Salmonellosis was a significant disease of hamsters prior to the improvement of sanitation practices, and the commercial production of diets and bedding. In recent decades, the disease in laboratory hamsters is rarely diagnosed (Renshaw et al., 1975). However, *Salmonella* has been diagnosed in hamsters bred and distributed for retail pet stores (Swanson et al., 2007).

Salmonella enterica serovars *enteritidis* and *typhimurium* have been isolated from affected hamsters. Organisms have been cultured from heart blood, liver, spleen, lungs, intestines, and feces. Incubation period is usually 3–6 days and transmission is by the oral route. A carrier state may exist where apparently normal hamsters shed *Salmonella* organisms in the feces (Soave, 1963).

Hamsters have been shown to be more susceptible to *Salmonella* infection than mice (Innes et al., 1956). The mortality rate in affected hamsters in a retail pet distributor was approximately 60% (Smith et al., 2005).

Clinical Manifestations

The disease in hamsters produces symptoms and lesions which are very similar to salmonellosis of other rodents (Habermann and Williams, 1958; Soave, 1963). Clinical signs include lethargy, rough hair coat,

diarrhea, anorexia, weight loss, and increased respiratory rate. Feces may appear as normal pellets or may be lighter in color and soft. With chronic salmonellosis, there may be no observable signs or animals may show progressive cachexia. Hamsters that survive weeks may show distended abdomens from enlargement of the liver and spleen.

Pathology

Gross necropsy reveals small white foci in the liver, patchy hemorrhagic lungs, and reddened lymph nodes. Enteritis may be observed, however, it may not be apparent in all cases (Innes et al., 1956). Microscopically, there is focal hepatic and focal splenic necrosis. Lung sections show focal congestion, intra-alveolar hemorrhage, and focal interstitial pneumonitis. Bronchopneumonia is only rarely observed (Innes et al., 1956). Phlebothrombosis involving the venous side of pulmonary circulation was reported as a prominent lesion (Innes et al., 1956). Pulmonary veins and venules were partially occluded by septic thrombi. Venous thrombosis was also noted in the liver. Mediastinal lymph nodes may show congestion, hemorrhage, erythrophagocytosis, and foci of necrosis.

Pathogenesis

The pathogenesis of *Salmonella* infection of hamsters was studied by Innes et al. (1956). They found that the hamster was highly susceptible to infection causing death in all inoculated hamsters by the second day after intraperitoneal injection and by the ninth day orally. Histologically, embolic glomerular lesions, purulent pericarditis, and necrotizing placentitis occurred. Acute enteritis with necrosis of Peyer's patches developed after oral inoculation.

Diagnosis

The diagnosis of salmonellosis should be suspected whenever there are unexpected deaths in a hamster colony. Differential diagnosis can usually be easily made because the organism can be readily isolated from many parenchymal organs. Screening colonies of hamsters for *Salmonella* can be done with PCR assays of feces.

Prevention and Therapy

The most effective strategy to manage a *Salmonella* outbreak in hamsters is through preventive measures rather than treatment. Antibiotics and drug treatments have no lasting benefit (Frisk, 1987). Multidrug-resistant *S. enterica* serovar *typhimurium* were isolated from hamsters destined for the retail pet trade where there was widespread use of prophylactic antibiotics including spectinomycin and tetracycline (Swanson et al., 2007). Eradication of the disease from a colony, once it is established, is best done by depopulation, sanitizing all equipment and environment, and restocking

with unaffected hamsters. To prevent the introduction of *Salmonella* into an existing colony, incoming hamsters should be quarantined and their feces cultured. Species separation should also be practiced because other species such as mice, rats, and guinea pigs are susceptible to infection.

Good sanitation practices and the use of commercially prepared diets and bedding will reduce the chances of introducing salmonellosis. Bacteriological screening of food, bedding, and water can be useful in detection of contaminants. Stress, such as overcrowding or feeding an inadequate diet, can change unrecognized salmonellosis in a colony to an epizootic with high mortality (Soave, 1963).

Salmonellosis can be latent or produce high morbidity and high mortality in hamster colonies; it is more commonly a problem in distributors and breeders for the retail pet industry. Salmonellosis is transmissible to many species including man. Handling of pet hamsters should be considered a potential health risk. Cases of salmonellosis in humans caused by multidrug-resistant *S. enterica* serovar *typhimurium* were associated with exposure to pet hamsters, mice, or rats (Swanson et al., 2007).

Tularemia

Etiology and Epizootiology

There has been one reported outbreak of tularemia in hamsters (Perman and Bergeland, 1967). This highly fatal disease occurred in a closed hamster breeding colony over a 1-month period. *Francisella tularensis* can infect many species of animals including all wild rodents and lagomorphs (Frisk, 1987).

Clinical Manifestations and Pathology

The tularemia outbreak described in hamsters was depicted by sudden onset; the disease's course was less than 48 hours. Hamsters were unexpectedly found dead or moribund. In this outbreak, hamsters 4–6 weeks of age in different areas of the room were affected; however, breeding animals were unaffected. Gross pathological lesions included mottled lungs with subpleural petechial and ecchymotic hemorrhages. Livers were enlarged and pale, spleens were enlarged with miliary white foci, and lymph nodes were enlarged and mottled. Histopathologically, the most consistent lesion was necrosis of lymphoreticular tissue associated with large numbers of small Gram-negative bacteria contained within phagocytes.

Diagnosis

Tularemia in hamsters would be a very unexpected diagnosis; however, it should be included along with other differential diagnoses in any disease outbreak

which causes high mortality. A definitive diagnosis can be confirmed from bacteriological cultures.

Prevention

The source of the tularemia in this single reported outbreak was not definitely identified. Contaminated diet supplements were suspected as the source of the organism because when the supplements were eliminated, no additional cases of tularemia occurred within the colony. A tularemia outbreak, although very rare and unexpected, would be a very significant public health issue because the organism is infectious to humans.

Bacterial Respiratory Infections

Bacterial respiratory infections of hamsters do occur, but they have not been extensively studied. In the United States, pneumonia of hamsters was recognized by 43% of laboratories (six of 14) surveyed and was listed as the second most common clinical condition (Renshaw et al., 1975). In a German survey to determine the incidence of diseases of hamsters, respiratory infections were noted in 8% (ten of 121) of total clinical cases (Lindt, 1958). In both of these surveys, viruses as well as bacteria accounted for the respiratory infections that were reported. Bacterial respiratory infections occur with much less frequency in hamsters than in mice, rats, or guinea pigs.

Bacterial respiratory infections can be caused by several organisms, including *Pasteurella pneumotropica* (Brennan et al., 1965; Gleiser, 1974; Harkness and Wagner, 1995; Silverman and Chavannes, 1983), *Pasteurella* sp. (Castleman, 1983), *Streptococcus pneumoniae* (Frisk, 1987; Renshaw et al., 1975), *Streptococcus agalactiae* (Kummeneje et al., 1975), *Streptococcus* sp. (Frisk, 1987), and *Salmonella* sp. (Innes et al., 1956). These respiratory conditions in hamsters include pneumonia, conjunctivitis, otitis media, and otitis interna which can progress to encephalitis. Hamsters may also carry potentially pathogenic organisms in their respiratory tract without showing clinical signs. Organisms which are screened for in nasopharyngeal cultures of hamsters include *P. pneumotropica*, *P. multocida* (Orcutt, 1980), cilia-associated respiratory (CAR) bacillus (Shoji-Darkye et al., 1991), *S. pneumoniae*, *Staphylococcus aureus* (Castleman, 1983), *Klebsiella pneumoniae* (Castleman, 1983), *Bordetella* sp. (Castleman, 1983), and *Salmonella* sp.

