 1995; Suckow et al., 1996a).

Regardless of which antibiotic is used for treatment of pasteurellosis, treatment should be discontinued in the event of anorexia, reduced fecal production, or diarrhea. Antibiotic therapy can cause gastrointestinal disturbances and has been associated with fatal enterocolitis (Rehg and Lu, 1981).

ENTEROTOXEMIA

Background

Enteric diseases are second only to pasteurellosis as a health problem in domestic rabbits. The primary clinical sign of these diseases is diarrhea, which is sometimes accompanied by sudden death. The etiologic agents and mechanisms responsible for enteric diseases of rabbits are varied and poorly understood. In some instances a specific etiologic agent can be identified, but frequently the cause of diarrhea is obscure. Many infectious agents have been associated with diarrhea, including coccidia (*Eimeria* sp.), rotavirus, and bacteria such as

clostridia, coliforms, and *Salmonella* (Percy et al., 1993). Therefore, enteric diseases are often grouped together under the designation “rabbit enteropathy complex.”

The term enterotoxemia is used to refer to enteropathy caused by toxigenic micro-organisms of the genus *Clostridium*. The first association of *Clostridium* spp. with rabbit enteric disease was made by Morcos (1932), who isolated an organism that he named *Bacillus* (*Clostridium*) *tympani-cuniculi*. Several years later, Lesbouyries and Berthelon (1936) observed spiral-shaped organisms in the feces of rabbits with diarrhea. Subsequent reports on rabbit enteropathy did not establish a definite link with *Clostridium* spp. until Patton et al. (1978) reported the presence of clostridial iota toxin in the cecal contents of rabbits which died in an outbreak of enteritis. At about the same time, iota toxin was found in cecal contents of rabbits that were challenged with clindamycin or lincomycin in an attempt to model *C. difficile*-mediated antibiotic associated colitis of humans (Katz et al., 1978; La Mont et al., 1979; Reh and Pakes, 1982).

When iota toxin was first identified in rabbits with diarrhea, the source of the toxin was thought to be *C. perfringens* type E (Baskerville et al., 1980; Eaton and Fernie, 1980; Patton et al., 1978). This was because *C. perfringens* type E antitoxin had the ability to neutralize the toxin, but *C. perfringens* was not isolated from the affected rabbits. Later studies implicated *C. spiroforme* as the source of the iota toxin, because it was consistently isolated from toxin-positive cecal contents (Carman and Borriello, 1982). The initial confusion about the causative organism was probably due in part to the fact that the two species produce toxins that are almost identical (Wilkins et al., 1985).

C. spiroforme is clearly an important cause of rabbit enterotoxemia. Therefore, the disease has been referred to as *C. spiroforme*-mediated diarrhea (SMD) (Carman and Evans, 1984). The importance of *C. spiroforme* in rabbits is in contrast to most animal species, in which gastrointestinal infections are associated primarily with *C. perfringens* (Borriello, 1995). In rabbits, *C. perfringens* and other clostridial species such as *C. difficile* are involved infrequently (Dubos et al., 1984; Kunstyr et al., 1975; Reh and Lu, 1981). *C. difficile* has usually been associated with prior antibiotic administration, but in at least one case it has been confirmed as the cause of a small outbreak in which there was no antibiotic exposure (Perkins et al., 1995). This outbreak was different from most cases of *C. spiroforme* enterotoxemia, in that *C. difficile* was found primarily in the ileum rather than the cecum.

Etiologic Agent

C. spiroforme is a Gram-positive spore-forming non-motile anaerobe that can be isolated from the feces of healthy humans (Cato et al., 1986). It is distinguished

FIGURE 13.9 Enterotoxemia: etiologic agent *Clostridium spiroforme*. (Courtesy of Dr. Roland Gunther)

from most other species of *Clostridium* by its curved or coiled shape, the coils being produced by long chains of linked curved organisms (Figure 13.9). *C. spiroforme* can be differentiated from *C. cocleatum*, a similar species which also has been reported in rabbits (Lelkes and Chang, 1987), by the inability of the former organism to ferment galactose (Kaneuchi et al., 1979). *C. spiroforme* organisms are able to agglutinate human erythrocytes, which implies the presence of adhesins on the bacterial surface (Baldassarri et al., 1989).

Rabbit isolates of *C. spiroforme* produce a toxin that is neutralized by antiserum to *C. perfringens* iota toxin. The toxin is cytotoxic, lethal to mice, and causes dermonecrosis in guinea pigs. Production of toxin in vitro requires the use of chopped meat medium supplemented with glucose. Non-toxigenic variants of *C. spiroforme* exist, but virtually all rabbit isolates are toxigenic (Borriello and Carman, 1983).

C. spiroforme produces a binary protein toxin consisting of two components, A and B, which are physically separate in solution. The mechanism of action involves activation of the B component by host serine proteases, either in solution or on the target cell surface. Upon activation, the B component, which is responsible for host cell binding and translocation, forms a complex with A component, which has enzymatic activity. The complex then gains access to the cytosol via receptor-mediated endocytosis. Cell damage occurs primarily as a result of disruption of the cytoskeleton by ADP ribosylation of actin (Barth 2008; Barth and Stiles, 2004; Perelle et al., 1997; Popoff et al., 1989).

Epizootiology

Recently weaned rabbits are most susceptible to enterotoxemia. The disease may occur sporadically,

but epizootics are common. One report documents the death of 47% of weanling animals over a period of 1 year in a barrier-maintained rabbit colony (Yonushonis et al., 1987). The relatively high prevalence of enterotoxemia in young rabbits is probably the result of an unstable and incompletely developed gastrointestinal flora, which allows proliferation of *C. spiroforme* in exposed animals (Carman and Borriello, 1984; Lelkes and Chang, 1987).

Adult rabbits may develop enterotoxemia, but they are more resistant than young animals. Disease in adults depends on disruption of the normal gastrointestinal flora by a mechanism such as antibiotic administration or coinfection with other pathogens (Carman and Borriello, 1984). One study showed that 86% of rabbits with enterotoxemia were coinfecting with other potentially pathogenic gastrointestinal micro-organisms such as enteropathogenic *E. coli*, *Clostridium piliforme*, rotaviruses, and *Eimeria* spp. (Peeters et al., 1986a).

Clinical Manifestations

Enterotoxemia is most likely to follow an abrupt change in the animal's life, such as weaning, lactation, change of feed, illness, or antibiotic administration. Rabbits with enterotoxemia have an acute onset of brown watery diarrhea that soils the perineal area. This is sometimes preceded by a 6–12-hour period of anorexia, during which *C. spiroforme* can be recovered from cecal contents. After the onset of diarrhea, rabbits rapidly become hypothermic and moribund, with death following in 24–48 hours. Occasionally, rabbits may survive for several days, and in rare cases they may recover. Enterotoxemia sometimes occurs without concomitant diarrhea, either as a peracute fatal illness, or as a chronic disease manifested by anorexia and weight loss (Carman and Evans, 1984; Harris and Portas, 1985).

Pathology

The pathologic changes seen in enterotoxemia have been described (Carman and Evans, 1984; Eaton and Fernie, 1980; Patton et al., 1978). Most cases have fecal soiling of the perineum, abdomen, and rear legs. The animals are usually in good condition with adequate body fat, but dehydration may be evident. The most characteristic gross finding is the presence of petechial and ecchymotic hemorrhages on the serosal surface of the cecum. The appendix, proximal colon, and distal ileum also may be involved. The cecum may be distended with gas and contain fluid to mucoid dark brown feces. Hemorrhages are evident on the mucosa, accompanied in some cases by ulcers or pseudomembranes. On cut section the submucosa of the cecum is thickened and edematous (Figure 13.10).

FIGURE 13.10 Enterotoxemia: mucosal hemorrhage and submucosal edema of cecum.

Microscopically, the most consistent changes are serosal hemorrhages and edema of the cecal submucosa. Numerous inflammatory cells, mostly neutrophils, are present in the submucosa and lamina propria, but in some cases inflammatory cells are rare. Mucosal lesions consist principally of swollen, vacuolated, and necrotic epithelium with focal erosions and ulcers. The ulcers are often overlaid by a layer of exudate composed of proteinaceous fluid, inflammatory cells, and cell debris. In some cases, areas of intact mucosa have evidence of epithelial cell proliferation, such as increased numbers of mitoses and lengthening of crypts. In others, mucosal attenuation is a prominent lesion.

Pathogenesis

Enterotoxemia is generally preceded by a change in the normal flora of the gastrointestinal tract that permits colonization and proliferation of *C. spiroforme*. Coliforms proliferate as well, but this is probably incidental and not critical for the development of enterotoxemia (Fesce et al., 1977; Sinkovics, 1976, 1978). Enteropathogenic and enterohemorrhagic strains of *E. coli* can be primary pathogens of rabbits, but the role of these strains in enterotoxemia is unclear.

Healthy rabbits have a diverse population of micro-organisms in the cecum, including ciliated protozoa, large anaerobic metachromatically staining bacilli, and small Gram-positive rods, but *C. spiroforme* is usually absent (Carman and Evans, 1984; Lelkes and Chang, 1987). Several conditions can alter the normal flora and favor colonization and proliferation of *C. spiroforme*. These include weaning, change in diet, parturition and lactation, illness, and antibiotic administration. One of the most important predisposing factors is the feeding of high-energy, low-fiber diets to weanlings.

This practice favors disruption of cecal flora by inducing cecal hypomotility and increasing the availability of simple carbohydrate substrates, such as glucose, required by pathogenic micro-organisms. *C. spiroforme* is known to require substantial amounts of glucose for toxin production (Borriello and Carman, 1983; Cheeke and Patton, 1980; Cheeke et al., 1986; Patton et al., 1978; Whitney, 1976).

Since *C. spiroforme* is not normally present in the intestinal tract of healthy rabbits, induction of enterotoxemia requires exposure to the organism. In weanlings, exposure alone is sufficient to induce disease, probably because of the unstable cecal flora characteristic of this age. In adults, exposure to *C. spiroforme* does not produce disease unless the normal intestinal flora is first disrupted. Experimentally, this has been accomplished by administration of clindamycin and lincomycin (Carman and Borriello, 1984; Fesce et al., 1977).

Diagnosis

A definitive diagnosis of *C. spiroforme*-mediated enterotoxemia requires isolation of toxigenic micro-organisms and neutralization of toxic cecal contents with specific antisera. A presumptive diagnosis can be made by identifying typical coiled Gram-positive organisms in the feces or cecal contents (Carman and Borriello, 1983).

Isolation of *C. spiroforme* is facilitated by centrifuging cecal contents for 15 minutes at 20000g (Holmes et al., 1988). This procedure concentrates the organism at the interface of the pellet and supernatant. The surface of the pellet is washed and an aliquot is taken for Gram staining. Another aliquot is plated on sheep blood agar and incubated anaerobically for 24–48 hours at 37°C. Rifampicin or tylosin can be added to the media to promote selection of the organism (Agnoletti et al., 2009; Carman and Wilkins, 1991). *C. spiroforme* can be identified by its characteristic coiled appearance, which is evident both in fresh samples and after growth in vitro.

The supernatant fluid from centrifuged cecal contents can be analyzed for the presence of toxin. Various assays have been recommended, including the guinea pig dermonecrosis assay (Yonushonis et al., 1987), mouse lethality assay (Harris and Portas, 1985; Patton et al., 1978), and an in vitro cytotoxicity assay using Vero cells (Butt et al., 1994). The supernatant is injected intradermally for the dermonecrosis assay and intraperitoneally for the lethality assay. Identification of toxin depends on neutralization of the supernatant's toxic effects by specific antiserum. Immunologic assays have also been proposed for detection of *C. spiroforme* toxin (Carman and Evans, 1984).

Polymerase chain reaction protocols have been developed for detection of *C. spiroforme* and its toxin (Drigo et al., 2008). Primers specific for detection of

the organism are based on 16S rDNA sequences; primers specific for detection of toxin are based on the sequences of the toxin genes *sas* and *sbs*. One disadvantage of this approach to diagnosis is that cecal contents typically contain polymerase inhibitors that limit somewhat the sensitivity of the assay.

Prevention and Therapy

As with all infectious diseases of rabbits, prevention of enterotoxemia depends on maintaining optimal husbandry and minimizing stress. Feeding practices are especially important (Whitney, 1976). A high-quality feed with up to 20% fiber should be fed and sudden changes in diet avoided. If a change in diet must be made, a gradual introduction of the new feed over 7 days is recommended. Infant rabbits should have feed available at 2–3 weeks of age, and early or forced weaning should be avoided.

Dietary supplementation may be helpful in reducing the incidence of enterotoxemia in rabbits. Copper sulfate, when added to the diet at 400ppm, appears to reduce the mortality from enterotoxemia in rabbit colonies (Patton et al., 1982). This may be due to inhibition of toxin production by *C. spiroforme*; levels over 250ppm have been shown to inhibit toxin production in vitro (Grobner et al., 1986). Probiotics, which are orally administered preparations of lactobacilli, yeasts, and other micro-organisms, also appear to reduce mortality from enterotoxemia when given to weanlings. Probiotics are commercially available and may be mixed with either food or water (Hollister et al., 1989, 1990).

In the event of a large outbreak, it is possible to protect against enterotoxemia by vaccinating susceptible animals with a toxoid prepared from supernatant of *C. spiroforme* cultures. Optimal protection requires two injections administered 14 days apart (Ellis et al., 1991).

Antimicrobial administration in feed or water has been advocated to reduce the prevalence of rabbit enteric diseases, but with the possible exception of coccidiosis the value of this practice is not well established (Whitney, 1976). In general, antibiotics should be used cautiously in rabbits, since they may precipitate enteric disease in some animals (Hara-Kudo et al., 1996; Rehag and Lu, 1981). This is especially true when penicillin or one of its derivatives, such as ampicillin, amoxicillin, lincomycin, clindamycin, and erythromycin, is given orally (Carman and Evans, 1984).

Antimicrobials have limited value in treating enterotoxemia. Although isolates of *C. spiroforme* are often sensitive to amoxicillin, ampicillin, chloramphenicol, sulfaquinoxaline, and erythromycin, there is little evidence that these antibiotics are effective in treating individual cases or controlling outbreaks (Agnoletti et al., 2009; Carman and Evans, 1984). This may be in

part due to the rapid progression of the clinical disease. On the other hand, imidazole derivatives, which have a good anaerobic spectrum, may be of value in controlling an outbreak. In vitro, metronidazole is uniformly active against *C. spiroforme* (Carman and Wilkins, 1991). Iprnidazole, dimetridazole, and metronidazole have been reported to reduce the number of deaths from enterotoxemia when added to the drinking water or the food (Carman and Evans, 1984; Eaton and Fernie, 1980). The efficacy of these agents is, however, variable and influenced by the stage and extent of the outbreak.

A novel approach to prevention of enterotoxemia is the use of cholestyramine, an ion exchange resin capable of binding bacterial toxins. When administered daily by gavage at a dose of 2g/20ml of water for 18 or 21 days, cholestyramine prevented mortality in rabbits with clindamycin-induced enterotoxemia (Lipman et al., 1992).

TYZZER'S DISEASE

Background

Tyzzler's disease is an enterohepatic infection caused by *Clostridium piliforme*, a poorly characterized filamentous bacterial organism. Until 1993 the organism was known as *Bacillus piliformis* based on morphologic criteria, but it was reassigned to the genus *Clostridium* based on its 16S rRNA sequence (Duncan et al., 1993). The disease has been reported in many species, including mice, rabbits, rats, hamsters, gerbils, cats, and rhesus monkeys (Ganaway, 1971a). In addition, a case of *C. piliforme* infection has been reported in a patient infected with HIV-1 (Smith et al., 1996). Clinical signs in animals typically include profuse diarrhea and rapid death. Lesions are most common in the liver and cecum.

Tyzzler's disease was first described in 1917, when Ernst Tyzzler observed an epizootic of focal hepatitis and enteritis in Japanese waltzing mice (Tyzzler, 1917). He found the etiologic agent in hepatic parenchymal cells and in cecal epithelium, but was unsuccessful in propagating it on artificial media. In the years following Tyzzler's original description the disease was reported occasionally in mice, but it was not recognized in rabbits until 1965, when Allen et al. described two epizootics which had clinical and pathologic features similar to the mouse disease. Weanlings were most often affected, and death ensued rapidly after a period of brief diarrhea. Lesions included multifocal hepatic necrosis, necrosis of cecal mucosa, and edema of cecal submucosa. Intracytoplasmic bacilli were visible in all affected organs, but attempts to isolate them on artificial media were unsuccessful. The disease was transmitted to healthy rabbits treated with cortisone and then exposed to contaminated bedding.

Tyzzler's disease has been reported in rabbits many times since it was first recognized (Cutlip et al., 1971; Ganaway and Allen, 1981; Ononiwu and Julian, 1978; Peeters et al., 1985; Prescott, 1977; Simon, 1977; Van Kruiningen and Blodgett, 1971). Most of these reports describe clinical and pathologic features similar to those outlined by Allen et al. (1965).

Etiologic Agent

Clostridium piliforme is a large, pleomorphic, Gram-negative, spore-forming, obligate intracellular bacterium. It possesses peritrichous flagella and is therefore motile. *C. piliforme* is a unique pathogen and poorly characterized, in part because it is difficult to propagate in vitro. Although there are two reports of isolation of the organism on cell-free media (Kanazawa and Imai, 1959; Simon, 1977), these findings have not been replicated and attempts using 190 different microbiological media have been unsuccessful (Thunert, 1984). It is now generally accepted that living cells are required for propagating the organism.

C. piliforme can be isolated and serially passaged by yolk sac injection of embryonated hens' eggs (Craigie, 1966a, 1966b; Fries, 1977a; Ganaway et al., 1971b). Under these conditions the organism retains its pathogenicity for numerous passages. Cell culture can also be used for cultivation of *C. piliforme* (Ganaway et al., 1985b). Various established mammalian cell lines are suitable, including mouse and rat hepatic cells and mouse fibroblasts (Riley et al., 1990).

Studies of *C. piliforme* isolates from various species indicate a high degree of antigenic diversity, but some shared antigens do exist (Fujiwara et al., 1971, 1973, 1985; Riley et al., 1990; Toriumi et al., 1986). Most notable is a cross-reacting group of immunodominant antigens with molecular weights of approximately 56–59 kDa. These are believed to represent bacterial flagellar proteins (Motzel and Riley, 1991). The high degree of antigenic diversity is probably related to the fact that isolates of *C. piliforme* differ in host specificity; some have the ability to infect only the species from which the isolate was obtained, whereas others have a broad host range (Franklin et al., 1994).

Epizootiology

Tyzzler's disease is widespread in rabbit colonies. Infection is probably transmitted by ingestion of spores, since the vegetative form of *C. piliforme* is unstable outside the host (Ganaway and Allen, 1981). Classically, the disease occurs epizootically. At the peak of outbreaks, the mortality rate may approach 50%. Losses are particularly high in 6–12-week-old rabbits, but younger rabbits and adults may also contract the disease (Allen et al., 1965; Cutlip et al., 1971; Ononiwu and Julian,

1978; Peeters et al., 1985; Van Kruiningen and Blodgett, 1971). Tyzzer's disease may also occur as an enzootic infection, with large numbers of subclinically infected animals and only sporadic clinical cases (Fries, 1979b; Prescott, 1977). A serologic survey of rabbits from 15 breeding or research facilities in Japan revealed antibody to *C. piliforme* in nine facilities (Goto et al., 1991). In positive facilities, approximately 15% of tested rabbits had detectable antibody.

Clinical Manifestations

Most *C. piliforme* infections are subclinical, but when clinical signs occur they typically appear suddenly. Young animals are the most susceptible, with entire litters sometimes affected. The most prominent signs are profuse watery diarrhea and fecal staining of the perineum. Affected rabbits are listless, anorectic, and dehydrated. Death occurs within 1–2 days after the onset of symptoms in about 90% of the animals (Allen et al., 1965; Cutlip et al., 1971). Rabbits that survive acute infection sometimes develop chronic disease, the signs of which include progressive weight loss and cachexia (Peeters et al., 1985).

Pathology

Lesions of Tyzzer's disease in rabbits are described in detail by Allen et al. (1965). They are characterized principally by necrosis and occur in the cecum, adjacent intestine, liver, and heart. The cecum and intestine are consistently affected, but the heart is frequently spared. Lesions are usually present in the liver, but may be absent in peracute cases (Licois, 1986).

Grossly, there is fecal soiling of the perineum and dehydration may be evident. The serosal surface of the cecum has ecchymotic or petechial hemorrhages, the wall is thickened and edematous, and the mucosa contains patchy areas of necrosis. These lesions often extend to the adjacent distal ileum and proximal colon. In chronic cases there may be stenosis of the intestine due to fibrosis at the sites of necrosis. The liver contains numerous pinpoint white foci, usually 2 mm in diameter or less, throughout the parenchyma (Figure 13.11). White streaks or pale foci may be present in the myocardium, most often in the left ventricle and septum.

Microscopically, there are hemorrhages in the subserosa of the cecum. Submucosal edema and mucosal necrosis are consistent findings in the cecum and adjacent intestine. Mucosal necrosis sometimes extends into the submucosa and muscularis. The liver contains focal areas of necrosis that are often close to portal areas (Figure 13.12). Polymorphonuclear leukocytes may be present around the necrotic foci and in hepatic sinusoids. Chronic hepatic lesions may be calcified, with

FIGURE 13.11 Tyzzer's disease: liver, small foci of necrosis. Similar lesions occur in diseases such as listeriosis and tularemia.

FIGURE 13.12 Tyzzer's disease: focal area of necrosis. Similar lesions occur in diseases such as listeriosis and tularemia.

surrounding areas of fibrosis and multinucleated giant cells. Myocardial lesions consist of focal or linear areas of necrosis, sometimes associated with a moderate inflammatory cell response, in close proximity to myocardial blood vessels.

C. piliforme can be demonstrated in affected tissues, especially the liver, by special stains (Figure 13.13). The Warthin-Starry silver stain is most effective but periodic acid-Schiff or Giemsa stains can also be used. With the Warthin-Starry stain the bacilli appear as light brown to black rods in the cytoplasm of viable hepatocytes surrounding areas of necrosis. In longstanding lesions the bacilli are not present.

Pathogenesis

C. piliforme is transmitted by the fecal-oral route. Spores are shed in the feces and infection occurs by

FIGURE 13.13 Tyzzer's disease: *Clostridium piliforme* in hepatocytes. Warthin-Starry stain. (courtesy of Dr. Roland Gunther)

ingestion of contaminated material (Allen et al., 1965; Tyzzer, 1917). It is not known whether other routes of transmission are important in rabbits, but transplacental transmission has been documented in rodents (Fries, 1978, 1979a). Other events in the pathogenesis of the disease are unclear. The presence of specific antibody in apparently healthy animals suggests that the organism initially resides latently in the intestinal tract (Goto et al., 1991). Subsequently, stress or immunosuppression appears to precipitate overt disease, possibly by favoring invasion of the intestinal mucosa and systemic spread of the organism. This is suggested by the need for corticosteroid administration to consistently reproduce the disease experimentally (Allen et al., 1965). After the organism penetrates the mucosa, infection of the liver occurs by way of the portal circulation, whereas infection of the heart occurs via the lymphatics (Allen et al., 1965). Studies in mice suggest that host defenses that are particularly important in determining the course of disease include neutrophils and natural killer cells, with macrophages playing a much more limited role (Van Andel et al., 1997).

Diagnosis

A presumptive diagnosis of Tyzzer's disease can be made on the basis of typical gross and microscopic lesions, but a definitive diagnosis depends on demonstration of characteristic intracellular bacteria in affected tissues. Immunofluorescence may help identify *C. piliforme* when the organisms are not evident in specially stained preparations (Fries, 1977; Savage and Lewis, 1972). Isolation of the organism by inoculation of embryonated eggs or tissue culture is desirable but not often attempted in practice. Rabbit carriers of *C. piliforme* can

sometimes be identified by housing weanling gerbils on soiled bedding. Since gerbils are particularly susceptible to *C. piliforme* infections, they can be expected to develop histologically evident Tyzzer's disease when exposed to spores present in feces (Gibson et al., 1987).

Screening for serum antibodies against *C. piliforme* can be used as a means of rabbit colony surveillance. Antibodies are produced in subclinically infected animals and persist for long periods, possibly throughout life (Fries, 1979b). They can be detected in rabbits with an indirect fluorescent antibody assay (Fries, 1977b). Enzyme-linked immunosorbent assays can also be used and have the advantage of being simpler to perform while providing comparable results (Motzel et al., 1991; Waggle et al., 1987). Antigens for either assay can be prepared from *C. piliforme* grown in primary chick embryo liver cultures or a rat hepatic cell line (BRL 3A). An alternative antigen for the enzyme-linked immunosorbent assay is a trivalent preparation of purified *C. piliforme* flagella (Motzel and Riley, 1991).

Polymerase chain reaction (PCR) protocols for detection of *C. piliforme* infection have been described. Goto and Itoh (1996) developed an avidin-biotin-based enzyme assay to detect DNA amplified by PCR from rodent tissue specimens, using a primer directed toward a conserved area of the 16S rRNA gene. Detection of *C. piliforme* in rodent fecal specimens by PCR has also been reported (Furukawa et al., 2002). Feldman et al. (2006) further refined PCR methodology and extended its application to rabbit isolates.

A problem confronting the development of reliable *C. piliforme* PCR assays is that there is significant nucleotide sequence diversity in 16S rRNA genes of individual isolates; it is also likely that some sequences are shared by closely related non-pathogenic clostridia (Feldman et al., 2006). Therefore, the sensitivity and specificity of any given assay remain uncertain. In an effort to address this problem, Niepceron and Licois (2009) developed a nested PCR designed to maximize specificity while retaining adequate sensitivity.

Regardless of which PCR assay is used, it is important to recognize that positive results not confirmed by clinical or pathologic signs of disease may represent latent *C. piliforme* infection or, alternatively, cross reaction with a similar but non-pathogenic strain. Similarly, negative PCR results in the presence of serologic evidence of infection may suggest elimination of the organism, intermittent shedding, or the presence of a *C. piliforme* strain with a different DNA sequence in the region where the PCR primers bind. A study reported by Pritt et al. (2010) demonstrated negative PCR results in a group of 20 rabbits seropositive for *C. piliforme*, underscoring the importance of not relying on a single diagnostic technique when attempting to ascertain whether the organism is present in a colony.

Prevention and Therapy

There is no treatment known to be of value for clinically ill rabbits. Antibiotic therapy yields poor results, perhaps because the intracellular location of the organism limits efficacy. This is substantiated by a study in which six antibiotics were tested for their ability to inhibit the growth of *C. piliforme* in embryonated eggs (Ganaway et al., 1971b). None was effective: chlortetracycline, penicillin, streptomycin, and erythromycin were only partially inhibitory, whereas chloramphenicol and sulfamethazine completely lacked inhibitory properties. Although antibiotics are ineffective in clinical cases, anecdotal evidence suggests they may be of value in limiting epizootics. In one outbreak, oxytetracycline was added to the drinking water and the epizootic ended in 36 hours (Van Kruiningen and Blodgett, 1971). In another instance, clinical disease was eliminated from a colony of mice after administration of tetracycline in the drinking water (Hunter, 1971).

No vaccine is available for Tyzzer's disease, so prevention depends mostly on good husbandry. Practices such as frequent cage cleaning, prevention of crowding, and dust control should be of value in reducing exposure of animals to spores. Spores can be inactivated by sodium hypochlorite solution (0.3%) or by heating at 80°C for 30 minutes (Ganaway, 1980). Removal of sick animals and minimization of stress are of obvious value in reducing the likelihood of disease outbreaks. Sulfonamides should be administered cautiously to rabbits, since sulfaquinoxaline administration has been associated with losses from Tyzzer's disease (Ganaway et al., 1971a).

Elimination of Tyzzer's disease from an infected colony might be possible by serologically screening the colony and removing animals testing positive. Cesarean derivation might be possible, but transplacental transmission has been documented in rodents and may occur in rabbits as well (Fries, 1979a).

COLIBACILLOSIS

Background

Escherichia coli is recognized as a cause of enteric disease in many species, but as recently as the late 1970s the prevailing view was that *E. coli* is not a primary pathogen in rabbits (Holmes, 1984). Conclusive evidence to the contrary has been presented since that time. The earlier view stemmed from the fact that *E. coli* proliferates as a secondary response to an altered intestinal environment (Prohaszka, 1980). *E. coli* is frequently present in rabbits with diarrhea but is uncommon in the intestinal tract of healthy animals (Gouet and Fonty, 1979; Peeters et al., 1984b; Vetesi and Kutas, 1973). This

pattern would seem to implicate *E. coli* as an etiologic agent of enteric disease, but it was difficult to confirm that *E. coli* is a primary cause of gastrointestinal disease until Koch's postulates were fulfilled.

This was accomplished in 1977, when Cantey and Blake reproduced diarrhea in rabbits by oral inoculation of *E. coli* strain RDEC-1 (Rabbit Diarrhea *E. coli*-1), which had been isolated from diarrheic rabbits. As few as 150 organisms were capable of producing severe disease, yet they failed to invade the mucosa or produce classic *E. coli* enterotoxins (Cantey and Blake, 1977). This was one of the first reports documenting a role for non-invasive, non-toxicogenic *E. coli* in enteric disease. RDEC-1 is now referred to as an "enteropathogenic" strain of *E. coli*. Enteropathogenic strains are the most common causes of rabbit colibacillosis, although other pathotypes, such as enterohemorrhagic and necrotoxicogenic strains, have been reported as well (see below).

Since Cantey and Blake's work with RDEC-1, many investigators have isolated similar strains of *E. coli* from rabbits and successfully reproduced diarrhea (Camguilhem, 1985; Camguilhem and Milon, 1989; Okerman and Devriese, 1985; Peeters et al., 1984a, 1984c; Prescott, 1978; Varga and Pesti, 1982). The interest of these investigators stems from frequent epizootics of fatal enteropathy in the commercial rabbitries of Europe, many of which are associated with enteropathogenic *E. coli* (Camguilhem and Milon, 1989; Milon et al., 1990; Peeters et al., 1984c). These epizootics remain a problem, particularly in European rabbitries. This, coupled with the fact that the rabbit disease is useful as a model for human *E. coli* infection, has generated much research interest.

Etiologic Agent

E. coli is a facultatively anaerobic Gram-negative bacillus, which is either motile by peritrichous flagella or non-motile. Most strains ferment glucose and other carbohydrates; the ability to ferment lactose is an important distinguishing characteristic of *E. coli* and closely related species. In addition to flagella, many strains have pili, which function as adhesive organelles. *E. coli* are serogrouped according to the presence or absence of specific somatic (O) and flagellar (H) antigens. Capsular (K) antigens may be used as well, but they are absent from a high percentage of strains (Ørskov, 1984). Another method of grouping *E. coli* is biotyping, which is based on carbohydrate fermentation patterns (Camguilhem and Milon, 1989; Okerman and Devriese, 1985; Peeters et al., 1988).

Most isolates of *E. coli* do not cause disease, but some strains possess plasmid- or bacteriophage-acquired virulence factors that render them pathogenic. At least five types of pathogenic *E. coli* can produce diarrheal

disease: enteropathogenic, enterotoxigenic, enterohemorrhagic, enteroinvasive, and enteroaggregative. A necrotoxic group has also been proposed (DebRoy and Maddox, 2001). In rabbits, enteropathogenic strains are by far the most important cause of *E. coli*-associated diarrhea (Okerman, 1987; Peeters et al., 1988). Enteropathogenic *E. coli* produce neither classical toxins nor invasion factors, depending instead on microvillus attachment and effacement for expression of pathogenicity (Moon et al., 1983). Other types of pathogenic *E. coli* do not typically cause disease, although an outbreak of bloody diarrhea in Dutch Belted rabbits was attributed to enterohemorrhagic *E. coli* (Garcia et al., 2002) (Figures 13.14 and 13.15). Further investigation found that 25% of Dutch Belted rabbits from a

FIGURE 13.14 Enterohemorrhagic *E. coli* infection. Locally extensive erosion of cecal mucosa. (Courtesy of Dr. James G. Fox and Infectious Diseases Society of America)

FIGURE 13.15 Enterohemorrhagic *E. coli* infection. Thrombi in glomerular capillaries exhibit positive staining for fibrin. Carstairs's stain. (Courtesy of Dr. James G. Fox and Infectious Diseases Society of America)

commercial vendor carried the organism (Garcia and Fox, 2003). The authors experimentally reproduced intestinal and renal lesions in Dutch Belted rabbits following oral inoculation with enterohemorrhagic *E. coli* or intravenous infusion with Shiga toxin (Garcia et al., 2006, 2008). Necrotoxic *E. coli* have also been reported in rabbits, but this group appears to be an infrequent cause of disease (Ansuini et al., 1994).

Many serotypes of enteropathogenic *E. coli* have been associated with rabbit diarrhea. Serotype O109:H2 is mainly isolated from suckling rabbits, whereas other serotypes (O15:H-, O103:H2, O20:H7, O109:H2; O128:H2, O132:H2, O153, and others) are isolated from weanlings (Cantey and Blake, 1977; Peeters, 1984c; Penteado et al., 2002; Prescott, 1978; Varga and Pesti, 1982). The most pathogenic, and perhaps the most common, serotypes from weanlings are O15:H- and O103:H2; small numbers of these can induce diarrhea and result in over 50% mortality (Peeters et al., 1988). Serotype O103:H2 is particularly prevalent in European rabbits, with animals of 4–5 weeks of age most susceptible to infection (Fiederling et al., 1997; Licois et al., 1992).

Biotyping can be used as an alternative to serotyping for characterizing rabbit isolates of enteropathogenic *E. coli*. Biotyping is based on carbohydrate fermentation patterns, so it can readily be performed by most laboratories. A method for biotyping has been described by Okerman and Devriese (1985), with modifications proposed by Peeters et al. (1988) and Camguilhem and Milon (1989). There is good correlation between biotype and pathogenicity, so biotyping is a potentially useful pathologic and epidemiologic tool. For example, isolates from weanling rabbits with severe clinical signs are usually rhamnose-negative, whereas isolates from weanlings with mild signs are rhamnose-positive (Camguilhem and Milon, 1989; Fiederling et al., 1997). An important exception to this rule is serotype O15:H- (RDEC-1-like), which causes high mortality in weanlings yet is rhamnose-positive.

Studies of the genetics of enteropathogenic *E. coli* have contributed enormously to an understanding of disease pathogenesis. The genome sequence of enteropathogenic *E. coli* has been reported and will facilitate future work to identify and characterize unique virulence determinants (Iguchi et al., 2009; Rasko et al., 2008). Some of the main genes and protein gene products important for pathogenicity are described below.

Enteropathogenic *E. coli* has developed a sophisticated mechanism for initial attachment to epithelial cells. In the case of human isolates, attachment is mediated, at least in part, by bundle-forming pilus proteins (BFP), which are encoded by 14 genes located on a plasmid. Other proteins promoting colonization, including fimbriae or flagella, play a role as well (Chen and Frankel, 2005; Erdem et al., 2007). Fimbriae are

particularly important in rabbit isolates, which have not been shown to express BFP (Newton et al., 2004).

At least three different plasmid-encoded fimbrial adhesins have been reported in rabbit strains of enteropathogenic *E. coli*. These have been termed AF/R1, AF/R2, and Ral fimbriae and appear to play a role in host species specificity (Fiederling et al., 1997; Hart et al., 2009; Krejany et al., 2000; Pillien et al., 1996; Robins-Browne et al., 1994, 1994a). Any given isolate does not typically contain all three types of adhesins; the prevalence of each adhesin varies depending on geographical region and serotype (Dow et al., 2005; Penteado et al., 2002). AF/R1 and Ral are usually expressed on serotype O15:H-, whereas AF/R2 is expressed on serotype O103:H2.

In addition to plasmid-encoded fimbriae, long polar fimbriae that are encoded by O-islands on the bacterial chromosome have been identified in a rabbit strain designated 83/39 (Newton et al., 2004). Recently, in the same strain, a gene coding for yet another possible adhesive structure has been identified. The gene has been designated as *rpeA* (rabbit enteropathogenic *E. coli* plasmid encoded autotransporter) and appears to be related to serine protease adhesins from other Gram-negative pathogens (Leyton et al., 2007). Experiments with mutant strains lacking the ability to express the various types of fimbriae mentioned above suggest that fimbriae enhance virulence but are not essential for colonization and disease to occur; other virulence factors appear to be involved as well.

Once bacterial attachment occurs, enteropathogenic *E. coli* relies on effector proteins to disrupt host cellular functions (Dean and Kenny, 2009). The most well-known effector proteins are encoded by a segment of the genome called the locus of enterocyte effacement (LEE), although some are encoded outside this region. Those encoded by LEE include Tir, Map, EspA, EspB, EspF, EspG, EspH, and EspZ. The Esp designation refers to 'enteropathogenic *E. coli* secreted protein'. These proteins have multifunctional, cooperative, and redundant properties. They act in concert to interfere with phagocytosis, disrupt microvilli and tight junctions, induce pedestal formation by the host cell, and modulate inflammatory pathways. A study of the role of EspF from a rabbit isolate suggests that it plays a role in tight junction disruption and pedestal formation (Peralta-Ramirez et al., 2008). Regulation of LEE gene expression occurs via the LuxS quorum sensing (QS) signaling system (Zhu et al., 2007).

Proteins encoded by the LEE region appear to be important for pathogenicity in rabbits. For example, in a prototype rabbit isolate of serotype O103, insertional mutagenesis studies have shown that several proteins encoded by the LEE region are important for cytopathic effects in vitro and virulence in vivo (De Rycke et al.,

1997). More specific analyses of individual proteins have shown that EspA and EspB proteins are essential for virulence of rabbit isolates; mutations constructed in the genes coding for these proteins inhibit the formation of typical lesions in vivo (Abe et al., 1997, 1998).

Effector proteins are delivered directly into host epithelial cells by a type three secretion system (T3SS) that is encoded by 12 genes on the LEE segment of the genome. This type of system resembles a needle and syringe on the molecular level and is used by many enteric pathogens to inject the effector proteins into the host cell cytosol. A major constituent of the system is EspA protein, which forms hollow tubular structures through which effector proteins are translocated (Chen and Frankel, 2005).

Enteropathogenic *E. coli* uses an outer membrane protein known as intimin to induce enterocyte effacement and promote intimate bacterial attachment to the host cell. Intimin is encoded by a gene named *eae* (for *E. coli* attaching and effacing) located on the LEE region of the genome. Intimin is necessary for full virulence. The *eae* gene is present in most highly pathogenic strains isolated from rabbits (Blanco et al., 1996, 1997; Penteado et al., 2002; Pohl et al., 1993). The *eae* gene from rabbit strain RDEC-1 has been sequenced and shown to have a high degree of homology with other pathogenic bacteria that produce enterocyte effacement (Agin and Wolf, 1997; Agin et al., 1996).

Intimin promotes close attachment with the host cell by a unique mechanism, whereby the bacterium actually inserts a receptor for intimin into the host cell membrane via the type III secretion system. This receptor is known as Tir (translocated intimin receptor). The binding of intimin to Tir allows initiation of pathogenic effects while keeping the organism on the extracellular surface. Tir seems to have a particularly important role in initiation of host cell pedestal formation at the site of attachment (Chen and Frankel, 2005; DeVinney et al., 1999; Nougayrede et al., 2003; Oliver-Gonzalez et al., 2008). Both Tir and intimin have been shown to be essential for full pathogenicity in rabbit isolates belonging to serotype O103; *eae* and *tir* mutants survive in the rabbit intestinal tract but do not cause clinical disease (Marches et al., 2000).

Epizootiology

Rabbit colibacillosis has attracted more attention from European than American investigators. The disease may be more prevalent in Europe than in North America, but there are no specific data to support this view. Indeed, the disease may be present but largely unrecognized in American rabbit colonies.