Mycoplasma pulmonis was isolated from the respiratory system of hamsters that were exposed to aerosolized graphite (Battiegelli et al., 1971). *M. pulmonis* could not be isolated from control hamsters or hamsters in groups treated with low concentrations of graphite or calcium sulfate. The significance of the presence of *M. pulmonis* in this particular experimental group was not established. The possible role *M. pulmonis* has as an

etiologic agent in naturally occurring respiratory infections of hamsters is not well defined. From the lack of reported clinical cases, it appears that the occurrence of *Mycoplasma* infection in the hamster is extremely rare.

Apparent bacterial pneumonias based on gross and microscopic lesions have been reported in the past (Hagen et al., 1965; Kleinerman, 1972). Cultures from affected lungs were not reported, therefore, the exact etiology of the lesions in these reports is unknown.

Further discussions of specific bacterial respiratory infections are found in the sections on *Pasteurella* infections, CAR bacillus, streptococcal infections, and salmonellosis.

Pasteurella Infections

P. pneumotropica is commonly present in the nasal cavities of carrier hamsters that do not show clinical signs (Gleiser, 1974; Harkness and Wagner, 1995; Leshner et al., 1985). *P. pneumotropica* may occasionally cause pneumonia and rarely cause enteritis in hamsters. Stress, including parturition, may be associated with the precipitation of clinical disease. *P. pneumotropica* is a small, Gram-negative, non-motile, bipolar rod. Pneumonia, cutaneous abscessation, conjunctivitis, otitis interna, and enteritis have been reported by natural infection (Harkness and Wagner, 1995; Leshner et al., 1985). Clinical signs associated with pneumonia may include labored breathing, nasal exudate, and weight loss. Experimentally, hamsters inoculated with *P. pneumotropica* could not be infected nor were lesions produced (Jawetx, 1948, 1950). In a colony, the most effective control measure for *P. pneumotropica* is elimination of carrier animals by isolating and culturing new animals before introduction into the existing population.

Cilia-Associated Respiratory (CAR) Bacillus

Although natural infections have not been reported, hamsters are susceptible to experimentally induced infection with CAR bacillus (Shoji-Darkye et al., 1991). Hamsters were inoculated intranasally with CAR bacillus isolated from a spontaneously infected mouse. As compared with mice, histopathologic lesions in hamsters were milder. Eight weeks after inoculation, pathologic changes included mild submucosal mononuclear cell proliferation of bronchi and trachea with marked thickening of bronchial epithelium. After experimental infection, CAR bacillus antigen was detected by immunostains throughout the respiratory tract and could be reisolated from tracheal washes (Shoji-Darkye et al., 1991). Successful experimental infections of hamsters with CAR bacillus suggest that natural infections could occur (Shoji-Darkye et al., 1991). PCR assays for CAR

bacillus, typically done on tracheal washes or lung, are commercially available.

Corynebacterium

Corynebacterium kutscheri may be isolated from clinically and pathologically normal hamsters. *C. kutscheri* was isolated from oral cavities, esophagus, cecal contents, colon/rectum, submaxillary lymph nodes, nasal cavities, and trachea of aged hamsters (Amao et al., 1991). In this same survey, the organism could not be isolated from lung, stomach, kidney, spleen, and mesenteric lymph nodes. Experimentally, hamsters inoculated subcutaneously or intramuscularly with pure cultures of *C. kutscheri* did not result in systemic disease (Amao et al., 1995). Only local inflammatory lesions including abscesses were noted. Although hamsters may be asymptomatic carriers, *C. kutscheri* apparently is not a systemic pathogen for hamsters. However, because *C. kutscheri* may be pathogenic for mice and rats, hamsters carrying the organism in their intestinal or respiratory tracts for long periods of time may serve as a source of infection for other rodents. For hamster health-monitoring programs, selective media for isolation of *C. kutscheri* should be considered (Amao et al., 1991).

An isolated case of acute pneumonia in a hamster caused by *C. paulometabulum* has been reported (Tansey et al., 1995). A single hamster from a small colony showed rapid, shallow breathing which did not clinically improve with tetracycline treatment. At necropsy, lungs showed acute edematous pneumonia from which *C. paulometabulum* was isolated. Based on only a single animal within a colony with no other clinical cases, this organism is not a significant pathogen for hamsters.

Streptococcal Infections

Streptococci have been isolated from hamsters with pneumonia. Streptococcal pneumonias are relatively uncommon and oftentimes are associated with stress. In a survey of naturally occurring diseases of hamsters, diplococcus (*Streptococcus pneumoniae*) was the cause of pneumonia from one of 14 laboratories (Renshaw et al., 1975). *S. agalactiae* has been reported to cause acute pleuropneumonia and septicemia in hamsters (Kummeneje et al., 1975). Diplococci and *Streptococcus* sp. have been reported to cause pneumonia and cervical lymphadenitis in hamsters (Frisk, 1987). The course of the disease is short (3 days), the route of infection being aerosol. Clinical signs include depression, anorexia, nasal and ocular discharge, dehydration, and weight loss. Diagnosis is made by clinical signs, lesions, and culture. Treatment may be attempted with antibiotics that are specifically effective against the isolated organism.

Bacterial Mastitis

A beta hemolytic *Streptococcus* was isolated from two female hamsters with acute bacterial mastitis (Frisk et al., 1976). The infection occurred 7–10 days after parturition. Litters were noted to be runt until 1 week of age when they were cannibalized by the affected female. Affected mammary glands were hemorrhagic, firm, and contained suppurative exudate. Histopathologically, myriads of polymorphonuclear inflammatory cells had infiltrated glandular parenchyma. The frequency of occurrence of streptococcal mastitis in breeding hamsters is very low.

Multiple nodules were diagnosed in the caudal mammary gland of a hamster 10 days after parturition (Heurkamp and Dillehay, 1990). Two prominent firm subcutaneous masses which were discrete and pink-yellow in color were noted. The cut surface had many small cystic cavities that contained a caseous yellow exudate. *E. coli* was cultured from the affected mammary glands. Histopathology revealed focal areas of coagulative necrosis and neutrophilic infiltration. These histologic changes were felt to be caused by endotoxins. Mastitis in this hamster caused by coliforms was thought to be from an ascending infection from contamination of the teat rather than via a hematogenous route.

Post Irradiation Infections

Bacterial infections may occur in hamsters after whole-body irradiation. Smith et al. (1955) irradiated groups of hamsters with a range of 760–10000r. These animals had 67–90% positive heart blood cultures for *Pasteurella* and/or *Streptococcus* up to 28 days following exposure. Infections caused by *Pseudomonas* resulted in the shortest survival time post irradiation. Hamsters showed rapid deterioration 4–5 days after being exposed to between 700 and 2000r (Mayo et al., 1962). Abscesses that were midway between the eye and ear were reported in hamsters that received 500–5000r (McKenna et al., 1970). *Pasteurella pneumotropica* was cultured from these abscesses which appeared 2–3 weeks following exposure.

The portal of entry for these bacteria is most likely the nasopharynx. Clinical signs of post-irradiation infections of hamsters are diarrhea, weight loss, dehydration, and edema of the face. Lesions may include suppurative blepharitis, orbital abscesses, and foci of necrosis in the oral cavity.

Bacterial infections can alter the results of experiments utilizing hamsters in whole-body irradiation studies. The occurrence and severity of these infections may depend upon the bacterial microflora within the upper respiratory tract. Therefore, it may be prudent to screen a percentage of hamsters by culturing the nasopharynx for *P. pneumotropica*, *Pseudomonas* sp., and beta hemolytic *Streptococcus* prior to radiation exposure.

Cutaneous Bacterial Abscesses

Skin abscesses can occur in hamsters at any location, but are most prevalent near the head, sometimes involving the cheek pouch (Burke, 1979). Abscesses can contain a variable amount of purulent exudate. The most commonly reported organism isolated from skin abscesses is *Staphylococcus aureus*. Other organisms associated with cutaneous abscesses are *Streptococcus* sp. (Frisk, 1987), *Actinomyces bovis* (Gorlin and Chaudry, 1959) and *Pasteurella pneumotropica* (Harkness and Wagner, 1995; McKenna et al., 1970). Abscesses may be associated with superficial injuries caused by poor caging or fighting (Frisk, 1987; Gleiser, 1974).

The oral route of infection may be predominant when abscessed lesions involve the submandibular and cervical lymph nodes (Frisk, 1987). The most predominant clinical sign is a swelling which may rupture and cause matting of the fur. Cervical lymphadenitis takes weeks to develop and may become severe enough to cause anorexia and death (Frisk, 1987).

Treatment may be attempted through surgical drainage and flushing with an antiseptic. Topical and systemic antibiotic therapy may also be employed. Caging should be examined for sharp edges or protruding wire and affected hamsters should be isolated from others to prevent fighting.

Pseudotuberculosis

Infections of *Yersinia pseudotuberculosis* in hamsters are very rare and do not occur in well-managed colonies. The chronic form of pseudotuberculosis produces gastrointestinal lesions which resemble tubercular lesions (Handler, 1965). The clinical course of the disease progresses slower in hamsters than other species (Frisk, 1987). Clinical signs may include intermittent diarrhea and cachexia prior to death. The organism can be cultured from small necrotic nodules that may occur in the intestines, mesenteric lymph nodes, liver, spleen, and lungs. Introduction of *Y. pseudotuberculosis* into a hamster colony can usually be attributed to contamination of food or water with the feces of wild rodents or birds (Gleiser, 1974). Sources of food and water and husbandry practices should be critically reviewed. Control of pseudotuberculosis is best accomplished by depopulation followed by sanitation of all equipment prior to repopulation with unaffected hamsters.

Actinomycosis

The occurrence of *Actinomyces bovis* infection in hamsters appears to be extremely rare. A tumor in the submaxillary salivary gland of a hamster where the salivary gland duct had been previously ligated was

attributable to *A. bovis* infection (Gorlin and Chaudry, 1959). Infection with this organism should be considered whenever an abscess is found.

Miscellaneous Bacterial Infections

Several conditions and/or lesions of hamsters have been reported to have a bacteria associated with them; however, there is a paucity of specific information on each disease. An "unidentified coryneform organism" has been associated with vaginitis (Sebesteny, 1979). Kidney lesions were reported to be due to *Proteus vulgaris*, *Proteus mirabilis*, and *E. coli* (Sebesteny, 1979). *Pseudomonas aeruginosa* has been listed as a cause of generalized fatal septicemia in hamsters (Sebesteny, 1979). *Staphylococcus aureus* may be associated with ulcerative dermatitis as well as cutaneous abscesses (Gleiser, 1974).

FUNGAL DISEASES

Although the hamster has been used as an animal model for fungal infections, spontaneously occurring fungal diseases are extremely rare. *Encephalitozoon cuniculi* is presently classified as an atypical fungus.

Dermatomycosis

Although dermatomycosis caused by *Trichophyton mentagrophytes* has occurred in the Djungarian hamster, cases in Syrian hamsters are not well documented. Sebesteny (1979) includes *Trichophyton* and *Microsporum* as causes of skin lesions in hamsters. The report states that infections with these organisms may be asymptomatic or may cause dry scaly encrustations with broken hair. Diagnosis can be confirmed with culture. Treatment with antifungal agents is reported by Sebesteny (1979) as not reliable; however, topical fungicides and oral griseofulvin may be attempted. Incidence of infection in hamsters or individual case reports are not described by Sebesteny (1979). Ringworm infections may be transmissible to humans as evidenced by a case of *T. mentagrophytes* infection which occurred on the arm of an employee working with hamsters in Romania (Alteras, 1966). Although hamsters were reported as the source of this human infection, cultures from suspected carrier hamsters were not recorded.

Cryptococcosis

Cryptococcal infection occurred concurrently with tuberculosis in a group of hamsters that experimentally received cortisone and a tumor transplant from a

human with tuberculosis (Chesterman, 1972). Multiple nodules containing mycobacterium and fungi, "morphologically indistinguishable from *Cryptococcus neoformans*", were observed. Nodules occurred in peritoneum, spleen, mesentery, and lungs 4 months after the tumor transplant.

INTRODUCTION

Compared to other species, such as the mouse and the rat, there are only very few viruses that have definitively been associated with the hamster and those that are, generally, affect the Syrian hamster. While we can only speculate as to the reasons for this phenomenon two explanations come to mind. It seems that the number of viruses found in laboratory rodents seems to be directly proportional to their popularity as experimental animals. Most rodent viruses, and the hamster is no exception, only produce subclinical infections in their hosts and they generally were only discovered accidentally. It stands to reason that these accidental discoveries would be more frequent, the more frequently an animal species is used in research.

Another possible explanation may be found in the history of the hamster, again primarily the Syrian hamster, and how they became introduced into the laboratory. All Syrian hamsters used today in animal research are believed to be descendants of only a handful of animals captured in Syria in 1930. One could argue that if there indeed has not been any additional contact with the wild population all hamster-specific viruses we know today must have been present in the initially captured animals. It is therefore not surprising that most of the agents described in this chapter have a broader host range and naturally infect other rodent species as well.

As mentioned above most viral infections in hamsters are clinically silent with the notable exception of the hamster polyomavirus and to a lesser degree the hamster parvovirus. These seem to be the only agents that consistently produce clinical disease. Not surprisingly these viruses may actually not be natural pathogens of the Syrian hamster. However, despite the lack of clinical signs the agents described in this chapter may have a significant negative impact on the research that is conducted while using infected animals. As the number of viruses, the potential for confounding biomedical research is most likely underreported. The one hamster virus that arguably has the most significant impact on human medicine is lymphocytic choriomeningitis virus (LCMV) due to its zoonotic potential. While it also is primarily a mouse virus, the hamster, albeit the pet hamster, is the most common animal species to transmit the virus to humans.

DNA VIRUSES

Hamster Polyomavirus

Background

Hamster polyomavirus was first reported by Graffi et al. in 1967 in a colony of Z3/BlnA Syrian hamsters. The hamsters developed spontaneous skin epitheliomas

from which viral particles were later identified (Graffi et al., 1968a, 1968b, 1970). The same virus also causes lymphoma, which is atypical of a polyomavirus (Delmas et al., 1985). The agent was previously misidentified as a papillomavirus; however, DNA sequencing and analysis of genetic structure have confirmed the virus as a polyomavirus (Bastien et al., 1985; Delmas et al., 1985; Simmons et al., 2001). The agent has been rarely reported in laboratory hamsters in the US and Europe, has been reported in an 8-week-old pet Syrian hamster and may be common in certain colonies of pet hamsters (Foster et al., 2002; Percy and Barthold, 2007; Simmons et al., 2001).