Several different syndromes of colibacillosis have been identified, each of which is associated with

specific serotypes and biotypes of *E. coli* (Camguilhem and Milon, 1989; Okerman and Devriese, 1985; Peeters et al., 1988). These syndromes include: (1) neonatal diarrhea with high mortality, (2) weanling diarrhea with high mortality, and (3) weanling diarrhea with low mortality. Neonatal diarrhea is associated with serotype O109:H2. Weanling diarrhea with high mortality is usually caused by serotype O103:H2, which is rhamnose-negative, or by serotype O15:H- (RDEC-1-like), which is rhamnose-positive. Weanling diarrhea with low mortality is caused by serotypes O123, O128, O132, and others, most of which are rhamnose-positive.

The prevalence of the various serotypes of enteropathogenic *E. coli* depends on geographic location. In the United States serotype O15:H- predominates (Cantey and Blake, 1977). In France, serotype O103:H2 is isolated most often (Camguilhem and Milon, 1989; Fiederling et al., 1997), whereas in Belgium serotypes O15:H-, O128:H2, and O132:H2 are the most common (Peeters et al., 1988).

Clinical Manifestations

The clinical signs of colibacillosis are similar to those of other diarrheal diseases of rabbits. Colibacillosis can occur in two distinct age groups: 1–2-week-old sucklings and 4–6-week-old weanlings, the latter being most commonly affected. In suckling rabbits, clinical signs include severe yellowish diarrhea and high mortality, sometimes encompassing an entire litter. In weanlings, two types of enteropathy occur with quite different clinical signs. The first is characterized by profuse liquid diarrhea, dehydration, weight loss, and high mortality within 5–14 days. This type is caused by highly virulent strains such as O15:H- and O103:H2. The second type of enteropathy is characterized by mild diarrhea without dehydration, transient growth retardation, and minimal mortality. This type is caused by less virulent strains such as O123, O128, and O132 (Camguilhem and Milon, 1989; Okerman and Devriese, 1985; Peeters et al., 1988).

Pathology

Gross necropsy findings in colibacillosis include thickening of the wall of the ileum, cecum, and colon. Paintbrush hemorrhages are sometimes evident on the serosal surface, and mesenteric lymph nodes may be swollen. Cecal contents are watery and brown. Microscopically, “attaching and effacing” lesions of the intestine are characteristic. There is atrophy and fusion of microvilli in the affected portions of intestine. Epithelial cells are flattened and disorganized (effaced), and ulcers may be present, but the basement membrane is usually intact. Infiltration of the lamina propria by polymorphonuclear leukocytes and submucosal edema are common

findings. An important feature is the presence of large numbers of coliform bacilli intimately attached to the epithelium (Cantey and Blake, 1977; Coussement et al., 1984; Peeters et al., 1984b, 1988). There may be prominent adherence of organisms to the epithelial cells overlying Peyer’s patches, especially with the O15:H- serotype (Inman and Cantey, 1983, 1984).

Electron microscopic studies of experimental infections with serotype O103 reveal classic attaching and effacing lesions. Bacterial fimbriae can be identified within 24 hours of infection. At 48 hours, bacteria are adhered to microvilli overlying Peyer’s patches, the microvilli are disorganized, and intestinal mucus secretion appears increased. Interestingly, at this time fimbriae are no longer evident. At 72 hours, cuplike projections indicative of pedestal formation are apparent in the epithelial cells underlying attached bacteria (Heczko et al., 2000). The extent of early bacterial association with epithelium overlying Peyer’s patches may vary depending on the particular isolate and conditions of infection. For example, another electron microscopic study found that bacterial association with Peyer’s patches was less apparent with the O103 serotype than with the O15 serotype (Licois et al., 1991).

Pathogenesis

E. coli is present in low numbers in the intestine of healthy rabbits, yet it proliferates in diarrheic rabbits regardless of the primary etiologic agent. This may be due in part to an increase in cecal pH that accompanies most cases of diarrhea. In the normal rabbit cecum, at pH below 6.8, fatty acids exert an inhibitory effect on the growth of *E. coli* (Skrivanová and Marounek, 2007). This is particularly true prior to weaning, during which time medium-chain fatty acids (capric and caprylic acid) present in does’ milk appear to inhibit bacterial growth (Gallois et al., 2008; Skrivanová et al., 2009). This effect is evidently independent of specific antibody directed against *E. coli* (Gallois et al., 2007; Skrivanová et al., 2009). The loss of a source of these fatty acids at weaning, coupled with an increase in pH that occurs at the same time, means that the inhibitory effect of the remaining fatty acids is reduced and conditions become favorable for *E. coli* proliferation (Prohaszka, 1980; Prohaszka and Baron, 1981; Vetesi and Kutas, 1973).

The changes in intestinal environment that occur at weaning are necessary but not sufficient for disease to occur. In colibacillosis the key event in pathogenesis, without which disease does not occur, is attachment of enteropathogenic *E. coli* to the mucosal surface and subsequent effacement of epithelial cells. The ability to attach to and efface rabbit intestinal epithelium is possessed only by enteropathogenic serotypes of *E. coli*; isolates from healthy rabbits do not have this ability.

There are two groups of enteropathogenic serotypes, with tropisms for different age groups and intestinal compartments. Isolates from suckling rabbits attach to the entire length of the small and large intestine, whereas isolates from weanling rabbits attach only to the distal small intestine and large intestine. Cross-infection experiments have shown that weanling isolates are only weakly pathogenic for sucklings and vice versa (Peeters et al., 1984c, 1984d).

Differences in bacterial attachment that vary with animal age and intestinal location may be mediated in part by characteristics of intestinal mucins, some of which have been shown to inhibit bacterial attachment (Mack and Sherman, 1991; Mack and Blain-Nelson, 1995). Other factors that influence colonization include the presence of other bacterial species in the intestine. For example, segmented filamentous bacteria, a poorly characterized family of bacteria that colonize ileal Peyer's patches in a variety of species, appear to inhibit the colonization ability of enteropathogenic *E. coli*, which attach preferentially to the same site (Heczko et al., 2000a).

Mucosal adhesion of enteropathogenic *E. coli* has been studied extensively, especially for serotype O15:H- (strain RDEC-1), and the mechanism is similar for other serotypes. Serotype O15:H- adheres in a two-step process. Initial adhesion occurs at the tips of the microvilli overlying Peyer's patches (Von Moll and Cantey, 1997). This is mediated by fimbriae, designated AF/R1 (attaching factor/rabbit 1), which consist of subunits of molecular weight of about 19000 (Berendson et al., 1983). Ral fimbriae are probably involved as well (Krejany et al., 2000). Expression of AF/R1 is mediated by an 86-MDa plasmid (Wolf et al., 1988), and the gene has been cloned (Wolf and Boedeker, 1990). The second step in adhesion involves attachment of the organism to the cell membrane after effacement of microvilli. This event is independent of fimbriae expression, and can occur even when not preceded by the initial step. Therefore, fimbriae are not essential for pathogenicity; rather, they serve as an accessory virulence factor that promotes initial interaction of the organism with normal epithelial cells (Cantey et al., 1989; Wolf et al., 1988). This view is supported by the observation that there is a weak correlation between the ability of an isolate to adhere to epithelial cells in vitro and its ability to induce disease in vivo (Robins-Browne et al., 1994, 1994a).

Adhesion of highly pathogenic O103 strains has also been studied, and is mediated by the fimbrial protein designated AF/R2. AF/R2 is important for pathogenicity, but for strain RDEC-1 there are probably other factors involved as well (Milon et al., 1990; Okerman, 1987).

From the bacterial standpoint, the pathogenesis of infection following initial adhesion is governed by

the secretion of effector proteins via a type 3 secretion system, the details of which are described above (see Etiologic Agent, above). Binding occurs between intimin and the translocated bacterial receptor, Tir, and this produces the intimate attachment required for the effacement of microvilli and the formation of actin-rich epithelial cell pedestals. Comprehensive reviews of bacterial factors important in pathogenesis have been prepared by Chen and Frankel (2005) and Dean and Kenny (2009).

The development of diarrhea after intimate bacterial attachment is likely due to multiple perturbations of host cell function. The exact mechanisms are poorly characterized, but may include: (1) loss of microvilli with subsequent malabsorption; (2) alterations in electrolyte transport; (3) alteration in epithelial cell permeability by disruption of tight junction integrity; (4) production of proinflammatory cytokines (Chen and Frankel, 2005; Ramirez et al., 2005). Increased apoptosis is one recognized mechanism by which intestinal pathogens produce diarrheal disease, but conflicting results about the role of apoptosis have been reported in rabbits. Tsalie et al. (2006) reported an increase in epithelial cell apoptosis in the ileum, whereas Heczko et al. (2001) concluded that there was little evidence that rabbit isolates caused increased apoptosis.

Resistance of rabbits to strain RDEC-1 is probably mediated by antibodies to fimbriae or O antigen (Cantey et al., 1987; McQueen et al., 1992). High levels of anti-fimbrial IgA are produced by lymphoid cells in the intestinal mucosa, then transported to the liver and secreted into the bile. Surprisingly, antigen-specific lymphoid cells are most numerous in the duodenum and jejunum, whereas colonization is densest in the ileum, cecum, and colon. This may be due to migration of B lymphocytes from the distal intestine to more proximal sites (McQueen et al., 1992).

Diagnosis

A presumptive diagnosis of rabbit colibacillosis can be made by demonstration of bacterial attachment and effacement of intestinal epithelium. Although other lesions are often present as well, they are less specific and easily confused with lesions of enterotoxemia. A definitive diagnosis requires isolation of enteropathogenic *E. coli*. Enteropathogenic strains can be differentiated from non-pathogenic ones by serotyping, biotyping, or by PCR detection of the *eae* gene that codes for intimin. It is important to recognize that not all isolates of a given serotype or biotype are equally pathogenic. For example, there are non-pathogenic O103 strains as well as highly pathogenic ones.

A capture enzyme-linked immunosorbent assay (cELISA) has been developed for screening rabbitries for

the presence of enteropathogenic *E. coli* (Vandekerckhove et al., 2002). This assay uses monoclonal antibodies to intimin to “capture” antigen from a crude *E. coli* outer membrane protein preparation. The cELISA detects serum antibody specific for intimin.

Prevention and Therapy

Therapy of colibacillosis consists of supportive care and antibiotic administration. In severe cases treatment is likely to be unrewarding, but in cases of weanlings with mild diarrhea therapy is sometimes worthwhile. Rabbit isolates of *E. coli* are susceptible to a variety of antibiotics, including ampicillin, amoxicillin, gentamicin, and colistin (Milon et al., 1990). Empirically, it would seem prudent to select an antibiotic with minimal activity against Gram-positive bacteria, so as to interfere as little as possible with re-establishment of normal intestinal flora. In colibacillosis caused by serotype O15H-, chloramphenicol and neomycin have each been used successfully (Peeters et al., 1986b). Regardless of which antibiotic is chosen, severely affected animals should be culled and facilities thoroughly sanitized. In addition, high-fiber diets should be offered, both as a therapeutic measure and a preventive one.

Attempts have been made to use dietary administration of medium-chain fatty acids to protect weanling rabbits against *E. coli* infection. The rationale behind this strategy was the recognition that fatty acids present in does' milk appear to offer protection to suckling rabbits. Although these compounds are bacteriostatic in vitro, dietary administration of caprylic acid or triglycerides of medium-chain fatty acids did not affect the course of disease in rabbits that were challenged experimentally. Treated groups did, however, have fewer coliforms present in the intestine (Gallois et al., 2008; Skrivanová et al., 2008).

Several novel approaches have been evaluated for their ability to prevent, or reduce the severity of, enteropathogenic *E. coli* infections. These include dietary administration of vitamin E and orogastric administration of epidermal growth factor.

Vitamin E has been shown to have beneficial effects on the outcome of *E. coli* infections in some animal species, possibly by modulating the inflammatory response. In experimentally challenged rabbits, however, administration of vitamin E did not prevent colonization or clinical signs of disease, although it ameliorated somewhat the disruption of mucosal architecture and enhanced the inflammatory response (Tsalie et al., 2006).

Epidermal growth factor (EGF) causes diffuse lengthening of microvilli, so administration of it might be expected to protect against enteropathogenic *E. coli* infection. Indeed, daily orogastric administration

beginning 3 days prior to challenge was associated with inhibition of colonization, reduced microvillous injury, and absence of diarrhea (Buret et al., 1998).

There is no commercially available vaccine for rabbit colibacillosis, but several studies demonstrate that immunization can prevent the disease. In one study, an orally administered vaccine made from formalin-killed serotype O103 organisms protected weanlings against challenge with homologous live organisms (Camguilhem and Milon, 1990). At least four daily doses, however, were required to induce protection. In another study, oral administration of live non-pathogenic bacteria protected weanlings against challenge with heterologous pathogenic O103 organisms (Milon et al., 1992). The bacteria used for vaccination expressed one of the two factors important for the pathogenicity of O103 strains: either lipopolysaccharide or fimbriae. This approach to vaccination had the advantage of requiring only one dose.

Recent approaches to developing enteropathogenic *E. coli* vaccines have focused on the construction of live, but avirulent, mutants. Mutations have been generated in various genes known to be important in virulence, including *tir*, *espB*, and *ler* (Boullier et al., 2003; Stakenborg et al., 2006; Zhu et al., 2006, 2007). Vaccination with all of these attenuated mutants offers strong protection against homologous challenge, but protection against challenge with organisms of a different serotype is typically weak or absent.

SALMONELLOSIS

Background

Salmonellosis is an uncommon disease of rabbits, but it can produce epizootics of high morbidity and mortality. It is primarily a septicemic disease with a brief clinical course, but diarrhea and abortion may be observed in some animals. In rabbits, the disease is most often caused by *S. enterica* serotypes Typhimurium or Enteritidis, but other serotypes have been reported. Typhimurium and Enteritidis are also the most common serotypes associated with non-typhoidal salmonellosis in humans (Velge et al., 2005).

Although uncommon now, salmonellosis was prevalent in the early 1900s. Several authors reported explosive outbreaks of the disease that resulted in the deaths of large numbers of rabbits (Duthie and Mitchell, 1931; Grasovsky, 1939; Olney, 1928). In most cases there was rapid death from septicemia, but diarrhea was occasionally seen as well. An outbreak of salmonellosis affecting pregnant does was reported by Garofolo (1936). *S. enteritidis* was isolated from this outbreak, which was characterized by abortion and subsequent death.

In recent years salmonellosis has been reported infrequently, but it is not entirely a disease of the distant past. *S. typhimurium* was the cause of an outbreak of salmonellosis which began in breeding does and spread to young stock, eventually resulting in 50% mortality (Harwood, 1989). In another instance, *S. mbandaka* was isolated from rabbits that died peracutely after extensive experimental manipulation (Newcomer et al., 1984).

Etiologic Agent

Bacteria of the genus *Salmonella* are Gram-negative, facultatively anaerobic bacilli that are members of the family *Enterobacteriaceae*. Most isolates are motile by peritrichous flagella, produce gas from glucose, and can use citrate as a sole carbon source. Lactose is ordinarily not fermented; this is an important distinguishing characteristic of the genus.

Salmonellae possess three major antigens: H or flagellar antigen, O or somatic antigen, and Vi or capsular antigen. These antigens are used to classify members of the genus into over 2000 serologically distinct types, each of which is designated by a name, as if it were a separate species. This is done for diagnostic and epidemiologic purposes and does not reflect the true taxonomic relationships among the organisms.

The genus *Salmonella* was at one time viewed as encompassing many different species. With the advent of DNA hybridization analysis, however, it became apparent that there was a high degree of homology among the species (Le Minor, 1984). Therefore, in the late 1990s salmonella taxonomy was revised, such that the members of the genus are assigned to only two species: *S. enterica* and *S. bongori*. *S. enterica* is responsible for most infections of warm-blooded vertebrates and is divided into six subspecies: *enterica*, *salamae*, *arizonae*, *diarizonae*, *indica*, and *houtenae*. Most commonly isolated human and animal pathogens belong to subspecies *enterica*, and this is true of the organisms formerly known as *S. typhimurium* and *S. enteritidis*. They are now commonly known as *S. enterica* serotype Typhimurium and *S. enterica* serotype Enteritidis. Subspecies other than *enterica* are usually isolated from the environment or from cold-blooded animals (Uzzau et al., 2000).

Epizootiology

Salmonellosis is usually transmitted by ingestion of contaminated food. Transmission can also occur by way of contaminated water, bedding, and cages, as well as by direct contact with infected animals. Contamination occurs when organisms are shed in the feces of carriers or clinically ill animals. There is a wide animal host range for salmonellae, but poultry and wild rodents are especially likely to harbor the organism and transmit it

to susceptible animals. One outbreak of salmonellosis in rabbits was attributed to feeding of contaminated chicken eggs (Olney, 1928). Another occurred in a rabbitry in close proximity to an area where chickens were housed, and the outbreak was eventually attributed to feeding contaminated hay (Harwood, 1989).

Rabbits are not common reservoirs of *Salmonella*, but they sometimes carry the organism. One survey conducted on a group of *Pasteurella* and *Eimeria*-free rabbits demonstrated that 38% were carriers of *S. mbandaka* (Newcomer et al., 1983). It is therefore important to consider rabbits as a potential source of salmonellae in an outbreak.

Martin et al. (2000) proposed that rabbits exhibit seasonal variation in susceptibility to *S. enterica* serotype Typhimurium infection, with the nadir of susceptibility occurring in the mid-summer. This conclusion was based on experimental studies that demonstrated a decrease in invasiveness for rabbit terminal ileum during the months of June and July and a maximum in the winter months.

Clinical Manifestations

Salmonellosis is frequently a peracute disease, and clinical signs are not observed. Sometimes fever, anorexia, and depression are noticed prior to death. This pattern, typical of septicemia, was observed in a study in which rabbits were experimentally infected with wild-type *S. enterica* serotype Typhimurium (Boedeker et al., 1995). In another experimental infection study, however, the same serotype produced primarily diarrheal disease (Hanes et al., 2001). The difference may be due to factors such as inoculum size, host susceptibility, and bacterial expression of virulence factors under the conditions of the experiment.

In spontaneous salmonellosis diarrhea has been reported, but it is an inconsistent finding (Ghosh and Chatterjee, 1960; Grasovsky, 1939; Iyer and Uppal, 1956). If the respiratory tract is involved, dyspnea and cyanosis may be observed (Newcomer et al., 1984). In pregnant does, abortion and endometritis are important clinical signs and may be the first indication of an outbreak (Garofolo, 1936; Harwood, 1989).

Pathology

Peracute salmonellosis is characterized by lesions compatible with septicemia, which include vascular congestion of many organs and diffusely distributed petechial hemorrhages. In acute cases, foci of necrosis surrounded by polymorphonuclear leukocytes are sometimes present in liver, kidney, spleen, and myocardium. Lymph nodes and gut-associated lymphoid tissue may be edematous and contain similar

foci of necrosis. Lesions of the respiratory system are prominent in some cases of salmonellosis (Duthie and Mitchell, 1931; Newcomer et al., 1984; Onyekaba, 1985). Congestion, edema, focal hemorrhages, and atelectasis occur early in the disease and progress rapidly to terminal suppurative bronchopneumonia. In pregnant does, especially in late gestation, there may be evidence of abortion or fetal death, together with suppurative necrotizing metritis (Harwood, 1989).

Pathogenesis

A great deal is known about the pathogenesis of *Salmonella* infections, but because the disease is uncommon in rabbits only a brief overview will be presented here. For a detailed discussion, refer to the excellent review articles by McGhie et al. (2009) and Haraga et al. (2008).

Salmonellae enter the host either by oral ingestion of contaminated food or water, or by direct contact with a carrier. Salmonellae can survive the low pH of the stomach and readily gain access to the small intestine, where they traverse the intestinal mucous layer and attach to the apical surface of epithelial cells. Salmonellae have multiple mechanisms for crossing the intestinal barrier, but they preferentially enter antigen-sampling M cells overlying Peyer's patches and are transported to the underlying lymphoid cells. They may also be taken up by CD18-positive phagocytes that penetrate the epithelial cell layer or, alternatively, gain direct entry into ordinary intestinal epithelial cells by bacterial-mediated endocytosis. Once the bacteria are intracellular, they proliferate within phagosomes termed *Salmonella*-containing vacuoles. The ability to survive within these vacuoles is critical for virulence and is mediated by over 30 specific bacterial effector proteins, which essentially hijack the host cell to create a milieu conducive to bacterial replication. Major functions include modulation of host cell signal transduction and membrane trafficking, as well as production of pro-inflammatory cytokines. Effector proteins are delivered to the host cell cytoplasm by two type 3 secretion systems that resemble those found in *E. coli* and other Gram-negative pathogens. Other bacterial virulence factors include toxins and lipopolysaccharide (Chitra et al., 2002; Giannella et al., 1973; Martin et al., 2000).

Salmonellae often persist in the gastrointestinal tract for long periods, producing either gastroenteritis or a chronic asymptomatic carrier state. Organisms may spread to regional lymph nodes and other organs, especially if they gain initial entry via CD18-positive phagocytes, but in most hosts they are cleared by the monocyte-macrophage system before disease develops. If the host is compromised or if the organism is especially virulent, clearance mechanisms fail and systemic

disease occurs (Giannella, 1991). The importance of stress and immunosuppression in salmonellosis is demonstrated by a study in which prednisone, either alone or together with minor surgery, precipitated peracute disease in carrier animals (Newcomer et al., 1984).

Diagnosis

Diagnosis of salmonellosis in rabbits depends on isolation and identification of the etiologic agent. Special procedures are usually required for isolation of *Salmonella*, especially when samples contain a mixed bacterial flora. Samples should be inoculated into liquid enrichment media, such as selenite or tetrathionate broth. After incubation, the enrichment culture can be plated on moderately selective media such as MacConkey's or desoxycholate citrate agar, or on highly selective media such as SS agar, brilliant green agar, or Hektoen medium. These media contain lactose and a pH indicator. Since a distinguishing feature of *Salmonella* is its inability to ferment lactose, suspect colonies can be selected by color. These can then be differentiated from related species by biochemical tests (LeMinor, 1984).

Prevention and Therapy

Treatment of active salmonellosis has been attempted rarely in rabbits, and is not recommended due to the zoonotic potential of the disease and the possibility of survivors becoming inapparent carriers. In the event that the disease is diagnosed, animals in contact with infected rabbits should be bacteriologically monitored to detect carriers. Control of salmonellosis depends on eliminating potential sources of exposure, such as poor-quality feed and wild rodents.

If treatment is required, chloramphenicol is ordinarily the drug of choice and the animals should be housed in biocontainment facilities. This approach is complicated, however, by the emergence in the 1990s of multiple-antibiotic-resistant strains, which are especially common in serotype Typhimurium. These strains are resistant to chloramphenicol, ampicillin, streptomycin, sulfonamides, and tetracycline (Velge et al., 2005).

STAPHYLOCOCCOSIS

Background

Staphylococcosis is a common disease of rabbits caused by *Staphylococcus aureus*. It is characterized by suppurative inflammation of any organ, but the skin and subcutaneous tissues are most frequently involved. It can also be manifested as fatal septicemia. The

susceptibility of rabbits to staphylococci has made the species valuable as an experimental model for orthopedic and ophthalmic infections, but this review will concentrate on spontaneous rather than experimentally induced disease.

Several investigators recognized rabbit staphylococcosis in the early 1900s. In 1945, Lesbouyries (Lesbouyries, 1945) reviewed what was known about the disease and described subcutaneous and mammary gland abscesses, as well as septicemia. Hagen (1963) described similar lesions associated with disseminated disease in 3–5-day-old rabbits. Affected animals had widespread subcutaneous abscesses, as well as abscesses in the lungs and heart. Disseminated disease in adult animals was reported by Snyder et al. (1976), who observed not only subcutaneous abscesses and visceral abscesses, but also conjunctivitis, rhinitis, and fibrinous pneumonia.

Staphylococcosis is a major problem in some European rabbitries, but appears to be less common in the United States. The reason for this is unknown, but it may be that the most virulent strains have a geographic distribution concentrated in Europe.

Etiologic Agent

There are at least 20 species of *Staphylococcus*, most of which are non-pathogenic. They are common inhabitants of skin and mucous membranes and many species prefer certain habitats, such as the head, auditory canal, axilla, or perineum. Even pathogenic staphylococci can reside on epithelial surfaces without causing disease; *S. aureus* is a common inhabitant of the upper respiratory tract of humans and other species, including rabbits (Renquist and Soave, 1969).

Staphylococci are unencapsulated Gram-positive cocci that occur singly, in short chains, or in irregular grape-like clusters. They are non-motile, non-sporeforming, and catalase-positive. *S. aureus* is the primary pathogenic species and the only one which has been recovered from rabbits. It can be distinguished from non-pathogenic staphylococci by a positive coagulase test, which measures ability to coagulate plasma. Most isolates of *S. aureus* have hemolytic activity as well. A few isolates have the ability to produce capsules; these tend to be more virulent than ordinary strains.

S. aureus can be categorized into biotypes based on biochemical properties and phage types based on bacteriophage susceptibility. This is done primarily for epizootiologic purposes. Most animal species, including rabbits, tend to carry unique bio- and phage types of *S. aureus* that are distinct from those of other species. Although biotypes and phage types tend to be host-species specific, it is not always the case.

Both low- and high-virulence strains of *S. aureus* can be isolated from rabbits, and bio- and phage typing can

be used to characterize each type of isolate. The low- vs. high-virulence distinction is particularly significant in European rabbitries, where low-virulence strains cause relatively minor lesions in small numbers of animals in some colonies, and high-virulence strains cause epizootic disease and widespread losses in others (Hermans et al., 2003).

Low-virulence strains belong to biotypes usually associated with humans or poultry. High-virulence strains belong to a biotype designated “mixed CV-C”, which differs from the low-virulence biotypes by the ability to produce beta hemolysin. Not all mixed CV-C isolates are equally virulent, however, so within the mixed CV-C biotype it is necessary to distinguish among strains of differing virulence. Phage susceptibility typing can do this. Virulent isolates are usually phage type 3A/3C/55/71, so the complete biotype-phage type designation is mixed CV-C 3A/3C/55/71 (Hermans et al., 2003).

Genotype analysis has also been used to characterize low- and high-virulence strains. One useful technique is randomly amplified polymorphic DNA (RAPD) analysis, which involves performing polymerase chain reaction with a single short oligonucleotide primer of random sequence. RAPD analysis reveals specific banding patterns that can be used to distinguish between high- and low-virulence strains (Hermans et al., 2000a, 2001a).

Some genotypic studies have focused on the presence of specific virulence-associated genes in high- vs. low-virulence strains. Of particular interest are genes that code for bacterial adhesins and extracellular toxins. Regarding adhesins, one study showed that virulent, but not avirulent, strains typically harbor the *bbp* gene, which encodes for bone sialoprotein binding protein and appears to mediate bacterial adhesion to host cells (Vancraeynest et al., 2004). Regarding toxins, another study demonstrated that virulent strains almost always possess the enterotoxin gene cluster (*egc*), which mediates production of an extracellular toxin (Vancraeynest et al., 2006a).

Epizootiology

In rabbit colonies, staphylococcosis typically presents in one of two ways – either as a sporadic syndrome affecting only small numbers of animals, or as a widespread epizootic associated with large losses. Sporadic cases may be caused by several avirulent biotypes, but when an epizootic of staphylococcosis occurs, one virulent biotype-phage type is usually responsible (mixed CV-C, 3A/3C/55/71). This type is common in Europe, and genotype analysis of many different isolates suggests a clonal origin with subsequent international dissemination (Vancraeynest et al., 2006).

Biotypes associated with clinical disease can often be isolated from the nasopharynx of asymptomatic animals, suggesting that carriers can serve as a reservoir of infection (Lenz et al., 1978). In European rabbitries suffering epizootics of staphylococcosis, as many as 90% of the animals may be carriers. In carriers, staphylococci can be recovered from many anatomical sites, but ear and perineum appear to be colonized most intensely (Hermans et al., 1999).

Even though distinct biotypes of *S. aureus* predominate in different animal species, it is still possible for interspecies transmission to occur. Isolates from humans, dogs, and cattle can infect rabbits under experimental conditions (Adekeye, 1980). The potential for transmission between humans and rabbits is suggested by studies that identified the same biotype in infected animals and apparently healthy personnel (Lenz et al., 1978; Renquist and Soave, 1969). Meticillin-resistant *S. aureus* strains are being identified with increasing frequency worldwide, and there is evidence that these strains can be transmitted among humans and various animal species, including rabbits (Morgan, 2008; Walther et al., 2008).

Clinical Manifestations

Healthy rabbits frequently carry *S. aureus* as a part of the flora of the nasopharynx, conjunctiva, and skin. When disease is present, the signs may be suggestive of pasteurellosis and include pneumonia, rhinitis, conjunctivitis, and otitis media. But more commonly, subcutaneous abscesses, pododermatitis, or mastitis are observed (Hermans et al., 2003). A common clinical presentation of staphylococcosis is infection of the mammary glands, which can occur either as localized abscesses or disseminated, gangrenous mastitis (Adlam et al., 1976; Carolan, 1986; Millichamp and Collins, 1986; Okerman et al., 1984; Snyder et al., 1976). Septicemia can also occur, sometimes accompanied by disseminated abscesses in parenchymatous organs. The milk of does with mastitis may act as a vehicle for transmission of *S. aureus* to nursing offspring, resulting in septicemia and death of the nurslings (Krishna and Kaushal, 1988).

Pathology

Staphylococcosis is characterized by suppurative inflammation, which is indistinguishable from that caused by other pyogenic bacteria, including *P. multocida*. The skin, subcutis, mammary gland, and respiratory system are most commonly involved, but if septicemia occurs, lesions may develop in any internal organ. In acute lesions, there is a diffuse infiltrate of neutrophils accompanied by edema, hemorrhage, and fibrin deposition. In subacute or chronic lesions,

inflammation is more localized and abscesses develop. Abscesses contain viscous, creamy exudate composed mostly of neutrophils and necrotic cell debris. In long-standing cases they may be surrounded by a fibrous capsule.

Pathogenesis

Because *S. aureus* is part of the resident flora of healthy laboratory rabbits, it is sometimes considered an opportunistic pathogen. Disease is likely to occur when an appropriate portal of entry, such as a skin wound, is available. Host resistance and bacterial virulence govern the severity of disease. Regarding host resistance, rabbits as a species are unusually susceptible to systemic infection with *S. aureus*, and stress increases the susceptibility of individual animals (Snyder et al., 1976).

The virulence of various *S. aureus* strains depends on their ability to adhere to host cells, produce biofilms, and elaborate extracellular protein toxins. In rabbits, the role of biofilm production is unclear, but the ability of organisms to adhere to host cells is clearly important. Bacterial colonization, which is critical for virulence, is facilitated by production of adhesion proteins such as bone sialoprotein binding protein, the product of the *bbp* gene. The *bbp* gene is produced by most high-virulence strains (Hermans et al., 2000, 2000a; Vancraeynest et al., 2004).

Extracellular toxins are also important for virulence, and *S. aureus* produces several types, including exfoliative toxins, leukotoxins (such as hemolysins and leukocidins), and superantigens (enterotoxins and similar molecules with immunomodulatory capability). Leukotoxins and superantigens appear to be more important in rabbit infections than exfoliative toxins (Vancraeynest et al., 2006a). At least three leukotoxins are lethal for rabbit neutrophils: alpha toxin, delta toxin, and Panton-Valentine leukocidin (Adlam et al., 1980). Virulent strains secrete superantigens as well, typically possessing the enterotoxin gene cluster (*egc*), which mediates production of an extracellular toxin with superantigen properties (Vancraeynest et al., 2006a).

In addition to toxins, a variety of enzymes such as coagulase, lipase, nuclease, and hyaluronidase may be produced, as well as protein A, which non-specifically binds the Fc portion of IgG. IgG binding inhibits opsonization and phagocytosis and blocks complement-mediated bactericidal mechanisms (Cohen, 1991). A study of *S. aureus* isolates from Spanish rabbitries showed that strains associated with lesions typically carry genes for coagulase and protein A, as well as clumping factor B (Viana et al., 2007). Another study compared the presence of extracellular secreted antigens between virulent and avirulent strains. Virulent

strains produced two specific proteins, of approximately 29 and 27 kDa, that were not produced by avirulent strains (Hermans et al., 2001, 2001a). Whether these proteins represented some of the enzymes or extracellular toxins mentioned above is uncertain.

An in vivo rabbit model that could be useful in further studies of the pathogenesis of high- and low-virulence infections has been described by Meulemans et al. (2007). The model involves scarification and inoculation of the flank, with subsequent development of abscesses, the severity of which is proportional to the virulence of the isolate. This model could also be useful in evaluating potential vaccine candidates.

Diagnosis

Diagnosis of staphylococcosis depends on isolation and identification of the organism. Culture is essential for reliable differentiation of staphylococcosis from pasteurellosis. Gram-positive cocci that ferment mannitol and produce coagulase can be presumptively identified as *S. aureus* (Snyder et al., 1976).

A multiplex polymerase chain reaction (PCR) assay for rapid identification of high-virulence isolates has been described (Vancraeynest et al., 2007). The test relies on detection of two genes: the *bbp* gene, which is important for adhesion, and the *selm* gene, which is part of the *egc* gene cluster responsible for production of enterotoxin genes with superantigen activity.

Prevention and Therapy

Staphylococcosis should be treated locally and systemically with antibiotics. In vitro antibiotic sensitivity testing should be performed to help select the most effective antibiotic. Penicillin is the antibiotic of choice for penicillin-sensitive isolates. Alternatively, enrofloxacin is almost always effective (Vancraeynest et al., 2004a). Other choices for penicillin-resistant organisms include cephalosporins, aminoglycosides, or chloramphenicol. Antibiotic resistance is rare in rabbit isolates, but aminoglycoside- and meticillin-resistant strains have been reported and may have originated in, or be a threat to, human populations (Goni et al., 2004).

Despite the susceptibility of rabbit isolates to many antibiotics, antimicrobial therapy appears incapable of eliminating infections from rabbit colonies (Hermans et al., 2003; Vancraeynest et al., 2004a). This is a particular problem for colonies infected with a high-virulence strain. Administration of tetracycline in the food, accompanied by cleaning and disinfection of cages and equipment, may reduce the severity of disease temporarily but will not eliminate it. Probably the only way to eliminate infection is to depopulate the colony, disinfect the premises, and start over.

All animals introduced into a new colony or added to a pre-existing colony should be screened to make sure they do not carry a virulent strain. This can be done by culture of multiple sites on new animals, followed by evaluation of any *S. aureus* isolates by biotyping-phage typing, or by genomic analysis. Genomic analysis is simpler, and either RAPD typing or multiplex PCR typing can be used to differentiate virulent from avirulent isolates (Hermans et al., 2003; Vancraeynest et al., 2007).

Attempts have been made at immunizing rabbits against staphylococcosis, using either killed bacteria or purified toxins. Most of the attempts have been unsuccessful. In one trial, vaccination with killed bacteria protected against intradermal challenge with living organisms, but there was no correlation between degree of protection and titer of serum antibodies (Cameron, 1971). In another trial, a killed bacterial vaccine was ineffective in preventing mastitis (Adlam et al., 1976). One report describes the use of an autogenous bacterin to treat staphylococcal conjunctivitis in rabbits (Hinton, 1977). Clinical improvement occurred, but the number of rabbits was small and some also received antibiotic therapy. As an alternative to killed bacteria, immunization with purified staphylococcal toxins has been tried. These preparations evoked significant antibody titers, but they were largely ineffective in preventing mastitis (Adlam et al., 1977, 1980). Limited studies on rabbit vaccine development have occurred since the 1980s, and it is noteworthy that successful immunization against staphylococcal infections has been problematic, regardless of the species.

TREPONEMATOSIS

Background

Treponematosis is a disease of domestic and wild rabbits caused by *Treponema paraluiscuniculi* (formerly *T. cuniculi*), a spirochete similar to *T. pallidum*, the causative agent of human syphilis. The disease is characterized by inflammatory lesions of the genitalia. The face and regional lymph nodes are sometimes involved as well. Treponematosis has many synonyms, including venereal spirochetosis, treponemiasis, and rabbit syphilis.

Treponematosis was first reported by Ross (1912), who observed spiral-shaped organisms in the blood of rabbits that had inflammatory lesions of the genitalia and mouth. Bayon (1913) isolated and described the causative organism and passed the disease successfully in rabbits. He questioned the validity of much of the syphilis research that had been done previously on rabbits, because they were not known to be free

of the naturally occurring infection. Treponematoses was studied in more detail by [Noguchi \(1921, 1922\)](#), who proposed the name *Treponema cuniculi* for the causative organism and noted its striking morphologic resemblance to *T. pallidum*. [Levaditi et al. \(1921a\)](#) documented the venereal mode of transmission of the disease and described the histologic changes in affected tissues.

Because of the resemblance between *T. paraluiscuniculi* and *T. pallidum*, some investigators thought that the two organisms might be identical. This question was resolved when attempts to infect humans with *T. paraluiscuniculi* failed. [Levaditi et al. \(1921b\)](#) believed that the organisms were distinct, so they inoculated themselves with *T. paraluiscuniculi* in the hope that an asymptomatic infection would occur that would convey protection against *T. pallidum*. Infection did not occur and antibodies were not detected, but if the outcome had been different a vaccine against syphilis might have resulted. The organisms are closely related serologically, and rabbits infected with *T. paraluiscuniculi* are substantially but not completely resistant to challenge with *T. pallidum* ([Graves, 1980](#)).

By the 1930s rabbit treponematoses had been reported in many countries, including England ([Adams et al., 1928](#)), Belgium ([Bessemans et al., 1928](#)), Russia ([Fried and Orlov, 1932](#)), and the United States ([Noguchi, 1922](#)). The disease is known to occur not only in domestic rabbits, but also in wild lagomorphs, including hares ([Horvath et al., 1980](#)). Although widespread, treponematoses is not ubiquitous. For example, the disease is virtually non-existent in some wild rabbit populations in Australia ([Graves et al., 1980](#)).

Etiologic Agent

Rabbit treponematoses is caused by *T. paraluiscuniculi*, which is a slender, spiral-shaped, microaerophilic, Gram-negative organism closely related to *T. pallidum*, the cause of human syphilis ([Figure 13.16](#)). The genus *Treponema* contains pathogenic and non-pathogenic species. The non-pathogens are part of the normal flora and are especially prominent in the oral cavity (although *T. denticola* may play a role in periodontal disease). The pathogens include *T. pallidum* (which has several subspecies), *T. carateum*, and *T. paraluiscuniculi*, none of which can be cultured continuously in vitro. Organisms must be propagated in vivo, with inoculation of rabbit testis being the most common method. It is generally agreed that the pathogenic treponemes are indistinguishable on the basis of morphology, protein content, or physiology ([Strouhal et al., 2007](#)). They all are approximately 6–15 µm long and 0.1–0.2 µm wide with tapered ends and exhibit characteristic motility, consisting of longitudinal rotation and flexion ([Fitzgerald, 1985](#)). Nevertheless, one author asserted that *T. paraluiscuniculi*

FIGURE 13.16 Treponematoses: erosions on vulva.

can be differentiated from *T. pallidum*, the former being thicker and with blunt rather than pointed ends ([Warthin et al., 1923](#)).

The high degree of relatedness among pathogenic treponemes extends to the immune responses that they generate in the host. Antibodies produced in response to infection with *T. paraluiscuniculi* cross-react with *T. pallidum* and vice versa. This makes serologic differentiation difficult, but it means that serologic tests for *T. pallidum* can be used for detection of *T. paraluiscuniculi* infection in rabbits.

Even though antibody produced in response to infection with one *Treponema* species, subspecies, or strain cross-reacts strongly with heterologous organisms, that antibody does not protect against heterologous challenge. Protection against homologous challenge is complete, however. The reason for this is unclear, but the observation suggests that protective antigens must exhibit diversity among species, subspecies, or strains. A key protective antigen was at one time thought to be a strongly immunogenic 15-kDa lipoprotein produced by all pathogenic *Treponema*. Doubt was cast upon this hypothesis when, rather than exhibiting the antigenic diversity necessary to explain lack of cross-protection, the protein proved to be virtually identical for all isolates. The gene coding for the protein also showed only minor differences among isolates, and these were limited to the flanking sequences ([Centurion-Lara et al., 1997, 1998](#)). Conclusive evidence that the protein was not protective was obtained when immunization of rabbits failed to alter the course of experimental challenge or induce production of opsonic antibody. The 15-kDa lipoprotein is still thought to have a role in pathogenesis, however, possibly mediating early inflammatory changes that occur during infection ([Centurion-Lara et al., 1997](#)).

Although traditional methods largely have failed to discriminate among pathogenic treponemes, comparative genomic methods have been used with somewhat more success. The complete genome sequence of *T. pallidum* has been elucidated and shown to be relatively small, suggesting that the organism depends on the host for its metabolic requirements. Within the genome, a family of repeat genes, the *tpr* genes, may be important in virulence by encoding proteins that mediate attachment to host tissues (Peeling and Hook, 2006). This gene family has been extensively studied and has shed light on potential virulence mechanisms and on the evolutionary relationships among members of the genus (Gray et al., 2006).

The *tpr* genes have been classified into subfamilies designated I, II, and III, all of which appear fully functional in *T. pallidum*. This is in contrast to *T. paraluiscuniculi*, in which subfamilies I and II are rendered inactive by a frameshift caused by an extra guanosine in the coding sequence. This means that only subfamily III is fully active. Within this subfamily, the *tprK* locus is of interest because it is immunogenic and appears to have an ability to undergo antigenic variation. The latter property may be relevant to successful host adaptation (Giacani et al., 2004).

Another gene that has received attention is the acid repeat protein gene (*arp*). This gene has been proposed as a component of a typing system for pathogenic treponemes. The number of base pair repeats in *arp* is variable among isolates and this is the basis for its potential for its use in a typing system. *T. paraluiscuniculi* and *T. pallidum* subspecies *pallidum* are both sexually transmitted pathogens and share a high number of repeats with diverse motifs in the *arp* region. This is in contrast with non-sexually transmitted strains. Thus, the *arp* gene can be used to help differentiate venereal from non-venereal isolates (Harper et al., 2008).

The entire genome of *T. paraluiscuniculi* has been compared to that of *T. pallidum* by DNA microarray hybridization, whole genome fingerprinting, and DNA sequencing (Strouhal et al., 2007). There was a high degree of sequence similarity, with the most significant differences in the *tpr* loci, which is consistent with the observations of Giacani et al. (2004). The differences at these loci suggest that they may represent determinants that govern host species specificity.

Epizootiology

Clinical treponematosis is uncommon in modern, well-managed rabbit colonies. When the disease was first recognized in the early 1900s, as many as 30% of animals had clinical signs (Adams et al., 1928; Fried and Orlov, 1932; Noguchi, 1922). More recently, the prevalence rate was estimated at well under 10% in

enzootically infected colonies (Cunliffe-Beamer and Fox, 1981a). Although clinical signs are infrequent, serologic evidence indicates that subclinical infections are common. Screening of apparently healthy rabbits suggests that 15–25% are infected (Clark, 1970; Pannu et al., 1967). One survey of a single colony found serological evidence of infection in virtually all experienced breeders. Clinical disease in this colony was almost non-existent (DiGiacomo et al., 1983b).

T. paraluiscuniculi is usually transmitted horizontally during breeding. Infection is unusual in virgin rabbits and prevalence increases with age and length of time in a breeding program. The incidence in males and females is roughly comparable (Cunliffe-Beamer and Fox, 1981b; DiGiacomo et al., 1983b, 1984).

Although the major mode of *T. paraluiscuniculi* transmission is venereal, the occasional presence of infection in non-breeding rabbits suggests that the organism can also be transmitted by other routes (Cunliffe-Beamer and Fox, 1981b; Fried and Orlov, 1932; Gaertner and Barthold, 1989). Vertical transmission may be responsible for some cases of treponematosis and may help perpetuate infection in a colony. Although transplacental transmission has not been documented, cross-fostering experiments have shown that infection can occur at birth or during the nursing period (Cunliffe-Beamer and Fox, 1981b). This might be expected to be an important means of transmission, but serologic data suggest that it actually happens infrequently (DiGiacomo et al., 1983b). This could be because neonatal rabbits are more resistant to infection than adults (Cunliffe-Beamer and Fox, 1981b).

Genetic factors appear to influence the susceptibility of rabbits to treponematosis. Cunliffe-Beamer and Fox (1981b) studied susceptibility and expression of the disease in several inbred strains of rabbits, and found significant differences between strains. The most severe disease occurred in X/J rabbits; lesions were common on the face as well as the genital area. Less severe disease occurred in other strains, including AC/J, ACEP/J, and III/J.

Clinical Manifestations

Lesions of treponematosis are usually restricted to vulvar or preputial epithelium and adjacent areas (Figure 13.16). The nostrils, eyelids, and mouth are sometimes involved as well, probably as a result of auto-infection (Figure 13.17). Surprisingly, facial lesions can occur without apparent genital involvement (Cunliffe-Beamer and Fox, 1981a; DiGiacomo et al., 1984; Gaertner and Barthold, 1989). Lesions begin near mucocutaneous junctions as areas of erythema and edema sometimes accompanied by minute papules or vesicles. They progress quickly to ulcers and finally to characteristic scales

FIGURE 13.17 Treponematoses: erosions adjacent to nares.

and crusts, which are the most frequently recognized evidence of infection. Lesions usually persist but sometimes resolve after several weeks (Cunliffe-Beamer and Fox, 1981a).

Pathology

Treponematoses ordinarily involves only the skin and mucous membranes. Occasionally, regional lymph nodes are involved, but systemic infections have not been described. Gross lesions of treponematoses are described above. Microscopic lesions consist of ulceration, hyperkeratosis, hyperplasia, and acanthosis of the epidermis. Ulcers are frequently overlaid by crusts composed of exudate, necrotic epithelial cells, and inflammatory cells. The dermis contains a prominent inflammatory cell infiltrate, consisting mainly of macrophages and plasma cells. In early lesions, epidermal microabscesses or vesicles are sometimes present (Adams et al., 1928; Cunliffe-Beamer and Fox, 1981a; Noguchi et al., 1922). Spirochetes can be demonstrated in the superficial dermis and epidermis by Warthin-Starry or modified Dieterle silver staining techniques (Gaertner and Barthold, 1989). Hyperplasia of regional lymph nodes has been reported to occur in some cases of treponematoses (Small and Newman, 1972).

Pathogenesis

T. paraluiscuniculi usually infects rabbits by penetration of intact or damaged mucous membranes (Cunliffe-Beamer and Fox, 1981b). Once infected, proliferation of the organism occurs locally. The incubation period is lengthy: lesions do not appear until 3–6 weeks after exposure, and another 5–6 weeks may be required for the development of a positive serologic test. Lesions can persist for long periods, over 20 weeks in many

rabbits. When lesions resolve in untreated animals, serologic tests often remain positive (Cunliffe-Beamer and Fox, 1981b). In contrast, rabbits treated with antibiotics experience a gradual decline or disappearance of detectable antibody (DiGiacomo et al., 1984).

The presence of antibody in rabbits without lesions suggests the possibility of inapparent infections. Regional lymph nodes may be involved in such infections, since they can harbor the organism for long periods in apparently healthy rabbits (Smith and Pesetsky, 1967). It is not known whether rabbits with infection restricted to the lymph nodes can subsequently develop overt cutaneous lesions.

As with other bacteria, pathogenesis depends on bacterial virulence and host response. Genes important in virulence include the *tpr* region of the genome, which is discussed in detail above. Host response has been studied with special emphasis on *T. pallidum* infections in humans, but the striking similarity between this species and *T. paraluiscuniculi* suggests that similar responses occur in rabbits.

Infection produces a strong humoral and cell-mediated immune response, but neither results in elimination of the organism from the host. Opsonizing antibody is produced against strain-specific antigens rather than antigens that are shared with other spirochetes (Shaffer et al., 1993). Of particular importance are opsonizing antibodies to the TprK protein, which is encoded by a segment of the *tpr* gene. Immunization with this protein offers partial protection against homologous challenge. Cellular immune responses involve both CD4+ and CD8+ cells, and cytokines such as IL-2 and IFN- γ have been detected in lesions (Peeling and Hook, 2006).

Diagnosis

Definitive diagnosis depends on demonstration of spirochetes in typical lesions. The direct fluorescent antibody test is the most sensitive and specific test when lesions are present (Ratnam, 2005; Wicher et al., 1999). Classically, the Warthin-Starry silver technique has been used to selectively stain the organisms in smears or tissue sections, but dark-field examination of wet mounts of lesion scrapings is a simpler method; the organism can be readily identified by its characteristic spiral morphology and corkscrew motility. Lesion scrapings can also be stained with Giemsa, but detection of the organisms is more difficult than by dark-field examination (Cunliffe-Beamer, 1981a).

A variety of serologic tests can be used to detect infected rabbits. All were developed for diagnosis of human syphilis, but the similarity between the causative organisms makes the tests applicable to rabbits. Two types of tests are available: “non-treponemal”

tests, such as the Venereal Disease Research Laboratory slide test (VDRL) and the Rapid Plasma Reagin card test (RPR), and “treponemal” tests, such as the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination *T. pallidum* test (MHA-TP). The non-treponemal tests are ordinarily used for screening, whereas the treponemal tests can be used for confirmation. Non-treponemal tests detect antilipid antibodies (traditionally referred to as reagins) produced in response to lipoidal antigens generated in treponemal disease. These tests may detect antilipid antibodies associated with other disease processes, so they are not highly specific. Treponemal tests, on the other hand, detect antibodies specific for treponemal antigens. Treponemal tests have not been used as widely as non-treponemal tests, in part because the inability to grow *T. pallidum* in vitro makes it difficult to obtain antigen (Bradford and Larsen, 1985). This problem has been circumvented by new treponemal tests that use recombinant treponemal antigens (Wicher et al., 1999).

The tests available for serodiagnosis of syphilis were compared by DiGiacomo et al. (1983). The FTA-ABS treponemal test was chosen as the benchmark test because of its recognized sensitivity and specificity. Of the two non-treponemal tests, the VDRL was more sensitive and the RPR more specific. Compared to the FTA-ABS, the overall sensitivity and specificity of the non-treponemal tests was 77% and 87% for the VDRL, and 55% and 100% for the RPR. The MHA-TP treponemal test agreed almost exactly with the FTA-ABS, with a sensitivity and specificity of 100% and 99%, respectively. Therefore, given that the MHA-TP is much simpler to perform than the FTA-ABS, the most suitable screening test for treponematosi is the microhemagglutination assay. If non-treponemal tests are selected, care must be used in the interpretation of results since false-positive reactions can occur, particularly with the VDRL (Tight et al., 1981).

A number of polymerase chain reaction-based methods have been developed for detection of *Treponema* in clinical samples. These tests are highly sensitive and specific, but are used mostly in research laboratories because of lack of standardization and commercial availability (Ratnam, 2005; Wicher et al., 1999). It is likely that standard protocols will be developed so that PCR tests will be readily available in the future.

Prevention and Therapy

Penicillin is the drug of choice for treatment of treponematosi. Three injections at 7-day intervals of a combination of benzathine and procaine penicillin should be given at doses of 42000–84000 IU/kg. Following treatment, lesions heal within 2 weeks and RPR and

VDRL titers decline markedly or disappear within several months. In contrast, FTA-ABS titers may persist for a year (Cunliffe-Beamer and Fox, 1981c; DiGiacomo et al., 1984). This treatment is not only effective for individual rabbits; it can also be used to eradicate treponematosi from a colony if all animals are treated (Cunliffe-Beamer and Fox, 1981c). In colonies that are free of infection, introduction of new breeding stock should be avoided. If it is necessary to bring in new animals, they should be examined for lesions and serologically tested before entering the colony.

NECROBACILLOSIS

Background

Necrobacillosis, also known as Schmorl’s disease, is an infection of the skin and subcutaneous tissues, usually of the head and neck, caused by *Fusobacterium necrophorum*. It occurs sporadically and is characterized by necrosis, ulceration, and abscessation.

Necrobacillosis was first described in rabbits by Schmorl in 1891, who also isolated the etiologic agent and named it *Streptothrix cuniculi*. He noted that the organism caused severe necrotizing lesions of the skin, which occasionally led to fatal septicemia and widespread necrosis of visceral organs. Schmorl reproduced the clinical disease experimentally by subcutaneous inoculation of the organism.

Although necrobacillosis is ordinarily caused by *F. necrophorum*, there is one report of a clinically and pathologically identical disease caused by *F. nucleatum* (Ward et al., 1980).

Etiologic Agent

Fusobacterium necrophorum is an anaerobic, non-spore-forming, non-motile, Gram-negative bacterium. There are two subspecies, *necrophorum* and *fundiliforme*, the former being more virulent (Tan et al., 1996). All members of the genus *Fusobacterium* produce butyrate as a major end product of amino acid utilization and are poor fermenters of carbohydrates. *F. necrophorum* morphology is variable, ranging from coccobacillary to filamentous, but filamentous organisms are most common, especially in new cultures. The key to differentiating *F. necrophorum* from similar species is its ability to form propionate from lactate (Moore et al., 1984). There are several obsolete synonyms for *F. necrophorum*, including *Sphaerophorus necrophorus*, *Fusiformis necrophorus*, and *Bacillus necrophorus*. The bacterium is a normal inhabitant of the gastrointestinal tract, but it can be pathogenic for many species, including humans. Ruminants are highly susceptible to hepatic abscesses and foot abscesses but carnivores

are resistant (Garibaldi et al., 1990a; Moore et al., 1984; Schmorl, 1891; Tan et al., 1996).

F. necrophorum produces several toxins, the most important being leukotoxin. This is a high-molecular-weight protein with specific activity against leukocytes. Leukotoxin has been sequenced and shown to encode a protein of 3241 amino acids (Narayanan et al., 2001). The gene sequence is markedly different from those of other bacterial leukotoxins. Interestingly, *F. necrophorum* leukotoxin is substantially more active against ruminant than rabbit leukocytes, which may explain the difference in prevalence of infection among these species (Tan et al., 1994).

Epizootiology

Necrobacillosis is a sporadic disease with no apparent age, sex, or breed predisposition. The organism is present in the feces of rabbits, and most infections are thought to result from fecal contamination of wounds to the skin or oral cavity. Such contamination is especially likely under conditions of poor husbandry. Schmorl (1891) observed that lesions often originated near the oral cavity and proposed that this was due to exposure of skin wounds to fresh feces during coprophagy. Factors other than skin wounds and poor husbandry may predispose rabbits to necrobacillosis. In one reported case, a retained premolar root acted as a nidus for infection (Garibaldi et al., 1990a).

Clinical Manifestations

Clinical signs of necrobacillosis include swelling, inflammation, abscessation, and necrosis of the skin and subcutaneous tissue. The head and neck are most often affected, but infections involving the plantar surfaces of the feet can also occur. Osteomyelitis of the mandible or maxilla sometimes develops by extension of infection from overlying tissue. Cases with osseous involvement tend to resist treatment and are prone to recrudescence. In animals with chronic necrobacillosis, anorexia and cachexia are prominent findings (Garibaldi et al., 1990a; Schmorl, 1891; Ward et al., 1981). Widely disseminated embolic abscesses involving lung, liver, myocardium, brain, and other organs have been reported in a rabbit in which infection appeared to originate in the oropharyngeal cavity (Seps et al., 1999).

Pathology

Lesions of necrobacillosis typically include ulceration and caseous necrosis of the skin and subcutaneous tissue. Sometimes necrosis and inflammation of the underlying bone occur as well. Caseous lesions consist

of necrotic cellular debris surrounded by a zone of suppurative inflammation. Depending on the duration of the lesions, they may be partially encapsulated by fibrous tissue. If the infection spreads hematogenously, similar lesions, accompanied by thrombophlebitis, may occur in visceral organs (Garibaldi et al., 1990a; Schmorl, 1891; Seps et al., 1999; Ward et al., 1981).

Pathogenesis

Necrobacillosis begins as an acute inflammation of the subcutaneous tissue. This is rapidly followed by necrosis and ulceration of the overlying skin, and sometimes by direct invasion of deeper tissue, including bone. Hematogenous spread can occur, leading to necrotizing lesions in visceral organs (Schmorl, 1891; Seps et al., 1999).

The pathogenesis of this infection is not well defined, but several bacterial products have been implicated. These include leukotoxin, hemolysin, endotoxin, hemagglutinin, proteases, and adhesins (Nagaraja et al., 2005). Leukotoxin appears to be particularly important and is discussed in detail under Etiologic Agent, above. Hemolysin has been shown to increase guinea pig ileal smooth muscle motility, and this has been proposed as a mechanism that facilitates colonization (Kanoë et al., 1999). A cell wall component of *F. necrophorum* causes hemorrhagic dermonecrosis in guinea pigs and rabbits (Kanoë et al., 1995). This component, which appears distinct from endotoxin, has been termed a collagenolytic cell wall component and has been shown to exhibit toxicity for rabbit granulocytes and hepatocytes (Okamoto et al., 2006). Adhesins produced by *F. necrophorum* are not well characterized, but may play a role in infection. One study demonstrated that the organism adheres strongly to rabbit cheek cells, in contrast to cells from several other species. Bacterial hemagglutinin may mediate this attachment in part, because hemagglutinin antiserum inhibits attachment (Okada et al., 1999).

Diagnosis

A tentative diagnosis can be made based on the appearance and location of lesions, but isolation of the agent should be attempted. *F. necrophorum* can be cultured on blood agar by incubating anaerobically for 2 days at 37°C. Isolation is essential for a definitive diagnosis, since similar lesions can be caused by other organisms, such as *P. multocida*, *S. aureus*, and *P. aeruginosa* (Dominguez, 1975; Garibaldi et al., 1990a; Jepsen, 1977).

An enzyme-linked immunosorbent assay (ELISA) designed to detect antibody in animal sera has been described (Evans and Berg, 1985). The ELISA used a ribosome-rich extract as an antigen preparation. The ELISA was developed using rabbit sera, but the assay

was designed primarily for use in cattle. A polymerase chain reaction assay capable of detecting *Fusobacterium* spp. in clinical specimens has also been described, but it has not been used in rabbits (Nagano et al., 2007).

Prevention and Therapy

Treatment of necrobacillosis is difficult because lesions tend to recur. If therapy is attempted, it should include drainage and debridement of the lesions, coupled with antibiotic administration. *F. necrophorum* is susceptible to several antibiotics, including penicillin, cephalosporins, chloramphenicol, and tetracycline (Moore et al., 1984). Metronidazole may be suitable as well. Penicillin is normally the antibiotic of choice, but cephalosporins may be preferable in cases of osteomyelitis because of their good distribution in osseous tissue (Ward et al., 1981). *F. necrophorum* is usually resistant to aminoglycosides (Tan et al., 1996).

Prevention of necrobacillosis should be focused on preventing cutaneous wounds and minimizing fecal contamination of wounds that do occur. Cages and accessories should be kept clean and free of sharp edges. As for most bacterial diseases, good management practices are imperative for prevention of necrobacillosis. No vaccine is available.

LISTERIOSIS

Background

Listeriosis, which is caused by *Listeria monocytogenes*, is a septicemic disease of rabbits characterized by sudden death, chronic cachexia, or abortion. The disease was first described by Murray et al. (1926) in young rabbits and guinea pigs. The authors isolated a small Gram-positive organism and named it *Bacterium monocytogenes*, to reflect the high number of monocytes in the peripheral blood of affected animals. The name of the genus was changed to *Listeria* by Pirie (1940), who studied the disease in African rodents and reproduced it experimentally in rabbits and other species. At about the same time, the first case of listeriosis in a pregnant rabbit was described by Paterson (1940). Pregnant does have since been shown to be more susceptible to the disease (Gray et al., 1955a, 1955b; Watson and Evans, 1985).

Etiologic Agent

Listeria monocytogenes is a short, non-sporeforming, motile, Gram-positive rod with rounded ends. It is facultatively anaerobic and grows over a wide temperature range. In contrast to several other non-pathogenic members of the genus, it is hemolytic on blood

agar. Isolation of the organism from clinical cases can be difficult and special enrichment or selective procedures are often required. A cold enrichment technique has been described, and chemicals such as potassium thiocyanate, thallos acetate, and nalidixic acid can be added to media to help facilitate isolation (Seeliger and Jones, 1986). *L. monocytogenes* is pathogenic for many animal species, especially ruminants. In humans, meningitis and materno-fetal infections are common manifestations. Gastroenteritis can also occur in response to ingestion of the organism via contaminated food. In other species, similar syndromes have been reported, including abortion, encephalitis, and septicemia.

Listeria is normally a saprophyte that undergoes a transition to an intracellular parasite after ingestion by a susceptible host. Many bacterial products facilitate this process; some of the most important include internalin A and B (InlA and InlB), which bind to host cell receptors and facilitate entry; listeriolysin O (LLO), which breaks down the host cell phagosome once the organism is internalized; Hpt (hexose phosphate transporter), which helps obtain hexose sugars for bacterial metabolism; ActA, which polymerizes actin as a means to induce motility; and phosphatidylcholine phospholipase C, which acts in concert with LLO to help release organisms that are incorporated into vacuoles during cell-to-cell spread. Expression of these genes is controlled by PrfA (Positive regulatory factor A), which is in turn regulated in part by environmental conditions (Cossart and Toledo-Arana, 2008; Freitag et al., 2009). For example, temperatures and carbon sources found in animal hosts appear to enhance expression of this protein, thereby causing production of the various virulence-associated proteins that facilitate entry and survival in the host cell.

Epizootiology

Listeriosis is an uncommon disease of rabbits, usually occurring only in animals that are immunocompromised or have experienced stress or pregnancy. Stress may have been a factor in the outbreak reported by Murray et al. (1926), because the rabbits were young and received inadequate amounts of a poor-quality diet. The importance of pregnancy was demonstrated by Gray et al. (1955a, 1955b), who observed that pregnant does challenged with the organism developed severe disease, whereas non-pregnant females and males did not. The increased susceptibility of pregnant animals may be partly a result of physiologic stress, but it is also true that the pregnant uterus is a favorable environment for replication of the organism. Colonization of the female reproductive tract occurs readily; the organism can be isolated from the uterus and vagina even when exposure occurs by another route (Gray, 1955a, 1955b).

Transmission of listeriosis occurs by ingestion of the organism, which is a frequent contaminant of food. Another potential means of exposure is by inhalation. Evidence for this is that the organism can be recovered from the nasal cavity of ruminants and humans (Gray and Killinger, 1966). Once exposed, animals may become asymptomatic carriers and shed bacteria in the feces. The prevalence of carriers is unknown, but one study conducted in Spain suggests that there may be significant numbers in some rabbit colonies (Rodríguez-Calleja et al., 2006). Rabbit carcasses tested for presence of bacterial foodborne pathogens revealed that 13.7% were positive for *Listeria*. In contrast, neither *Salmonella* nor *E. coli* O157:H7 was detected.

Clinical Manifestations

In males and non-pregnant females, the clinical signs of listeriosis are non-specific. In acute cases sudden death may occur, whereas in chronic cases there may be anorexia, depression, and weight loss. In pregnant females, listeriosis should be suspected in cases of abortion or vaginal discharge.

Pathology

The most consistent lesions in listeriosis are pinpoint pale gray foci throughout the parenchyma of the liver (Figure 13.13). Similar foci are sometimes present in the spleen and adrenal glands. Microscopically, these are areas of necrosis surrounded by varying numbers of inflammatory cells, mostly neutrophils (Figure 13.14). In addition to focal to multifocal hepatic necrosis, in pregnant does there is necrotizing acute suppurative metritis, and dead fetuses may be present. Gram-positive organisms are readily identifiable within and adjacent to the necrotic lesions (Murray et al., 1926; Paterson, 1940; Watson and Evans, 1985).

Pathogenesis

After ingestion by the host, *L. monocytogenes* penetrates epithelial cells of the gastrointestinal tract. This is mediated by interaction of internalin (InlA and InlB) with host cell receptors, including cadherin. It is then taken up by macrophages and enters the systemic circulation, eventually being found in the liver and spleen (Ireton, 2007; Watson and Evans, 1985).

Species susceptibility to infection may be influenced by the ability of internalin to bind host cell receptors and thus gain entry into cells. For example, InlB binds to a cell surface receptor called Met (hepatocyte growth factor receptor) in humans but not in rabbits. Similarly, InlA binds to cadherin in humans but not in mice; rabbits were not studied (Khelef et al., 2006). These

observations may help explain not only species susceptibility to infection, but also tissue tropisms that differ from one species to another. For example, *Listeria* infections in humans are frequently associated with central nervous system involvement, but CNS involvement is uncommon in rabbits.

Because *L. monocytogenes* is a facultative intracellular pathogen, the cell-mediated immune response is generally considered more important for protection than the humoral response (Hof, 1991). Nevertheless, a humoral response occurs in rabbits, and is particularly strong against internalin, as well as five other proteins of unknown function, designated IspA-E (Yu et al., 2007). There is evidence that antibody produced in response to *Listeria* is opsonizing and may enhance bacterial killing by neutrophils and macrophages (Suga et al., 1996; Vahidy and Jehan, 1996).

Diagnosis

Diagnosis of listeriosis depends on isolation of the organism, but a presumptive diagnosis can be made upon identification of Gram-positive organisms in typical lesions. It is important to consider other possible causes of focal hepatocellular necrosis, such as Tyzzer's disease, salmonellosis, and tularemia.

Several serologic screening techniques are available for listeriosis. The most popular are a microagglutination test using heated and trypsinized antigen and an immunofluorescent assay using lyophilized antigen. An immunoperoxidase technique performed on histologic sections of liver from intraperitoneally challenged mice has also been described. Regardless of the method, a high percentage of normal animals have titers, indicating either a carrier state or prior exposure to the organism (Briones et al., 1989).

Polymerase chain reaction techniques can also be used for diagnosis. Various assays have been described; some can identify species and allow differentiation of serotypes, whereas another uses primers specific for internalin genes to facilitate simultaneous confirmation of species identity and virulence (Borucki and Call, 2003; Doumith et al., 2004; Liu et al., 2007).

Prevention and Therapy

There are no reports that describe treatment of rabbits with listeriosis. In vitro, most antibiotics except cephalosporins are active against *L. monocytogenes*, but a combination of ampicillin and aminoglycoside is probably the most effective (Hof, 1991). In a rabbit model of experimentally induced meningitis, treatment with a combination of ampicillin and gentamicin was compared to moxifloxacin. Both regimens were similarly effective (Sipahi et al., 2008). Whatever antibiotic is

used, treatment efficacy is likely to be hindered by the intracellular location of the bacterium.

Since listeriosis is an uncommon disease of rabbits, prevention has received little attention. Good husbandry practices should be employed to minimize stress, and since food is a common source of the organism, high-quality feed should be used. This is especially important in breeding colonies. Vaccination is not practiced in rabbits, but killed vaccines have been used in ruminants and appear to be partially effective (Burdarov and Savova-Burdarova, 1985).

TUBERCULOSIS

Background

Tuberculosis is a rare disease of domestic rabbits. As in other species, it is characterized by granulomatous inflammation of the lungs, digestive tract, liver, kidneys, and lymph nodes. It is almost always caused by *Mycobacterium bovis*, but *M. avium* and *M. tuberculosis* have been isolated from some cases. This review will concentrate on spontaneously occurring tuberculosis, although the rabbit has been used extensively as a model for study of the pathogenesis of the disease.

Robert Koch recognized rabbit tuberculosis in 1884, only 2 years after he first isolated and cultivated mycobacteria. His description was followed by a similar report by Guérin, in 1908. These papers, along with many others published in the following decades, were reviewed in detail by Flatt (1974). Most of the reports described nodular lesions with caseous centers which primarily involved the lungs. Other organs, including the kidneys, liver, lymph nodes, gastrointestinal tract, and bones, were sometimes affected as well. Most cases were attributed to the bovine variety of mycobacteria, now known as *M. bovis*, but the avian variety was also described.

Rabbits are also susceptible to paratuberculosis, which is caused by *M. avium* subspecies *paratuberculosis*. Rabbits challenged experimentally with the organism develop intermittent diarrhea and multifocal granulomas in the sacculus rotundus and cecum (Mokresh and Butler, 1990). Spontaneous paratuberculosis was first reported in a wild rabbit with typical lesions. The etiologic agent was not cultured, but the rabbit had contact with a deer herd that experienced an epizootic of the disease (Angus, 1990). Since then the presence of paratuberculosis in wild European rabbits (*Oryctolagus cuniculus*) has been well documented (Beard et al., 2001; Greig et al., 1997). Rabbits are known to be an important reservoir of the organism, thereby posing a potential risk to grazing livestock (Daniels et al., 2003a, 2003b).

Etiologic Agent

Tuberculosis is caused by members of the genus *Mycobacterium*, all of which are slender, rod-shaped, aerobic, slow-growing, non-motile, Gram-positive, and acid-fast. The cell wall contains complex waxes and glycolipids that stimulate the granulomatous inflammatory response seen in tuberculosis. Species of *Mycobacterium* that have been associated with tuberculosis in rabbits include, in order of frequency, *M. bovis*, *M. avium*, and *M. tuberculosis*. These can be differentiated based on biochemical reactions, molecular diagnostic techniques such as PCR, agglutination by specific antisera, or pathogenicity for various species of experimental animals. For animal species other than non-human primates, *M. bovis* and *M. avium* are typically more pathogenic than *M. tuberculosis* (Himes et al., 1989; Wayne and Kubica, 1984).

M. bovis, the most important cause of spontaneous tuberculosis in rabbits, is a member of the *M. tuberculosis* complex, which is a group of very closely related species with over 99.9% similarity at the DNA level. Other members of the group include *M. africanum*, *M. caprae*, *M. microti*, and *M. pinnipedii*. *M. tuberculosis* and *M. africanum* affect humans almost exclusively, whereas the latter three species affect goats, voles, and pinnipeds, respectively. *M. bovis* has the largest host range. From an evolutionary standpoint, the traditional view is that *M. tuberculosis* originated as a zoonotic pathogen derived from *M. bovis*, but recent genomic analyses of members of the complex suggest that the reverse is true; evidently, successive loss of DNA segments from *M. tuberculosis* gave rise to *M. bovis* and other members of the complex (Gordon et al., 2009).

M. bovis and other members of the *M. tuberculosis* complex produce various gene products that are critical for host-pathogen interactions. These include enzymes that are important in the synthesis and transport of several lipids and glycolipids that are present on the cell surface and appear to be necessary for persistence and multiplication in the host. Secreted proteins are also important, including ESAT-6 (early secreted antigenic target), which is recognized by T cells and induces production of interferon gamma (Gordon et al., 2009).

Epizootiology

Rabbit tuberculosis is a rare disease in laboratory rabbits, but the large number of reports in the early 1900s suggests that it was once more prevalent than it is today. Many of the early cases may have been acquired from cattle, since it was a common practice to feed cow's milk to rabbits as a growth promoter (Harkins and Saleeby, 1928). Discontinuation of this practice, together with control programs for bovine tuberculosis,

are probably responsible for the fewer number of cases reported in recent years. Interestingly, current trends indicate that the tables have turned: rather than cattle serving as a source of *M. bovis* for rabbits, rabbits now appear to be a source of *M. avium* subspecies *paratuberculosis* for cattle, at least in the United Kingdom (Daniels et al., 2003a, 2003b).

As in other species, transmission of tuberculosis in rabbits occurs by inhalation or ingestion. Inhaled organisms colonize the lungs and bronchial lymph nodes, whereas ingested organisms penetrate the gastrointestinal epithelium and colonize the mesenteric lymph nodes or intestinal wall. In either case, organisms sometimes gain access to the systemic circulation and disseminate throughout the body. Following exposure by inhalation, organisms may be coughed up and swallowed, resulting in secondary exposure via the gastrointestinal route.

Wild rabbits in the United Kingdom have a high prevalence of infection with *M. avium* subspecies *paratuberculosis*, ranging from 17–40%. Organisms can be isolated from reproductive tissues and from feces. Gross lesions are not typically present, but histopathologic lesions can occur in almost 20% of infected animals. Transmission is thought to occur horizontally via ingestion of contaminated feces or vertically via the placenta or by ingestion of contaminated milk (Beard et al., 2001; Daniels et al., 2003a, 2003b; Judge et al., 2006).

Clinical Manifestations

Clinical signs of tuberculosis are non-specific and include findings such as anorexia, weight loss, and pallor. Occasionally there are signs referable to a particular organ system. Diarrhea, suggesting gastrointestinal involvement, has been reported; this may be more likely in cases of *M. avium* infection. Swollen joints and ocular lesions have also been observed (Flatt, 1974).

Pathology

Gross lesions of tuberculosis consist of tan to gray caseous nodules in various organs, especially the lungs, bronchial lymph nodes, kidneys, and liver. Cavitory lesions in the lungs can occur in cases of *M. bovis* infection, but such lesions are rarely associated with other mycobacterial species, except under carefully controlled experimental challenge conditions (Manabe et al., 2003; Nedeltchev et al. 2009).

The gastrointestinal tract may contain caseous nodules, especially at sites of lymphoid tissue, and the mucosa overlying the nodules may be ulcerated. With skeletal involvement there is caseous necrosis of bone, accompanied by areas of osseous proliferation. Widespread central nervous system involvement can occur, with caseous nodules in the cerebrum, medulla,

and leptomeninges. Ocular lesions such as uveitis also have been observed (Collins et al., 1983; Flatt, 1974; Himes et al., 1989).

Microscopic lesions consist of foci of caseous necrosis surrounded by epithelioid macrophages, lymphocytes, and fibrous tissue. Acid-fast organisms can be found in impression smears or histologic sections of the lesions. Mineralization of the lesions is uncommon, and multinucleated giant cells are usually scarce (Himes et al., 1989).

Lesions associated with *M. avium* subspecies *paratuberculosis* involve the intestine and associated lymph nodes. Granulomas characterized by macrophages, giant cells, and intracellular acid-fast bacteria are present in the small intestine (Beard et al., 2001; Greig et al., 1997).

Pathogenesis

Mycobacteria are facultative intracellular pathogens, accumulating in large numbers in macrophages at the site of a lesion. The organisms provoke a granulomatous inflammatory response, in part because of the high lipid content of their cell walls. Infection also stimulates an intense cell-mediated immune response, which ordinarily inhibits dissemination of organisms and blocks progression of disease. In some cases, however, there is an aberrant immune response characterized by hypersensitivity. This accelerates the development of lesions and induces clinical disease. The nature of the immune response and the consequent level of resistance are influenced by host genotype (McMurray, 1991). A relationship between genotype and resistance has been seen in experimental infection studies performed in rabbits (Dorman et al., 2004; Lurie, 1963; Mendez et al., 2008). Susceptible rabbits have impaired delayed-type hypersensitivity responses and impaired TNF- α production, underscoring their importance in the pathogenesis of the disease (Dorman et al., 2004).

Diagnosis

Because the clinical signs are non-specific, diagnosis of tuberculosis is ordinarily made at necropsy. Demonstration of typical lesions containing acid-fast organisms is highly suggestive, but culture and identification of the organism are required for definitive diagnosis. Molecular diagnostic techniques such as polymerase chain reaction allow rapid presumptive diagnosis and species identification from clinical specimens (Balasingham et al., 2009; Gopinath and Singh, 2009).

Prevention and Therapy

There have been no reports of treatment of naturally occurring tuberculosis in rabbits. Theoretically, drugs

such as isoniazid and rifampin should be effective. Rifampin is helpful in treating experimentally induced *M. avium* infection in rabbits, but it is not curative (Singh et al., 1981). Because of the rarity of the disease, prevention of tuberculosis by vaccination or other strategies has received little attention and need not be a major concern.

TULAREMIA

Background

Tularemia is an acute septicemic disease caused by *Francisella tularensis*. It can occur in many vertebrate species and is common in wild rabbits and hares, but in domestic rabbits the disease is rare.

Tularemia was first described as a plague-like disease occurring in ground squirrels (*Citellus beecheyi*) from California (McCoy, 1911). The etiologic agent was isolated and named *Bacterium tularense* after Tulare County, California (McCoy and Chapin, 1912). The first human cases were described in 1914, and were characterized by ulcerative conjunctivitis, fever, weakness, and lymphadenopathy (Wherry and Lamb, 1914a, 1914b). These and most subsequently reported human cases were associated with exposure to rabbits. Francis (1925) recognized the importance of this association and also studied the etiologic agent and the pathogenesis of the disease. *Francisella* was named in his honor, in recognition of this early work on tularemia.

Etiologic Agent

Tularemia is caused by *Francisella tularensis*, a Gram-negative, aerobic, non-motile, pleomorphic bacterium that is distantly related to the genera *Brucella*, *Yersinia*, and *Pasteurella*. It cannot be cultured on standard laboratory media, but glucose cysteine agar or cysteine heart agar can be used successfully provided they are first enriched with blood. Classically, two biovars of *F. tularensis* are recognized: *tularensis* and *palaeartica*. Biovar *tularensis* is highly virulent and found almost exclusively in North America, whereas biovar *palaeartica* is less virulent and found in Eurasia as well as the Americas. Lagomorphs are especially likely to harbor biovar *tularensis*, thus explaining the strong association between rabbit exposure and human cases (Eigelsbach and McGann, 1984; Morner et al., 1988).

Recent DNA-sequence-based classifications of the species *Francisella tularensis* reflect four subspecies: *tularensis*, *holarctica*, *mediasiatica*, and *novicida* (Foley and Nieto, 2010; Keim et al., 2007). Subspecies *holarctica* and *mediasiatica* were previously included within biovar *palaeartica*; subspecies *novicida* was previously regarded as a separate species.

Epizootiology

F. tularensis is widely distributed in nature and has been isolated from over 200 species of wildlife, including mammals, birds, reptiles, fish, and arthropods, including ticks and biting insects. Clinically, the most important subspecies are *tularensis* and *holarctica*; the other subspecies have relatively low virulence. *F. tularensis* subspecies *tularensis* is restricted almost exclusively to North America, whereas *F. tularensis* subspecies *holarctica* exists in both North America and Europe. This means that subspecies *holarctica* is the only significant cause of tularemia in Europe, whereas either subspecies can cause tularemia in North America (Foley and Nieto, 2010).

Several studies attest to the prevalence of *F. tularensis* in wild lagomorphs, both in Europe and North America. In a survey of wild cottontail rabbits from Illinois, 16% had detectable antibodies to *F. tularensis* (Lepitzki et al., 1990). Another study, conducted in Sweden, found that 7% of wild hares submitted for necropsy died from tularemia (Morner et al., 1988). Interestingly, tularemia occurred in the varying hare (*L. timidus*) but not in the brown hare (*L. europaeus*). Cases were most common in the autumn and may have been transmitted by blood-sucking arthropods, most likely ticks. Ticks are important vectors of tularemia, and the genera *Dermacentor*, *Amblyomma*, and *Ixodes* have all been incriminated. In North America, *Dermacentor andersoni* have been shown capable of transmitting tularemia to rabbits (Gordon et al., 1983).

Many species that harbor *F. tularensis* may transmit the infection to humans, but rabbits are most often incriminated. Up to 90% of human cases have been linked to lagomorph exposure, with rabbits of the genus *Sylvilagus* presenting the greatest risk in North America (Hoff et al., 1975; Jellison, 1974). In Europe, hares of the genus *Lepus* present the greatest risk; there have been no reported cases of tularemia acquired from *Oryctolagus cuniculus*.

The incidence of tularemia in humans declined from a peak of 2291 cases in the United States in 1944 to around 10% of that level in the 1980s (JAMA, 1987; Jellison, 1974; MMWR, 1986). During the period from 2000 to 2008, an average of 126 cases per year were reported (http://www.cdc.gov/tularemia/Surveillance/Tul_CasesbyState.html). Rabbits still represent the primary source of exposure, but transmission from arthropods to humans has been recognized more frequently (Boyce, 1975; Foley and Nieto, 2010).

Transmission of tularemia can occur by several routes. The organism usually enters the host through the skin or conjunctiva, either via a wound or by penetrating intact mucosal epithelium. This can be mediated by direct contact with infected material or by an

arthropod bite. Transmission may also occur by ingestion of infected meat or contaminated water, or by inhalation of infectious aerosols (JAMA, 1987).