Historically, hamster polyomavirus has been abbreviated to HaPV. This abbreviation is confusing since hamster parvovirus is also abbreviated as HaPV. The International Committee on Taxonomy of Viruses uses the abbreviation HaPyV in reference to hamster polyomavirus, therefore that abbreviation will be used for this text (ICTV, 2002).

Etiology

HaPyV is a member of the Polyomaviridae family in the *Polyomavirus* genus (ICTV 2009). HaPyV is a closed, circular, supercoiled double-stranded, non-enveloped DNA virus, which has a 5366-bp genome, which is larger than mouse polyomavirus and SV40 (Bottger et al., 1971; Delmas et al., 1985; Scherneck et al., 1979). The ability of HaPyV to undergo episomal amplification and successfully integrate into the host genome is a quality that distinguishes it from papillomaviruses, which only replicate as episomes (Delmas et al., 1985; Simmons et al., 2001). Sequence homology also indicates that HaPyV is evolutionarily related to murine and simian polyomaviruses (Scherneck et al., 1979; Vogel et al., 1986). Similar to mouse polyomavirus strain A2, HaPyV has coding capacities on both DNA strands for the early and late transcriptional units of viral replication and they are the only polyomaviruses that produce middle T antigens (Delmas et al., 1985; Simmons et al., 2001; Vogel et al., 1986). Small, middle, and large T antigens are early-phase transcripts that regulate replication of the viral genome, activate the late-phase transcriptional unit, autoregulate the early promoter, and induce tumor formation (Courtneidge et al., 1991; Pipas, 1992; Simmons et al., 2001). It is known that HaPyV and its cloned DNA can transform rodent cell lines (Scherneck et al., 1987). Of the primate polyomaviruses, monkey lymphotropic virus (LPV) shares the greatest base sequence homology with HaPyV and also shares its lymphotropism (Vogel et al., 1986).

Epizootiology and Pathogenesis

Although the exact origin of HaPyV has not been determined, the virus has been isolated from the spleen

and kidney of subclinically infected European hamsters and this suggests that they are the natural hosts of the virus (Hannoun et al., 1974; Mahy, 2001). It is likely that the organism was transmitted to laboratory strains after the two species co-mingled (Barthold, 1991; Percy and Barthold, 2007).

Transmission of HaPyV is likely horizontal through ingestion of virions in the environment or from contaminated fomites and less likely from aerosolization of dried dirty litter (Ambrose and Coggin, 1975; Coggin et al., 1983). The virus enters target cells by endocytosis and is transported to the nucleus where it is uncoated and begins to replicate (Simmons et al., 2001). There are three reported phases of viral replication that include acute infection, viral clearance, and viral DNA accumulation leading to tumor induction (Prokoph et al., 1996). Within epitheliomas, infected cells are permissive to viral replication resulting in cell lysis and release of viral particles. Alternatively, cells may be non-permissive to replication leading to either genomic integration of the virus or, more commonly, episomal amplification with non-random deletions in the late coding regions of the genome. Lymphocytes appear to be non-permissive to viral replication resulting in neoplastic transformation of the host cell (Mazur et al., 1995; Scherneck et al., 1987; Simmons et al., 2001).

HaPyV is a unique viral entity in the papovavirus family in that it displays tropism for both undifferentiated keratinocytes and lymphocytes. Viral DNA has been localized within transformed lymphocytes, lymph nodes, bone marrow, renal tubular epithelium of the papillary collecting ducts, uterus, amnion, embryos, and in large quantities in jejunal enterocytes (Prokoph et al., 1996; Simmons et al., 2001). Some papers have reported only rare observation of viral DNA in trichoepitheliomas (Mazur et al., 1994; Prokoph et al., 1996). After inoculation with cell-free tumor extracts the virus proliferates in secondary lymphoid tissues in the thymus, spleen, and lymph nodes, as well as non-hematopoietic tissues such as the liver and less commonly in the lung and kidney (Mazur et al., 1994; Prokoph et al., 1996; Scherneck et al., 1979). Experimentally, thymectomy greatly reduces the occurrence of lymphoma in HaPyV-infected hamsters and supports the notion of viral tropism for T lymphocytes (Graffi et al., 1970; Rudolph and Graffi, 1973). It is presumed that viral spread occurs hematogenously through infected circulating lymphocytes.

HaPyV infection may be subclinical or, due to its variable tissue tropism, it may cause two different disease syndromes. The syndrome observed depends upon the immunological status of the colony and the age of the animal when infected. The first disease course is noted in naïve juvenile hamsters resulting in epizootic multicentric lymphoma mainly forming in the

mesentery, intestines, and liver, and often other organs such as the kidney and thymus (Barthold et al., 1987; Graffi et al., 1969; Simmons et al., 2001). In one report approximately half of a colony of inbred LSH and random bred LVG hamsters developed epizootic lymphomas around 17–19 weeks old when there had been no occurrences of lymphoma noted in the colony over the previous 5 years (Ambrose and Coggin, 1975; Coggin et al., 1983). Graffi et al. (1969) hypothesized that HaPyV induced lymphoma formation via activation of a secondary virus of a C-particle type, hamster leukemia virus. However, this was later discounted when other groups did not observe C-type particles in lymphomas or observed them in non-infected animals. The observation of C-type particles in lymphomas is now considered an incidental finding (Coggin et al., 1983; Graffi et al., 1969; Percy and Barthold, 2007; Scherneck et al., 1987).

Lymphoma may be induced by injection of virus or viral DNA (Barthold et al., 1987; Graffi et al., 1969, 1970). The agent has been successfully isolated from homogenized lymphomas in cell-free media using protamine sulfate buffer and although transmission of lymphoma is possible, Coggin et al. (1981) were unable to detect any viral or viral-like particles in the lymphoma using electron microscopy. Cell-free tumor transmission of epithelioma extracts may result in a 30–80% incidence of leukosis in naïve neonatal hamsters post-injection in 1–2 months, but can vary from 3 weeks to 8 months (Graffi et al., 1968b, 1969, 1970). The induced tumors can then be transferred into hamsters of all ages and produce localized tumors (Graffi et al., 1968a).

The second syndrome is observed in older hamsters or in colonies of endemically infected animals and results in the formation of trichoepitheliomas on the face, feet, neck, back, flanks, and less commonly on the abdomen of animals ranging in age from 3 months to over a year (Coggin et al., 1985; Graffi et al., 1968a, 1970; Simmons et al., 2001). One colony of random-bred HaB hamsters developed multiple skin epitheliomas in 5–10% of animals 6–9 months old (Graffi et al., 1968a, 1970, 1972; Scherneck and Feunteun, 1990). Young hamsters typically do not develop lymphomas due to protection from maternal antibodies (Barthold et al., 1987).

Simultaneous formation of epitheliomas and lymphomas in a single animal is a rare occurrence and the life cycle of HaPyV does not require tumor formation (Barthold et al., 1987). In contrast to HaPyV, murine polyomaviruses result in disease only in neonatal or immunocompromised animals, making HaPyV unique in causing disease in enzootically infected hamster colonies. Another difference between the two agents is noted in the ability of murine polyomavirus to induce multiple tumor types with the exclusion of lymphomas and leukemia (Courtneidge et al., 1991).