Clinical Manifestations

Tularemia usually causes sudden death in affected animals, but depression, anorexia, and ataxia may be observed. In humans, tularemia is an acute, febrile disease. A primary lesion consisting of a skin ulcer occurs, and inflammation of regional lymph nodes follows. This is termed the ulceroglandular form of the disease and represents the most common syndrome seen in humans. In severe cases, there may be progression to septicemia and pneumonia (Eigelsbach and McGann, 1984).

Pathology

The main lesions of tularemia in lagomorphs include focal coagulative necrosis and congestion of the liver, spleen, and bone marrow (Figure 13.18). The extent of these lesions depends on the duration of the disease, so they may be absent or minimal in peracute cases. Sometimes hemorrhagic enteritis and typhlitis are observed in addition to the classic lesions, particularly in hares that develop the disease in winter months (Morner et al., 1988).

Pathogenesis

Asymptomatic infection with *F. tularensis* probably occurs frequently; this is suggested by the high prevalence of antibody in wild rabbits and the occasional isolation of *F. tularensis* from apparently healthy animals (Lepitzki et al., 1990). Factors that determine whether

disease occurs could be expected to include the immunologic status of the host, the route of exposure, and the dose and virulence of organisms. There is a substantial difference in virulence between subspecies of *F. tularensis*, subspecies *tularensis* being more virulent than the others (Morner et al., 1988). The reason for this difference in virulence is not known, but early studies suggested that virulent organisms have higher catalase activity and higher levels of cytochrome *b1* than non-virulent ones (Eigelsbach and McGann, 1984). The presence of a capsule is also associated with virulence.

Recent experimental studies of tularemia suggest that the ability of organisms to survive and replicate within macrophages is critical for disease pathogenesis. This ability depends on the bacterial gene *mgla*, which regulates transcription of genes located within a segment of the genome referred to as the *Francisella* Pathogenicity Island (Barker and Close, 2007). Other bacterial components, such as lipopolysaccharide and pili, may be important as well.

Diagnosis

Tularemia is usually diagnosed at necropsy. Typical lesions are suggestive of the disease, but definitive diagnosis requires identification or isolation of *F. tularensis*. Classically, isolation of the organism is performed by first inoculating guinea pigs intraperitoneally with suspect material. The guinea pigs die within 10 days, at which time the organism can be readily isolated from the tissues. This technique has the disadvantage of being hazardous to personnel, and is usually not necessary if appropriate culture techniques are used. Blood-enriched glucose cysteine agar or cystine heart agar can be inoculated directly with clinical or necropsy specimens and incubated at 37°C aerobically for 48–96 hours. Isolation is facilitated by incorporation of antibiotics in the media to suppress normal flora (Eigelsbach and McGann, 1984).

As an alternative to isolation of the organism, a fluorescent antibody technique can be used for identification of the organism in fixed tissue; this is probably the safest method to arrive at a definitive diagnosis in a suspected clinical case (Morner, 1981).

Serologic screening procedures for *F. tularensis* infection have been developed, including a rapid slide test for agglutinating antibodies and several enzyme-linked immunosorbent assays (Lepitzki et al., 1990; Schmitt et al., 2005).

Methods for detection of organisms in biological specimens have been described. These include a capture enzyme-linked immunosorbent assay that is specific for bacterial lipopolysaccharide and several polymerase chain reaction assays (Grunow et al., 2000; Molins et al., 2009).

FIGURE 13.18 Tularemia: multiple foci of hepatic necrosis. Similar lesions occur in diseases such as listeriosis and Tyzzer's disease. (Courtesy of Dr. James G. Fox)

Prevention and Therapy

Because tularemia exists almost exclusively in wild animal populations, treatment is rarely attempted. If an opportunity for treatment arises, fluoroquinolones or aminoglycoside antibiotics should be effective. Alternatively, tetracyclines can be used and have the advantage of oral administration, but recrudescence of the disease may occur when therapy is stopped. *Francisella* is resistant to penicillin and first-generation cephalosporins (Foley and Nieto, 2010).

Control of tularemia in wild animal populations has not been attempted. To prevent spread to humans or domestic animals, is it important to minimize contact with animal carcasses and biting arthropods when in enzootically infected areas. In addition, meat from wild-caught lagomorphs should be thoroughly cooked. For exceptionally high-risk individuals, vaccination may be attempted. Several different candidates have been produced, including killed bacterins and live attenuated strains. The best-studied vaccine candidate is an attenuated strain designated LVS (live vaccine strain). LVS was derived from *F. tularensis* subspecies *holarctica* after multiple passages and laboratory manipulations that gave way to various mutations in parts of the genome thought to be important for virulence (Barker and Close, 2007). Progress in vaccine development will depend on further characterization of bacterial genes associated with virulence, followed by induction of attenuating mutations in virulence-associated genes.

PROLIFERATIVE ENTEROPATHY

Background

Proliferative enteropathy is caused by *Lawsonia intracellularis*, an obligate intracellular bacterium that causes disease in a wide range of hosts including pigs, hamsters, rabbits, ferrets, dogs, horses, and macaques. The disease is characterized by thickening of the ileum, mucosal hyperplasia, and intracellular organisms in crypt enterocytes. Early reports in rabbits described the intracellular bacteria as morphologically similar to *Campylobacter*, but immunologic and molecular evidence suggested that the organisms were not closely related to known *Campylobacter* species (Moon et al., 1974; Schoeb and Fox, 1990; Umemura et al., 1982). Eventually, it became evident that the causative organism was a member of a newly recognized genus named *Lawsonia*, which caused a nearly identical disease in pigs, ferrets, and hamsters (Fox and Lawson, 1988; Fox et al., 1994; Hotchkiss et al., 1996).

Etiologic Agent

Lawsonia intracellularis is a Gram-negative, non-spore-forming, curved intracellular pathogen that has

not been cultivated in cell-free media. Sequencing of DNA encoding 16S rRNA suggests that it is closely related to the genus *Desulfovibrio* (Hotchkiss et al., 1996). *L. intracellularis* has been cultured in a rat small intestinal cell line designated IEC-18 and in a mouse fibroblast line known as McCoy cells (Lawson et al., 1993; Watarai et al., 2008). The mouse fibroblast line may offer better passage efficiency.

The extent to which *L. intracellularis* isolates vary depending on the host species is uncertain, but there is evidence that isolates from rabbits and pigs are antigenically distinct and have different biological properties. Rabbit and pig isolates cultured in mouse fibroblasts have distinct antigenic profiles that could be useful in serologic typing or epizootologic analysis (Watarai et al., 2008). Furthermore, rabbit and pig isolates demonstrate different levels of pathogenicity in BALB/c mice (Murakata et al., 2008).

Epizootiology

Little is known about the prevalence of *Lawsonia intracellularis* infection in rabbits, especially with respect to whether animals can be asymptomatic carriers. Most reports describe outbreaks involving multiple animals during a short time frame, which could imply that a carrier state is unlikely. On the other hand, there is at least one report of rabbits that had typical lesions at necropsy but no prior clinical signs (Duhamel et al., 1998). In this case it is possible that overt disease simply did not have enough time to develop.

Clinical Manifestations

Proliferative enteropathy is typically characterized by diarrhea, weight loss, dehydration, and depression, although rabbits infected with *L. intracellularis* may show no clinical signs. The disease is most common in weanlings, although adults can be affected. Mortality is typically low, but morbidity can approach 30% (Duhamel et al., 1998; Horiuchi et al., 2008; Hotchkiss et al., 1996).

Although mortality is ordinarily low, coinfection with other enteric pathogens might be expected to exacerbate clinical signs. In fact, an outbreak of enterocolitis characterized by unusually high mortality was observed in rabbits coinfecting with *L. intracellularis* and enteropathogenic *E. coli* (Schauer et al., 1998).

Pathology

Gross necropsy findings in cases of proliferative enteropathy involve thickening of the small intestine, cecum, and colon, with the ileum most prominently affected. Mesenteric lymph nodes are often enlarged.

Microscopic lesions consist of marked thickening of the mucosa accompanied by hyperplasia and distortion of villous and crypt epithelium. Inflammation is typically modest, but cell inflammatory cell infiltrates may be observed in the lamina propria, consisting primarily of histiocytes, plasma cells, lymphocytes, and a few neutrophils. Warthin-Starry staining reveals curved silver-staining bacteria in the apical cytoplasm of crypt enterocytes (Duhamel et al., 1998; Horiuchi et al., 2008; Hotchkiss et al., 1996).

Pathogenesis

Studies of the pathogenesis of proliferative enteropathy are limited, perhaps because of challenges presented by the obligate intracellular nature of the causative organism. In contrast to other intestinal pathogens, factors influencing colonization, host cell attachment, and cell entry are not well defined at the molecular level. Organisms enter via a mechanism that resembles uptake by clathrin-coated pits, and reside for a brief time in an intracellular vacuole. The bacteria quickly escape from the vacuole and live freely in the cytoplasm. *L. intracellularis* has a strong tropism for crypt cells rather than mature intestinal epithelial cells. Only infected cells proliferate, but the mechanism that mediates proliferation is not known (Smith and Lawson, 2001).

Host immune response is surprisingly limited, considering the dramatic proliferative lesions that are observed; this may facilitate persistence of the organism within epithelial cells. Nevertheless, animals often recover from the disease and appear to clear organisms from the epithelium. There is evidence from experimental studies in mice that this may be mediated, at least in part, by gamma interferon production (Smith et al., 2000).

Diagnosis

L. intracellularis can be identified in tissue sections by classical Warthin-Starry staining or by immunohistochemical techniques that rely on monoclonal antibodies or polyclonal antiserum against *Lawsonia* surface antigens. Alternatively, polymerase chain reaction can be used to amplify DNA extracted from fixed tissue specimens (Duhamel et al., 1998; Horiuchi et al., 2008; Schauer et al., 1998; Watarai et al., 2004).

For clinical specimens, an enzyme-linked immunosorbent assay using synthetic *Lawsonia* surface antigens can be used to detect the presence of serum antibody. Another approach, which allows detection of *Lawsonia* in fecal samples, uses magnetic beads coated with anti-*Lawsonia* antibodies. Bacteria captured by the beads are then detected by ATP bioluminescence (Watarai et al., 2005).

Prevention and Therapy

Treatment of rabbits suspected of having proliferative enteropathy should be symptomatic. Ill animals should be isolated from others in the colony, and fluid support should be provided as needed. Antibiotics should be used with caution because they may exacerbate diarrhea. There are no reports of the use of antibiotics in rabbits with the disease, but in ferrets, chloramphenicol was shown to be effective at a dose of 50 mg/kg body weight, given every 12 hours for up to 21 days (Krueger et al., 1989).

MISCELLANEOUS BACTERIAL DISEASES

Actinobacillus

Several cases of soft tissue swelling and inflammation around the joints of the extremities have been attributed to *Actinobacillus* spp. (Arseculeratne, 1962). Histologically, the affected tissues were characterized by granulomatous inflammation. The lesions contained colonies of Gram-negative organisms surrounded by a zone of eosinophilic radially arranged club-shaped structures.

A. capsulatus has been isolated from visceral organs of North American snowshoe hare (*Lepus americanus*) (Zarnke and Schlater, 1988). This organism appears to be prevalent in wild lagomorphs. A serological survey showed that over 40% of snowshoe hares from Alaska or Alberta have titers to the organism (Zarnke et al., 1990).

Isolated cases of *Actinobacillus* infections have been reported in pet rabbits, most commonly as opportunistic infections. In one case, a rabbit with Tyzzer's disease was found to have concurrent infection with *A. equuli*, which was isolated from lungs and liver (Moyaert et al., 2007). In another, a rabbit with gastric stasis syndrome developed a febrile illness and died shortly thereafter. *A. capsulatus* was isolated in pure culture from the lungs and fibrin thrombi were present in blood vessels (Meyerholz and Haynes, 2005). *Actinobacillus* may be confused with *Pasteurella multocida* in standard microbiological testing, so it is important to use care in differentiating between the two organisms. Both are members of the family *Pasteurellaceae* and therefore non-motile, facultatively anaerobic, oxidase-positive, and catalase-positive; carbohydrate fermentation patterns may be required for conclusive identification.

Actinomyces

Osteitis involving the bones of the head, vertebral column, and distal extremities has been attributed to *Actinomyces* spp. (Sorenson and Saliba, 1961). Lesions in affected rabbits included granulomatous inflammation

with “sulfur granules,” as well as bone lysis and proliferation. The inflammatory process extended into the soft tissue adjacent to bone.

Actinomyces israelii has been identified as an occasional cause of rabbit mandibular or maxillary abscesses (Tyrell et al., 2002). Interestingly, this study identified a variety of organisms associated with these abscesses (see also *Fusobacterium nucleatum*, below), but *Pasteurella* was not isolated.

Bordetella

Bordetella bronchiseptica is a common inhabitant of the upper respiratory tract of laboratory rabbits. Other species of laboratory animals, such as dogs, cats, and guinea pigs, also harbor the organism. Colonization of weanling rabbits is common, and the number of infected animals increases as the animals mature (Deeb et al., 1990; Glass and Beasley, 1989). Rabbits naturally infected with *B. bronchiseptica* ordinarily remain free of respiratory disease unless concurrently infected with another pathogen such as *P. multocida* (Deeb et al., 1990). Under experimental conditions, however, the organism can be pathogenic. For example, intranasal challenge with *B. bronchiseptica* results in acute serous rhinitis and bronchopneumonia in some animals, especially sucklings (Glavits and Magyar, 1990; Maeda and Shimuzu, 1975; Watson et al., 1975; Yoda et al., 1982).

Colonization of the respiratory tract depends on bacterial attachment to ciliated epithelium; this, in turn, requires expression of multiple adhesins, including filamentous hemagglutinin, pertactin, fimbriae, adenylate cyclase-hemolysin toxin, and dermonecrotic toxin. Host mechanisms for defense against colonization include both humoral and cell-mediated responses, but at the earliest stages of infection non-specific surfactant proteins predominate (Edwards et al., 2005).

Although *B. bronchiseptica* is primarily an opportunistic pathogen, colonized animals have abnormal immune responses. Alveolar macrophages demonstrate decreased adherence, phagocytic uptake, and bactericidal activity compared to macrophages from non-colonized animals (Zeligs et al., 1986). This suggests that *B. bronchiseptica* can act as a copathogen, particularly in rabbits infected with *P. multocida* or other respiratory pathogens.

Because of its high prevalence and limited pathogenicity, control of *B. bronchiseptica* infection is not usually attempted. If elimination of the organism from a rabbitry is desired, embryo transfer or cesarian rederivation can be used (Suzuki et al., 1990). Subsequently, animals should be housed under barrier conditions to prevent reintroduction of the organism. Monitoring for the presence of *B. bronchiseptica* can be done with standard microbiologic techniques, an enzyme-linked

immunosorbent assay, or by molecular diagnostic techniques (Boot et al., 1993; Friedman et al., 2006).

Borrelia

Borrelia burgdorferi, the spirochete that causes Lyme disease, has been isolated from several species of mammals, most notably mice, which are considered the primary reservoir. Spontaneous infection of *O. cuniculus* has not been reported, however. In fact, the species is generally considered to be a non-permissive host for long-term infection, although some evidence to the contrary has emerged (Embers et al., 2007).

B. burgdorferi has been cultured from eastern cottontail rabbits (*Sylvilagus floridanus*) and the cottontail rabbit tick *Ixodes dentatus* (Anderson et al., 1989). *B. burgdorferi* has also been found in another widely distributed lagomorph, the black-tailed jackrabbit (*Lepus californicus*). In areas where Lyme disease is endemic, jackrabbits are especially likely to be infected. Therefore, serologic monitoring of this species can be used as a surveillance procedure for the presence of borreliosis in various geographic areas (Lane and Burgdorfer, 1988).

Brucella

Brucellosis is almost unknown in domestic rabbits, but it is common in wild lagomorphs, particularly members of the genus *Lepus*. The disease is widespread in the European hare (*L. europaeus*) and is usually caused by *Brucella suis*. In fact, hares, along with wild boars, are thought to be the natural reservoir of *B. suis*.

Hare brucellosis is characterized by multifocal chronic granulomatous inflammation of the reproductive organs, liver, and spleen. The lesions are similar to those of tuberculosis, containing a central area of caseous necrosis surrounded by histiocytes and sometimes Langerhans giant cells. Although *B. suis* is usually isolated from the lesions, *B. melitensis* and *B. abortus* have been recovered as well (Sterba, 1982, 1983; Vitovec et al., 1976; Witter and O'Meara, 1970). Brucellosis has also been reported in black-tailed jackrabbits (*L. californicus*) from Utah (Thorpe et al., 1965).

Serologic methods of screening for hare brucellosis include traditional methods such as the complement fixation test, as well as an enzyme-linked immunosorbent assay (Szulowski et al., 1999). Molecular diagnostic techniques such as polymerase chain reaction have been reported, but identification to the species level is difficult due to high interspecies homology of the genus (Mayer-Scholl et al., 2010).

Cilia-associated Respiratory (CAR) Bacillus

Cilia-associated respiratory (CAR) bacillus is a Gram-negative, filamentous, rod-shaped bacterium responsible

for some cases of chronic respiratory disease in rats and mice. The bacillus colonizes the ciliated epithelial cells of the respiratory tract, resulting in peribronchial infiltration and hyperplasia of mononuclear cells in the lamina propria (Ganaway et al., 1985a).

Spontaneous infection with CAR bacillus also occurs in rabbits, but rabbit isolates are substantially different from rodent isolates, with the two sharing less than 50% sequence homology. This suggests that the strains of CAR bacillus isolated from rodents and rabbits are host-specific and may actually represent different bacterial genera (Cundiff et al., 1994, 1995; Schoeb et al., 1993).

CAR bacillus appears to be prevalent in some rabbit colonies (Caniatti et al., 1998). In contrast to rodents, however, clinical disease has not been observed and lesions are mild. Lesions are restricted to the bronchi and trachea and are characterized by slight hypertrophy and hyperplasia of ciliated epithelium, coupled with infiltration of the lamina propria with inflammatory cells. In sections stained with Grocott's methenamine silver, argentophilic filamentous bacteria can be seen aligned perpendicular to the epithelial surface, situated among the cilia (Caniatti et al., 1998; Kurisu et al., 1990; Oros et al., 1997).

Interestingly, two experimental studies reported no lesions at all following inoculation of CAR bacillus, although seroconversion did occur (Matsushita et al., 1989; Shoji-Darkye et al., 1991). This may be because of the strain used for inoculation; in both cases rodent isolates were administered to rabbits; subsequent work by other investigators revealed that rodent isolates are generally non-pathogenic for rabbits and vice versa (Cundiff et al., 1994, 1995).

Chlamydophila

According to current taxonomy, the family Chlamydiaceae is divided into the genera *Chlamydophila* (Cp.) and *Chlamydia* (C.). *Chlamydophila* includes the species *Cp. psittaci*, *Cp. pneumoniae*, *Cp. abortus*, *Cp. pecorum*, *Cp. felis*, and *Cp. caviae*. *Chlamydia* includes the species *C. suis*, *C. trachomatis*, and *C. muridanum* (Everett, 2000).

Rabbits are often used as an experimental model for the study of atherosclerosis associated with *Cp. pneumoniae*, but there are few reports of spontaneous disease caused by this organism or other members of the genus. A specific strain of *Cp. psittaci*, designated M56, causes epizootic chlamydiosis with high mortality in snowshoe hares (*L. americanus*). The organism proliferates in the monocyte-macrophage system, producing congestion and focal necrosis of the liver and spleen (Spalatin et al., 1966). Strain M56 is the only *Cp. psittaci* strain known to be pathogenic for the snowshoe hare, and other lagomorphs are resistant to infection (Iversen

et al., 1976). *S. floridanus* and *O. cuniculus* ordinarily survive experimental challenge with few lesions, although anterior uveitis can occur in *O. cuniculus* after intravenous inoculation (Iversen et al., 1974).

There are several other reports of isolation of chlamydiae from rabbits, but their significance is unclear. Krishna and Kulshrestha (1985) reported spontaneous conjunctivitis in six rabbits and attributed the condition to a chlamydial organism. The diagnosis was based on indirect fluorescent antibody tests of conjunctival smears, and treatment with tetracycline was followed by remission of clinical signs. Flatt and Dungworth (1971b) isolated a chlamydial agent from the lungs of a domestic rabbit with pneumonia. They reproduced pneumonia experimentally by injecting the agent intratracheally. The disease was mild and self-limiting. Lesions included mild exudation of heterophils and a pronounced accumulation of macrophages in alveoli and alveolar septae. A similar case was reported by Krishna and Gupta (1989). The predominant lesions were interstitial pneumonia and proliferation of lymphoid tissue around vessels and airways. Eosinophilic inclusions and elementary bodies were demonstrated by special stains. Finally, Zumpt (1976) claimed that chlamydiae were responsible for a high percentage of gastrointestinal disease in the rabbitries of South Africa, but this report was incomplete in its description of lesions and isolation procedures for the organism.

Polymerase chain reaction assays have been developed to detect *Chlamydophila* and *Chlamydia* species of veterinary interest (Pantchev et al., 2009). Four rabbits screened because of unspecified clinical signs of chlamydial infection were infected with *Cp. caviae*. The significance of this finding is unclear, however, because the rabbits were in close contact with guinea pigs, which are considered to be the natural host for the organism.

Corynebacterium

There is one reported case of spontaneous disease due to *Corynebacterium bovis* (Arseculeratne and Navaratnam, 1975). The organism was isolated from a testicular abscess and lung of a rabbit. A similar disease was produced by intravenous injection of *C. bovis* in an experimental rabbit. Both animals developed agglutinating antibody to the *C. bovis* isolate.

Dermatophilus

Dermatophilus congolensis is an actinomycete that infects the skin of many species, producing a superficial, purulent dermatitis with abundant crust formation. Rabbits are susceptible to infection with *D. congolensis* and have been used as experimental

models to study the disease (Abu-Samra and Imbabi, 1976; Abu-Samra and Walton, 1981; Bucek et al., 1992; How and Lloyd, 1990). Only one spontaneous case has been reported, and that was in a cottontail rabbit (*S. floridanus*). The rabbit had typical lesions, consisting of scabs and heavy encrustations overlying a layer of purulent material. The foot pads, rear legs, and perineum were most severely affected (Shotts and Kistner, 1970). If dermatophilosis is suspected, direct smears of purulent material should be made. *D. congolensis* can be identified as two or more long parallel rows of Gram-positive cocci.

Fusobacterium nucleatum

Mandibular and maxillary abscesses are common in rabbits, and in the absence of culture it is tempting to assume that they are caused by *Pasteurella multocida*. A study by Tyrrell et al. (2002) demonstrates that *Pasteurella multocida* is actually seldom involved; rather, *Fusobacterium nucleatum* is the most common cause. *F. nucleatum* is a Gram-negative non-spore-forming rod that shares at least two antigens with *F. necrophorum* (Kaur and Falkier, 1992). Other bacterial species associated with odontogenic abscesses include *Actinomyces* spp. and Gram-positive cocci of the *Streptococcus milleri* group. This pattern is similar to that observed in humans.

Antibiotic treatment of mandibular or maxillary abscesses should be based on culture and sensitivity. The organisms responsible are typically sensitive to clindamycin, chloramphenicol, penicillin, cefazolin, and ceftriaxone (Tyrrell, 2002). Clindamycin is generally contraindicated in lagomorphs; care should be taken with any antibiotic because of the risk of serious gastrointestinal side effects.

Haemophilus

There are few reports of rabbit infections caused by bacteria of the genus *Haemophilus*, but the organism can be cultured from the respiratory tract in clinically normal rabbits (Boot et al., 1999). An organism identified as *Haemophilus* sp. was described by Gibbons (1929) as a common cause of subcutaneous abscesses, but it is likely that this organism was actually *Pasteurella multocida*. There is one reported case of conjunctivitis in a rabbit caused by *Haemophilus* sp. (Srivastava et al., 1986). When the organism was inoculated into the eyes of experimental rabbits, transient blepharitis was observed and the organism was reisolated. An organism named *H. paracuniculus* has been recovered from the gastrointestinal tracts of rabbits with mucoid enteropathy, but it is not known whether it contributes to the pathogenesis of the disease (Targowski and Targowski, 1979b).

Helicobacter

Helicobacter species have been reported to occur occasionally in laboratory rabbits, with one study detecting the organism in the stomach of four out of 65 rabbits tested by polymerase chain reaction (Van den Bulck et al., 2006). The organisms were identified as enterohepatic helicobacters and were not associated with clinical signs or significant gastric inflammation.

Leptospira

Leptospirosis has not been described in domestic rabbits, but wild lagomorphs are susceptible to the disease and may be an important reservoir. Serologic surveys indicate that it is prevalent in some populations, including cottontail and swamp rabbits from the southeastern United States (Shotts et al., 1971). Up to 40% of European hares from local populations in the Netherlands have antibodies to *L. interrogans* serovar *grippotyphosa*; the infection is probably acquired from contact with field mice (Hartman and Broekhuizen, 1980).

Moraxella

Moraxella spp. are frequent inhabitants of the conjunctiva and nasolacrimal duct apparatus of rabbits, but disease is rare (Marini et al., 1996). There is one reported case of *Moraxella bovis*-induced metritis and septicemia in a rabbit (Soave et al., 1977). The rabbit was presented with a copious purulent vaginal discharge, and on necropsy was found to have necrotizing suppurative metritis. There was also serofibrinous pneumonia and multifocal areas of necrosis in the liver. *M. bovis* was cultured from the uterus, lung, liver, and spleen. Cattle may have been the source of infection, since they were housed in close proximity to the affected rabbit.

Mycoplasma

Two strains of *Mycoplasma pulmonis* have been isolated from rabbits and characterized immunologically (Deeb and Kenny, 1967a, 1967b). These isolates were recovered from the upper respiratory tract, but were not associated with clinical disease.

***Pasteurella* spp.**

Pasteurella species other than *P. multocida* are occasionally isolated from rabbits. *P. pneumotropica*, which is a major cause of clinical pasteurellosis in laboratory rodents, sometimes colonizes the nasopharynx of rabbits (Kirchner et al., 1983). It is ordinarily not pathogenic in this species, but there is one report of a rabbit with *P. pneumotropica*-associated rhinitis (Okuda and

Campbell, 1974). *P. aerogenes* has been isolated from the uterus of a rabbit which aborted due to suppurative metritis (Thigpen et al., 1978). Mouse pathogenicity tests indicated that the organism was of low virulence and therefore probably an opportunistic pathogen.

Pseudomonas

Pseudomonas aeruginosa is difficult to culture from clinically normal rabbits, but up to 75% have IgG antibodies to outer membrane proteins or lipopolysaccharide, suggesting that many animals are exposed to the organism and either clear or retain it as part of their resident flora (Weisner et al., 2005).

Occasionally, *P. aeruginosa* causes an exudative, moist dermatitis which involves the dewlap or other areas of the skin that have contact with moisture (Garibaldi et al., 1990b; O'Donoghue and Whatley, 1971; Schoenbaum, 1981; Williams and Gibson, 1975). A blue-green discoloration is sometimes evident in affected areas due to the presence of pyocyanin pigment produced by the organism. Treatment of the condition involves clipping the hair and cleansing the lesions, followed by application of a topical antibiotic preparation. Depending on severity, systemic antibiotics may be indicated as well. Since water is a frequent source of *P. aeruginosa*, the water supply should also be evaluated for the presence of the organism.

In addition to moist dermatitis, *P. aeruginosa* can cause abscesses and septicemia. It has been isolated from a rabbit with a mandibular abscess (Dominguez et al., 1975), and from rabbits involved in an outbreak of fulminating pneumonia and diarrhea (McDonald and Pinheiro, 1967).

Streptococcus

Streptococcus is an infrequent pathogen of laboratory rabbits. Prior to 1950, there were several reports of *Streptococcus* sp. as the cause of an acute septicemic syndrome that usually involved young rabbits. These reports, all in the European literature, are reviewed by Flatt (1974). In recent decades no similar reports have appeared, but there is one description of *Streptococcus*-associated osteomyelitis secondary to a subcutaneous abscess (Yanoff, 1983).

Yersinia

Pseudotuberculosis is caused by *Yersinia pseudotuberculosis*. The disease is rare in domestic rabbits, yet quite common in rodents, especially guinea pigs. Pseudotuberculosis can occur in wild lagomorphs, and in Europe, the hare is an important reservoir of the causative agent, which can be isolated from the oral

cavity as well as many visceral organs (Nikolova et al., 2001). There are also several reports of isolation of *Y. pseudotuberculosis* from feces or cecal contents (Borg, 1968; Mollaret, 1968; Schneider, 1968). In Japan, similar attempts to isolate the organism from hares have been mostly unsuccessful, suggesting that a different species harbors the organism in that country (Tsubokura et al., 1984). Lesions of pseudotuberculosis usually include large areas of caseous necrosis in the mesenteric lymph nodes, liver, and spleen. Necrosis is also common in Peyer's patches of the small intestine and in the cecum. Other organs, including the lungs and kidneys, may be involved as well (Flatt, 1974).

<i>Rotavirus Infections</i>	386		

INTRODUCTION

The major focus of this chapter is the naturally occurring viral diseases of rabbits and hares although asymptomatic infections are also discussed (Tables 14.1 and 14.2). Some viral infections of rabbits have provided fundamental information on basic mechanisms of agent–host interrelationships, e.g., *Myxoma virus*, and others have been useful as models for human diseases,

e.g., *Rotavirus*. Although the principal emphasis is on virus infections of domestic rabbits of the genus *Oryctolagus*, naturally occurring and experimental infections of other rabbits and hares are also discussed.

In indoor facilities, it is unlikely that rabbits will encounter any of these viruses. Incoming rabbits should be obtained from sources free of these infections, however appropriate quarantine and screening measures should be standard operating procedure. With outdoor

TABLE 14.1 DNA Virus Infections of Rabbits

Family/subfamily	Genus	Species/strain	Host	Geographic Distribution
Poxviridae	Leporipoxvirus	Myxoma virus	<i>Sylvilagus brasiliensis</i>	South America
			<i>Sylvilagus bachmani</i>	North America
			<i>Oryctolagus cuniculus</i> (wild and domesticated)	South America, North America, Europe, Australia, New Zealand
		Rabbit (Shope) fibroma virus	<i>Sylvilagus floridanus</i>	North America
		Hare fibroma virus	<i>Lepus europaeus</i>	Europe
	Orthopoxvirus	Rabbitpox	<i>Oryctolagus cuniculus</i> (domesticated) ^a	United States (laboratory colonies), Holland
Herpesviridae/ Gammaherpesvirinae	Rhadinovirus	Leporid herpesvirus 1	<i>Sylvilagus floridanus</i>	United States
		Leporid herpesvirus 2	<i>Oryctolagus cuniculus</i> (domesticated)	England, United States (laboratory colonies)
Herpesviridae/ Alphaherpesvirinae	Simplexvirus	Leporid herpesvirus 4	<i>Oryctolagus cuniculus</i> (domesticated)	North America
		Human herpesvirus 1	<i>Oryctolagus cuniculus</i> (domesticated) ^a	United States
Papillomaviridae	Kappa-papillomavirus	Cottontail rabbit papillomavirus	<i>Sylvilagus floridanus</i>	United States
			<i>Oryctolagus cuniculus</i> (domesticated)	United States
		Rabbit oral papillomavirus	<i>Oryctolagus cuniculus</i> (domesticated)	United States, Mexico, New Zealand
Polyomaviridae	Polyomavirus	Rabbit kidney vacuolating virus	<i>Sylvilagus floridanus</i>	United States
			<i>Oryctolagus cuniculus</i> (domesticated)	United States
Adenoviridae	Mastadenovirus	Adenovirus	<i>Oryctolagus cuniculus</i> (domesticated)	Hungary, Quebec ^b

facilities, appropriate measures should be undertaken, as described in the "Control" section for each of the viral diseases, to prevent spread of viruses from wild rabbits in the surrounding environment. None of the viral infections of rabbits are known to be of public health importance as there are no reports of the definitive spread of viruses from rabbits to humans.

The viral diseases of rabbits are discussed in an order based on the taxonomic groups to which the viruses belong and are independent of the order of importance of the various diseases. The material is presented under uniform subject headings, including history, etiology, epidemiology, clinical signs, pathology, diagnosis, and control. Control is interpreted broadly and includes both prevention and eradication. This review uses the most widely accepted viral terminology. The recommendations of the VIII International Committee on Taxonomy of Viruses (Fauquet et al., 2005) are followed, but well-established common names for viruses are used when appropriate. Rabbits and hares are referenced by common names as indicated in *Mammals of the World, A Checklist* (Duff and Lawson, 2004).

DNA VIRUS INFECTIONS

Poxvirus Infections

Poxviruses cause several important diseases in domestic and wild mammals and birds. Infection with poxviruses usually results in relatively mild disease involving the skin of infected animals, but generalized and often fatal disease may also occur, as, for example, in myxomatosis in rabbits. Close antigenic relationships exist among many poxviruses derived from different animal species. In spite of close antigenic relationships, the poxviruses of rabbits which produce distinct disease syndromes are discussed as separate entities.

Myxoma Virus

HISTORY

The disease myxomatosis, caused by *Myxoma virus*, was first recognized by Sanarelli (1898) in Uruguay in 1896. European rabbits of the genus *Oryctolagus*, acquired for antiserum production, developed a highly fatal disease characterized by numerous mucinous skin tumors. Sanarelli (1898) named the disease "infectious myxomatosis of rabbits" and, since no microbial agents were detected, proposed that the disease was caused by a newly recognized group of infectious agents known as "filterable viruses." The virus which caused the first known outbreak of myxomatosis is believed to have originated from the Forest rabbit (*Sylvilagus brasiliensis*) in which the virus causes relatively mild disease. Transmission from wild to domestic rabbits probably

occurred by mosquitoes of the genus *Aedes* (Aragao, 1943; Fenner and Ratcliffe, 1965).

Myxomatosis spread to other countries of South America where it occasionally causes sporadic outbreaks in domesticated rabbits. In Chile, the disease is considered endemic in the wild European rabbit population (Fenner and Ratcliffe, 1965). The disease was first recognized in North America in 1928 when natural outbreaks of a fatal disease of rabbits occurred in several rabbit colonies near San Diego, California (Kessel et al., 1931). The virus which caused the first outbreaks in southern California may have been introduced into the United States from Mexico by importation of infected domestic rabbits (Vail and McKenney, 1943). The disease is endemic in the western United States, where the Brush rabbit (*Sylvilagus bachmani*) is the natural reservoir (Marshall and Regnery, 1960; Regnery and Miller, 1972).

Myxomatosis was introduced intentionally into Australia in an effort to control what had become Australia's major animal pest, the European rabbit (*Oryctolagus cuniculus*). The virus was first introduced into Australia in 1926 and used only in experimental studies aimed at determining its feasibility as a control measure for rabbits. In 1950, the virus was released into the wild rabbit population where it decimated the rabbit population of the continent by 1953. The disease is now endemic in the wild rabbit population of Australia, where it occasionally assumes epidemic proportions when climatic conditions favor vector activity. Within a decade following release of *Myxoma virus* into the rabbit population, it became evident that through natural selection genetically resistant strains of rabbits had emerged. In these rabbits, a virulent strain of *Myxoma virus* caused only 25% mortality compared to 90% mortality in non-resistant strains of rabbits (Fenner and Ratcliffe, 1965). This selective pressure continues with regional increases in resistance of Australian rabbits (Williams et al., 1990).

Genetic modification of *Myxoma virus* was recognized soon after its release into the rabbit population, and by the fourth year markedly attenuated strains of virus had replaced virulent virus as the dominant strains. The naturally attenuated viruses caused a milder disease of longer duration, which favored vector transmission and thus persistence of the virus (Fenner and Woodroffe, 1965; Fenner et al., 1957). The evolution of myxomatosis in Australia is a classic example of natural modification of both a virus and host until a state of equilibrium is reached, permitting the continued existence of both.

The introduction of myxomatosis into Europe followed the early successes of the Australian campaign. In 1952, while French officials were considering the desirability of introducing the disease, a private individual acquired the virus and released it on his own estate in an effort to control the rabbit population. The

virus spread rapidly through the countryside, and by the end of 1953 myxomatosis had been diagnosed in Belgium, the Netherlands, Germany, Luxembourg, Spain, and England (Armour and Thompson, 1955; Fenner and Ratcliffe, 1965; Lubke, 1968). Myxomatosis is now endemic in rabbits of the genus *Sylvilagus* in both North and South America and in wild European rabbits (*Oryctolagus cuniculus*) in South America, Europe, Australia, and New Zealand.

ETIOLOGY

Myxomatosis is caused by one of several strains of the species, of which *Myxoma virus* is the type species of the genus *Leporipoxvirus* in the *Chordopoxvirinae* subfamily of the family *Poxviridae* (Fauquet et al., 2005). Antigenic differences, demonstrated among different strains of the virus (Fenner, 1965; Reisner et al., 1963), have prompted some to consider the California strains of virus as distinct from *Myxoma virus*, and the designation "California rabbit fibroma virus" has been used to describe this virus. However, the demonstrable antigenic differences are insufficient to justify this distinction, and California strains of virus are considered strains of *Myxoma virus* (Fauquet et al., 2005).

Myxoma virus is antigenically closely related to the *Rabbit fibroma virus* as demonstrated by agar-gel diffusion microprecipitation techniques (Fenner, 1965). Heat-inactivated *Myxoma virus* has been reactivated by fibroma virus (Berry and Dedrick, 1936; Fenner, 1962), further demonstrating the close relationship between these two viruses. The Berry-Dedrick phenomenon of poxvirus reactivation was confirmed by Smith (1952), who demonstrated a spectrum of virulence for strains of myxoma and fibroma viruses. Fenner and Marshall (1957), in a study involving 92 strains of virus, established a virulence spectrum ranging from strains causing over 99% mortality in European rabbits to others causing less than 30% mortality. The most virulent strains were the Standard Laboratory, Lausanne, and California strains, whereas the least virulent were the neuromyxoma and Nottingham strains. Ecological pressures such as those previously described in Australia could have been responsible for the emergence of many of these strains of viruses. In many instances, however, viruses have been manipulated in the laboratory to the point of permanent modification (Kilham, 1957, 1958). The entire genome of the Lausanne strain has been sequenced (Cameron et al., 1999). Infection of *Oryctolagus cuniculus* with *Myxoma virus* has provided a model system for elucidating the immunopathogenesis of poxvirus in the host (Stanford et al., 2007).

The chemical and physical characteristics of *Myxoma virus* have been described (Andrewes and Porterfield, 1989; Fenner, 1953; Fenner and Ratcliffe, 1965). *Myxoma virus* is readily propagated at 35°C on the chorioallantoic

membrane of embryonated hens' eggs, forming distinct pocks (Fenner and McIntyre, 1956). Different strains of virus cause pocks of various sizes, the variation being sufficiently distinct to allow tentative strain identification. The South American strains cause large pocks, whereas the California strains produce small focal lesions on the membrane (Fenner and Marshall, 1957). The virus can also be propagated in cell cultures derived from rabbits and other species, including chicken, squirrel, rat, hamster, guinea pig, and human (Andrewes and Porterfield, 1989; Woodroffe and Fenner, 1965). Distinct differences in plaque size on rabbit kidney cell cultures can be demonstrated between the South American and California strains, the former causing much larger plaques (Woodroffe and Fenner, 1965). The most sensitive method for isolation of *Myxoma virus* under laboratory conditions is inoculation of the skin of European rabbits (Fenner and McIntyre, 1956).

EPIDEMIOLOGY

Myxomatosis is endemic on four continents: Australia, Europe, North America, and South America. In Brazil and Uruguay, the virus is endemic in wild rabbits (*Sylvilagus*), particularly *Sylvilagus brasiliensis* (Aragao, 1943). A similar situation may exist in Panama and Colombia, where the strains of virus are similar in virulence to South American strains, but antigenically more closely related to the California strains (Fenner, 1965). In the forested area of Argentina, the virus is also endemic in *Sylvilagus* rabbits, but in the southern part of the country and in Chile the principal reservoir is the wild European rabbit (*Oryctolagus cuniculus*) (Fenner and Ratcliffe, 1965). The California strains of *Myxoma virus*, also known as the California rabbit fibroma virus (Andrewes and Porterfield, 1989), are endemic in wild rabbits (*Sylvilagus*), especially *Sylvilagus bachmani*, which serves as the principal source of infection for domestic rabbits (Marshall et al., 1963). A similar situation exists in Mexico, where *Sylvilagus bachmani* has been shown to be the reservoir in Baja California (Licón Luna, 2000). In Australia, the *Myxoma virus* has been endemic in wild European rabbits (*Oryctolagus cuniculus*) since its introduction into the rabbit population in 1950. Following the introduction of the virus into France in 1952, myxomatosis has become established in most countries of Europe, the wild European rabbit serving as the predominant host species. In Europe, *Myxoma virus* and *Rabbit hemorrhagic disease virus* occur endemically in the same free-living populations of *Oryctolagus cuniculus* (Calvete et al., 2002) and seropositivity to both viruses occurs significantly suggesting the possibility of predisposition (Marchandeau et al., 2004). In rabbit farms in Belgium, the Netherlands, and Germany, the seroprevalence of *Myxoma virus* was

higher in herds with recurrent respiratory or digestive diseases (Marlier et al., 2001).

The naturally susceptible species are the European rabbit (*Oryctolagus cuniculus*), the European hare (*Lepus europaeus*), the Mountain hare (*Lepus timidus*), the Forest rabbit (*Sylvilagus brasiliensis*), the Brush rabbit (*Sylvilagus bachmani*), and the Eastern Cottontail rabbit (*Sylvilagus floridanus*). Experimentally, several additional species of *Sylvilagus* can be infected (Fenner and Ratcliffe, 1965; Regnery and Marshall, 1971).

The principal mode of transmission of the virus is mechanical transport of virus on mouth parts by arthropod vectors, mosquitoes and fleas being most often incriminated (Grodhaus et al., 1963), but biting flies, gnats, mites, and lice may serve as vectors (Fenner and Woodroffe, 1953; Mykytowycz, 1957). The source of virus is usually the superficial layers of the skin, especially of the eyelids and at the base of the ears (Fenner and Woodroffe, 1953), where surface-feeding arthropods obtain the virus and serve as mechanical vectors. Experimentally, virus can spread by contact in the absence of arthropod vectors, and such transmission may occur under natural conditions in rabbit warrens (Mykytowycz, 1958, 1961). An outbreak in Hungary at a rabbit farm was attributed to airborne transmission as the disease occurred in winter when mosquitoes and fleas were uncommon (Farsang et al., 2003). Windborne spread was suspected in France (Arthur and Louzis, 1988). Transmission of *Myxoma virus* by contaminated spines of thistles (*Cirsium vulgare*) has been described (Dyce, 1961; Mykytowycz, 1961). The claws of predatory birds and carrion feeders, such as buzzards and crows, may be contaminated with virus, and such birds may play a role in dissemination of the virus (Borg and Bakos, 1963).

In an attempt to improve the usefulness of myxomatosis in rabbit control, the European rabbit flea, *Spilopsyllus cuniculi*, was introduced into Australia in 1966 (Sobey and Menzies, 1969). The flea reproduced in wild rabbit populations and transmitted both introduced and field strains of *Myxoma virus* (Shepherd and Edmonds, 1977; Sobey and Conolly, 1971). As a result of flea introduction, myxomatosis has become more prevalent in drier tableland areas (Parer and Korn, 1989), and outbreaks of myxomatosis have shifted from summer to spring (Shepherd and Edmonds, 1978; Shepherd et al., 1978). In France, there is evidence that mosquitoes of the genus *Anopheles* are the principal vectors of summer epidemics. The rabbit flea, *Spilopsyllus cuniculi*, is probably a major vector, especially during winter months when mosquito activity is low (Fenner and Ratcliffe, 1965).

Myxomatosis in Britain is characterized by milder seasonal fluctuations in disease incidence than in Australia, California, and France (Ross and Tittensor, 1986). Mosquitoes play a minor role as vectors,

whereas the rabbit flea, *Spilopsyllus cuniculi*, which is less influenced by seasonal changes, is the major vector (Andrewes et al., 1959; Armour and Thompson, 1955; Lockley, 1954; Mead-Briggs, 1964). The *Myxoma virus* in Britain has not undergone the rapid loss of virulence observed with the Australian and French viruses. The increase in resistance to myxomatosis in wild rabbit populations has resulted in the appearance of more virulent strains of *Myxoma virus* (Ross and Sanders, 1987). While mildly virulent strains have emerged in Britain, the predominant strains are moderately virulent (Chapple and Bowen, 1963; Chapple and Lewis, 1964; Fenner and Chapple, 1965), with recent estimates of between 47% and 69% mortality in infected rabbits (Ross et al., 1989). The different evolution of *Myxoma virus* in Britain has been attributed to the fact that the virus is predominantly flea-transmitted. The flea is less seasonal and less mobile than the mosquito. That fleas move in large numbers from dead animals while moving only occasionally from live ones would seem to favor transmission of virulent virus strains (Fenner and Marshall, 1957). The proportion of infective fleas produced is inversely related to the survival time of rabbits following infection (Mead-Briggs and Vaughan, 1975). The flea is also an effective reservoir of virus, possessing a longer life span than mosquitoes. The life span of active female mosquitoes is usually 2–3 weeks, whereas fleas have been known to feed actively for over 1 year. The *Myxoma virus* can persist for 105 days in rabbit fleas with no rabbit contact in artificial burrows (Chapple and Lewis, 1965).

In experimental studies of viral pathogenesis and host resistance, a virulent strain of *Myxoma virus* (SLS) inoculated into laboratory European rabbits (*Oryctolagus cuniculus*) resulted in fatal infections whereas wild European rabbits with naturally acquired innate resistance recovered (Best and Kerr, 2000). Conversely, inoculation of laboratory European rabbits with an attenuated, naturally derived field strain of *Myxoma virus* resulted in recovery from infection and rabbits with innate resistance experienced only mild disease. A similar study examined the pathogenesis of two Californian strains of *Myxoma viruses* (MSW and MSD) in European rabbits and found that both susceptible rabbits and rabbits that had naturally acquired innate resistance, experienced acute fatal infections with the MSW strain, whereas, the MSD strain caused classical signs of myxomatosis in both strains of rabbits (Silvers et al., 2006).

CLINICAL SIGNS

Considerable differences in the virulence of *Myxoma virus* strains complicate discussion of the clinical disease, as does the fact that different species and strains of rabbits vary considerably in susceptibility to *Myxoma virus*. Major emphasis is given to discussion of disease

in *Oryctolagus* by the major strains of virus found in Australia, California, Europe, and South America.

SIGNS IN SYLVILAGUS SPECIES Rabbits of the genus *Sylvilagus*, the natural host of the virus, are relatively resistant to infection and generally develop skin tumors and lesions, but rarely systemic disease, except in young rabbits (Aragao, 1943). Generally, the nodules occur at the site of infection, persist for a variable amount of time, and then regress. The size of the skin nodule and its persistence vary with the strain of rabbit and the strain of virus (Fenner and Ratcliffe, 1965; Marshall and Regnery, 1963; Regnery and Miller, 1972; Silvers et al., 2009).

SIGNS IN LEPUS SPECIES The European hare (*Lepus europaeus*) is resistant to *Myxoma virus* under experimental conditions, and field experience supports this observation. Occasionally, however, individual hares (*Lepus europaeus* and *Lepus timidus*) with mild to severe generalized myxomatosis have been encountered (Fenner and Ratcliffe, 1965).

SIGNS IN ORYCTOLAGUS CUNICULUS *Myxoma virus* infection in the European rabbit usually results in severe disease with high mortality (Marshall et al., 1963; Patton and Holmes, 1977). The severity and variety of clinical disease is largely determined by the strain of virus as well as the strain of rabbit (Sobey, 1969; Sobey et al., 1970) and have been described in detail (Fenner and Marshall, 1957; Fenner and Ratcliffe, 1965). The discussion which follows is a summation of the findings of these workers and others (Chapple and Bowen, 1963; Kessel et al., 1931).

Signs which develop following infection with California strains of the virus in susceptible rabbits can be categorized as peracute, acute, or chronic. Rabbits with the peracute form of disease die within 1 week after exposure to the virus, exhibiting only edema of the eyelids and lethargy prior to death. In the acute form of disease, in which rabbits survive for 1–2 weeks, usually edema of the eyelids, resulting in a “droopy” appearance of the eyes, appears at 6–7 days. Inflammation and edema around the anal, genital, oral, and nasal orifices are also observed. Skin hemorrhages and convulsions precede death on the ninth or tenth day. The few rabbits which survive beyond 10 days and have a chronic form may develop purulent blepharoconjunctivitis and edema at the base of the ears, signs more often associated with other myxoma strains (Figure 14.1). The nodule which develops at the site of inoculation is not a clearly defined tumor, and under natural conditions the development of myxomas is not characteristic. Although nodules on the ears, head, and legs have been reported (Kessel et al., 1934), other workers have

been unable to induce nodule development (Fenner and Marshall, 1957).

The original South American isolate of Moses (1911), results in an acute disease with a mean survival time of 11 days. From 3–4 days following inoculation or natural infection with virus, a primary tumor may become evident, and generalized tumors usually appear by the sixth or seventh day. Edema of the eyelids occurs followed by mucopurulent blepharoconjunctivitis, often resulting in complete closure of the eyes. Mucopurulent nasal discharge and pronounced edema of the base of the ears, the perineal region, the external genitalia, and lips are frequently seen. By the tenth day, hard convex lumps may cover the body, head, and ears and occasionally the legs. The lumps are not sharply demarcated but may become markedly congested and ultimately necrotic in rabbits surviving for 2 weeks. Dyspnea is often seen in protracted cases, but appetite may be maintained until shortly before death. Terminal convulsions frequently precede death, which usually occurs 8–15 days after infection. Infection with less virulent South American and Australian strains results in milder disease with less edema and nasal and ocular discharge, more clearly demarcated nodules, and lower mortality. The laboratory-attenuated neuromyxoma virus induces a mild disease with little or no mortality (Hurst, 1937b).

The predominant myxoma strains in Europe are the virulent Lausanne strain and its naturally attenuated derivatives originating from the virus introduced into France from Brazil in 1952. The more virulent European viruses cause severe disease in rabbits, resulting in mortality of up to 100%, but modified strains which have emerged are of lower morbidity and mortality (Arthur and Louzis, 1988). With some of the naturally attenuated British viruses, mortality is also decreased, and tumors are flat rather than convex, resembling some of the attenuated field strains in Australia (Chapple and Bowen, 1963). In France and Belgium, two forms of the disease are recognized, nodular and amyxomatous forms (Marlier et al., 1999). The former is characterized by florid skin lesions and severe immunosuppression, accompanied by bacterial infections of the respiratory tract, whereas in the latter, skin nodules are few and small, with acute respiratory distress and copious nasal discharge.

PATHOLOGY

The gross and microscopic pathology of myxomatosis has been comprehensively reviewed (Fenner and Ratcliffe, 1965; Hurst, 1937a; Rivers, 1930). In adult *Sylvilagus*, *Myxoma virus* usually causes localized skin tumors. The tumors resemble the fibromas in European rabbits produced by the *rabbit fibroma virus* (see later). Hares or young *Sylvilagus* usually develop a mild localized infection, although disseminated cutaneous

FIGURE 14.1 Rabbit with myxomatosis displaying facial edema with mucopurulent conjunctivitis. Courtesy of Dr. G. Van Hoosier.

fibromatous to myxomatous nodules similar to those in acute myxomatosis may be found. Prominent gross lesions in European rabbits with myxomatosis are skin tumors (not characteristic of the California disease) and pronounced cutaneous and subcutaneous edema, especially of the face and around body orifices. Hemorrhages of the skin, heart, and subserosa of the gastrointestinal tract may be observed, especially following infection with the California virus.

Lesions in the skin involve epithelial cells, fibroblasts, and endothelial cells and range from proliferative to degenerative, depending on the strain of virus. The skin tumors result from proliferation of undifferentiated mesenchymal cells, which become the characteristic large stellate (myxoma) cells surrounded by a homogeneous matrix of mucinous material interspersed with capillaries and inflammatory cells (Figure 14.2). There is typically vascular endothelial proliferation and hypertrophy with narrowing of the lumen (Hurst, 1937a; Percy and Barthold, 2007). Central necrosis of myxomas may be attributed to occlusion of blood vessels by endothelial proliferation. Epithelial cells overlying the tumor may appear normal in early tumors, or show hyperplasia or degeneration. Intracytoplasmic inclusions, in various cells types, are especially prominent in the epidermis (Patton and Holmes, 1977; Rivers and Ward, 1937).

Lesions in other organs, although not consistently present, reflect the potential generalized nature of myxomatosis. Cellular proliferation, invariably present in the skin, has also been described in pulmonary alveolar epithelium and in reticulum cells of lymph nodes and spleen (Hurst, 1937a). Focal hemorrhages may be observed in skin, kidneys, lymph nodes, testes, heart, stomach, and intestines. Degeneration and necrosis occur frequently in lymph nodes, pulmonary alveoli, spleen, and central veins of hepatic lobules. Stellate cells may occur in lymph nodes, bone marrow, uterus, ovaries, testes, and lungs (Marcato and Simoni, 1977).

FIGURE 14.2 Myxoma virus expressing lacZ-infected primary skin lesion immunostained with antibody to β -galactosidase demonstrates the wide distribution of the virus within the dermis and subcutis. Hematoxylin and eosin counterstain. Courtesy of Dr. G. McFadden.

In a survey of 66 rabbits, presumably *Oryctolagus cuniculus*, that died of respiratory disease, *Myxoma virus* was isolated from seven (10%), mainly from rabbits with acute hemorrhagic pneumonia (Marlier et al., 2000). The mechanisms by which the virus manifests the development of disease in rabbits have been described (Stanford et al., 2007).

DIAGNOSIS

Myxomatosis in European rabbits can usually be diagnosed by the clinicopathological features, particularly the nodular form, due to the characteristic skin lesions. Infection with the California viruses may be harder to diagnose, however, owing to the frequent absence of skin nodules and other signs of disease. Diagnosis should be confirmed by virus isolation. Intracutaneous inoculation of young susceptible rabbits with fresh tissue collected from lesions free of bacterial contamination results in lesions at the site of inoculation within 1 week. The virus can be isolated by chorioallantoic membrane inoculation of 11–13-day-old embryonated chicken eggs followed by incubation at 35°C for 4–6 days. Distinct focal pocks develop if the virus is present. The South American viruses cause large pocks, the California virus intermediate-sized pocks, and the fibroma virus minute pocks. Virus isolation on chicken embryo fibroblast, Vero or RK13 cells can also be accomplished. A cytopathic effect typical of poxviruses usually develops in 1–2 days but may take up to 7 days with some strains. The virus isolated can be identified as *Myxoma virus* by direct fluorescent antibody test (Takahashi et al., 1958, 1959), the plaque-neutralization test (Woodroffe and Fenner, 1965), the agar-gel diffusion microprecipitation test (Fenner, 1965), or the

indirect immunoperoxidase test (Marlier et al., 1999). Myxoma virus DNA in tissue samples can be detected by polymerase chain reaction (PCR) (Barcena et al., 2000; Kritas et al. 2008; Pérez de Rozas et al., 2008).

Rabbits that survive infection develop antibodies to the virus, which can be detected by an enzyme-linked immunosorbent assay (ELISA) that has been shown to be more sensitive and specific than agar gel immunodiffusion, complement fixation (CF), or indirect immunofluorescence (Gelfi et al., 1999). Serum neutralization has also been used to detect antibodies (Marlier et al., 1999). Infection of *Sylvilagus* rabbits with *Myxoma virus* clinically resembles fibromatosis and should be differentiated from the latter disease by PCR or inoculation of young susceptible rabbits of the genus *Oryctolagus*. Myxomatosis causes severe to fatal disease, whereas fibromatosis causes a localized fibroma.

CONTROL

Control of myxomatosis is of prime importance in areas where the virus is endemic in wild rabbit populations. Vector control, including adequate screening to exclude mosquitoes, serves to keep the disease under control. Newly introduced rabbits should be quarantined in an insect-proof facility for 2 weeks. To prevent spread within a colony, all sick rabbits should be isolated. Fibroma virus has been used as a live vaccine for myxomatosis, but results have been variable (Fenner and Ratcliffe, 1965). A live attenuated myxomatosis vaccine (the MSD strain) results in a mild reaction followed by immunity persisting for 9 months (McKercher and Saito, 1964). Jiran et al. (1970) found this virus to be too virulent for use as a vaccine and further attenuated it by serial passage in rabbit kidney cell cultures. The additionally modified virus, designated MSD/B, was safe and highly immunogenic.

However, efficacy of a vaccine has yet to be demonstrated in commercial rabbits. In an outbreak of atypical myxomatosis in Hungary, fibroma vaccine was not protective, whereas in experimental studies, a live myxomatosis vaccine protected rabbits (Farsang et al., 2003). An assessment of the Borgi strain vaccine of *Myxoma virus* was reported during an outbreak of myxomatosis in Greece (Kritas et al., 2008). Two-month-old vaccinated pregnant does were obtained by two commercial rabbitries, only one of which had vaccinated resident does. Within several weeks of their arrival, an explosive outbreak of myxomatosis with high morbidity and mortality occurred on both farms in both unvaccinated and vaccinated rabbits, both imported and resident, with the Lausanne strain of *Myxoma virus*. Since vaccinated rabbits were affected within 6 months of vaccination, the efficacy of the vaccine was questionable.

Field trials using various strains have been conducted in free-living rabbit populations. A field trial of a recombinant vaccine, using a naturally attenuated myxoma

field strain (6918) that expressed a *Rabbit hemorrhagic disease virus* VP60 protein, conducted on an island off the coast of Spain, revealed that the vaccine induced antibodies to both viruses in vaccinated rabbits without any adverse side effects (Torres et al., 2001). Furthermore, the vaccine exhibited limited horizontal transmission, either by direct contact or fleas, as uninoculated rabbits also exhibited seroconversion. Although the observation period was brief (32 days), the vaccine appeared to be both safe and efficacious. An attenuated strain (SG33) was used in a field trial in juvenile rabbits in France and vaccinated rabbits had a 1.8-fold greater odds of surviving than unvaccinated rabbits over 4 years of surveillance (Guitton et al., 2008). In a field trial in Zaragoza province in northeast Spain, young European rabbits (*Oryctolagus cuniculus*) born in the current year and unvaccinated, were 13.6 times more likely to die than rabbits vaccinated against both myxomatosis (POX-LAP) and *Rabbit hemorrhagic disease* (CYLAP-VHD), over a 90-day observation period after vaccination (Calvete et al., 2004).

Rabbit (Shope) Fibroma Virus

HISTORY

The transmissible tumor-inducing agent now known as rabbit or Shope fibroma virus was isolated from an Eastern Cottontail rabbit (*Sylvilagus floridanus*) in 1932 (Shope, 1932a). The virus was transmissible to Eastern Cottontail and European rabbits (*Oryctolagus cuniculus*), producing localized fibromas in both species. Shope (1932a) described the gross and microscopic lesions of both the natural and experimental disease and identified the causative agent as a virus antigenically related to *Myxoma virus* (Shope, 1932b). Similarities between *Rabbit fibroma* and *Myxoma viruses* have subsequently been confirmed by cross-immunity tests (Shope, 1936), ether sensitivity (Andrewes and Horstmann, 1949; Fenner, 1953), virus-reactivation studies (Berry and Dedrick, 1936), microprecipitation procedures (Fenner, 1965), and sequence comparison (Willer et al., 1999). The *Rabbit fibroma virus*, initially believed to cause only localized benign fibromas, was later shown to cause severe generalized disease in newborn European (Duran-Reynals, 1940; Joiner et al., 1971) and Eastern Cottontail rabbits (Yuill and Hanson, 1964). The disease is historically considered a benign endemic disease of wild *Sylvilagus* rabbits, of little economic significance to commercial rabbit producers or laboratory investigators. However, an outbreak of fibromatosis in a commercial rabbitry resulting in high morbidity and mortality in newborn rabbits was reported in 1971 (Joiner et al., 1971). Thus, the disease can be a threat to commercial rabbits in areas where it is endemic in wild rabbit populations and outdoor husbandry practices permit contact with arthropod vectors.

Another tumor-producing virus, designated malignant rabbit fibroma virus, has been recovered from *Oryctolagus cuniculus* with experimentally induced Shope fibromas (Strayer et al., 1983a). Although the virus was present in a stock of *Rabbit fibroma virus*, its origin is unclear. The virus is antigenically similar to both *Rabbit fibroma* and *Myxoma* viruses and is considered a recombinant of the two viruses (Block et al., 1985). The virus induces a syndrome of severe immunosuppression resulting in disseminated malignancy and opportunistic infections (Corbeil et al., 1983; Skaletsky et al., 1984; Strayer and Sell, 1983; Strayer et al., 1983a, 1983b, 1983c). The disease may be a useful model for the study of virus-induced immunologic impairment (Strayer et al., 1985).

ETIOLOGY

Rabbit fibroma virus is a *Leporipoxvirus* of the family *Poxviridae* (Fauquet et al., 2005) and is closely related to *Myxoma virus* (Fenner, 1953) and the hare and squirrel fibroma viruses (Fenner, 1965). The complete genome of *Rabbit fibroma virus* has been sequenced (Willer et al., 1999). The chemical and physical characteristics of fibroma virus have been summarized by Gross (1983). The virus can be propagated on the chorioallantoic membrane of chicken embryos, but characteristic lesions as observed with *Myxoma virus* are not produced (Gross, 1983). The virus has been propagated in cell cultures derived from rats, guinea pigs, and humans (Chaproniere and Andrewes, 1957) and also in rabbit cell cultures derived from Eastern Cottontail and domestic rabbits (Constantin et al., 1956; Hinze and Walker, 1964; Kasza, 1974; Kilham, 1956; Padgett et al., 1962). Fibroma virus in cultured rabbit kidney cells induces pronounced changes in cell growth and morphology, and inoculation of virus-transformed cells into the cheek pouch of hamsters results in tumor formation (Hinze and Walker, 1964).

EPIDEMIOLOGY

Since *Rabbit fibroma virus* was first isolated from an Eastern Cottontail rabbit in New Jersey (Shope, 1932a), the disease has been recognized in several other states, as well as in Canada. Herman et al. (1956) found that more than 50% of wild *Sylvilagus* rabbits trapped in the Patuxent Wildlife Refuge in Maryland had *Rabbit fibroma virus* or antibodies to *Rabbit fibroma virus*. The virus has also been isolated from *Sylvilagus* rabbits in Wisconsin (Yuill and Hanson, 1964), Michigan (Herman et al., 1956), and Ohio (Kasza, 1974). Recognition of the disease in Texas (Joiner et al., 1971) indicates that it may be more widespread in the U.S. than was formerly believed.

The natural transmission cycle of *Rabbit fibroma virus* has not been completely elucidated. The virus may persist in the epidermis of experimentally infected *Sylvilagus* rabbits for 5–10 months (Kilham and Dalmat,

1955; Kilham and Fisher, 1954), which would enhance the likelihood of mechanical arthropod transmission. Experimentally, several species of mosquitoes as well as triatomines, fleas, and bedbugs can serve as vectors (Dalmat, 1959; Kilham and Dalmat, 1955; Kilham and Woke, 1953). Infected mosquitoes are capable of infecting wild *Sylvilagus* rabbits (Kilham and Dalmat, 1955). Experimental and circumstantial evidence suggests that the principal mode of transmission for fibroma virus is biting arthropods, a situation similar to that described for myxomatosis. Infection may also occur by direct contact with skin injuries being a predisposing factor (Grilli et al., 2003).

The natural host of fibroma virus is the Eastern Cottontail rabbit (*Sylvilagus floridanus*). Three other species of *Sylvilagus* (*Sylvilagus bachmani*, *Sylvilagus nuttalli*, and *Sylvilagus auduboni*) are refractory to fibroma virus (Fenner and Ratcliffe, 1965). A closely related virus, isolated from fibromas in *Sylvilagus bachmani*, failed to induce lesions in other *Sylvilagus* species (Marshall and Regnery, 1960). This virus, considered a strain of *Myxoma virus*, is a related virus named California *Rabbit fibroma virus* (Andrewes and Porterfield, 1989). The European rabbit (*Oryctolagus cuniculus*) is susceptible to fibroma virus (Shope, 1932a) as is the Snowshoe hare, *Lepus americanus* (Yuill, 1981), but the European hare, *Lepus europaeus*, is refractory to the virus (Fenner and Ratcliffe, 1965). Whereas the European rabbit is readily infected, it does not serve as a good source of infection for mosquitoes because of low virus concentrations in the skin (Fenner and Ratcliffe, 1965).

CLINICAL SIGNS

The clinical signs are largely those described by Shope (1932a, 1932b, 1936). The tumors observed in natural fibromatosis of Eastern Cottontail rabbits are almost invariably on the legs or feet, usually one to three tumors occurring on an infected rabbit. Tumors may occur on the muzzle and around the eyes, and measure up to 7 cm in diameter and 1–2 cm in thickness. The tumors are subcutaneous, unattached to underlying tissues, and may persist for several months, and in some instances for nearly a year (Kilham and Dalmat, 1955). Other clinical signs are usually absent, the tumor-bearing rabbit remaining apparently normal throughout the disease. Metastases do not occur (Shope, 1932a). The clinical signs in experimentally infected European rabbits resemble those in *Sylvilagus* rabbits. However, regression of tumors is usually more rapid than in *Sylvilagus* rabbits. Inoculation of newborn European rabbits frequently results in fatal systemic infections (Duran-Reynals, 1945). Systemic infections of adult European rabbits have also been described (Hurst, 1937c), but the usual result of infection is the development of localized benign tumors. In the only reported

natural outbreak of fibromatosis of European rabbits, diffuse subcutaneous induration involving the underlying tissues occurred (Joiner et al., 1971). Subcutaneous tumors were the predominant sign in adult rabbits but suckling rabbits had lethargy and loss of condition, in addition to the skin lesions. Hyperemia and edema of the external genitalia of male and female rabbits were also observed.

A survey of tumors in pet rabbits submitted to the surgical biopsy service of a veterinary school in Pennsylvania over a 16-year period revealed that Shope fibroma was diagnosed in 19 tumors from 179 rabbits (von Bomhard et al., 2007). The species of rabbits was not provided and diagnosis was based on histopathologic findings. The limbs, head, and pinna were affected in 75% of cases. Case reports of keratitis with a perilimbal mass due to fibroma virus have been diagnosed in individual European rabbits (*Oryctolagus cuniculus*) (Keller et al., 2007; McLeod and Langlinais, 1981).

PATHOLOGY

The gross and microscopic changes associated with fibroma virus infection in naturally and experimentally infected *Sylvilagus* rabbits and in experimentally infected European rabbits have been described by several workers (Ahlgren, 1938; Andrewes, 1936; Dalmat and Stanton, 1959; Fisher, 1953; Grilli et al., 2003; Kilham and Fisher, 1954; Shope, 1932a; Yuill and Hanson, 1964). The pathological changes in the only reported natural outbreak of fibromatosis in European rabbits were described by Joiner et al. (1971). The earliest gross lesion in experimentally infected *Sylvilagus* rabbits is a slight thickening of the subcutaneous tissue, followed by development of clearly demarcated soft swellings usually evident 6 days after inoculation. The tumors enlarge, increase in density, and usually reach maximum size by 12 days. The average size of the tumors is 4–6 cm with a thickness of 2 cm. Tumors may persist for months before regressing, leaving the rabbit essentially normal. Experimentally infected newborn *Sylvilagus* rabbits may die of generalized fibromatosis. Under natural conditions, however, this form of the disease has not been observed. Gross lesions in experimentally infected European rabbits are similar to those observed in *Sylvilagus* rabbits but regression of the tumors occurs more rapidly.

The earliest microscopic lesions in *Sylvilagus* rabbits are an acute inflammation followed by localized fibroblastic proliferation, accompanied by both mononuclear and polymorphonuclear leukocyte infiltrations. Fibroblasts proliferate until a distinct tumor is formed, consisting of spindle-shaped and polygonal connective tissue cells with abundant cytoplasm. Mitotic figures are few. Many tumor cells may have large intracytoplasmic inclusions characteristic of poxvirus infections. Mononuclear leukocyte cuffing of vessels adjacent to

the tumor may be observed, and a pronounced accumulation of lymphocytes at the base of the tumor is often seen. Degeneration of the overlying epidermis may result from pressure ischemia, followed by necrosis and sloughing of the epithelium and tumor. In many instances, however, the tumors regress without epithelial sloughing. Regression is usually complete within 2 months after appearance of tumors. Andrewes (1936) described a strain of fibroma virus which caused a more inflammatory and less proliferative lesion than the fibroma virus isolated by Shope (1932a).

Histologically, typical fibromas are observed in European rabbits experimentally infected with fibroma virus. The lesions differ only slightly from those in *Sylvilagus* rabbits, the principal difference being the absence of epidermal degeneration often observed in the latter species (Shope, 1932a). However, Ahlgren (1938) described epidermal degeneration in European rabbits. Microscopic lesions in the natural outbreak of fibromatosis in European rabbits ranged from tumors resembling myxomas to typical fibromas (Joiner et al., 1971). Eosinophilic cytoplasmic inclusions were occasionally observed in tumor cells, and similar inclusions, possibly of viral origin, were seen in epithelial cells overlying the tumors. The lesions encountered in adult and newborn rabbits did not differ significantly.

DIAGNOSIS

Fibromatosis should be differentiated from papillomatosis and myxomatosis. Clinically, differentiation from papillomatosis can be readily accomplished as fibromas are essentially flat, subcutaneous, loose, rubbery tumors, whereas papillomas are tumors of the skin which are heavily keratinized and project in irregular fashion from the skin surface. Histopathological differentiation is also easily accomplished, especially when intracytoplasmic inclusion bodies are observed. Historically, subcutaneous inoculation of young European rabbits with a tumor cell suspension was used to differentiate the two viruses. Rabbit fibroma virus induces local fibromas, whereas Myxoma virus causes severe systemic and often fatal disease. Virus isolation in cell cultures or on the chorioallantoic membranes of chicken embryos should be attempted to confirm the diagnosis. The virus can be identified by serum neutralization tests (Yuill, 1981).

CONTROL

Because the disease is endemic and of little significance in *Sylvilagus* rabbits, no control measures have been developed. Fibromatosis is also not an important problem in domestic rabbits; however, since the disease has been encountered in a rabbitry in an area where the disease is apparently endemic in wild rabbits, control measures might be considered. In such areas, the

method of choice for preventing infection of rabbits held in outdoor enclosures is vector control. Careful analysis of the role of possible vectors in natural outbreaks should be made in preparation for the establishment of vector control methods.

Hare Fibroma Virus

HISTORY

Epidemics of a fibromatous disease in European hares (*Lepus europaeus*) occurred in France and Northern Italy in 1959 (Lafenetre et al., 1960; Leinati et al., 1959). The causative agent was a poxvirus related to *Myxoma virus* (Leinati et al., 1961). In retrospect, a nodular skin disease of hares in Germany designated hare sarcoma was probably hare fibromatosis (Dungern and Coca, 1909).

ETIOLOGY

The causative agent of hare fibromatosis is a *Leporipoxvirus* in the family *Poxviridae* (Fauquet et al., 2005), which has been shown by plaque-neutralization and cross-protection tests to be antigenically related to myxoma, rabbit fibroma, and squirrel fibroma viruses (Woodroffe and Fenner, 1962). Agar-gel diffusion micro-precipitation techniques reveal that hare fibroma virus shares more common antigens with *Rabbit fibroma virus* than with *Myxoma virus* (Fenner, 1965). A considerable degree of cross-protection exists between hare fibroma and myxoma viruses. European rabbits immune to *Myxoma virus* are completely refractory to hare fibroma virus, whereas rabbits immunized with hare fibroma virus develop signs when infected with *Myxoma virus* but survive, indicating some protection (Woodroffe and Fenner, 1965).

EPIDEMIOLOGY

Hare fibromatosis has been recognized only in Europe, where under natural conditions it infects the European hare. However, dermal tumors were reported on Cape hares (*Lepus capensis*) in the Laikipia District of Kenya that had gross and histopathologic similarities to hare fibromatosis (Karstad et al., 1977). In 2001, an outbreak of fibromatosis occurred in farmed game European hares (*Lepus europaeus*) in Italy (Grilli et al., 2003). The European rabbit (*Oryctolagus cuniculus*) is susceptible to the virus, but natural outbreaks of disease in rabbits have not been reported. A seasonal occurrence of disease has been reported, with the peak incidence in late summer and autumn (Lafenetre et al., 1960; Leinati et al., 1959). The mode of transmission and interepidemic survival of the virus are unknown.

CLINICAL SIGNS

In European hares, the disease is characterized by development of numerous skin nodules, up to 2.5 cm

in size, occurring especially on the face, eyelids, and around the ears. In farmed game European hares, fibromas also occurred on the legs (Grilli et al., 2003). The nodules closely resemble rabbit fibromas (Leinati et al., 1961). In adult European rabbits the virus causes formation of small fibromas, but newborn rabbits exhibit large fibromas resembling the lesions of rabbit fibromatosis (Fenner and Ratcliffe, 1965).

PATHOLOGY

The gross and microscopic appearance of the lesions of hare fibroma is similar to that of the lesions of rabbit fibroma (Lafenetre et al., 1960; Leinati et al., 1961).

DIAGNOSIS

The disease is usually diagnosed from clinicopathological features. The diagnosis can be confirmed by virus isolation in rabbit kidney cell cultures or on the chorioallantoic membrane of chicken embryos. Serological characterization of the virus can be achieved using the agar-gel diffusion technique (Fenner, 1965).

CONTROL

Because the disease is endemic and of little significance in hares, no control measures have been developed. Farmed game hares, used for stocking areas, should be free of infection to avoid dissemination of the virus (Grilli et al., 2003).

Rabbitpox

HISTORY

Rabbitpox was first diagnosed at the Rockefeller Institute in New York when a highly fatal disease occurred spontaneously in the European rabbit (*Oryctolagus cuniculus*) colony in 1932 (Greene, 1933, 1934a; Pearce et al., 1933; Rosahn and Hu, 1935). A smaller outbreak had occurred in 1930. Rabbits developed an erythematous rash followed by cutaneous eruptions closely resembling the pocks seen in human infection with variola virus (smallpox). The disease was extremely contagious and caused high mortality, especially in young rabbits and pregnant females. Belgian hares were also susceptible to the disease. The causative agent of the disease was a poxvirus (Pearce et al., 1936; Rosahn et al., 1936a).

A spontaneous outbreak of a similar disease in a laboratory rabbit colony in Holland was described by Jansen (1941). The disease was highly fatal and differed from the Rockefeller outbreak in that it was not exanthematous, giving rise to the name "pockless" rabbitpox (Jansen, 1947). This disease was also caused by a poxvirus closely related to vaccinia virus (Jansen, 1946). A second outbreak of the disease in Holland was reported by Verlinde and Wersinck (1951). The second

outbreak of rabbitpox reported in the United States occurred in New York (Christensen et al., 1967) and was also of the pockless type first observed by Jansen (1947) in Holland. Another serious outbreak of the disease, resulting in mortality of 95%, occurred following the introduction of supposedly inactivated rabbitpox virus of the Dutch (Utrecht) strain into the rabbit colony of a medical school (Christensen et al., 1967). Various aspects of the infection have been reviewed by Fenner et al. (1989). Rabbitpox virus infection in rabbits can serve as a model for human smallpox infection as a fatal systemic disease developed with a low inoculum and inoculated rabbits naturally transmitted the virus to susceptible rabbits by aerosol (Adams et al., 2007).

ETIOLOGY

Rabbitpox virus is an *Orthopoxvirus* in the family *Poxviridae* (Fauquet et al., 2005) and is antigenically related to vaccinia virus (Fenner, 1958; Hu et al., 1936; Jansen, 1946). The biological properties of the Utrecht (Jansen, 1941) and Rockefeller (Greene, 1934a) strains of rabbitpox viruses are indistinguishable from certain neurovaccinia strains (Fenner, 1958; Fenner et al., 1989). The close antigenic relationship between rabbitpox virus and vaccinia virus, taken together with the fact that all reported outbreaks of rabbitpox have occurred in laboratory colonies, suggests that rabbitpox may be a laboratory variant of vaccinia virus (Greene, 1935a; Verlinde and Wersinck, 1951). Wittek et al. (1977) used genome mapping to show that rabbitpox virus (Utrecht strain) was a strain of vaccinia virus. The viruses have been shown to exhibit over 95% sequence similarity (Li et al., 2005).

Rabbitpox virus can be propagated on the chorioallantoic membrane of chicken embryos with development of distinct pocks. The predominant pock type is hemorrhagic (Jansen, 1946), but white pock mutants have been described (Fenner and Sambrook, 1966; Fenner et al., 1989). Rabbitpox virus has been propagated in several cell lines, including HeLa, Chang Liver, L929 (mouse fibroblast), human heart, KB (human epithelial), FL (human amnion), AT (Chinese hamster epithelial), PK-2A (pig kidney), and FAF cells (Chinese hamster fibroblast) (Christensen et al., 1967). The Rockefeller strain of rabbitpox virus hemagglutinates chicken erythrocytes, but the Utrecht strain and the strain isolated from the first American outbreak of pockless rabbitpox do not (Christensen et al., 1967).

EPIDEMIOLOGY

Rabbitpox is relatively rare, and all reported outbreaks have occurred in laboratory colonies in the United States and Holland. The highest mortality occurs in rabbits and pregnant or lactating females (Greene, 1934a, 1935b). Differences in susceptibility by rabbit breed also occur

(Greene, 1935b). Within infected colonies, the spread of disease is extremely rapid, and, in the outbreak of 1932, removal and isolation of infected rabbits failed to prevent the disease from spreading throughout the colony (Greene, 1934a). The virus appears to spread by nasal discharges, which usually appear on the third day after infection. Airborne droplets may be inhaled or ingested by susceptible rabbits (Bedson and Duckworth, 1963). Recovery from infection does not appear to result in establishment of a carrier state, as recovered rabbits can be safely mated with susceptible rabbits and clean colonies derived from recovered stock (Greene, 1934a). Arthropods have not been shown to play a role in the epidemiology of rabbitpox infection. In general, the primary sources of infection resulting in outbreaks of disease have not been determined, although the origin may have been rabbits inoculated with vaccinia virus (Greene, 1935a).

CLINICAL SIGNS

The clinical disease has been described in detail (Bedson and Duckworth, 1963; Christensen et al., 1967; Greene, 1934a). The virus initially infects and multiplies in the nasal mucosa and later in lymph nodes of the respiratory tract and in the lungs and spleen. Fever and a profuse nasal discharge usually occur 2–3 days after infection. Another early sign is enlargement and induration of the lymph nodes, especially the popliteal and inguinal nodes, which usually persist throughout the course of disease. Widely distributed skin lesions usually appear about 5 days after infection, initially as an erythematous macular rash which becomes papular and may progress to nodules up to 1 cm in size. These nodules eventually form dry, superficial crusts. Macules and papules may also occur on the mucous membranes of the oral and nasal cavities. Extensive edema of the face and oral cavity is often observed, as is focal necrosis of the hard palate and the gums. Hemorrhages in the skin may occur in severe cases.

Male rabbits frequently develop severe orchitis with extensive scrotal edema, and papules in the prepuce and urethra are observed. Similar lesions may also occur in the vulvae of females. If edema is extensive, urine retention may occur in either sex. Pregnant females usually abort. The eyes are almost invariably affected and exhibit blepharitis, purulent conjunctivitis, and acute keratitis with corneal ulceration. Death usually occurs 7–10 days after infection but may occur as early as 5 days, or rabbits may survive for several weeks before dying.

The generalized disease syndrome described above represents the findings of Greene (1934a) and Bedson and Duckworth (1963) with the Rockefeller strain of virus. This strain may occasionally result in peracute disease in which death is preceded only by fever, anorexia, and occasionally blepharitis. The peracute

form is unusual with the Rockefeller strain, but natural outbreaks of rabbitpox of the pockless type (Jansen, 1941, 1946, 1947; Christensen et al., 1967), without erythema or skin lesions, have occurred. In the first Dutch outbreak, some rabbits died within 1 week after infection, with only anorexia, fever, and lethargy (Jansen, 1941). In the first American outbreak of pockless disease, rabbits developed conjunctivitis and diarrhea and died 7–9 days after experimental infection (Christensen et al., 1967). Jansen (1941, 1946, 1947) and Christensen et al. (1967) described the occasional presence of scattered papules on the lips and tongues of rabbits with pockless rabbitpox. Experimentally, both the Utrecht and Rockefeller strains of virus produce skin lesions (Bedson and Duckworth, 1963).