It is believed that, similar to mouse polyomavirus, HaPyV persists in the renal tubular epithelium and sheds viral particles in the urine thus contaminating the environment although some reports have indicated only small amounts of viral DNA in the kidneys (Mazur et al., 1994; Simmons et al., 2001). Additional routes of viral shedding are through virally infected keratinocytes exfoliated during grooming or aggressive interactions and virus-containing enterocytes released in feces that contaminate the environment and consumed by coprophagic cage mates (Simmons et al., 2001).

Clinical Manifestations

Animals with lymphoma may have variable clinical signs depending on the region infiltrated by the neoplasm, but may include reduced appetite, weight loss, diarrhea, dehydration, poor grooming, dyspnea, and ataxia. On physical examination animals may have palpable abdominal masses or enlarged lymph nodes (Barthold et al., 1987; Coggin et al., 1978, 1983; Simmons et al., 2001). Numerous secondary disease conditions have been reported in hamsters with epizootic lymphoma including non-bacterial enteritis, ileitis, ulcerative bowel disease, multiple intussusceptions, pyelonephritis, and hepatic disorders (Coggin et al., 1978, 1983; Mancini et al., 1984).

Trichoepitheliomas are observed as miliary nodules that develop and progress to coalescing nodules within the cutis. Tumor growth may be gradual and masses may regress spontaneously (Graffi et al., 1968a, 1970). No other adverse clinical effects have been noted.

Pathology

Lymphomas can appear in almost any tissue, but are most common in the intestines, mesentery, and liver. Tumors are also frequently observed in the spleen, cervical and mesenteric lymph nodes (Figure 31.1), occasionally in the thymus, stomach, kidney, skin, lung, diaphragm, aorta, skeletal muscle, bone marrow, testes, perirenal and axillary lymph nodes, variably in the spleen, and rarely in the eye and inguinal lymph nodes. Tumors may be single or multiple, and may be primary or metastatic lesions (Ambrose and Coggin, 1975; Barthold et al., 1987; Coggin et al., 1983; Graffi et al., 1968a, 1970). Tumors are round, soft, yellow-white in color and may have centralized necrosis (Coggin et al., 1983). Multiple adhesions may also be noted within the abdominal cavity (Simmons et al., 2001).

The morphological appearance of lymphomas can vary from immunoblastic to plasmacytoid. Cells may have round to oval nuclei that may be occasionally cleaved with varying degrees of mitosis or lymphomas may show moderated pleomorphism with increased cytoplasm, fascicular nuclei, irregular nuclear

FIGURE 31.1 Abdominal viscera of a hamster infected with epizootic hamster polyomavirus resulting in the formation of a large mesenteric mass (arrow) and hepatic lymphoma (Barthold et al., 1987).

membranes, and multiple nucleoli (Ambrose and Coggin, 1975; Coggin et al., 1983). Tumors are typically lymphoid, with myeloid, reticular and erythroid cellular types occurring less frequently (Graffi et al., 1968b, 1969; Prokoph et al., 1996). The majority of lymphomas in a large outbreak were B-cell origin, but T-cell lymphomas have been identified in the thymus (Coggin et al., 1978, 1983; Mazur et al., 1994). Lymphomas, in contrast to skin epitheliomas, do not contain viral particles (Graffi et al., 1970). Non-randomly deleted extrachromosomal viral DNA has been detected in large quantities in the neoplastic cells of lymphomas (Scherneck et al., 1987). These deletions are unique to DNA molecules of the lymphoma and may lead to the inactivation of viral production due to defects in late

FIGURE 31.2 Multiple trichoepitheliomas on the chin of a hamster infected with polyomavirus (Foster et al., 2002).

protein synthesis; consequently, tumor induction may not require viral production and viral mutations with accumulation of viral DNA may be favorable for oncogenesis (Mazur et al., 1995; Scherneck et al., 1987).

Trichoepitheliomas are observed as multicentric to coalescing nodules (Figure 31.2) within the cutis and subcutis (Courtneidge et al., 1991; Graffi et al., 1968a, 1969, 1970). Histologically, the epitheliomas originate from the hair follicular epithelium (Figure 31.3) and form cyst-like structures containing cornified cells and occasionally melanin (Figure 31.3) (Graffi et al., 1968a, 1968b, 1970). HaPyV virions are easily identified as approximately 40-nm diameter viral particles in the nuclei of keratinized cells, but they are never observed within the cells of the stratum basale or spinosum (Graffi et al., 1968a, 1970). Large numbers of mitotic figures may be observed within the basal epithelium (Graffi et al., 1968a). HaPyV has tropism for the hair follicular keratinocytes, which additionally distinguishes it from papillomaviruses that localize within interfollicular epidermal keratinocytes (Scherneck and Feunteun, 1990).

Diagnosis

Diagnosis of lymphoma in a hamster less than 2 years of age is strongly suggestive of HaPyV since lymphoma is rarely observed in young HaPyV-free hamsters (Coggin et al., 1983; McMartin, 1979; Trentin, 1987). The observation of trichoepitheliomas has always been associated with HaPyV infection in hamsters and is therefore diagnostic (Percy and Barthold, 2007). Confirmatory laboratory tests including PCR, histology, immunohistochemistry, and electron microscopy have all been described (Simmons et al., 2001). The virus can also be successfully grown in GD36 cells resulting in virions that are indistinguishable, both structurally and functionally, from virions isolated from epitheliomas (de la Roche Saint Andre et al., 1990).

FIGURE 31.3 Follicular lesions with central keratinization from a contact-exposed hamster with HaPyV cutaneous trichoepithelioma (Barthold et al., 1987).

Sentinel hamsters may help to identify epizootics of lymphoma. It has been reported that non-contact sentinels can develop lymphoma and contact sentinels can develop lymphoma or cutaneous epitheliomas (Barthold et al., 1987).

Prevention and Control

Therapy is not recommended due to potential for contamination of the animal facility. Culling of the entire colony, aggressive decontamination of the facility and improved use of personal protective equipment has failed to prevent new outbreaks in some facilities. In these colonies, incoming hamsters had no history of infectious lymphoma (Ambrose and Coggin, 1975; Coggin et al., 1978). The virus is stable in the environment for prolonged periods of time, is resistant to UV light, formaldehyde vapor, RNase, proteinase K, chlorinated and iodinated disinfectants, but susceptible to DNase, phenols, and KOH (Ambrose and Coggin, 1975; Coggin et al., 1983; Mancini et al., 1984).

Hamster Parvovirus

Background

Hamster parvovirus is a relatively new viral agent affecting multiple organ systems resulting in high mortality. It was first described in 1982 in a colony of Syrian hamsters that experienced high mortality in suckling and weanling animals (Gibson, 1983). Rodent parvoviruses are common contaminants of laboratory animal colonies, tumor transplants, and cell cultures, and may have confounding influences on immune, transplant, and cancer research (Jacoby et al., 1995; Shek et al., 1998; Smith et al. 1993).

Etiology

Hamster parvovirus is a 20-nm diameter, non-enveloped single-stranded DNA virus with an icosahedral capsid in the family Parvoviridae (Cotmore and Tattersall, 1987; Soderlund-Venermo et al., 2001). Approximately 92.6% of the negative-sense DNA genome is encapsidated (Besselsen et al., 1996). Molecularly, HaPV shares 94.6% sequence homology with MPV-1 and over 98% homology with MPV-3. HaPV also shares great similarity with the NS1 proteins of MVMc, MVMm, and MPV-3 and has similar VP1 amino acid sequences as MPV-1a, MPV-1b, and MPV-1c (Besselsen et al., 1996, 2006).