PATHOLOGY

The gross and microscopic pathology of rabbitpox has been described in detail by Greene (1934b) for the Rockefeller Institute outbreak and by Christensen et al. (1967) for the first outbreak of pockless rabbitpox in the United States. The most distinctive gross lesions are the skin lesions, which may range in severity from a few localized papules to severe, almost confluent skin lesions with extensive necrosis and hemorrhage. Nodules occur in the mouth, upper respiratory tract, spleen, liver, and lungs but may also occur elsewhere in the body. Subcutaneous and oral submucosal edema and edema of other body orifices are common. Only rabbits with severe lesions of the mouth are emaciated at necropsy.

The liver is enlarged, yellowish, and has numerous small, gray nodules. Focal areas of hepatic necrosis may be seen. Small nodules may also occur in the gallbladder. The spleen is usually moderately enlarged with occasional focal nodules or areas of focal necrosis. Scattered diffusely throughout the lungs may be small white nodules and, in advanced cases, focal areas of necrosis. The testicles, ovaries, and uterus frequently exhibit diffuse white nodules and marked edema. Necrosis of the testes occurs frequently, and the uterus may contain focal abscesses. Focal nodules may be present in lymph nodes, adrenal glands, thyroid glands, parathyroid glands, peritoneum, omentum, and, rarely, the heart. Specific gross lesions are seldom observed in the central nervous system or kidneys. In the pockless form of the disease, a few pocks may be found in the mouth, and occasional skin lesions may be revealed by shaving the rabbit. The prominent gross lesions at necropsy are pleuritis, multifocal hepatic necrosis, splenomegaly, and edema and hemorrhage of the testes. The small white nodules, abundant in the more typical form of the disease, occur occasionally in the lungs and adrenal glands.

The predominant histological lesion in rabbitpox is the papule or nodule which occurs in the skin and

many other organs. A typical nodule consists of a central zone of necrosis, surrounded by mononuclear cells. Adjacent tissues are frequently edematous and occasionally hemorrhagic. Diffuse lesions with massive mononuclear cell infiltration, necrosis, hemorrhage, and edema often occur. Typical variola-like vesicles and pustules are not characteristic of rabbitpox infection. Vascular occlusion from the pronounced swelling of the endothelium may result in necrotic lesions.

In the lungs, focal nodular lesions and diffuse pneumonitis, with perivascular mononuclear and polymorphonuclear cell infiltration occur. Focal to diffuse pulmonary necrosis may be found. There is severe congestion of the spleen, with marked distention of sinuses by mononuclear cells, edema of Malpighian corpuscles, and focal to diffuse necrosis. Lymph nodes are generally greatly enlarged, mainly from severe edema. Extensive necrosis of lymph nodes and other lymphoid tissues such as Peyer's patches may occur. Hemorrhage and necrosis of the bone marrow occur frequently, interspersed with areas of mononuclear cell infiltration. Degeneration and necrosis of hepatic parenchyma may be focal or diffuse and may involve the whole organ. Focal necrosis with edema is detected in the testes, as are necrotic foci in the adrenal glands, uterus, thyroid glands, thymus, and salivary glands. The characteristic cytoplasmic inclusions associated with poxvirus infections are seldom encountered in rabbitpox.

DIAGNOSIS

Rabbitpox can be diagnosed by the clinical signs and the characteristic gross and microscopic lesions. Confirmatory diagnosis can be made by detection of viral antigen in tissues by fluorescent antibody on tissue impression smears (Christensen et al., 1967) or by virus isolation and identification. A PCR assay, using four primers, followed by electrospray ionization mass spectrometry, has been described which identified and speciated orthopoxviruses (Eshoo et al., 2009). The virus can be isolated by chorioallantoic membrane inoculation of chicken embryos or by cell culture propagation of the virus on cells derived from rabbits, mice, or any of several animal species (Christensen et al., 1967). The virus may be identified by the fluorescent antibody procedure, hemagglutination inhibition (some strains), or cross-protection tests using vaccinia-immunized and susceptible rabbits. Vaccinia-immunized rabbits should be resistant, whereas severe disease with high mortality should occur in susceptible rabbits.

CONTROL

Because the natural source of virus causing outbreaks has not been determined, control measures to prevent the occurrence of disease have not been

developed. In outbreaks, preventing spread of the virus in the colony by isolation of sick rabbits has met with mixed success (Christensen et al., 1967; Greene, 1934a). Investigators using rabbitpox virus experimentally should take exceptional precautions to prevent the virus from reaching susceptible rabbit populations. In an outbreak in a large colony, vaccination with vaccinia virus can be used to protect uninfected rabbits (Appleyard and Westwood, 1964; Boulter et al., 1971; Rosahn et al., 1936b).

Herpesvirus Infections

Herpesviruses have long been recognized as the causative agents of respiratory and genital diseases in humans, cattle, horses, and swine. They are also the recognized causes of other disease syndromes in many species of animals, including neoplastic diseases in frogs, chickens, rabbits, monkeys, and humans. An important characteristic of the herpesviruses is the capacity to cause mild or subclinical disease after which viral persistence in a latent state may ensue. Stresses of various kinds may result in viral recrudescence even after prolonged periods of latency. The possible existence of latent virus infections may have an important influence on the quality of experimental animals and potentially on the validity of experimental findings. In addition, there are numerous examples of herpesviruses that cause severe disease when infecting an abnormal host as demonstrated when *Human herpesvirus 1* infects rabbits. The *Herpesviridae* of rabbits and hares can be subdivided into *Gammaherpesvirinae* and *Alphaherpesvirinae* (Fauquet et al., 2005). The *Gammaherpesvirinae* contain two tentative members of the genus *Rhadinovirus*, Leporid Herpesvirus 1 and Leporid Herpesvirus 2. Two members of the *Alphaherpesvirinae*, genus *Simplex virus*, are known to infect rabbits, Leporid Herpesvirus 4 and *Human herpesvirus 1*.

Leporid Herpesvirus 1

HISTORY

Leporid herpesvirus I (synonyms *Herpesvirus sylvilagus*, cottontail virus, Hinze herpesvirus lymphoma) was isolated from primary kidney cell cultures from apparently healthy weanling Eastern Cottontail rabbits (*Sylvilagus floridanus*) trapped in Wisconsin (Hinze, 1968, 1971a). The virus was detected when focal areas of cell destruction were observed in cell monolayers 14 days after incubation. The virus has since been propagated in kidney cells of both Eastern Cottontail and domestic rabbits. Another herpesvirus, apparently distinct from the original isolate of Hinze (1971a), was recovered from primary kidney cell cultures of *Sylvilagus floridanus* (Cebrian et al., 1989).

ETIOLOGY

The virus possessed the physical, chemical, and biological properties of a herpesvirus and was named *Herpesvirus sylvilagus* (Heine and Hinze, 1972; Hinze, 1971a). Although infectious virus could not be demonstrated in lymphocytes from infected *Sylvilagus* rabbits, it could be detected after in vitro cocultivation with rabbit kidney cells (Hinze and Wegner, 1973; Wegner and Hinze, 1974). The virus is strongly cell-associated (Ley and Burger, 1970), and both B and T lymphocytes are infected (Kramp et al., 1985). The virus can be propagated in cells of both Eastern Cottontail and domestic New Zealand White rabbits but not in cells from humans, monkeys, hamsters, mice, nor in chicken embryos. The highest concentrations of virus are obtained by the use of primary kidney cell lines established from newborn or juvenile Eastern Cottontail rabbits (Cohrs and Rouhandeh, 1982; Medveczky et al., 1984). The virus possesses no antigenic relationship to Leporid herpesvirus 2 or to four other Leporid herpesviruses (Hinze, 1971a). The genome of the virus is similar to those of *Herpesvirus saimiri* and Epstein-Barr virus, in that it contains a variable number of repetitive DNA elements at both ends (Heine and Hinze, 1972; Cohrs and Rouhandeh, 1987; Rouhandeh and Cohrs, 1987; Medveczky et al., 1989).

EPIDEMIOLOGY

A serological survey in Wisconsin revealed antibodies to the virus in six of 101 wild Eastern Cottontail rabbits (Spieker and Yuill, 1976). In experimentally infected Eastern Cottontail rabbits, herpesvirus was not recovered from feces, urine, milk, ejaculates, or conjunctival and genital secretions, but was isolated from the oral secretions of one of 15 infected rabbits (Spieker and Yuill, 1977a). Shedding of infectious virus in oral secretions, unrelated to age, sex, or season, was demonstrated in naturally infected Eastern Cottontail rabbits (Hinze and Lee, 1980). The tonsils are the likely site of persistent infection and virus is released into the oral cavity. Transplacental transmission of virus was not found (Spieker and Yuill, 1977a). Transmission by insect vectors was not detected (Spieker and Yuill, 1977b). Repeated attempts to infect domestic New Zealand White rabbits have met with failure (Hinze, 1971a). Only rabbits of the genus *Sylvilagus* appear to be susceptible.

CLINICAL SIGNS

Inoculation of Eastern Cottontail rabbits by various routes results in a chronic low-grade viremia that persists, in most instances, for the life of the rabbit (Hinze, 1971b; Hinze and Chipman, 1972; Hinze and Wegner, 1973). Persistently infected rabbits have a pronounced lymphocytosis, with differential lymphocyte counts of up to 95% compared to 50–60% in normal rabbits (Hinze, 1969).

PATHOLOGY

The lymphoproliferative lesions in Eastern Cottontail rabbits occur in the lymphoid and other organ systems (Hesselton et al., 1988; Hinze, 1969, 1971b; Hinze and Wegner, 1973). Extensive infiltration of various tissues, commonly the kidneys, liver, lungs, and myocardium, with immature, actively proliferating lymphocytes occurs 6–8 weeks after experimental inoculation. The experimentally induced lymphoproliferative disease varies from benign lymphoid hyperplasia to lesions consistent with malignant lymphoma. Juvenile rabbits are affected more frequently and severely than adult rabbits.

DIAGNOSIS

Natural infection with Leporid herpesvirus 1 in Eastern Cottontail rabbits may result in leukocytosis, splenomegaly, and lymphadenopathy. Virus can be isolated from the oral cavity and circulating lymphocytes of infected rabbits cocultured with rabbit kidney cells (Hinze and Lee, 1980). Antibodies can be detected by indirect immunofluorescence and plaque reduction assays (Spieker and Yuill, 1976; Yang et al., 1990).

Leporid Herpesvirus 2

HISTORY

Nesburn (1969) isolated Leporid herpesvirus 2 (synonyms *Herpesvirus cuniculi*, virus III of rabbits, Leporid herpesvirus 3) from primary kidney cell cultures from *Oryctolagus cuniculus* and named it *Herpesvirus cuniculi*. This may represent a reisolation of virus III of rabbits (Rivers and Tillett, 1923), but, as the original isolate was not available, a direct serological comparison could not be made. Comparison of the reported characteristics of virus III with *Herpesvirus cuniculi*, however, indicates that they are identical (Nesburn, 1969). Virus III was isolated during attempts to find the etiologic agent of varicella (chicken pox). When inoculated into rabbits, the agent induced fever, exanthema, skin vesicles, corneal lesions, and intranuclear inclusions reminiscent of varicella infection (Rivers and Tillett, 1923). Convalescent sera from human varicella patients failed to inactivate the virus (Rivers and Tillett, 1924a). A similar virus was isolated from serially passaged normal rabbit testicular tissue during investigations of the etiology of rheumatic fever (Miller et al., 1924). McCartney isolated the virus while working on scarlet fever in England (Topacio and Hyde, 1932), and the agent has also been isolated by Doerr in Switzerland (Andrewes, 1928).

ETIOLOGY

Nesburn (1969) showed that the viral isolate possesses the physical, chemical, cytopathic, histological, and electron microscopic characteristics of a herpesvirus. The virus can be propagated in primary

or established cell lines of rabbit origin as well as in African green monkey kidney cells. The virus is now designated Leporid herpesvirus 2 (Roizman, 1982).

EPIDEMIOLOGY

Rivers and Tillett (1924a) found that four of 20 rabbits possessed antibodies to the virus and that 15% of 200 rabbits were immune to infection. Andrewes (1928), in England, found 98% of 377 experimental rabbits susceptible to the virus. He concluded that the virus was probably endemic in some rabbit colonies. Topacio and Hyde (1932), in Maryland, found that 17% of 76 rabbits were immune to infection. They suggested that older bucks, resistant to infection, were carriers of the virus. Neutralizing antibodies to the virus were detected in 6% of 196 rabbits from Connecticut and Maryland (Swack and Hsiung, 1972). Nesburn (1969) was unable to reisolate the virus from over 100 batches of primary rabbit kidney cell cultures prepared since initial isolation of the virus. Experimentally, virus was recovered from the blood of rabbits more than 100 days after inoculation (Swack and Hsiung, 1972). Appreciable titers of virus were detected in leukocytes, spleen, liver, lungs, and salivary glands, whereas the concentration of virus in kidneys was variable. However, transmission of the virus by direct contact or transplacentally failed to occur.

CLINICAL SIGNS

All reported isolations of virus have been from apparently normal rabbits, and no naturally occurring disease has been attributed to infection with the virus. However, a viral agent, presumably a herpesvirus, was recovered from the nares of rabbits with respiratory disease (Renquist and Soave, 1972). Experimentally, intradermal inoculation of rabbits with virus resulted in pronounced erythema at the site of inoculation after 4–7 days, which usually disappears within 2 weeks (Rivers and Tillett, 1924a). Occasionally, generalized reactions with anorexia, diarrhea, emaciation, fever, and skin vesicles have been reported. Intradermal inoculation may result in erythematous papules, whereas corneal scarification caused swelling and vesiculation of corneal cells (Topacio and Hyde, 1932). Intratesticular inoculation of rabbits results in acute orchitis and fever within 3–4 days (Andrewes, 1928). Intramuscular and subcutaneous inoculation of rabbits failed to induce clinical signs; however, corneal scarification with virus resulted in mild punctate keratitis (Nesburn, 1969). Similarly, intraperitoneal inoculation of virus did not induce clinical disease (Swack and Hsiung, 1972).

PATHOLOGY

No gross pathological changes have been observed in internal organs of experimentally infected rabbits.

Microscopically, testes, skin, and cornea show edema and an intense mononuclear leukocyte infiltration. Large eosinophilic intranuclear inclusions, typical of herpesviruses, characteristically occur in corneal epithelium, interstitial cells of the testicles, and in endothelial leukocytes of the skin (Rivers and Tillett, 1924b). Severe myocarditis with typical herpesviral inclusions occurred in rabbits inoculated intracardially with virus (Pearce, 1950, 1960). The absence of reported cases could be attributed to the relative rarity of disease or to lack of intensive etiologic investigation of cases which do occur.

DIAGNOSIS

Pathological findings described above including herpesviral inclusions in domestic rabbits (*Oryctolagus cuniculus*) are suggestive of Leporid Herpesvirus 2. PCR, in situ hybridization, and immunohistochemical labeling would be necessary to separate Leporid Herpesvirus 2 from the *Alphaherpesvirinae* described below (Gruber et al., 2009; Jin et al., 2008a; Weissenböck et al., 1997).

CONTROL

Both herpesvirus 1 of Eastern Cottontail rabbits and herpesvirus 2 of domestic rabbits possess the capacity to persist in infected hosts as a subclinical infection. Such infections, if not recognized, could result in considerable confounding in experimental studies, especially if conditions cause recrudescence of latent infections.

Leporid Herpesvirus 4

HISTORY

Leporid herpesvirus 4 (LHV 4) was isolated from a naturally occurring outbreak with high morbidity and mortality affecting miniature and crossbred domestic European rabbits (*Oryctolagus cuniculi*) in a rabbitry in Alaska (Jin et al., 2008a). Two other outbreaks, with similar clinical signs and pathology, have been reported in North America, although the virus was not identified (Onderka et al., 1992; Swan, 1991).

ETIOLOGY

Electron microscopy of LHV 4 demonstrated capsid and core particles similar in size and structure to *Human herpesvirus 1*. The genome of LHV 4 is 120–130kbp and partial sequences compared to other *Alphaherpesvirinae* demonstrated the closest homology by nucleotide identity with *Bovine herpesvirus 2* (Jin et al., 2008b). *Bovine herpesvirus 2* was originally isolated from cattle in Africa, but has been found in a variety of domestic and wild ruminants (Borchers et al., 2002; Kálmán and Egyed, 2005). LHV 4 infects rabbit skin and Vero (monkey kidney) cells with cytopathic effects similar to *Human herpesvirus 1* (Jin et al., 2008a).

EPIDEMIOLOGY

LHV 4 was isolated from an outbreak of acute disease in an outdoor rabbitry in Alaska (Jin et al., 2008a). The mode of herpesvirus introduction in this outbreak was not determined as there had been no travel or introduction of new rabbits. However, feral domestic European rabbits (*Oryctolagus cuniculus*) and Snowshoe hares (*Lepus americanus*) were in the area. In addition, the outbreak occurred in July and August, when mosquito and biting fly activity is typically high. A second outbreak occurred in the same rabbitry the following year in the spring and summer, although it could not be determined if this was due to a re-introduction or reactivation of a chronic infection (Jin et al., 2008b). Two outbreaks of disease caused by herpes-like viruses that were not identified were reported in Canada (Onderka et al., 1992; Swan, 1991). The clinical signs and pathology of those outbreaks were similar to the Alaska outbreak and may suggest that there is an animal reservoir in northwestern North America of this Alpha herpesvirus.

CLINICAL SIGNS

Clinical signs reported in the naturally occurring outbreaks included conjunctivitis and periocular swelling with purulent ocular discharge, ulcerative dermatitis, progressive weakness, anorexia, respiratory distress, torticollis, ataxia, weight loss, diarrhea, bruxism, genital swelling, and abortion (Jin et al., 2008a). Morbidity was approximately 50%, with 29% mortality. Some rabbits died acutely with anorexia, the only sign observed prior to death. Recovered virus administered intranasally or by the cornea to New Zealand White rabbits caused severe acute disease within 4 days of inoculation with one out of four affected animals being euthanized due to severity of the disease. The remaining rabbits recovered. Acute mortality associated with unidentified herpesviruses was reported in four adult *Oryctolagus cuniculus* in two rabbitries in Canada (Onderka et al., 1992; Swan, 1991). Acute death without clinical signs occurred in some rabbits as well as conjunctivitis, nasal discharge, edematous eyes and faces. Herpesviruses were recovered on rabbit kidney cells and experimental inoculation of rabbits with the virus reproduced the disease syndrome (Onderka et al., 1992; Swan, 1991). However, it is unclear if the herpesviruses responsible for these outbreaks are Gamma herpesviruses or Alpha herpesviruses related to LHV 4.

PATHOLOGY

Lesions included severe dermal and subcutaneous hemorrhage, edema, and necrosis with vascular necrosis and thrombosis (Jin et al., 2008a, 2008b). There was a mixed infiltrate of macrophages, lymphocytes, plasma cells with fewer heterophils. Necrosis and hemorrhage

were found within the ventricular walls, spleen, lymph nodes, and lungs. Areas of fibrin deposition were present in the spleen and lung. Intranuclear inclusions were found within the affected skin, subcutis, and ventricular walls, but not in the spleen, lungs, or lymph nodes. Similar lesions were seen following experimental infection (Jin et al., 2008b).

DIAGNOSIS

Typical lesions in the skin, spleen, lymph nodes, lungs, and heart with demonstrative intranuclear inclusions are suggestive of LHV 4 infection. DNA extracted from most tissues, including appendix, sciatic nerve, kidney, adrenal gland, spleen, liver, lung, lymph node, salivary gland, tonsil, and brain from an inoculated rabbit that died in the acute phase of the disease was specific for LHV 4 ribonuclease reductase gene by PCR (Jin et al., 2008b). At 14 days after inoculation, the eye, trigeminal ganglion, and tonsil were positive for LHV 4 by PCR analysis. In the second outbreak at the rabbitry in Alaska, the eye of an affected rabbit was positive for LHV 4 by PCR.

CONTROL

As latent infection is typical of Alpha herpesviruses, control measures are difficult. The rabbitry involved in the Alaska outbreak was depopulated after the second outbreak (Jin et al., 2008).

Human Herpesvirus 1 (HHV-1)

Herpesviruses of other species, including HHV-1, can cause encephalitis in rabbits experimentally inoculated (Chowdhury et al., 2000; Seto et al., 1995) and horizontal transmission of HHV-1 between rabbits has been reported (Kaplan, 1969). Spontaneous cases of HHV-1 encephalitis presumably transmitted from humans to pet domestic European rabbits have also been reported (Grest et al., 2002; Gruber et al., 2009; Müller et al., 2009; Weissenböck, et al., 1997). In each of these reports, rabbits with HHV-1 encephalitis were in close contact with a person with herpes labialis before they developed illness. The rabbits presented with neurological signs including anorexia, tonic-clonic spasms, circling, incoordination, ataxia, seizures, and opisthotonus. One rabbit also had a history of epiphora of the left eye, conjunctivitis, bruxism, and hypersalivation (Müller et al., 2009). Pathological findings included non-suppurative meningoencephalitis and large, eosinophilic intranuclear inclusion bodies in the neurons and glial cells. Diagnosis was confirmed by immunohistochemical labeling with polyclonal antibodies specific for HHV-1 (Grest et al., 2002; Gruber et al., 2009; Weissenböck et al., 1997), in situ hybridization using a DNA probe for HHV-1 (Gruber et al., 2009; Müller et al., 2009; Weissenböck et al., 1997),

or PCR specific for the UL42 gene of HHV-1 (Grest et al., 2002; Gruber et al., 2009; Weissenböck et al., 1997). Control measures would include preventing close contact between humans with active herpetic lesions and rabbits.

Papilloma and Polyoma Viruses

The family *Papillomaviridae* contains viruses in the genus *Kappapapillomavirus* which cause papillomas (warts) in various animals and includes two species of rabbit viruses, the *Cottontail rabbit papillomavirus* and the *Rabbit oral papillomavirus* (Fauquet et al., 2005). The family *Polyomaviridae* contains one genus, *Polyomavirus*, which includes the species *Rabbit kidney vacuolating virus*.

Cottontail Rabbit Papillomavirus

HISTORY

The Cottontail rabbit or Shope papillomavirus was recognized as a transmissible agent by Shope and Hurst (1933) while they were attempting to define the etiology of wart-like tumors on Eastern Cottontail rabbits (*Sylvilagus floridanus*) in the Midwestern United States. They demonstrated the filterability of the infectious agent, transmitted it to other Eastern Cottontail rabbits as well as domestic European rabbits, and described the histopathology of the disease (Shope, 1935). Rabbit papillomatosis was initially considered a natural benign disease of *Sylvilagus* rabbits only; however, spontaneous outbreaks of papillomatosis in *Oryctolagus cuniculus* indicate that the disease has greater relevance (Hagen, 1966). Soon after discovery of the virus, it was also shown to cause malignant neoplasms histologically resembling squamous cell carcinomas (Kidd and Rous, 1940; Rous and Beard, 1934, 1935). This was the first recognition of an oncogenic virus in mammals. The disease has served as a model system to elucidate the role of viruses in the pathogenesis of cancer in humans and animals (Evans and Thomsen, 1969; Evans et al., 1962a, 1962b; Georges et al., 1984; Kreider and Bartlett, 1981, 1985; Smith and Campo, 1985) and potential therapeutic interventions (Gambhira et al., 2007).

ETIOLOGY

The virus is the type species of the genus *Kappapapillomavirus* (formerly *Papillomavirus*) of the family *Papillomaviridae* (Fauquet et al., 2005) and possesses the characteristic circular DNA genome, icosahedral structure, and other chemical and physical properties of this family (Gross, 1983; Kass and Knight, 1965; Murphy et al., 1981). The complete genome contains 7863 nucleotides (Giri et al., 1985) and consists of ten genes. All of the papilloma viruses have two capsid proteins (major L1 and minor L2) and although the C terminus of L1 is

exposed on the surface of the viron, suggesting it may have an important role in immune responses, both proteins encode virus-neutralizing epitopes (Campo, 2003). The virus is antigenically distinct from other members of the genus *Kappapapillomavirus*. Nuclear (Yoshida and Ito, 1968) and cytoplasmic (Ishimoto et al., 1970) viral antigens have been demonstrated by immunofluorescence in virus-inoculated normal skin cells and virus-induced papillomas. However, the significance of these findings is difficult to interpret since controls for rabbit kidney vacuolating virus, a passenger virus (Hartley and Rowe, 1964), were usually not included (Kreider and Bartlett, 1981). The virus can be maintained by serial propagation in the skin of *Sylvilagus* rabbits, inoculated intracutaneously or scarified with virus (Shope and Hurst, 1933). Intramuscular inoculation does not result in clinical papillomatosis. Dogs, cats, pigs, goats, rats, mice, and guinea pigs are refractory to the virus. The skin of embryonic rats is susceptible to the virus, and typical papillomas develop following inoculation (Greene, 1953b); however, few papillomas develop, and they regress unless the host is immunosuppressed (Kreider et al., 1971). Cellular proliferation or neoplastic transformation by the virus has been reported in rabbit skin cell cultures (Coman, 1946), skin cultures derived from neonatal domestic European rabbits (DeMaeyer, 1962), and explants of embryonic rabbit skin (Greene, 1953a). Transplantation of transformed skin cultures into rabbits resulted in the formation of papillomas (Coman, 1946; Kreider, 1963). (see also Chapter 16).

EPIDEMIOLOGY

Papillomatosis occurs most frequently as a natural disease of *Sylvilagus* rabbits in the Midwestern United States extending from Minnesota and North Dakota to Texas (Gross, 1983; Hagen, 1966). The virus has apparently not become established in the eastern states. The only natural outbreaks of disease in domestic European rabbits were in southern California, suggesting that the virus is present in wild *Sylvilagus* rabbits of the area, and spreads to domestic European rabbits by arthropod vectors (Hagen, 1966). The disease in *Sylvilagus* rabbits also occurs on coastal islands in Washington, in a population of rabbits introduced from Kansas (Lancaster and Olson, 1982).

The *Sylvilagus* rabbit is the natural host, but the domestic European rabbit is also susceptible to the virus (Shope, 1935). Natural outbreaks have been reported in commercial rabbitries (Hagen, 1966). The Black-tailed jackrabbit (*Lepus californicus*) is also susceptible to the virus (Beard and Rous, 1935). Infection of the skin of domestic European rabbits results in the formation of papillomas essentially devoid of infectious virus (Shope, 1935). Papillomas, primary carcinomas, and metastases from domestic European rabbits have about 10–100 copies of viral DNA, whereas papillomas from *Sylvilagus*

rabbits have 2400–8800 copies (Stevens and Wettstein, 1979). Papillomas from domestic European rabbits can be serially transferred, but only small amounts of infectious virus are typically demonstrated (Gross, 1983; Hu et al., 2007; Selbie and Robinson, 1947; Shope, 1935), indicating that domestic European rabbits are not a source of virus for arthropod vectors.

Infection of *Sylvilagus* rabbits, Black-tailed jackrabbits, and Snowshoe hares (*Lepus americanus*) induces lesions containing a high concentration of virus (Lancaster and Olson, 1982; Syverton et al., 1950). Contact transmission of papillomatosis may occur, but transmission of the virus by the rabbit tick (*Haemaphysalis leporis-palustris*) is probably the most common natural mode (Larson et al., 1936). Transmission by mosquitoes and reduviid bugs has been demonstrated experimentally (Dalmat, 1958). In commercial rabbitries, the mosquito may be the principal vector between wild *Sylvilagus* and domestic European rabbits (Hagen, 1966). This hypothesis is strengthened by the observation that in natural cases of disease in domestic European rabbits, lesions were confined to the relatively hairless parts of the body around the eyes, ears, and anus, areas where mosquitoes are more apt to feed. Nematodes may be involved in the natural transmission of virus (Rendtorff and Wilcox, 1957). Experimentally, papillomas were induced when papilloma virus and larvae of the nematode *Nippostrongylus muris* were applied to rabbit skin, but not by virus or nematode larvae alone. See Chapter 16 for further information.

CLINICAL SIGNS

Papillomatosis of wild *Sylvilagus* rabbits is characterized by the presence of horny warts, usually on the neck, shoulders, or abdomen. The warts begin as red raised areas at the site of infection, grow to become typical papillomas with rough rounded surfaces, and may later develop into large, keratinized horny growths (Shope and Hurst, 1933). The virus was initially believed to cause only transient papillomatosis, but it was later shown that in naturally infected *Sylvilagus* rabbits papillomas may become malignant squamous cell carcinomas (Syverton and Berry, 1935). This phenomenon was later shown to be a relatively frequent occurrence in both naturally and experimentally infected *Sylvilagus* rabbits, as 25% of infected rabbits developed carcinomatous lesions following infection (Syverton et al., 1950). In approximately 35% of naturally infected rabbits, papillomas regress within 6 months after infection. In natural outbreaks of papillomatosis of domestic European rabbits in southern California (Hagen, 1966), papillomas most commonly occurred on the eyelids and ears. Experimentally induced papillomas develop more slowly in domestic European rabbits than in *Sylvilagus* rabbits, reach a stationary phase, and then occasionally regress (Syverton, 1952).

Regression occurs depending on the interaction of the genotype of the virus and host immunity (Hu et al., 2002, 2005). A variant virus that contains the regressive E6 gene has a high rate of regression (Hu et al., 2002). Certain MHC haplotypes have been associated with regression or persistence in domestic European rabbits (Salmon et al., 2000). In one study, papillomas persisted when a regressive viral strain was used if rabbits were immunosuppressed with cyclosporine A treatment, but regression also varied with the strain of rabbit as more papillomas regressed in outbred New Zealand White rabbits than inbred EIII/JC rabbits (Hu et al., 2005). Once immunosuppression was removed, most papillomas regressed in outbred rabbits (67–89%), whereas only 13% regressed in inbred rabbits, highlighting the importance of multiple factors in persistence of papillomas. Rous and Beard (1934, 1935) recognized the malignant potential of rabbit papillomavirus when they demonstrated that intramuscular inoculation of papillomatous tissue into domestic European rabbits resulted in invasive squamous cell carcinomas. In experimentally infected domestic European rabbits, 75% developed carcinomas if kept longer than 6 months (Syverton, 1952). *Sylvilagus* rabbits have a three-fold lower incidence of carcinomas than European rabbits (Rous and Beard, 1935; Syverton et al., 1950).

PATHOLOGY

The warts which develop following infection in *Sylvilagus* and domestic European rabbits are typical papillomas. The malignant tumors which arise from papillomas are squamous cell carcinomas. Metastasis to regional lymph nodes, particularly the axillary nodes, is common (Kreider and Bartlett, 1981) and about 25% of rabbits that succumb have pulmonary metastases. In addition, amyloid deposition in renal glomeruli, hepatic sinusoids and splenic red pulp is present in the majority of rabbits.

DIAGNOSIS

Cottontail rabbit papillomatosis is diagnosed clinically by the characteristic skin tumors, which never occur in the mouth, and may be confirmed by histopathological examination. A survey of tumors in pet rabbits submitted to the surgical biopsy service of a veterinary school in Pennsylvania over a 16-year period revealed that Shope papilloma was diagnosed in two tumors, both on the ears, from 179 rabbits (von Bomhard et al., 2007). No cell culture system is available for routine isolation of virus (Lancaster and Olson, 1982).

CONTROL

The endemic disease of *Sylvilagus* rabbits is of little economic significance, and thus no prophylactic methods have been developed. Because natural infection occurs in domestic European rabbits (Hagen, 1966), the

adoption of control methods may become necessary. In areas where the disease is endemic in wild *Sylvilagus* rabbits, where arthropod vectors are present, and where outdoor rabbit husbandry is practiced, arthropod control would appear to be a logical approach. Rabbits can be immunized by two intraperitoneal inoculations with glycerinated rabbit papilloma suspensions (Shope, 1937). Domestic rabbits with experimentally induced papillomas resist challenge with virus derived from papillomas of cottontail rabbits (Hagen, 1966). A tumor-specific vaccine composed of allogenic tumor cells increased the regression rate of papillomas (Evans et al., 1962a).

Rabbit Oral Papillomavirus

HISTORY

Oral papillomatosis of rabbits was recognized as a distinct viral disease of domestic European rabbits (*Oryctolagus cuniculus*) by Parsons and Kidd (1936). They found a 17% prevalence of small papillomas in the mouths of rabbits of several breeds in New York City. The lesions were usually confined to the ventral surface of the tongue. They transmitted the virus to both domestic European and *Sylvilagus* rabbits and by cross-immunity tests and tissue-susceptibility studies demonstrated that it was distinct from the Cottontail rabbit (Shope) papillomavirus. They also showed that virus is frequently present in the mouths of rabbits without lesions and that tattooing or licking of tar stimulated lesion development in such carrier rabbits (Parsons and Kidd, 1943). A spontaneous outbreak in New York of rabbit oral papillomatosis, involving several breeds of domestic European rabbits, was described (Weisbroth and Scher, 1970). New Zealand White rabbits with oral papillomas were reported in Illinois (Sundberg et al., 1985) and Mexico (Dominguez et al., 1981).

ETIOLOGY

The virus was partly characterized by Parsons and Kidd (1943) and was later included in the genus *Kappapapillomavirus* of the family *Papillomaviridae* (Fauquet et al., 2005). The virus consists of 7565 nucleotides and has the greatest amino acid sequence identity to *Cottontail rabbit papillomavirus*, although the greatest area of homology was only 68% (Christensen et al., 2000). However, the virus is immunologically distinct from the *Cottontail rabbit papillomavirus* and naturally infects only leporids (Parsons and Kidd, 1936, 1943). Nuclear viral replication, characteristic of the *Papovaviridae*, has been demonstrated (Rdzok et al., 1966; Richter et al., 1964). Neonatal hamsters, inoculated subcutaneously with a tumor suspension from naturally infected rabbits, developed fibromas (Sundberg et al., 1985). The virus has not been propagated outside of susceptible host animals.

EPIDEMIOLOGY

The virus probably spreads by direct contact, and lesion development may require oral trauma for viral entry. Coarse feed, maloccluded teeth, or other oral irritants may serve as the inciting event (Parsons and Kidd, 1943; Weisbroth and Scher, 1970). Experimentally induced lesions appear 9–38 days after inoculation (Parsons and Kidd, 1936), but the incubation period of the natural disease is unknown. The disease generally occurs in rabbits 2–18 months old (Sundberg et al., 1985; Weisbroth and Scher, 1970).

CLINICAL SIGNS

Oral papillomatosis is a benign disease characterized clinically by small discrete whitish growths on the ventral surface of the tongue. The early lesions are sessile, later become rugose or pedunculated, and ultimately ulcerate (Parsons and Kidd, 1936; Sundberg et al., 1985; Weisbroth and Scher, 1970). The lesions are seldom more than 5 mm in size and 4 mm in thickness and usually substantially smaller. Papillomas have been known to persist for as long as 145 days, but usually disappear in weeks (Parsons and Kidd, 1936). Lesions rarely occur elsewhere in the mouth and never on the body. However, in a Flemish Giant pet rabbit in New Zealand, virus recovered from lesions on the nictitating membrane and lower eyelid had 99.3% homology with *Rabbit oral papillomavirus* (Munday et al., 2007).

PATHOLOGY

The lesions are microscopically typical papillomas (Parsons and Kidd, 1943; Rdzok et al., 1966; Richter et al., 1964; Sundberg et al., 1985; Weisbroth and Scher, 1970). Cells in the stratum spinosum contain basophilic intranuclear inclusions (Dominguez et al., 1981; Sundberg et al., 1985).

DIAGNOSIS

The disease is diagnosed by typical lesions occurring only in the mouth, in contrast to rabbit papillomatosis, in which lesions are observed only on the skin. The lesions are typical papillomas, and papillomavirus antigens can be detected in cells of the stratum spinosum by the peroxidase antiperoxidase technique (Sundberg et al., 1985).

CONTROL

Rabbits recovering from disease are resistant to reinfection but are susceptible to *Cottontail rabbit papillomavirus*.

Rabbit Kidney Vacuolating Virus

The *Rabbit kidney vacuolating virus* was isolated in primary rabbit kidney cell cultures from papillomas of Eastern Cottontail rabbits (*Sylvilagus floridanus*) collected in Kansas (Hartley and Rowe, 1964). The virus causes

vacuolar cytopathic effects in cell cultures. The virus resembles the *Cottontail rabbit papillomavirus* but is a distinct virus. It does not produce papillomas when inoculated into rabbits and does not immunize rabbits against *Cottontail rabbit papillomavirus*. The virus is slightly smaller than the viruses of the genus *Papillomavirus* and resembles *Polyomavirus* in size, morphology, and DNA composition (Crawford and Follett, 1967). The virus has been classified as a member of the genus *Polyomavirus* within the family *Polyomaviridae* (Fauquet et al., 2005). Ultrastructurally, the virus is a typical *Polyomavirus* in its replication pattern (Chambers et al., 1966). The virus is not pathogenic for either domestic European or Eastern Cottontail rabbits or any other animal species. Inoculation of both neonatal and adult domestic and Eastern Cottontail rabbits by several routes did not induce disease (Hartley and Rowe, 1964). Antibodies to the virus have been found in wild *Sylvilagus* rabbits in Kansas and Maryland, but not in domestic European rabbits (Hartley and Rowe, 1964). The virus thus appears to be a fairly common non-pathogenic virus of *Sylvilagus* rabbits, causing only latent infections. Intranuclear inclusions consistent with rabbit kidney vacuolating virus have been found as an incidental finding in New Zealand White rabbits (Percy and Barthold, 2007). Although a contaminant of rabbit papillomas, the virus appears to have no role in the pathogenesis of papillomatosis (Goldman et al., 1972; Ito et al., 1968; Kreider and Bartlett, 1981).

Adenovirus Infections

Adenovirus infections of rabbits, spontaneous and experimental, have been reported. While the taxonomy of the spontaneous adenoviruses found in rabbits has not been determined, the human, swine, and bovine adenoviruses described belong to the genus *Mastadenovirus*. An adenovirus was isolated in Hungary from the spleen, kidneys, lungs, and intestines of rabbits, 6–8 weeks old, with diarrhea (Bodon et al., 1979). The virus was detected in primary rabbit kidney cultures stained with acridine orange although no cytopathic effect was observed. The virus failed to replicate in pig kidney, calf kidney, calf testicle, or human embryonic lung cells. Antisera to several swine and bovine adenoviruses failed to neutralize the virus, whereas a partial antigenic relationship to human adenoviruses was demonstrated by complement fixation and immunodiffusion tests. The virus agglutinated rabbit but not human erythrocytes. A serological survey of 30 *Oryctolagus cuniculus* from four rabbitries in Quebec revealed that three rabbits from three colonies had antibodies to bovine adenovirus type 1 (Descoteaux et al., 1980).

Experimental inoculation of rabbits with human adenovirus type 5 resulted in no clinical response but induced a persistent viral infection in lymphoid tissues for as long as 1 year (Reddick and Lefkowitz, 1969). Human adenovirus type 5 infects rabbit corneas following either intrastromal

injection or topical application to damaged cornea resulting in acute blepharoconjunctivitis, iritis, and corneal edema which peaks at 13 days after infection (Gordon et al., 1992; Trousdale et al., 1995). Other serotypes of human adenovirus induce disease as well, although adenovirus type 5 is commonly used as an animal model to test therapeutic approaches to adenovirus-induced keratoconjunctivitis (Romanowski et al., 1998). Recombinant adenoviruses have been used successfully to infect rabbits in many gene transfer protocols (Kozarsky et al., 1996; Schneider et al., 1999).

Parvovirus Infections

A virus that induced cytopathic effects in primary rabbit kidney cell cultures was isolated from the feces of a rabbit (*Oryctolagus cuniculus*) inoculated with *Herpesvirus cuniculi* in a laboratory in Japan (Matsunaga et al., 1977). The virus had the morphological, physical, and chemical properties of a parvovirus. The various proteins of the virus have been characterized (Matsunaga and Matsuno, 1983). Subsequently, parvovirus was recovered from kidney cells of neonatal rabbits in the United States (Metcalf et al., 1989). These viruses are of the species *Lapine parvovirus*, genus *Parvovirus*, family *Parvoviridae* (Fauquet et al., 2005).

Serological surveys have identified positive rabbitries in Japan, the United States, and Europe. Among 90 rabbits from a commercial source in Japan, 42 (47%) had hemagglutination-inhibiting antibody to the virus (Matsunaga et al., 1977). Of 46 rabbit sera, collected from various sources in the United States, 75% had antibodies detected by immunofluorescence or hemagglutination inhibition assays (Metcalf et al., 1989). In Switzerland, over 70% of 132 rabbit sera from various commercial breeding colonies had antibodies in the hemagglutination inhibition test (Metcalf et al., 1989). Experimental inoculation, orally or intravenously, induced anorexia, listlessness, and catarrhal enteritis in 1-month-old rabbits (*Oryctolagus cuniculus*) (Matsunaga and Chino, 1981). Pathologic changes included catarrhal enteritis with hyperemia, exfoliation of the small intestinal epithelial cells, and increased secretion of intestinal mucus. Virus was detected in feces, small intestine, liver, pancreas, spleen, appendix, and mesenteric lymph node. Rabbits developed hemagglutination-inhibiting antibodies.

RNA VIRUS INFECTIONS

Rotavirus Infections

Rotavirus

HISTORY

Rotavirus was initially isolated from rabbits with diarrhea by Bryden et al. (1976) in England. Virus was

recovered from both sporadic cases and outbreaks of diarrhea in weanling rabbits as well as from healthy rabbits. Subsequently, rotavirus was isolated from young rabbits with diarrhea in Japan (Sato et al., 1982), Europe (Castrucci et al., 1985; Eaton, 1984; Peeters et al., 1982, 1984), and the United States (DiGiacomo and Thouless, 1986; Schoeb et al., 1986). Various serological surveys have since revealed that rotavirus infection is widespread in domesticated European rabbits (*Oryctolagus cuniculus*).

ETIOLOGY

Rabbit rotaviruses belong to the family *Reoviridae*, genus *Rotavirus* (Estes and Kapikian, 2007; Fauquet et al., 2005). They are 75-nm icosahedral viruses with a triple-layered protein capsid that contains 11 segments of double-stranded RNA, each of which codes for a protein. The sixth gene (VP6) codes for an inner capsid protein which contains the subgroup specificity. The fourth (VP4) and seventh genes (VP7), code for outer capsid proteins that are the viral neutralization antigens. VP4 is the viral hemagglutinin and must be cleaved by a protease, e.g., trypsin, to yield VP5 and VP8 before the virus can infect cells (Matsui et al., 1989; Ramig and Ward, 1991).

The rotaviruses are classified serologically into seven groups (A to G). Groups A to C are found in animals and humans, whereas groups D to G are found only in animals. The rabbit rotaviruses described belong to group A (Tanaka et al., 1988; Thouless et al., 1986). Within each serogroup, rotaviruses are classified into serotypes, defined by reactivity against the outer capsid proteins VP4 (P type) and VP7 (G type). Since the glycoprotein VP7 appears to be immunodominant, classification of VP7 serotypes is more advanced and within group A, 15 serotypes (1–15) have been identified. All rabbit rotaviruses recovered to date have been serotype 3 (G3) (Tanaka et al., 1988; Thouless et al., 1986). Serotype 3 contains the largest and most diverse number of rotaviruses and is common to humans and several other animals. This reflects the genetic reassortment that occurs when different viruses of the same group simultaneously infect susceptible hosts.

Some rotavirus isolates from rabbits induce a cytopathic effect in MA104 rhesus monkey kidney cells in about 3 days (Castrucci et al., 1985; Sato et al., 1982; Thouless et al., 1986), whereas other isolates demonstrate cytopathic effect only after additional passages. Physicochemical studies reveal that rotaviruses are stable from pH 3.0 to 9.0 (Fauquet et al., 2000). Virus remains infectious for months at room temperature on porous and non-porous environmental surfaces, in fecal material, or if stabilized with CaCl₂. Rotaviruses can be inactivated when heated at 50°C for 30 min and by treatment with chlorine, formalin, phenols, and

betapropiolactone. Ethanol, 95%, is the most effective disinfectant as it renders the rotavirus non-infectious by removing the outer capsid layer.

EPIDEMIOLOGY

Serological studies indicate that rotavirus infection is widespread in domesticated European rabbits (*Oryctolagus cuniculus*). Of 91 adult rabbits from two commercial rabbitries in Ontario, Canada, 98% had antibodies to rotavirus (Petrie et al., 1978). Sera collected from fryer rabbits at two abattoirs in Ontario, Canada, revealed that 60% of 200 rabbits had antibodies (Percy et al., 1993). A survey in Tokyo prefecture, Japan, of 39 adult rabbits revealed that 82% had antibodies (Takahashi et al., 1979). A more extensive survey of ten breeding and 13 laboratory colonies in metropolitan Tokyo and Ibaragi, Saitama, Kanagawa, Shizuoka, and Nagano prefectures in Japan revealed antibodies to rotavirus in 83% of the 23 colonies and in 81% of 160 sera (Iwai et al., 1986). In Hungary, 74% of 112 sera from five large-scale rabbit farms had rotavirus antibodies (Kudron et al., 1982). In the United States, 95% of 149 sera from rabbits more than 2 months old in a commercial colony in Washington had antibodies (DiGiacomo and Thouless, 1984). Rotavirus was detected in fecal samples from rabbits in three other colonies in the state (DiGiacomo and Thouless, 1986). Antibodies against rotavirus have also been detected in 29% of 17 sera from Eastern Cottontail rabbits (*Sylvilagus floridanus*) in Ontario, 52% of 27 sera from Snowshoe hares (*Lepus americanus*) in the Yukon, and 6% of 48 sera from Snowshoe hares in Nova Scotia (Petrie et al., 1978).

In colonies with endemic rotavirus infection, nearly all adult rabbits have serological evidence of rotavirus infection (DiGiacomo and Thouless, 1984, 1986). Litters in such colonies have transplacentally acquired maternal antibodies to rotavirus at birth. In the absence of rotavirus infection, the antibodies fall to undetectable levels by 60 days of age. In colonies with endemic infection, shedding of rotavirus in the feces is detected in rabbits 4–7 weeks old (Peeters et al., 1984), followed by the appearance of naturally acquired antibodies in rabbits greater than 6 weeks old (DiGiacomo and Thouless, 1986). Subsequently, infected rabbits demonstrate antibodies for long periods. Hence, in infected colonies, rabbits usually acquire infection when maternal antibodies have declined to low concentrations, which usually coincides with weaning. Both sexes appear equally susceptible. Rotavirus infection in domesticated European rabbits has been reported in New Zealand White, Dutch, and Californian rabbits, suggesting no difference in breed susceptibility (Bryden et al., 1976).

Rotavirus is shed in the feces of infected rabbits. In a survey of 187 rabbits of mixed ages, rotavirus was detected in 4% of fecal samples (Petric et al., 1978). In

another study, 11% of 18 fecal samples contained virus (Kudron et al., 1982). Rotavirus was detected in 9% of 106 fecal samples from healthy rabbits, 1–2 months old, from four rabbitries (DiGiacomo and Thouless, 1986). Hence, transmission probably occurs by fecal-oral spread. Rabbits inoculated orally with rotavirus shed virus in the feces for 6–8 days, beginning 2–5 days after inoculation (Blutt et al., 2003; Castrucci et al., 1984; Conner et al., 1988; Hambraeus et al., 1989; Petrie et al., 1978; Thouless et al., 1988). Furthermore, uninoculated control rabbits maintained in the same room with inoculated rabbits also acquired rotavirus infection (Conner et al., 1988; Thouless et al., 1988). As fomite transmission appeared unlikely because of the handling of uninoculated rabbits first, it was concluded that rabbits were infected by airborne transmission of virus. In gastrically inoculated rabbits, rotavirus RNA was also detected in sera 4 days after inoculation (Blutt et al., 2003). Experimentally, rabbits were also infected with simian rhesus rotavirus (Ciarlet et al., 2000b).

Recent reports suggest that rabbits may be a source of rotaviruses for humans. Comparison of the sequence analysis of several rotavirus genes of rabbit and human origin revealed a close relationship with clustering of strains in phylogenetic analyses (De Leener et al., 2004; Matthijnsens et al., 2006, 2009). However, the molecular similarity of strains should not infer interspecies transmission without supporting epidemiologic evidence of spread.

CLINICAL SIGNS

Rotavirus was initially detected and recovered from rabbits with diarrhea by Bryden et al. (1976). That report included both sporadic cases and outbreaks in 5-week-old rabbits. A spectrum in the severity of disease associated with rotavirus infection has been reported, which is probably influenced by a synergy among various microorganisms responsible for diarrheal diseases in rabbits. In outbreaks of diarrhea associated with rotavirus infection, rabbits 30–80 days old are usually affected (Castrucci et al., 1985; Peeters et al., 1984; Sato et al., 1982). Rabbits exhibit severe mucoid or watery diarrhea, anorexia, and dehydration, with mortality of 60–80%. In one outbreak, rabbits 8–12 days old had a greenish-yellow watery diarrhea (Peeters et al., 1982). About 20% of litters were affected, with 98% mortality within 1–2 days after onset of signs. A similar disease was reported in a specific pathogen-free colony in which litters 7–21 days old exhibited watery diarrhea and lethargy (Schoeb et al., 1986). Approximately 40% of affected litters died within 2 days after onset of signs. That preweanling rabbits were affected in both outbreaks suggests that rotavirus had been recently introduced into the colonies.

In a comprehensive study of various infectious agents (parasites, bacteria, and viruses) associated with

diarrhea in 21 rabbitries, [Peeters et al. \(1984\)](#) detected rotavirus in 35% of 130 affected rabbits. However, the clinical signs associated with rotavirus infection consisted of watery diarrhea for 2–3 days, with low mortality. Hence, in endemically infected colonies, other factors, including other infectious agents, may enhance the pathogenicity of rotavirus ([Peeters et al., 1984](#)). That rotavirus may be only mildly pathogenic is supported by experimental studies. In general, orogastric inoculation of rabbits, 1–22 weeks old, with rotavirus did not result in diarrhea, although some rabbits developed soft or fluid feces for 2–4 days ([Conner et al., 1988](#); [Hambraeus et al., 1989](#); [Petric et al., 1978](#); [Thouless et al., 1988](#)). Whereas inoculation of one rotavirus strain induced diarrhea, depression, anorexia, and mortality in rabbits ([Castrucci et al., 1984](#)), this could not be repeated ([Hambraeus et al., 1989](#)). Inoculation of rabbits of various ages revealed that partially formed to liquid stools developed in 1-week-old rabbits but not in rabbits ≥ 2 weeks old ([Ciarlet et al., 1998](#)). Thus, in non-endemically infected rabbits, rotaviral disease may be age-restricted, occurring only in neonatal rabbits.

PATHOLOGY

In weanling rabbits infected with rotavirus, the intestines are markedly congested and distended, and petechiae are found in the colon ([Sato et al., 1982](#)). In addition to congestion, there are mucosal hemorrhages in the small intestine and distention of the cecum with fluid ([Castrucci et al., 1985](#)). However, in both of the reports, the presence of other infectious agents was not examined. [Peeters et al. \(1984\)](#) reported that, in pure rotavirus infection, gross lesions are limited to fluid cecal contents and swollen mesenteric lymph nodes. Histologically, the small intestine shows moderate to severe villous atrophy, more marked in the ileum. Apical enterocytes on the tips of villi are swollen, rounded, and desquamating; occasionally tips are denuded. The lamina propria is usually infiltrated with lymphocytes and occasional neutrophils. Lesions in the cecum are limited to focal areas of enterocyte desquamation. In outbreaks involving preweanling rabbits, gross lesions are most pronounced in the ileum ([Peeters et al., 1982](#)). Microscopically, there is villous atrophy and attenuation or desquamation of epithelial cells at the apical tips of jejunal or ileal villi ([Peeters et al., 1982](#); [Schoeb et al., 1986](#)). In some areas, the submucosa is edematous ([Schoeb et al., 1986](#)).

Experimentally, rabbits inoculated orally with rotavirus have markedly congested and distended intestines with accumulation of fluid and gas in the small intestine, cecum, and colon from 2–9 days after inoculation ([Castrucci et al., 1984](#); [Ciarlet et al., 1998](#); [Petric et al., 1978](#); [Thouless et al., 1988](#)). Microscopically, villi are shortened with villus blunting, fusion, and vacuolation, low to moderate numbers of lymphocytes and plasma

cells infiltrate the villi and lamina propria of the small intestine. There is mild lymphoid reactivity in mesenteric lymph nodes. Lesions are not observed in the cecum or colon. The pathologic changes are considered to be mediated by enterotoxin ([Ciarlet et al., 2000a](#)).

DIAGNOSIS

Diarrhea caused by rotavirus is diagnosed from clinical signs, histopathology, detection of the virus, and demonstration of antibodies. Clinical signs and pathological findings alone are not diagnostic, although villous atrophy and degeneration and desquamation of enterocytes at the tips of villi in the small intestine are characteristic features. Rotaviral diarrhea must be differentiated from other diarrheal diseases of rabbits such as coccidiosis, salmonellosis, Tyzzer disease, clostridial enterotoxemia, enteric coronaviral enteritis, and colibacillosis. In weanling rabbits with severe disease, the possibility of dual infections should be considered, since rotavirus infections are usually mild. Electron microscopy ([Ciarlet et al., 1998](#); [Peeters et al., 1984](#); [Schoeb et al., 1986](#)) or a capture enzyme-linked immunosorbent assay can be used to detect rotavirus in feces ([Blutt et al., 2003](#); [Conner et al., 1988](#); [De Leener et al., 2004](#); [Hambraeus et al., 1989](#); [Thouless et al., 1986, 1988](#)). A commercial human rotavirus detection kit, utilizing immunochromatography, tested with fecal samples from rabbits with diarrhea was shown to be applicable, as positive results were confirmed by reverse transcription-polymerase chain reaction (RT-PCR) and restriction endonuclease analysis ([Fushuku and Fukuda, 2006](#)). The electrophoretotype of rotaviruses can be determined by extraction of nucleic acid from feces and electrophoresis in polyacrylamide gel ([De Leener et al., 2004](#); [Herring et al., 1982](#)). Cytoplasmic fluorescence can be observed at the tips of ileal villi using indirect immunofluorescence ([Petric et al., 1978](#)). Reverse transcription-polymerase chain reaction (RT-PCR), immunohistochemistry, and in situ hybridization can be used to detect rotavirus in formalin-fixed tissues ([Tatti et al., 2002](#)). Serum antibodies to rotavirus can be detected by enzyme immunoassay ([Conner et al., 1991](#); [Hambraeus et al., 1989](#); [Kelkar et al., 2004](#); [Thouless et al., 1988](#)). Rabbits with rotaviral diarrhea usually have no or low concentrations of antibody to rotavirus, with a subsequent rise 2–4 weeks after onset of signs ([Bryden et al., 1976](#); [Sato et al., 1982](#)). Unaffected littermates develop high antibody concentrations, reflecting concurrent subclinical infections.

CONTROL

Rotavirus is highly infectious and is transmitted by fecal–oral spread; however, fomites cannot be excluded. Transplacental transmission has not been demonstrated. Infection appears to be acute and self-limiting. Experimentally, virus is shed in the feces for about

1 week following inoculation (Castrucci et al., 1984; Conner et al., 1988; Hambræus et al., 1989; Petric et al., 1978; Thouless et al., 1988). Recovered rabbits are refractory to challenge with homologous (Castrucci et al., 1984; Ciarlet et al., 1998; Conner et al., 1988, 1991; Hambræus et al., 1989) or heterologous rotaviruses (Hambræus et al., 1989). Hence, cessation of breeding or quarantine of the colony for 4–6 weeks, to prevent the introduction of susceptible rabbits, should permit the infection to run its course. As seropositive dams are not infectious, their offspring should remain free of infection after maternal antibodies disappear. Early weaning of rabbits with high concentrations of passively acquired maternal antibodies and removal to isolated facilities offer the possibility of rederiving rabbits free of infection. Prevention of rotavirus infection depends on barrier maintenance of rabbits.

Coronavirus Infections

Pleural Effusion Disease/Infectious Cardiomyopathy Virus

HISTORY

During the 1960s in Scandinavia, increased mortality in European rabbits (*Oryctolagus cuniculus*) inoculated with the Nichols strain of *Treponema pallidum* (Jorgensen, 1968) was attributed to a virus, named the Stockholm agent, present in rabbit testicular emulsions (Gudjonsson et al., 1970). As the principal necropsy finding was pleural effusion, the name pleural effusion disease was suggested (Fennestad et al., 1975). Later, it was shown that the major target organ was the heart, and the name infectious cardiomyopathy was suggested, since the etiologic agent appeared to be a coronavirus (Small et al., 1979). The resemblance of the clinicopathological features to feline infectious peritonitis, a systemic coronavirus infection of cats, was noted (Osterhaus et al., 1982). The failure to propagate the agent in vitro has precluded more definitive characterization. It is unclear whether the agent is a naturally occurring pathogen of rabbits or a virus from another species adapted to rabbits in contaminated treponemal stocks. However, the disease may be useful as a model for virus-induced cardiomyopathy (Alexander et al., 1992, 1993; Baric et al., 1990; Edwards et al., 1992).

ETIOLOGY

The disease, initially described in 1968, occurred in rabbits inoculated with suspensions of rabbit testes containing the Nichols strain of *T. pallidum* (Gudjonsson and Skog, 1970; Jorgensen, 1968). Rabbits developed fever, circulatory insufficiency with pulmonary edema, and pleural effusion and had high mortality (Gudjonsson and Skog, 1970; Gudjonsson et al., 1970). Subsequent inoculation of rabbits with pulmonary tissue and pleural fluid from dead rabbits, previously

inoculated with treponemes, resulted in a similar syndrome (Gudjonsson et al., 1970). Differential filtration of pleural fluid and serum from rabbits revealed an infectious particle size of 25–50 nm, which is ether-sensitive and inactivated at temperatures of 65°C or above but not at 56°C (Fennestad and MacNaughton, 1983; Gudjonsson et al., 1972; Small et al., 1979). Sera from rabbits contained pleomorphic virus particles, round or elliptic, 75–100 nm in diameter, bearing club-shaped projections 15–20 nm long (Small et al., 1979), whereas plasma from rabbits contained high concentrations of pleomorphic virus-like particles measuring 51–98 nm in diameter with projections 8–13 nm long (Osterhaus et al., 1982). Infectious sera, passed in various cell lines, produced a cytopathic effect in primary rabbit kidney and newborn human intestine cells (Small et al., 1979). However, the cellular pathogenic effect was lost after two passages. Disease was not induced in mice, hamsters, or guinea pigs (Gudjonsson et al., 1970; Small et al., 1979).

In a complement fixation test, antigens in infectious sera cross-reacted with antisera to the 229E (two-way cross) and OC43 (one-way cross) strains of human coronavirus (Small et al., 1979). Antisera to the rabbit cardiomyopathy agent cross-reacted with feline infectious peritonitis virus (FIPV), canine coronavirus (CCV), and porcine transmissible gastroenteritis virus (TGEV) by radioimmunoassay (Small and Woods, 1987). Prior incubation of the agent with antisera to CCV, FIPV, TGEV, or 229E virus reduced mortality in rabbits following inoculation. However, prior immunization of rabbits with CCV, FIV, or TGEV had little effect on survival. Immunofluorescent staining of cardiac tissue from diseased rabbits with antisera to 229E virus revealed antigen in myocardial interstitial tissue, and rabbits surviving infection developed antibodies to the virus in a complement fixation assay (Small et al., 1979). In another study, however, surviving rabbits failed to demonstrate antibodies against 229E virus in an enzyme immunoassay and neutralization test, and against OC43 virus in a complement fixation test (Fennestad and MacNaughton, 1983).

EPIDEMIOLOGY

When the disease was recognized in 1961, rabbits used in the serial propagation of *T. pallidum* had a mortality rate of 2%. By the end of the 1960s, however, mortality had increased to 35–40% owing to contamination of treponemal stocks with virus (Fennestad, 1985; Jorgensen, 1968). There is no difference in disease among breeds (Gudjonsson and Skog, 1970) or between rabbits in the United States and Sweden (Gudjonsson et al., 1970). The agent was detected in *T. pallidum*-infected rabbit tissues from Europe, the United States, and Japan (Fennestad et al., 1980). Nine isolates, obtained from treponema-infected rabbits in various countries,

exhibited a wide range in pathogenicity when inoculated into rabbits (Fennestad et al., 1986). Whereas virtually all rabbits had fever, mortality ranged from 0 to 88%, and all surviving rabbits resisted challenge with a virulent strain. Two of four dams from litters inoculated at 6–9 days of age became infected, whereas uninoculated littermates or introduced cagemates failed to develop infection after exposure for several months (Fennestad et al., 1981). Hence, transmission by direct contact occurs rarely.

CLINICAL SIGNS

Whereas clinical features vary by strain and passage of the agent, inoculated rabbits generally develop a fever in 1–4 days which persists for 5–10 days. During this early phase, acute deaths can occur without clinical signs of illness (Alexander et al., 1999). Clinical signs are often consistent with those of congestive heart failure including anorexia, weight loss, atony, tachypnea, and dyspnea. Iridocyclitis has been reported. With virulent strains, a third of infected rabbits die 3–5 days after inoculation, although deaths can occur until 14 days (Baric et al., 1990; Fennestad, 1985; Fennestad and MacNaughton, 1983; Fennestad et al., 1975, 1986; Fledelius et al., 1978; Gudjonsson and Skog, 1970; Gudjonsson et al., 1970; Small et al., 1979). Generalized or hindquarter muscular weakness was also reported in rabbits surviving the acute phase of infection (Gudjonsson et al., 1970; Small et al., 1979). During the acute phase of infection, rabbits have a transient lymphopenia, followed by heterophilia (Fennestad et al., 1975). Red cell indices were also reduced but returned to normal by 6 weeks after inoculation. There was a transient hypoalbuminemia; however γ -globulin increased significantly (Fennestad et al., 1975). Serum potassium and lactate dehydrogenase were elevated transiently. ECG abnormalities have been reported during the acute phase (days 3–5) including tachycardia in 74% of the infected rabbits, depressed R wave voltages (16%), reduced T wave voltages (45%) and QT (corrected) prolongation (32–42%) and correlated positively with mortality (Alexander et al., 1995, 1999). Ninety percent of rabbits had persistent tachycardia in the subacute phase (days 6–12 after infection), ECG changes persisted, and echocardiographic changes in the subacute phase correlated positively with mortality. Surviving rabbits usually returned to normal in 3–4 weeks. However, ECG abnormalities persisted after day 30 in some rabbits, reflecting the development of dilated cardiomyopathy (Alexander et al., 1999). Reinoculation of surviving rabbits was without effect, indicating development of resistance to the agent (Fennestad, 1985; Fennestad and MacNaughton, 1983; Fennestad et al., 1986; Gudjonsson et al., 1970).

PATHOLOGY

Rabbits dying during the acute phase of disease have pulmonary edema, pleural effusion, and dilation

of the right ventricle (Alexander et al., 1992, 1993; Baric et al., 1990; Christensen et al., 1978; Edwards et al., 1992; Fennestad et al., 1975; Small et al., 1979). The pleural cavities contain 2–50 ml of fluid, with or without fibrin, and few cells; ascites may also occur in rabbits dying after the first week. There are subepicardial and subendocardial hemorrhages. Other findings may include hepatosplenomegaly and congested lymph nodes. The heart weight is increased, and there is dilation of the right ventricle followed by dilation of the left ventricle. The cause of death appears to be congestive heart failure (Alexander et al., 1992, 1993; Baric et al., 1990; Edwards et al., 1992; Small et al., 1979). In fatal cases, there is lymphoid depletion of the splenic follicles, focal degenerative changes of the thymus and lymph nodes, and mild proliferative changes of renal glomeruli (Christensen et al., 1978; Small et al., 1979). In rabbits that survive the acute phase, there is multifocal to diffuse myocardial degeneration and necrosis, focal hepatic necrosis, and proliferative changes in the spleen, lymph nodes, interstitial pulmonary tissue, and renal glomeruli. Lesions similar to those in the heart can occur in the diaphragm (Small et al., 1979). A mild non-suppurative, non-granulomatous anterior uveitis develops during the acute phase of infection and regresses within 4 weeks (Fledelius et al., 1978). At 65 days after infection, myocarditis is evident, and about one-third of rabbits had evidence of right- and/or left-sided cardiac dilation (Baric et al. 1990). After 2 years, rabbits had pulmonary lymphoid hyperplasia, lymphoid hyperplasia of lymph nodes and spleen, siderosis in the spleen, necrosis and periportal inflammation in the liver and interstitial fibrosis of the myocardium (Fennestad et al., 1986). No evidence of circulating or tissue immune complexes was found (Fennestad et al., 1981, 1986).

DIAGNOSIS

It remains to be determined whether the agent is a naturally occurring pathogen of rabbits or perhaps a human virus adapted to rabbits in contaminated stocks of the Nichols strain of *T. pallidum*. The syndrome has only been reported in experimentally inoculated rabbits. The clinical course is characterized by onset of fever 1–3 days after inoculation. Deaths may occur from 2–17 days after inoculation, and mortality may exceed 75%. Other major signs include ocular disease, anorexia, weight loss, tachypnea, and atony. The gross and histological lesions are highly characteristic of the disease. Antibodies to the virus cross-react with the human coronavirus 229E and other members of the group I mammalian coronaviruses (FLPV, CCV, and TGEV) (Small and Woods, 1987; Small et al., 1979).

CONTROL

Because continued serial propagation of *T. pallidum* in rabbits coincided with emergence of disease associated with this agent, the possibility of contaminated stocks

should be considered (Fennestad, 1985; Fennestad et al., 1975; Gudjonsson et al., 1970). Rabbits inoculated with virus-contaminated *T. pallidum* stocks that elicited no or mild disease without mortality were protected from disease when challenged with stocks contaminated with more pathogenic virus (Fennestad, 1985; Fennestad and MacNaughton, 1983; Fennestad et al., 1980, 1986; Gudjonsson et al., 1970). This indicated that some *T. pallidum* stocks were contaminated with a non-pathogenic variant of the virus, which was able to confer protection. Furthermore, isolates decreased in pathogenicity, as a function of time, in rabbits that survived acute infection (Fennestad, 1985; Fennestad et al., 1986). Convalescent sera from rabbits that survived infection partially protected challenged rabbits against mortality but not disease (Fennestad et al., 1981; Gudjonsson et al., 1970; Small et al., 1979). Passage of contaminated *T. pallidum* stocks through hamsters removed the agent responsible for disease (Fennestad et al., 1980; Skovgaard Jensen, 1971). Subsequent reintroduction of these *T. pallidum* stocks in rabbits was without effect. Similarly, inoculation of rabbits, with popliteal lymph nodes from surviving rabbits, transferred treponemes but not the agent (Gudjonsson et al., 1970).

Rabbit Enteric Coronavirus

HISTORY

A coronavirus was detected in the feces of rabbits with diarrhea by LaPierre et al. (1980) in Canada. Rabbits were 6–10 weeks old and from several colonies. Subsequently, coronavirus was detected in young rabbits with diarrhea in several European countries (Eaton, 1984; Osterhaus et al., 1982; Peeters et al., 1984). Although the virus appears to be readily detected in rabbits by workers in Canada (Descoteaux et al., 1985; LaPierre et al., 1980), the failure to propagate the agent in vitro has hampered investigations of its prevalence in European rabbit (*Oryctolagus cuniculus*) populations.

ETIOLOGY

Feces of rabbits with diarrhea exhibit hemagglutination activity with rabbit erythrocytes, particularly with a peak of 1.18 g/cm³ from a sucrose density gradient (Descoteaux et al., 1985; LaPierre et al., 1980). Electron microscopy of fecal samples revealed pleomorphic particles with an inner diameter of 60–220 nm and surface projections of 20 nm (Eaton, 1984; LaPierre et al., 1980). Particles obtained from a Percoll gradient appeared as spherical enveloped particles 40–50 nm in size with projections of 10–12 nm (Descoteaux et al., 1985). In rabbits inoculated orally, pleomorphic particles 60–90 nm, with surface projections of 10 nm, were detected in the feces (Osterhaus et al., 1982). Electron microscopy of fecal samples using antisera to rabbit coronavirus revealed

immune aggregates of viral particles with morphological features of coronaviruses (Descoteaux et al., 1985). Analysis of structural polypeptides by immunoblotting revealed that antisera to avian infectious bronchitis virus (AIBV) and TGEV detected many of the same epitopes as antisera to the rabbit coronavirus (Descoteaux et al., 1985). Immune sera to 229E, but not AIBV nor porcine hemagglutinating encephalitis virus, inhibited the hemagglutination activity of the rabbit coronavirus. No cytopathic effect occurred following inoculation of various cell lines with fecal samples (Eaton, 1984; LaPierre et al., 1980).

EPIDEMIOLOGY

In a survey of 130 diarrheic rabbits from 21 rabbitries, coronavirus was detected in the cecal contents of one rabbit in association with *Escherichia coli* infection (Peeters et al., 1984). Rabbits with diarrheal disease associated with coronavirus infection are usually 3–10 weeks old (Eaton, 1984; La Pierre et al., 1980). Virus has also been detected in the feces of apparently healthy rabbits (Descoteaux et al., 1985). Experimentally, orally inoculated rabbits shed virus for up to 29 days (Descoteaux and Lussier, 1990). A serological survey of 238 *Oryctolagus cuniculus* from six rabbitries in Washington state revealed that 23 (10%) had antibodies to canine coronavirus (Deeb et al., 1993).

CLINICAL SIGNS

In an outbreak of enteric disease in 3–8-week-old rabbits in a barrier-maintained breeding colony, rabbits exhibited lethargy, diarrhea, and swollen abdomens (Eaton, 1984). Between 40 and 60% of rabbits were affected, and virtually all died within 24 h after onset of signs. LaPierre et al. (1980) also reported rapid death following the onset of clinical signs in the majority of affected rabbits. Experimentally, rabbits developed soft feces (Osterhaus et al., 1982) and transient watery diarrhea (Descoteaux and Lussier, 1990) after inoculation. None of the rabbits died (Descoteaux and Lussier, 1990).

PATHOLOGY

In rabbits with diarrhea, the perianal region is soiled with feces (Eaton, 1984). Rabbits appear cachectic and dehydrated. Although the stomach and intestines are unaffected, the cecum is distended with watery fluid (Eaton, 1984; Peeters et al., 1984). Histologically, in the small and large intestines there is a diffuse infiltration of inflammatory cells and mucosal edema (Eaton, 1984). In an experimental study, the small intestines were congested and the cecal contents watery (Descoteaux and Lussier, 1990). Microscopically, at 6 hours after inoculation, there was necrosis of enterocytes at the tips of intestinal villi. Villous atrophy and hypertrophic crypts

were present 2–3 days after inoculation. However, by 6 days, microscopic lesions were absent.

DIAGNOSIS

Rabbits with diarrheal disease are usually recently weaned and 3–10 weeks old (Eaton, 1984; LaPierre et al., 1980). Because the rabbit coronavirus agglutinates erythrocytes, the hemagglutination activity of the feces provides an indication of the presence of virus (LaPierre et al., 1980). Coronavirus particles can be demonstrated in the feces by electron (Eaton, 1984; LaPierre et al., 1980; Osterhaus et al., 1982; Peeters et al., 1984) and immunoelectron (Descoteaux and Lussier, 1990; Descoteaux et al., 1985) microscopy. The latter technique is more sensitive in detecting virus particles (Descoteaux et al., 1985). At necropsy, the cecal contents are fluid (Descoteaux and Lussier, 1990; Eaton, 1984); histologically, there is intestinal villous atrophy (Descoteaux and Lussier, 1990). Adult rabbits may have antibodies in the hemagglutination inhibition assay (LaPierre et al., 1980). As experimental inoculation of rabbits with coronavirus failed to mimic the field disease with its high morbidity and mortality, consideration should be given to the existence of co-pathogens (Descoteaux and Lussier, 1990; Osterhaus et al., 1982). In two studies where other agents were considered, coronavirus was associated with *Escherichia coli* and *Clostridium perfringens* infections (Eaton, 1984; Peeters, et al., 1984).

CONTROL

Because only one naturally occurring outbreak of diarrheal disease associated with coronavirus has been reported (Eaton, 1984), there is scant information on control of the disease. The feeding of hay, delay in weaning, and administration of coccidiostats and antibiotics were ineffective in preventing mortality.

Calicivirus Infections

The etiologic agents of necrotic hepatitis of leporids have profoundly affected world rabbit populations since 1984. They are classified as members of the family, *Caliciviridae*, and the genus, *Lagovirus*. This genus contains two distinct species which cause clinical disease denoted as *Rabbit hemorrhagic disease virus* (RHDV) and *European brown hare syndrome virus* (EBHSV) (Green et al., 2000). These diseases were first recognized in the mid-1980s. RHD was reported in China in 1984 and subsequently in other countries. EBHS was observed in Europe several years before RHD was diagnosed in domestic European rabbits. Antibodies to RHDV were in archived serum from 1961 in the Czech Republic and Austria (Nowotny et al., 1997) and viral RNA in serum samples from Britain stored in 1955 (Moss et al.,

2002). Antibodies to EBHSV were found as early as 1962 (Frölich and Lavazza, 2008) in serum in England and viral RNA in tissues collected in the 1970s in Sweden (Bascunana et al., 1997).

A third member of the genus *Lagovirus* was identified in domestic rabbits in Italy in 1996 and was named rabbit calicivirus (RCV) (Capucci et al., 1996). No clinical signs were associated with RCV infection although seroconversion resulted in protection from RHDV (Capucci et al., 1997). A closely related strain, denoted rabbit calicivirus, Australia 1 (RCV-A1) was recently isolated from wild European rabbits in Australia and partially sequenced (Strive et al., 2009). Whether antibodies which recognize RHDV epitopes in retrospective studies are associated with RCV and its variants rather than RHDV is unknown. Another closely related virus, denoted Michigan Rabbit Calicivirus (MRCV) was isolated from an outbreak of hemorrhagic disease in the United States in 2001 (Bergin et al., 2009). One member of the genus *Vesivirus*, family *Caliciviridae* has been described as a potential intestinal pathogen of rabbits (Martín-Alonso et al., 2005).

Rabbit Hemorrhagic Disease Virus (RHDV)

HISTORY

In early 1984, an acute fatal disease of rabbits was reported from many regions of China (Xu and Chen, 1989; Xu et al., 1988). The disease was unlike any previously reported syndrome and may have originated in rabbits imported from Europe. Tests of rabbit sera stored in Czechoslovakia in 1978 revealed antibodies to the virus (Rodak et al., 1990a). Although the syndrome was initially variously named, it came to be known as RHD. Subsequently, the disease was reported in several European countries in 1987 and 1988 (Gregg and House, 1989; Parra and Prieto, 1990; Patton, 1989). The negative impact of this disease on wild rabbit populations in Europe has been significant (Calvete et al., 2002; Marchandeu et al., 1998). Currently, it is endemic in most of Europe, Asia, Africa, Australia, and New Zealand.

By late 1988, the virus reached North America and was reported from many locations in Mexico (Gregg and House, 1989; Gutierrez, 1990; Patton, 1989). Mexico mounted an eradication campaign and has since remained free of the virus (McIntosh et al., 2007). Four outbreaks of RHDV were reported in the United States between 2000 and 2007 (Anonymous, 2000; Campagnolo et al., 2003; U.S.D.A., 2005; McIntosh et al., 2007). Each time the virus was contained, but how it was introduced was not determined (McIntosh et al., 2007).

In 1995, a laboratory strain of RHDV was being tested in field experiments under quarantine conditions at Wardang Island, Australia, to evaluate the virulence,

transmissibility, and persistence of RHDV (McColl et al., 2002). It was also being considered as a potential biological control agent for rabbits. The virus escaped and spread, first to other rabbits on Wardang Island, and then to the mainland. It resulted in significant mortality immediately, reducing rabbit populations in some areas by 95% (Mutze et al., 1998). It is currently endemic throughout Australia. In 1996, the New Zealand government was asked to consider the use of RHDV as a biological control agent (Thompson and Clark, 1997). The government denied these requests; however, RHDV was introduced to New Zealand illegally by farmers hoping to reduce local rabbit populations and is now widely distributed in both the North and South Islands of New Zealand (O'Keefe et al., 1999; Thompson and Clark, 1997).

ETIOLOGY

A virus has been consistently purified from the liver and spleen of affected rabbits, the characteristics of which have been described by several investigators (Du, 1990, 1991; Du et al., 1986; Liebermann et al., 1992; Ohlinger and Theil, 1991; Sihid et al., 1989; Smid et al., 1989; Xu, 1991; Xu and Chen, 1989; Xu et al., 1988). The virus is non-enveloped, spherical, and 28–34 nm in diameter and has a buoyant density of 1.32–1.38 g/cm³. The icosahedral capsid has 32 cylindrical capsomeres, 5–6 nm in diameter, comprised of four structural polypeptides. The virus is a member of the family, *Caliciviridae*, and is the type virus of the genus, *Lagovirus* (Green et al., 2000). RHDV was completely sequenced and has a positive strand RNA genome of 7437 kb (Meyers et al., 1991a). The genomic organization is similar to EBHSV with two open reading frames (ORF) rather than the three ORFs found in other caliciviruses (Wirblich et al., 1996). The first ORF encodes non-structural proteins as well as the large capsid protein and the second ORF encodes an additional capsid protein. One subgenomic RNA (2.2 kb) is present (Ohlinger et al., 1990; Parra and Prieto, 1990). Amino acid identity between RHDV and EBHSV is approximately 76% (Wirblich et al., 1994). The virus agglutinates erythrocytes of humans and guinea pigs, but not rabbits. Non-hemagglutinating strains of RHDV have been identified (Tian et al., 2007). While the majority of strains of RHDV have a high level of amino acid identity, antigenic variants have been described (Capucci et al., 1998; Asgari et al., 1999; Shirmmaier et al., 1999).

The virus is highly stable in the environment and sufficient infectious RNA is present to infect rabbits from liver samples stored for 20 days at 22°C (McColl et al., 2002). In a separate study, infectious virus was injected into bovine liver and then the liver was exposed outdoors to ambient temperatures (2–34°C) (Henning et al., 2005). Sufficient viral particles were

present at the longest time point studied, 91 days, to infect rabbits when inoculated undiluted. Viral infectivity is unaffected by treatment with ether, chloroform, exposure to pH 3, or heating at 50°C. However, the virus is inactivated by 1% sodium hydroxide or 0.4% formaldehyde at ambient temperature, 4°C or 37°C. The virus fails to grow in many primary and established cell lines but has been adapted to a transformed rabbit kidney cell line (Ji et al., 1991; Xu, 1991). Rabbits may be the only species susceptible to infection, as inoculation of guinea pigs, hamsters, rats, or mice failed to induce disease. Experimentally, inoculation of European hares (*Lepus europaeus*) failed to induce disease (Lavazza et al., 1996; Smid et al., 1991).

EPIDEMIOLOGY

Since the report of the first outbreak of RHDV in China in 1984, RHDV has rapidly spread throughout the world. The disease has been reported from China, Korea, most European countries, Asia, Africa, North America, Australia, and New Zealand (Chasey et al., 1997; McIntosh et al., 2007; Morisse et al., 1991). Countries experiencing epidemics with high morbidity and mortality include China (Xu and Chen, 1989), Korea (Lee and Park, 1987), Italy (Cancellotti and Renzi, 1991; Patton, 1989), Spain (Parra and Prieto, 1990; Villafuerte et al., 1994), France (Morisse et al., 1991), Germany (Loliger and Eskens, 1991), Mexico (Gregg and House, 1989; Gutierrez, 1990), Taiwan (Shien et al., 1998), Cuba (Farnós et al., 2007), Saudi Arabia (Abu Elzein and Al-Afaleqand, 1999), Bahrain (Forrester et al., 2006), Tunisia (Bouslama et al., 1996), the United Kingdom (White et al., 2004), and the United States (McIntosh et al., 2007). The disease has also been reported from India (Sundaram et al., 1991) and the Middle East (Kuttin et al., 1991). Viruses from China, Korea, and Europe appear to be similar (Du, 1990; Gregg et al., 1991), although evolution of viruses in restricted geographic areas has occurred (Muller et al., 2009). Recently, a virus isolated in the Netherlands was demonstrated to be 99% identical to RHDV from France (van de Bildt et al., 2006).