Epizootiology and Pathogenesis

It is suspected that the hamster may not be the natural host for HaPV due to the observation that many rodent parvoviruses, such as MPV, are subclinical in their host species and yet multiple rodent parvoviruses cause a similar course of disease in young hamsters (Christie et al., 2010). However, it should be noted that minute virus of mice and rat parvovirus can cause disease in their natural hosts (Christie et al., 2010; Jacoby et al., 1991; Kimsey et al., 1986). The mouse has been implicated as the natural host of HaPV due to the discovery of MPV-3 in mouse colonies that is nearly genetically identical to HaPV (Besselsen et al., 2006, 2008; Christie et al., 2010). Recent research has shown the experimental infection of immunocompetent and immunodeficient mice of various ages with HaPV that had similar pathogenesis to mice infected with MPV-1 and therefore HaPV may more appropriately be called MPV-3/HaPV until further characterization clarifies the relationship of these two organisms (Christie et al., 2010). Infection of hamsters with mouse MPV-3 has yet to be demonstrated.

MPV-3/HaPV is most likely acquired through ingestion or inhalation (Jacoby et al., 1996). Hamster parvovirus is distributed systemically throughout the infected animal possibly due to persistent viremia or viral DNA infection within endothelial cells (Besselsen et al., 1999; Christie et al., 2010).

Clinical Manifestations

Two- to 4-week-old hamsters ranging in weight from 15–20 grams are most susceptible to MPV-3/HaPV infection (Besselsen et al., 1999). Affected neonatal and weanling hamsters are runted with incisor abnormalities, domed craniums, small testicles, and a potbellied appearance (Gibson, 1983). Infection may also cause diarrhea, ataxia, and mortality resulting from hemorrhagic disease (Besselsen et al., 1999). Surviving hamsters seroconvert in 1–3 weeks, but animals remain persistently infected for several weeks. It is unclear whether persistently infected animals shed viral particles. Humoral immunity protects animals from subsequent infections. Infection in adult hamsters is typically subclinical (Jacoby et al., 1988, 1996).

Pathology

An array of lesions may be noted grossly and include incisor root abscesses, periodontal disease, discolored, malformed or absent incisors, and facial bone deformities (Besselsen et al., 1999). Internal examination may reveal intestinal hemorrhage, renal petechiation, a pale liver and spleen, testicular atrophy, and cerebellar hypoplasia (Besselsen et al., 1999).

Histologically, there may be necrosis, hemorrhage, inflammation, and mineralization of the incisive dental pulp with enamel hypoplasia (Figure 31.4) resulting from ameloblast necrosis (Besselsen et al., 1999; Gibson, 1983). Periodontitis, monocytic infiltration of the dental lamina, and alveolar bone osteoclasts are additional lesions noted in the oral cavity (Gibson, 1983). Hemorrhage beneath the renal capsule, adjacent to the cerebral lateral ventricles, and in the granular layer of the cerebellum, gastrointestinal tract, testicles, uterus, and hippocampus may be noted (Besselsen et al., 1999). Other lesions include multifocal cerebral mineralization, testicular hypoplasia with multifocal epithelial necrosis, mineralization of the seminiferous tubules, and pampiniform plexus perivasculitis (Gibson, 1983; Jacoby et al., 1996). Low viral doses of MPV-3/HaPV inoculated into young hamsters result in a mild disease with incisor and testicular abnormalities, whereas high viral doses result in a multi-systemic hemorrhagic syndrome involving multiple organ systems (Besselsen et al., 1999). Basophilic intranuclear inclusion bodies have been observed in the endothelial and mesenchymal cells of the small intestine (Besselsen et al., 1999).

MPV-3/HaPV may be cultured in baby hamster kidney (BHK-21) cells and rat RN cells. Culture in human NB3224K cells is possible but with lower kinetics whereas murine cells have not been shown to be permissive to viral infection with MPV-3/HaPV (Besselsen et al., 1996; Soderlund-Venermo et al., 2001).

FIGURE 31.4 Longitudinal photomicrographs of incisors from (A) a 6-week-old sham-infected hamster and (B) an age-matched HaPV-infected animal with enamel hypoplasia. E, enamel hypoplasia; F, fibrosis; M, mineralization (Besselsen et al., 1999).

Diagnosis

Diagnosis may be made with PCR using MPV-3/HaPV-specific primers for viral DNA or with bead-based suspension microarray for MPV-3/HaPV antibody detection (Besselsen et al., 1999, 2006; Christie et al., 2010; Redig and Besselsen, 2001). MPV-3/HaPV may cross-react to MPV-1 in hemagglutination inhibition assays (Besselsen et al., 1996).

Prevention and Control

Infection of mice with MPV can have serious research implications that include tumor suppression, accelerated graft rejection, and alteration in interferon production and lymphocyte proliferation and activity; therefore, careful consideration is required when using hamsters infected with MPV-3/HaPV in these types of studies (Christie et al., 2010; Shek et al., 1998; Smith et al., 1993). Monitoring cell lines, serum, and transplantable tumors prior to introduction into a colony is critical to preventing introduction of MPV-3/HaPV. If the agent is inadvertently introduced into the colony then control measures similar to those employed for mice should be used and include quarantine, thorough facility disinfection, and restocking with non-infected animal. The agent may be killed by heat sterilization of caging and equipment (Jacoby et al., 1996).

Adenovirus

Background

Adenoviral inclusion bodies are commonly found in naturally infected hamsters but no specific hamster adenovirus has been isolated. Hamsters can be experimentally infected with adenoviruses from a variety of other species (ICTV, 2002).

Clinical Manifestations

Adenoviral infections are typically subclinical unless an animal is stressed or immunocompromised (Richter, 1986). Seroconversion to two strains of murine adenovirus, FL strain (MAdV-1) and K87 strain (MAdV-2), has been reported to naturally infect laboratory hamsters (Gibson et al., 1990; Reed et al., 1974; Schoonermark-van de Ven et al., 2006; Suzuki et al., 1982; Wigand et al., 1977). Hamsters infected naturally with adenovirus are typically subclinical (Gibson et al., 1990). Experimental inoculation of neonatal hamsters with adenoviruses from other species, including primates, mice, bovids, and poultry, has been used to induce oncogenesis in a variety of tissues (Trentin, 1987; Trentin et al., 1962).

Pathogenesis and Pathology

In mice, MAdV-1 infection is chronic with persistent shedding of virus in the urine for months, whereas MAdV-2 infection is shed in the feces from infected intestinal cells for 3–4 weeks (Richter, 1986). Naturally infected weanling hamsters with antibodies to enteric MAdV-2 displayed large amphophilic intranuclear inclusions in ileal enterocytes overlying gut-associated lymphoid tissue, goblet cells, and rarely crypt cells of the ileum and jejunum. The adenoviral particles formed paracrystalline arrays only in condensed nuclei of pyknotic intestinal cells (Gibson et al., 1990). Only sporadic evidence of hamsters with antibodies to MAdV-1 has been reported (Suzuki et al., 1982).

Diagnosis, Prevention, and Control

Adenoviral infections may be diagnosed using serology and electron microscopy (Gibson et al., 1990; Percy and Barthold, 2007). The significance of adenoviral infection in hamsters is unknown (Percy and Barthold, 2007).

Cricetid Herpesvirus

Cricetid herpesvirus (CrHV-1), also known as hamster cytomegalovirus, is a double-stranded, linear DNA virus that has been rarely reported in adult Chinese hamsters (*Cricetulus griseus*) (Davison et al., 2009; ICTV 2002; Kuttner and Wang, 1934). Infection in Chinese hamsters is clinically silent (Kuttner and Wang, 1934). Sialodacryoadenitis due to viral infection resulting in keratoconjunctivitis sicca, exophthalmia, and proptosis has been suggested in pet hamsters (Donnelly, 2003). Young hamsters inoculated intracerebrally with tissues from infected adult hamsters died within days after inoculation with meningitis and intranuclear inclusions (Kuttner and Wang, 1934). Eosinophilic intranuclear and intracytoplasmic inclusions in the acinar epithelium and mononuclear cell infiltrates have been observed in the submaxillary glands in adult hamsters naturally infected with the virus (Kuttner and Wang, 1934). The impact and significance of this virus on research in laboratory colonies of Chinese hamsters remains unknown.

Hamster Oral Papillomavirus

Background and Etiology

Virally induced oral papillomas were discovered in a model of lingual carcinoma in Syrian hamsters after tumor induction with a combination of 9,10-dimethyl-1,2-benzanthracene (DMBA) and wounding (Iwasaki et al., 1997; Maeda and Kameyama, 1986; Maeda et al., 1989). Episomal nucleic acid was identified and the genome of the supercoiled DNA virus was digested revealing a unique viral entity distinct from other rodent papillomaviruses and HaPyV. The agent was classified as hamster oral papillomavirus (HaOPV) (ICTV, 2002; Iwasaki et al., 1997).

Epizootiology and Pathogenesis

It has been reported that the formation of lingual lesions requires application of a chemical carcinogen in combination with wounding as either method alone is not sufficient in hamsters (Maeda et al., 1989). The administration of a chemical carcinogen possibly reactivates a latent virus that can be identified in large quantities by PCR and Southern blot hybridization. In the same study, small amounts of HaOPV DNA were identified only by PCR in normal, untreated lingual tissue (Iwasaki et al., 1997).

Clinical Manifestations and Pathology

Lingual lesions were small (~1 mm in diameter) with squamous epithelium, disoriented stratification, cellular and nuclear pleomorphism, aggregations of perinuclear hyalin, basal cell proliferation, koilocytotic changes that are consistent with papillomas observed in other species

and a mild inflammatory response (Iwasaki et al. 1997; Maeda et al. 1989). The significance of HaOPV in other models and research remains unknown.

RNA VIRUSES

Sendai Virus

Background

In 1952 an unrecognized infectious agent was isolated from a mouse that had been inoculated with a lung emulsion from the autopsied lung of a newborn child (Kuroya et al., 1953; Sano et al., 1953). Because the isolated virus was thought to have originated in the newborn child, Sendai was initially believed to be a human respiratory virus and was subsequently named "Newborn Virus Pneumonitis (Type Sendai)" (Sano et al., 1953). In 1954 it was proposed that the virus was not of human origin and may have been present in the mice used for the initial viral isolation (Fukumi et al., 1954). The close relationship between Sendai virus and human parainfluenza 1 may have created confusion regarding the host origin of the virus. Human parainfluenza 1 was isolated subsequent to Sendai in 1958 (Brownstein, 2007; Chanock et al., 1958).

Sendai virus is considered to be the prototype virus of the family Paramyxoviridae (Homma et al., 1999) and is an agent of significance because it is capable of causing morbidity and mortality in mice, rats, and hamsters. Sendai is an undesirable pathogen in rodent research colonies because of the gross and microscopic lesions created by the virus and the ability of the virus to alter humoral and cell-mediated immune responses (Kay, 1978; Warr and Jakab, 1979). Additionally Sendai viral infections may also influence experimental carcinogenesis and Sendai has been reported to alter the tumorigenicity of transplantable tumor lines (Aderka et al., 1986; Matsuya et al., 1978; Peck et al., 1983).

Etiology

Sendai virus belongs to the genus *Respirovirus* of the subfamily *Paramyxovirinae* in the family *Paramyxoviridae* and is considered a murine subtype of human parainfluenza type 1 (ICTV, 2009). Sendai virus morphologically appears as an enveloped spherical to filamentous virion. The virus is composed of single-stranded negative-sense RNA genome (Homma et al., 1999). Viral replication occurs exclusively in the cytoplasm of the host cell. One replication cycle takes approximately 12–15 hours with one cell yielding thousands of virions (Homma et al., 1999).

One of the three functional proteins associated with the virion envelope, the fusion (F) protein, needs to be cleaved into two disulfide subunits before becoming

biologically active. Specific proteases within the host are responsible for initiating cleavage. These “activating” proteases are primarily found within the respiratory tract. One serine protease, “Trypsin Clara”, is thought to be partially responsible for the respiratory tropism of the virus. Trypsin Clara is secreted by Clara cells located throughout the terminal conducting airways and is a protease capable of cleaving F, thereby activating the virus (Kido et al., 1992; Tashiro et al., 1992).

Epizootiology and Pathogenesis

The natural host range includes mice, rats, and Syrian and Chinese hamsters (Parker et al., 1966; Percy and Barthold, 2007; Percy and Palmer, 1997). Guinea pigs have been shown to be susceptible to experimental infection (Elwood et al., 1993). Population studies in the 1960s and 1970s varied widely suggesting that 50–83% of hamster colonies were affected (Ishida and Homma, 1978; Parker et al., 1987). Alternatively, a study done in 1974 testing 201 Syrian hamsters, reported only 2% to have antibody to Sendai virus (Reed et al., 1974). No further epidemiological data in hamsters have been published since then, but based on more recent reports in mice and rats suggest a decreasing overall prevalence in laboratory animals (Zenner and Regnault, 2000).

Transmission studies in mice have indicated that direct contact with infected rodents or contaminated fomites constitutes the primary route of infection. Aerosol inhalation has been successfully used to experimentally infect hamsters (Blandford and Charlton, 1977). Findings in mice and rats suggest vertical transmission can occur after experimental infection. A study in hamsters found no difference in susceptibility to Sendai virus based on age at the time of exposure, however, virus replication was found to be higher in younger animals (van Nunen and van der Veen, 1967).

It has been determined in studies done in the mouse that natural infection causes a descending infection which is usually restricted to the mucociliary epithelium of conducting airways. Sendai virus is capable of spreading to the alveolar epithelium, although there seems to be limited viral replication at this level (Brownstein, 2007). Viral infection promotes the secretion of trypsin Clara (located in non-ciliated secretory cells of terminal conducting airways) and assists in viral replication by cleaving the F glycoprotein (Kido et al., 1992; Tashiro et al., 1992). In male Syrian hamsters intranasally inoculated with Sendai, viral antigen was present postinoculation day (PID) 3 in the respiratory tract epithelium of the nasal passages and trachea with bronchiolar extension by PID 5. Antibodies were first detected PID 7 with antibody titers remaining high throughout the 21-day study (Percy and Palmer, 1997).

Clinical Manifestations

Sendai infection in Syrian hamsters typically is clinically silent with low mortality rates (Parker et al., 1987; Profeta et al., 1969). Occasional deaths in suckling hamsters were reported from one enzootically infected colony (Profeta et al., 1969). Chinese hamsters and immunosuppressed Syrian hamsters can succumb to the disease and are documented to have extensive pulmonary lesions (Blandford and Charlton, 1977; Parker et al., 1987). Sendai virus may exacerbate secondary bacterial or *Mycoplasma* infections in hamsters. Increased lesion severity has been reported in mice experimentally co-infected with Sendai virus, *Haemophilus influenza*, and *Pasteurella pneumotropica* infections (Degre, 1970; Jakab, 1974).