There have been four outbreaks of RHDV in the US; in Iowa in 2000 (Anonymous, 2000), in Utah in 2001, which was transferred to Illinois by shipment of infected rabbits (Campagnolo et al., 2003), in a zoo in New York in 2001 (McIntosh et al., 2007), and in Indiana in 2005 (McIntosh et al., 2007; U.S.D.A., 2005). Isolates from these outbreaks were shown by comparative genomic analysis to be closely related to isolates from China, but to have separate origins (McIntosh et al., 2007).

There is evidence that RHDV was present in wild and domesticated populations of rabbits in Europe (Moss et al., 2002; Rodak et al., 1990a), Australia (Cooke et al., 2000; Nagesha et al., 2000), and New Zealand (O'Keefe et al., 1999) prior to the recognition of RHDV. Studies in

England demonstrated serological evidence as well as partial RNA sequences recovered from tissues or serum of apparently healthy rabbits (Moss et al., 2002; White et al., 2004). These partial sequences were more closely related to RHDV than RCV, suggesting that non-pathogenic RHDV viruses have circulated in parts of the world for some time.

No apparent difference in susceptibility to infection among breeds of *Oryctolagus cuniculus* has been reported (Xu and Chen, 1989; Xu et al., 1988). Outbreaks of disease have occurred mainly in rabbits 2 months of age and older, whereas younger rabbits were clinically unaffected. Of the rabbits that survived the infection, viral RNA has been detected in various organs including the spleen, liver, mesenteric lymph node, and bile for 15 weeks after infection suggesting that a chronic carrier state can occur (Gall et al., 2007).

Transmission of virus is horizontal, primarily by direct contact with secretions and excretions of infected rabbits and fecal-oral spread may be the major mode of transmission. Contaminated fomites, such as feed, water, utensils, and animal attendants, may be important in transmission as well. Transmission by insects has been suggested as an explanation for the spread of RHDV from Wardang Island to the mainland. Laboratory experiments demonstrated that RHDV can be transmitted by blowflies (*Phormia* sp.), bushflies (*Musca vetustissima*) and mosquitoes (Gould et al., 1997; McColl et al., 2002). Transmission by the lesser brown blowfly, *Calliphora dubia* was suggested by evidence that RHDV RNA was detected in fly feces after flies were fed a meal from a RHDV-infected liver (Asgari et al., 1998). There is no evidence of vertical transmission. Fecal shedding by carnivores after ingestion of RHDV-infected carcasses has been suggested as a potential mode of spread. Serological evidence of infection in foxes has been demonstrated in several studies, although no infectious particles have been demonstrated (Frölich et al., 1998; Leighton et al., 1995; Philbey et al., 2005). Experimentally, the routes of entry, in order of importance, are oral, conjunctival, nasal, and skin trauma. In China and Europe, epidemics of disease usually begin in November and end in March. Although *Oryctolagus cuniculus* appears to be the only species susceptible to disease, hares in China also appear to be infected and capable of transmitting the virus to rabbits experimentally (Xu, 1991).

A serological survey of 1461 rabbits from 43 farms, apparently free of viral hemorrhagic disease in Czechoslovakia revealed that 283 rabbits (19%) from 33 farms had anti-RHDV antibodies (Rodak et al., 1990a). Using another set of sera, collected between 1975 and 1987 from laboratory-maintained rabbits, antibodies were detected in 32 of 42 sera (76%). This suggests that rabbit colonies in Czechoslovakia harbored a viral agent with characteristics similar to those of Rabbit hemorrhagic disease virus, but with lower pathogenicity,

several years before the syndrome was recognized in China.

RHDV has been shown to bind to histo-blood group antigens expressed on the surface of respiratory and digestive tract epithelial cells (Ruvoën-Clouet et al., 2000). This binding may partially explain the differential susceptibility of young versus older rabbits (Rademacher et al., 2008; Ruvoën-Clouet et al., 2000). In addition, polymorphisms of these antigens in wild rabbits in France have been linked to differential survival from RHDV infection (Guillon et al., 2009).

CLINICAL SIGNS

In general, the disease is acute and highly infectious, with high morbidity and mortality (Marcato et al., 1991; Xu and Chen, 1989; Xu et al., 1988). The incubation period ranges from 1–2 days. Morbidity is 70–80%, and mortality approaches 100%. During outbreaks, the number of rabbits affected usually peaks in 2–3 days and lasts 7–13 days. After viral introduction, rabbits die suddenly with few clinical signs. Rabbits become febrile and exhibit depression, lethargy, and anorexia. Other clinical signs include tachypnea, cyanosis, abdominal distention, and constipation or diarrhea. Because the disease is acute, clinical signs may be brief and often are unnoticed. In the terminal stage, rabbits become hypothermic, recumbent, and have convulsions and epistaxis. Surviving rabbits exhibit depression, anorexia, and fever which usually abates in 2–3 days. In endemic areas, the form of disease observed in surviving rabbits is more common. Hematologic evaluation usually reveals a lymphopenia, a gradual decline in thrombocytes, and prolonged prothrombin and thrombin times. A paracoagulation test with protamine sulfate gives a strong positive reaction. Fibrin degradation products can be detected in most moribund rabbits.

In young rabbits, clinical signs of infection are typically absent (Ferreira et al., 2004, 2006; Mikami et al., 1999). However, liver inflammation as evidenced by increase in hepatic transaminases and increase in heterophil liver infiltrate occurs, although there is little hepatocyte damage (Ferreira et al., 2004, 2006; Mikami et al., 1999; Prieto et al., 2000) and less replication of the virus within hepatocytes than adults as evidenced by immunohistochemical staining (Preito et al., 2000). Elevation of transaminases persists for at least 3 weeks after infection (Ferreira et al., 2004). Young rabbits infected with RHDV develop a protective antibody response that persists and protects them from infection as adults (Ferreira et al., 2008). However, these rabbits may serve as healthy carriers of the virus (Ferreira et al., 2004, 2008).

PATHOLOGY

The pathological changes apparently result from viremia, with death attributable to an acute disseminated

FIGURE 14.3 Diffusely congested lungs from rabbit found dead with RHD. Courtesy of Dr. D. Gregg.

FIGURE 14.4 Reticular pattern of liver (bottom, center) consistent with periportal necrosis in a rabbit found dead with RHD. The kidney (top, center) is diffusely congested. Courtesy of Dr. D. Gregg.

coagulopathy with deep venous thrombosis (Gregg and House, 1989; Gregg et al., 1991; Marcato et al., 1991; Xu and Chen, 1989; Xu et al., 1986, 1988). Grossly, congestion and hemorrhage occur in most organs but are most pronounced in the lungs (Figure 14.3). The liver is pale and has a fine reticular pattern of periportal necrosis, the most consistent finding in the disease (Figure 14.4). The spleen and kidneys may be dark and swollen owing to acute infarction (Figure 14.4). Lymph nodes are edematous and may contain petechial hemorrhages. There is often segmental catarrhal enteritis.

In most fatal cases, rabbits die from a severe and massive intravascular coagulopathy (Gregg et al., 1991). The disease consistently causes acute hepatic necrosis, which may be the only lesion found. Hepatic necrosis

is periportal and diffuse, and when severe, may bridge acini and cause dissociation of hepatic cords (Gregg et al., 1991; Percy and Barthold, 2007). Small single or multiple intranuclear inclusion bodies can be found in degenerate hepatocytes. There is often little inflammation in necrotic areas. Many tissues, especially the lungs, spleen, and kidneys, may have varying degrees of congestion and hemorrhage due to microinfarction or major venous thrombi. Acute coagulative necrosis due to microinfarction may be found in any organ. Microinfarcts in the brain account for the terminal neurological signs. Pulmonary venous thrombosis accounts for the frothy serosanguinous discharge from the nares seen terminally. A segmental necrotizing enteritis with severe crypt necrosis and villous atrophy can be found (Gregg et al., 1991). Lymphoid tissues may have varying degrees of degeneration and karyorrhexis of lymphocytes. The spleen and thymus are more often affected than lymph nodes.

DIAGNOSIS

A presumptive diagnosis can be made on the basis of the epidemiological features, clinical signs, and pathological findings (Xu and Chen, 1989). Virus can be detected with RT-PCR using multiple tissues including blood (Gall et al., 2007; Guittre et al., 1995; Shien et al., 2000; Vende et al., 1995; Wang et al., 2008; Yang et al., 2008). No satisfactory in vitro isolation methods have been described, and rabbit inoculation is the only method available to isolate or propagate a new strain of virus (O. I. E. 2008). Immunocapture RT-PCR was developed to simplify the tissue processing required to analyze numerous samples (Le Gall-Reculé et al., 2001). By electron microscopy, viral particles, 28–34nm in diameter, are frequently found in hepatocytes (Valicek et al., 1990; Xu and Chen, 1989). The hemagglutination test, with type O human erythrocytes, is useful for detection of virus in suspensions of liver, lungs, spleen, and kidneys, from infected rabbits (Shien et al., 2000; Xu and Chen, 1989). Antisera or monoclonal antibodies to the virus can detect virus in hepatocytes in infected rabbits by immunoenzyme and immunofluorescence tests (Berninger and House, 1995; Capucci et al., 1991; Carrasco et al., 1991; Gregg and House, 1989; Gregg et al., 1991; Park and Itakura, 1992; Rodak et al., 1990b, 1991; Stoerckle-Berger et al., 1992). Serological tests include the hemagglutination inhibition test and the enzyme-linked immunosorbent assay, the latter being preferable because of increased sensitivity and specificity (Chasey et al., 1995; Cooke et al., 2000; Rodak et al., 1990b). Both indirect sandwich ELISAs and competitive-ELISAs have been developed for detection of antibodies (Guittre et al., 1995). Seroconversion to RHDV without clinical signs of disease is suggestive of RCV infection and should be interpreted with caution (Capucci et al., 1997).

CONTROL

Measures to prevent introduction of the virus include restricted access and disinfection of all equipment entering or leaving a facility (Xu and Chen, 1989). Cages and equipment can be disinfected with 0.5% sodium hypochlorite or 1% formalin. Rabbits from endemic areas should not be introduced directly into the colony, but quarantined for at least 1 month and tested serologically for anti-RHDV antibodies. Similarly, colonies with disease should be quarantined and depopulated, since surviving rabbits shed virus for at least a month and possibly longer (Gregg and House, 1989; Gregg et al., 1991). Antiserum has been shown to be protective (Du, 1990; Huang, 1991). Tissue-derived vaccines, inactivated with formaldehyde (Du, 1990; Du et al., 1986; Huang, 1991; Xu and Chen, 1989) or β -propiolactone (Arguello Villares, 1991; Smid et al., 1991), have been shown to be safe and efficacious in preventing disease. Resistance develops within 1–2 weeks after vaccination and lasts for 5–15 months. Although disease may be prevented in vaccinated rabbits, persistent infection may develop on exposure to the virus (House et al., 1990). Thus, vaccinated rabbits infected with virus should be considered infectious and should not be introduced into previously unexposed rabbitries. Additional vaccines have been developed, including those combining protection against both RHDV and myxomatosis (Bertagnoli et al., 1996; Calvete et al., 2004; Fernández-Fernández et al., 2001; Torres et al., 2001). Since the decline of rabbit populations in southern France and the Iberian peninsula has affected the survival of rabbit-prey species (Marchandeau et al., 2000), vaccination of free-living rabbits has been undertaken in a field trial on an island off Spain and subsequently on the mainland (Calvete et al., 2004; Torres et al., 2001).

European Brown Hare Syndrome Virus (EBHSV)

HISTORY

A disease, characterized by hemorrhages in the trachea and lungs, pulmonary edema, and necrotic hepatitis, with high mortality, has been observed since 1980–1985 in European hares (*Lepus europaeus*) and Mountain hares (*Lepus timidus*) in many European countries (Billinis et al., 2005; Duff et al., 1994; Frölich 1996; Frölich et al., 2001, 2003a, 2007; Gavier-Widen and Morner, 1991; Le Gall-Reculé et al., 2006; Morisse et al., 1990, 1991; Syrjälä et al., 2005). The virus has also been detected in European hares translocated to Argentina (Frölich et al., 2003b). The disease, named European brown hare syndrome (EBHS), is similar to RHD, but affects hares.

ETIOLOGY

Electron microscopy of hepatocytes from affected hares reveals non-enveloped, icosahedral particles about 30 nm in diameter (Chasey and Duff, 1990; Marcato et al.,

1991). Immunoblotting of the virus reveals a major structural protein of about 60 kDa, similar to RHDV; however, other proteins of the latter virus are absent, suggesting that the viruses are similar but not identical (Capucci et al., 1991; Ohlinger and Thiel, 1991). Sequencing of the genome (Gould et al., 1997; Le Gall et al., 1996; Meyers et al., 1991b; Nowotny et al., 1997; Parra et al., 1993; Rasschaert et al., 1995; Wirblich et al., 1994) revealed that RHDV and EBHSV have similar genomic organization and are both members of the family, *Caliciviridae*, and the genus, *Lagovirus*, however they represent two distinct species (Green et al., 2000). EBHSV and RHDV have been shown to have approximately 76% amino acid identity (Wirblich et al., 1994).

EBHSV fails to grow in primary hare and rabbit cell lines (Gavier-Widen and Morner, 1991; Henriksen et al., 1989), and inoculation of mice and guinea pigs failed to induce disease (Henriksen et al., 1989). In general, inoculation of rabbits (*Oryctolagus cuniculus*) with EBHSV, or tissues from infected hares, has not resulted in clinical disease in rabbits (Capucci et al., 1991; Chasey et al., 1992; Eskens and Volmer, 1989; Nauwynck et al., 1993) or cross-protective immunity (Nauwynck et al., 1993), although clinical disease similar to RHD was induced by Morrisset al. (1990) following inoculation of liver homogenates from affected hares in France.

EPIDEMIOLOGY

The disease has been reported in wild hares from several European countries, including England (Chasey and Duff, 1990), the Czech Republic (Nowotny et al., 1997), Greece (Billinis et al., 2005), Finland (Syrjälä et al., 2005), Slovakia (Frölich et al., 2007), Switzerland (Frölich et al., 2001), France (Le Gall-Reculé et al., 2006), Poland (Frölich et al., 1996, 2003a), as well as South America (Frölich et al., 2003b). EBHSV has also been reported from breeding farms for hares in Denmark (Henriksen et al., 1989) and Sweden (Gavier-Widen and Morner, 1991). In France, Germany, and Italy, the geographic distribution of EBHS coincides with RHD in wild and domesticated rabbits (Cancellotti and Renzi, 1991; Loliger and Eskens, 1991; Morisse et al., 1991). Seroprevalence has been determined in many countries. Thirty-eight percent of hares tested in Poland were positive for EBHSV antibodies (Frölich et al., 1996), 29% in Germany (Frölich et al., 2003) while 73% of hares shot by hunters in Slovakia had anti-EBHSV antibodies, suggesting some variation in the prevalence of infection.

Similar to RHDV, young hares are resistant to the virus (Morisse et al., 1991). The major mode of transmission appears to be fecal-oral (Morisse et al., 1991). Contamination of feed and water with excreta from infected hares is probably a common mode of transmission (Gavier-Widen and Morner, 1991). Among wild

and farmed hares in Denmark and Sweden, mortality is seasonal, beginning in October and continuing through March (Gavier-Widen and Morner, 1991; Henriksen et al., 1989), presumably as there are more young susceptible hares at the end of the breeding season. Recent evidence from Finland indicates that the majority of the cases occurred in the spring and summer, with a minor peak in October and November (Syrjälä et al., 2005). The hare population in Finland was lowest in winter and this may influence transmission. In England, excess mortality in wild hares was reported in September through November (Chasey and Duff, 1990).

CLINICAL SIGNS

In general, the disease is acute and highly infectious, with high morbidity and mortality (Henriksen et al., 1989; Marcato et al., 1991). Clinical signs include depression, anorexia, muscular tremors, incoordination, paralysis, convulsions, and occasionally epistaxis. Death occurs 5–24h after onset of signs, and affected hares rarely recover. The reported morbidity is 75%, and mortality approaches 100% (Gavier-Widen and Morner, 1991; Henriksen et al., 1989). In Argentina (Frölich et al., 2003b) and Slovakia (Frölich et al., 2007) evidence of a chronic, less pathogenic form of EBHSV has been demonstrated. In Argentina, no clinical signs suggestive of EBHSV were reported; however 11% of 80 spleen samples were positive for EBHSV antigen (Frölich et al., 2003b) whereas antibodies to EBHSV were present in only one sample. In Slovakia, antibodies against EBHSV were found in 73% of 86 sera tested although hare populations were reported to be stable with no increase in mortality noted before or during the sampling period (Frölich et al., 2007).

PATHOLOGY

Death is attributable to multiple organ failure resulting in pulmonary edema and hemorrhage, adrenocortical necrosis, renal circulatory disorders, and hepatic necrosis (Henriksen et al., 1989; Marcato et al., 1991). Gross examination of hares reveals marked pulmonary congestion and edema, as well as hepatic congestion and hemorrhages. Moderate splenomegaly and gastric ulceration are detected in some hares. A catarrhal to necrotizing conjunctivitis may be present. Microscopically, there is diffuse acute coagulation necrosis of hepatic periportal and midzonal areas, accompanied by formation of acidophilic bodies (Gavier-Widen and Morner, 1991; Henriksen et al., 1989). In many hares, there is basophilic stippling in the cytoplasm of hepatocytes in periportal areas, representing granular calcification. Many livers have microvacuolar fatty degeneration. About one-fourth of affected hares have splenic cellular depletion and hyaline-like changes in the sinuses and cords, and about one-third have renal tubular necrosis and calcification. In the brain, cerebral neurons and cerebellar Purkinje cells exhibit

granulovacuolar degeneration. In apparently healthy hares with antibodies to the virus, hepatic vacuolar degeneration, tracheitis, and hyperplasia of splenic follicles are observed (Marcato et al., 1991).

DIAGNOSIS

Diagnosis is similar to that for RHD. RT-PCR has been used to detect virus in tissues (Bascunana et al., 1997; Gould et al., 1997). The hemagglutination test for detection of virus in tissue specimens is less sensitive (Capucci et al., 1991). Use of two ELISAs, in series, employing monoclonal antibodies, in which the first test detects group antigen and the second virus-specific antigen, has also been used to detect virus (Capucci et al., 1991). The ELISA is preferred for detection of antibodies (Capucci et al., 1991).

CONTROL

Methods of control in breeding farms for hares are similar to those for rabbit hemorrhagic disease. Preventive measures include restricted access, disinfection of equipment, and quarantine of newly acquired hares. As subclinically infected hares may shed virus, serological screening of quarantined hares may be advisable. Only seronegative hares should be permitted entry into the colony. Colonies with the disease should be quarantined and depopulated. No vaccine has been developed for use in hares.

Rabbit Calicivirus (RCV)

HISTORY

Non-pathogenic rabbit caliciviruses were first isolated from rabbits (*Oryctolagus cuniculus*) in a rabbitry in Italy that seroconverted to RHDV without exhibiting clinical signs of disease (Capucci et al., 1996). Serological studies revealed rabbit populations in Europe with serological evidence of RHDV, but no clinical evidence of disease (Capucci et al., 1996, 1997; Forrester et al., 1997; Rodak, 1990). In addition, retrospective studies demonstrated serological evidence of anti-RHDV antibodies prior to the spread of RHDV virus in Europe (Moss et al., 2002; Rodak, 1990a), Australia, and New Zealand (Bruce and Twigg, 2004; Nagesha et al., 2000; Robinson et al., 2002). Investigators in Italy isolated a non-pathogenic calicivirus, rabbit calicivirus (RCV), from domestic rabbits (Capucci et al., 1996). Partial sequences of apparently non-pathogenic caliciviruses were detected in rabbits (*Oryctolagus cuniculus*) from Lambay Island, Eire in 2007 (Forrester et al., 2007). In 2009, another apparently non-pathogenic calicivirus, RCV-A1, was isolated from wild rabbits (*Oryctolagus cuniculus*) in Australia (Strive et al., 2009).

ETIOLOGY

RCV is considered a strain of RHDV (Fauquet et al., 2005). Currently, similar viruses have been isolated from

Italy (RCV), Eire (Lambay Island strain), and Australia (RCV-A1) (Capucci et al., 1996; Forrester et al., 2007; Strive et al., 2009). Genome organization is similar to RHDV and EBHSV in that there are two open reading frames as opposed to three which are found in other caliciviruses (Capucci et al., 1996; Strive et al., 2009). RCV is most closely related to RHDV with an amino acid identity of 91% of the capsid protein, VP60. The amino acid identity to EBHSV was 75% in the same study (Capucci et al., 1996). The average identity of the full-length sequence of RCV-A1 when compared to RHDV was 87%. Phylogenetic analysis of RCV, the Lambay Island strain, and the Ashington strain (England) suggests that these isolates are more closely related to each other than to other strains of RHDV (Capucci et al., 1996; Forrester et al., 2007; Strive et al., 2009). Interestingly, the Ashington strain was isolated from a rabbit (*Oryctolagus cuniculus*) with typical signs of RHDV. Antigenically, sera from rabbits infected with RCV cross-reacted with anti-RHDV antibodies, but not anti-EBHSV antibodies (Capucci et al., 1996). Sera from ten of 11 healthy rabbits on Lambay Island, Eire, also cross-reacted with antibody to RHDV (Forrester et al., 2007) and RT-PCR detected virus sequences shown to be closely related to RCV from two serum samples.

EPIDEMIOLOGY

RCV-A1 RNA was recovered from the small and large intestines of wild European rabbits (*Oryctolagus cuniculus*) as well as the fecal pellets from the distal colon, suggesting a fecal–oral method of transmission similar to RHDV (Strive et al., 2009). Viral RNA was detected in Peyer's patches, spleen, and less frequently in liver. Experimental inoculation of *Oryctolagus cuniculus* with RCV by oronasal route resulted in seroconversion by day 6 after inoculation (Capucci et al., 1996). Uninoculated cagemates of infected rabbits were seropositive 1–2 days later, presumably from contact. Rabbits housed in the same room that had no contact with the infected rabbits did not seroconvert. RT-PCR detected viral antigens from the intestine of infected rabbits 3, 5, 6, and 7 days after inoculation but not from the liver or spleen. Western blot analyses of intestinal extracts were also positive. Infection with RCV provided complete protection from challenge with RHDV. Inoculation of hares with RCV resulted in no seroconversion and 5 days after inoculation all organs were negative for RCV by RT-PCR. Hares previously inoculated with RCV and then challenged with EBHSV were not protected from disease.

CLINICAL SIGNS

Experimental inoculation of *Oryctolagus cuniculus* with RCV resulted in no clinical signs of disease (Capucci et al., 1996) and no clinical signs of disease were observed in rabbitries with positive serology (Capucci et al., 1997). No clinical signs were observed in wild rabbits (*Oryctolagus*

cuniculus) positive for the Lambay Island strain (Forrester et al., 2007) or RCV-A1 (Strive et al., 2009).

PATHOLOGY

Gross or histopathologic lesions have not been described.

DIAGNOSIS

Seroconversion to RHDV without clinical signs of disease is suggestive of RCV infection (Capucci et al., 1997). The virus can be detected by RT-PCR of intestinal contents or feces (Capucci et al., 1996; Forrester et al., 2007; Strive et al., 2009).

CONTROL

Serologically, RCV is difficult to definitively distinguish from RHDV. RCV may represent an older non-pathogenic lagovirus that provides protection from RHDV and thus explains why in some areas seroreactivity to RHDV occurs without evidence of disease.

Michigan Rabbit Calicivirus (MRCV)

In January, 2001, an outbreak of hemorrhagic disease with a 32.5% case fatality rate occurred in a private New Zealand White rabbitry in Michigan (Bergin et al., 2009). Clinical signs consisted of acute fatality, inappetance, vulvar hemorrhage, conjunctival congestion, opisthotonus, and cyanosis of the lips and ear tips. On gross necropsy, evidence of icterus, gastric petechiae and ecchymoses, colonic serosal hemorrhage, and multifocal hemorrhage in the caudal lung lobes was observed. Histopathology revealed multifocal random or periportal hepatocellular necrosis and inflammation, pulmonary and uterine hemorrhages with fibrin clots, bile duct proliferation, and periductal fibrosis. RT-PCR of tissue samples ruled out RHDV, however, positive hepatocytes were detected by immunohistochemistry utilizing RHDV-specific antibodies.

Further amplification of sequences from pooled liver samples demonstrated a calicivirus with capsid sequences that most closely aligned to RCV (91.7% similarity) but were also closely related to RHDV (89.8–91.3% similarity). When ORF-1 polypeptide genomic sequence was aligned, excluding the capsid sequences, MRCV was 77.9–78.5% identical to RHDV, although other strains of RHDV share similarities of 87.9–98.1% in these same comparisons. These sequences of RCV have not been determined (Bergin et al., 2009).

Inoculation of homogenized liver from infected rabbits into naïve, SPF (free of *Pasteurella* sp.) rabbits did not induce disease after 7 days, although inoculated rabbits had viral RNA in the liver detected by RT-PCR and in situ hybridization. This short time course did not allow for determination of seroconversion (Bergin et al., 2009).

Clinical signs of disease resolved and rabbits were depopulated approximately 2 months after the initial outbreak. Antibody against MRCV was detected in depopulated rabbits and 20% had gross and non-specific histopathological changes in their livers consisting of biliary hyperplasia and periductal to bridging portal to portal fibrosis. How the virus was introduced into the colony was not determined (Bergin et al., 2009).

Rabbit Vesivirus

A novel member of the family Caliciviridae was isolated from pooled intestinal contents of five European rabbits (*Oryctolagus cuniculus*) that died with intestinal disease in Oregon (Martín-Alonso et al., 2005). Coccidia were detected in two rabbits and *Escherichia coli* was cultured from the pooled intestinal contents. Calicivirus particles were observed by electron microscopy and a calicivirus was isolated on porcine kidney cell lines and partially sequenced. The virus was not neutralized with anti-calicivirus antibodies (from 40 different antisera) and sequence analysis indicated it is a novel member of the Vesivirus genus. The genome consists of a single-stranded positive sense RNA of 8295 nucleotides and contains a 2.6-kb subgenomic RNA. Its genomic organization is unlike lagoviruses, as it contains three ORFs, rather than two. Phylogenetic analysis grouped it in a clade containing marine caliciviruses and non-human primate calicivirus, Pan 1.

Paramyxovirus Infections

Rabbit syncytium virus was isolated in chicken embryos inoculated with extracts of liver and spleen from a wild Eastern Cottontail rabbit (*Sylvilagus floridanus*) in Virginia (Morris et al., 1965). The agent causes a cytopathic effect and syncytia in monkey and hamster kidney cell cultures. Experimentally, suckling mice are susceptible to the virus, but weaned mice, guinea pigs, domestic European and Eastern Cottontail rabbits failed to develop signs or lesions, although antibodies developed, following inoculation. Sera from eight of 25 (32%) Eastern Cottontail rabbits trapped in the same area as the original rabbit had antibodies to the virus. Antibodies to the virus were not detected in sera from seven other species trapped in the same area, *Oryctolagus cuniculus*, or humans. The virus resembles the paramyxoviruses in size, nucleic acid type, and in ether and heat sensitivity. Neither hemagglutination nor hemadsorption were observed, and the ultrastructure of the virus has not been described. The virus is serologically distinct from the known paramyxoviruses.

Evidence of another paramyxovirus, *Sendai virus*, has been found in domestic European rabbits (*Oryctolagus cuniculus*). *Sendai virus* is the type species of the genus *Respirovirus*, family *Paramyxoviridae* (Fauquet et al., 2005)

and a primary pathogen of mice (Percy and Barthold, 2007). A serological survey of 23 breeding and laboratory colonies, in metropolitan Tokyo and Ibaragi, Chiba, Saitama, Kanagawa, Shizuoka, and Nagano prefectures, revealed that 85 of 160 (53%) Japanese White or New Zealand White rabbits had antibodies to *Sendai virus* (Iwai et al., 1986). Ito et al. (1987) also detected antibodies to *Sendai virus* in rabbit sera in studies comparing antigenic relationships among paramyxoviruses. Intranasal inoculation of *Oryctolagus cuniculus* with *Sendai virus* resulted in infection as rabbits shed virus for 3–7 days after inoculation, and viral antigen was detected by immunofluorescence in the nasal cavities (Machii et al., 1989). Although rabbits showed no clinical signs and had only a moderate increase of goblet cells in the nasal epithelium, antibodies to the virus developed. One of three uninoculated rabbits exposed to inoculated rabbits acquired infection. These studies suggest that *Oryctolagus cuniculus* is susceptible to *Sendai virus* and that this or a related virus may be endemic in rabbit colonies. Experimentally, genetically modified Sendai viruses have been used in gene therapy in rabbits (Nakamura et al., 1998).

Bunyavirus Infections

Evidence of infection with several viruses of the genus *Orthobunyavirus* in the family *Bunyaviridae* has been detected in leporids. Strains of *California encephalitis virus* found to infect rabbits or hares include California encephalitis, Snowshoe hare, Tahyna, and Inkoo viruses (Fauquet et al., 2005). Similar evidence of infection has been found with viruses of the genus *Bunyamwera virus* including cache valley virus, Tensaw virus, and Northway virus. One other member of the *Bunyaviridae* that infects rabbits and is not assigned to a genus is the Silverwater virus.

Antibodies to California encephalitis virus were initially detected in Eastern Cottontail rabbits (*Sylvilagus floridanus*) and Black-tailed jackrabbits (*Lepus californicus*) in California (Hammon and Reeves, 1952). The first virus of the group to be recovered from leporids was the Snowshoe hare virus, isolated in 1959 from the blood of a sick Snowshoe hare (*Lepus americanus*) in western Montana (Burgdorfer et al., 1961). The virus is widespread in Snowshoe hare populations of North America, as serological surveys revealed prevalences of 40–97% in adult hares (Hoff et al., 1969; McLean et al., 1975; Mean, 1983; Newhouse et al., 1963; Yuill et al., 1969). The virus has been isolated from seven species of boreal forest mosquitoes, including 0.04% of *Aedes communis* (McLean, 1983), and also from the rabbit tick, *Haemaphysalis leporis-palustris* (Newhouse et al., 1963).

The European hare (*Lepus europeus*) and wild European rabbit (*Oryctolagus cuniculus*) appear to be the major reservoirs of Tahyna virus in Europe (Bardos,

1965, 1975; Danielova et al., 1969; Hannoun et al., 1969; Simkova, 1963). Clinical disease in infected hares has not been reported. Experimental infection of European rabbits results in viremia and antibody formation without clinical disease (Hammon and Sather, 1966; Simkova, 1962). Thus, domestic European rabbits are useful as sentinels of viral activity since they develop antibodies and can serve as a source for recovery of virus (Kolman et al., 1966; McKiel et al., 1966). A serological survey in Finland revealed that 5% of Mountain hares (*Lepus timidus*) and none of the *Lepus europeus* tested had antibodies against Inkoo virus (Brummer-Korvenkontio, 1973). Similar viruses have been isolated from mosquitoes and humans in Russia (Vanlandingham et al., 2002).

Cache valley virus, Tensaw virus, and Northway virus are mosquito-borne viruses of North America. Cache valley virus has a wide geographic distribution in North America (Blackmore and Grimstad, 2008), whereas Tensaw virus is found predominantly in the Southeastern United States (Bigler et al., 1975) and Northway virus in Alaska and California (Campbell et al., 1990, 1991; Walters et al., 1999; Zarnke et al., 1983). Recent evidence suggests these host ranges may not be as restrictive as earlier thought (Sahu et al., 2002). The amplifying hosts for all of these viruses are unclear, however antibodies recognizing Cache valley virus have been found in Desert cottontails (*Sylvilagus audubonii*), Eastern cottontails (*Sylvilagus floridanus*), and Black-tailed jackrabbits (*Lepus californicus*) (Blackmore and Grimstad, 2008). Antibodies to Tensaw virus have been found in the Swamp rabbit (*Sylvilagus aquaticus*) (Calisher et al., 1986), Marsh rabbit (*Sylvilagus palustris*) (Bigler et al., 1975), and New England cottontail rabbit (*Sylvilagus transitionalis*) (Sudia et al., 1969) and those to Northway virus in the Snowshoe hare (*Lepus americanus*) (Zarnke et al., 1983). Experimental infection of Eastern cottontail rabbits with Cache valley virus resulted in transient viremia of insufficient magnitude to infect mosquitoes (*Coquillettidia perturbans*) suggesting that this species may not be an important vertebrate host for this virus (Blackmore and Grimstad, 2008). In contrast, rabbits and hares may be important hosts for Tensaw and Northway viruses as experimental infection of New England cottontail rabbits (*Sylvilagus transitionalis*) with Tensaw virus resulted in viremia of sufficient magnitude to infect mosquitoes (*Anopheles quadrimaculatus*) (Sudia et al., 1969). Living near Snowshoe hares (*Lepus americanus*) was found to be a significant risk factor for human serologic reactivity to Northway virus (Walters et al., 1999).

Silverwater virus has been isolated from Snowshoe hares (*Lepus americanus*) and from rabbit ticks (*H. leporis palustris*) from Snowshoe hares in Ontario and Alberta, Canada (McLean and Larke, 1963; Yuill et al., 1969). Although no disease has been reported in infected hares, they appear to play a central role in the natural cycle of the virus.

Togavirus Infections

Serological evidence of infection with Western (WEE), Eastern (EEE), and Venezuelan (VEE) equine encephalitis viruses, members of the genus *Alphavirus*, in the family *Togaviridae* (Fauquet et al., 2005) has been found in rabbits and hares. Wild *Sylvilagus* as well as hares (*Lepus californicus* and *Lepus americanus*) have antibodies to WEE (Bowers et al., 1969; Yuill et al., 1969). Infection studies of *Oryctolagus cuniculus* with strains of WEE isolated from South America and North America demonstrated virus strain variation in clinical signs and mortality (Bianchi et al., 1997). A South American strain (AG80-646) resulted in early onset of anorexia and rear limb paralysis with rabbits dying 6 days after inoculation. The North American strain caused no detectable clinical signs, but the rabbits seroconverted. Antibodies to EEE (Yuill et al., 1969) and VEE (Hoff et al., 1970) have been detected in Snowshoe hares (*Lepus americanus*) and antibodies to VEE have been detected in Eastern cottontail rabbits (*Sylvilagus floridanus*) (Smart and Trainer, 1975).

Complement fixation, hemagglutination-inhibition, ELISA, and plaque reduction neutralization tests are commonly used for diagnosis of these infections in humans and animals, although cross-reactivity between different viruses is problematic with all of these tests (O. I. E., 2008). An epitope-blocking assay was developed and tested on rabbit sera to better separate the individual virus groups (Pässler and Pfeffer, 2003). The infectious agent can be identified by viral isolation or PCR (O. I. E., 2008; Vodkin et al., 1993).

Flavivirus Infections

Two members of the Japanese encephalitis group in the family *Flaviviridae*, genus *Flavivirus* have been shown to infect rabbits or hares, *St. Louis encephalitis virus* and *West Nile virus* (WNV) and one member of the mammalian tick-borne virus group of the genus *Flavivirus* has been shown to infect hares, *Powassan virus* (Fauquet et al., 2005). Antibodies to *St. Louis encephalitis virus* have been detected in Snowshoe hares (*Lepus americanus*) (Yuill et al., 1969). Experimentally, Eastern cottontail rabbits (*Sylvilagus floridanus*) have been shown to be susceptible to WNV infection (Tiawsirisup et al., 2005). WNV is a mosquito-transmitted pathogen of significant public health importance (Hayes et al., 2005). The major route of infection of humans is by the bite of a mosquito infected by ingesting a blood meal from an infected bird. In general, mammalian hosts of WNV are dead-end hosts and do not develop viremia of sufficient magnitude to infect mosquitoes (Bowen and Nemeth, 2007). However, certain species, including Eastern cottontail rabbits (*Sylvilagus floridanus*), develop viremia which infects mosquitoes (*Culex pipiens* and

Culex salinarius) and therefore, may contribute to the endemic cycle of WNV in North America (Tiawsirisup et al., 2005). Infection in rabbits occurs without clinical signs. *Powassan virus* is a tick-borne virus of emerging public health concern in the United States, Canada, and Russia (Ebel, 2010). Antibodies to *Powassan virus* have been found in Snowshoe hares (*Lepus americanus*) (McLean et al., 1961; Zarnke and Yuill, 1981). Snowshoe hares experimentally infected with the virus develop no clinical symptoms, but become viremic for 1–3 days. Other vertebrates, including red squirrels (*Tamiasciurus hudsonicus*), chipmunks (*Tamias amoenus*), groundhogs (*Marmota monax*), and white-footed mice (*Peromyscus leucopus*) may be more important in perpetuating the virus than Snowshoe hares (Ebel, 2010).

Picobirnavirus Infections

A rabbit *Picobirnavirus*, a member of the *Picobirnaviridae* family, was detected in rabbit feces in a study in which rabbits were inoculated with human *Picobirnavirus* (Fregolente et al., 2009; Gallimore et al., 1993). Picobirnaviruses are non-enveloped bisegmented, double-stranded RNA viruses of 35–40nm in diameter. Members of this family of viruses have been found in the feces of many different hosts, including humans, pigs, rabbits, dogs, rats, snakes, and birds (Fregolente et al., 2009). They are thought to be opportunistic gastrointestinal pathogens associated with clinical disease in humans (Giordano et al., 1999). These viruses have been associated with gastrointestinal disease in HIV-infected humans (Giordano et al., 1999; Grohmann et al., 1993) and may be important pathogens or co-pathogens in immunosuppressed rabbits. The *picobirnavirus* genome detected in rabbits consisted of two segments; 2.3kbp and 1.85kbp (Gallimore et al., 1993). The first segment contains one major ORF and two smaller ORFs and has been partially sequenced (Green et al., 1999). This segment is thought to encode a capsid protein while the second segment appears to encode an RNA-dependent RNA polymerase (Rosen et al., 2000). Picobirnaviruses do not replicate in tissue culture, although they were successfully detected in the feces of rabbits inoculated orally with rabbit *Picobirnavirus* (Gallimore et al., 1993; Ludert et al., 1995). No clinical signs of disease resulted, however, anti-*Picobirnavirus* antibodies developed (Gallimore et al., 1993).

Rabies Virus Infections

Rabies virus, the type species of the genus *Lyssavirus* and family *Rhabdoviridae* (Fauquet et al., 2005), is a neurotropic virus that infects mammals resulting in a generally fatal, progressive encephalomyelitis (Manning et al., 2008). It is found in high titers in the saliva

of clinically ill animals and is typically transmitted through a bite. Rabies virus infections in rabbits and hares are rare, as these species often do not survive encounters with rabid animals. From 1971 to 1984, seven rabid rabbits were reported to the CDC, including four Eastern cottontails (*Sylvilagus floridanus*) (Fishbein et al., 1986), while in the next 9 years, 17 cases of rabies in rabbits were reported to the CDC (Childs et al., 1997). Of these 17, 11 were domestic European rabbits (*Oryctolagus cuniculus*) and the others were unknown. Four viruses were typed and shown to be either raccoon or skunk variants of rabies virus. In 1995, raccoon-variant rabies was reported in seven domestic European rabbits in New York State (Eidson et al., 2005). Rabies is typically diagnosed by fluorescent antibody test on brain tissue, however, strains may be further identified using monoclonal antibodies or genetic means such as nucleic acid probes, PCR, and DNA sequencing (O. I. E., 2008).