Pathology

Microscopic lesions associated with natural Sendai virus infection in hamsters typically consist of a focal to segmental rhinitis progressing to necrotizing tracheitis and multifocal bronchiolitis (Percy and Barthold, 2007). Secondary bacterial infection of the lung can complicate the pathologic picture (Parker et al., 1987). Lung consolidation has been noted grossly in newborn hamsters (Hankenson and Van Hoosier, 2002b). In male Syrian hamsters inoculated intranasally with Sendai virus, gross necropsy findings were restricted to PID 5–7 and were consistent with pneumonia, characterized as dark pink to tan mottling at the hilus of the lung extending into the adjacent parenchyma (Percy and Palmer, 1997). At PID 3 minimal histopathologic findings were present, confined to the trachea and epithelium of the nasal turbinates. Cellular changes varied from hyperplasia to cytoplasmic vacuolation and degeneration of respiratory epithelial cells. Lesions were histologically evident in the lower portion of the respiratory tract by PID 7. Hyperplasia of the epithelial cells with peribronchial edema and peribronchial lymphocytic infiltration was found in affected airways. Microscopic reparative lesions could still be detected at PID 16 and 21 in the nasal passages, trachea, and alveoli (Percy and Palmer, 1997). A transient renal immune complex deposition has been reported in a small percentage of experimentally infected hamsters (Blandford and Charlton, 1977).

Diagnosis

Due to the non-specific nature of the lesions, a diagnosis of Sendai virus generally cannot be made based on gross or histopathologic lesions, nor can a single test detect viral infection at all stages of the disease. During the acute phase of the infection, virus isolation and reverse-transcriptase polymerase chain reaction (RT-PCR) can be used to detect virus in lung tissue or nasal washes. However, virus may no longer be present when the animal is displaying clinical symptoms

(Brownstein, 2007). RT-PCR can also be used to detect viral RNA in environmental samples and contaminated biological materials (Wagner et al., 2003).

Enzyme-linked immunosorbent assay (ELISA), indirect immunofluorescence assay (IFA), and multiplexed bead-based immunoassays are available serologic methods of detection. Antibody to Sendai virus can be detected 10–12 days following infection, although some studies demonstrate that antibody can occasionally be detected as early as day 7 (Liang et al., 1999; Parker et al., 1979).

Prevention and Control

There are no current published reports that document the elimination of Sendai from a hamster population. The best approach is to prevent introduction by purchasing animals that are known to be free of the virus (Parker et al., 1987). A program for colony surveillance should be established. Dirty-bedding sentinel programs have been found to be less efficacious at detecting Sendai virus in a colony of mice (Compton et al., 2004). In mice, seroconversion among dirty-bedding sentinels is variable and appears to be both dose- and strain-dependent (Artwohl et al., 1994). A more effective means of colony monitoring could include the exposure of dirty-bedding sentinels to exhaust air from individually ventilated caging systems (Compton et al., 2004). Animal biological products should be screened by PCR or by hamster antibody production (HAP) test before use in colony animals. If populations of rodents are suspected to be harboring Sendai virus infections within the same vivarium, hamsters should be maintained under strict isolation or barrier conditions to prevent cross-infection (Hankenson and Van Hoosier, 2002; Parker et al., 1987). Though never documented, culling of the colony should be an effective method to eliminate the virus. Another option could be isolation and a strict breeding moratorium for 8 weeks, which has been shown to effectively eliminate the infection in mice (Parker et al., 1987).

Lymphocytic Choriomeningitis Virus

Background

Lymphocytic choriomeningitis virus (LCMV) was discovered by Armstrong and Lillie during a 1933 investigation of an outbreak of St. Louis encephalitis in humans. The virus was named after the brain lesions it induced when inoculated into mice and monkeys (Armstrong and Lillie, 1934). LCMV was found to cause an aseptic meningitis in humans (Armstrong and Wooley, 1937). It was later discovered that the immune system played a significant role in the pathogenesis of LCMV-related disease (Buchmeier and Oldstone, 1978).

LCMV has been studied extensively and is considered the prototype virus of the arenavirus family, most often used as a model for virus-induced immune complex disease (Buchmeier and Oldstone, 1978; Oldstone and Dixon, 1969). Syrian hamsters are highly susceptible to persistent natural infections with LCMV, and the virus poses a serious public health risk due to its zoonotic potential. Congenital infection in humans has been implicated in causing chorioretinitis, hydrocephalus, microencephaly, or macroencephaly, and mental retardation in infants (Barton and Hyndman, 2000; Barton and Mets, 2001; Barton et al., 1995; Bonthius et al., 2008). Transfer of the virus from Syrian hamsters, as well as their transplantable tumors, to laboratory animal personnel or pet owners has been documented (Armstrong et al., 1969; Biggar et al., 1975, 1977; Bowen et al., 1975; Deibel et al., 1975; Gregg, 1975; Hinman et al., 1975; Hotchin et al., 1974; Maetz et al., 1976; Skinner et al., 1976). In addition, LCMV can persistently infect standard hamster cell lines which remain capable of infecting susceptible species (Biggar et al., 1976; van der Zeijst et al., 1983). LCMV transmission has also been documented with solid organ transplantation. In December 2003 and April 2005 a cluster of transplant recipients whose donor had been exposed to LCMV died of fatal lymphocytic choriomeningitis (Amman et al., 2007; CDC, 2005). LCMV viral sequences from the 2005 outbreak were identical to those found in the donor's pet hamster and the infection could be traced back to a hamster breeding colony that distributed animals nationwide (Amman et al., 2007). Medical practitioners speculate that LCMV may be frequently overlooked and underdiagnosed in human patients with neurologic disease (Barton and Hyndman, 2000; Jamieson et al., 2006).

Etiology

LCMV belongs to the family *Arenaviridae*, genus *Arenavirus* (ICTV, 2009). Arenaviruses are divided into Old World and New World serocomplexes which share genetic and antigenic relationships with one another. LCMV is included in the Old World group of viruses along with Ipply, Mobala, Mopeia, and Lassa viruses (Auperin et al., 1982; Mason et al., 2005).

Arenavirus virions are composed of a lipid-containing envelope which is covered with glycoprotein spikes evenly distributed over the envelope surface (Neuman et al., 2005). The *Arenaviridae* genome consists of two single-stranded negative-sense RNA molecules designated L (large) and S (small), coding for non-structural and structural proteins, respectively (Romanowski and Bishop, 1985; Salvato and Shimomaye, 1989).

Laboratory strains of LCMV include among others the Armstrong (Arm) and several of its variants, WE, and the Fortner strain (Dutko and Oldstone, 1983; Parker et al., 1976). The biological behavior of each strain varies.

Strains that are passaged intracerebrally, such as Arm CA 1371, enhance the neurotropism of the virus and can cause severe illness and mortality. Wild-type strains, such as the Fortner, tend to be “docile” and are more likely to induce immunosuppression (Hotchin et al., 1962; Parker et al., 1976).

Epizootiology and Pathogenesis

Mus musculus is considered the primary reservoir for LCMV (Hankenson and Van Hoosier Jr., 2002). The hamster has been implicated as a secondary reservoir and is highly susceptible to persisting natural infections (Bonthius et al., 2008; Skinner et al., 1976; Smadel and Wall, 1942). Guinea pigs, non-human primates, and humans also demonstrate a natural susceptibility to infection and disease (Skinner and Knight, 1979; Traub, 1936). A host of other species have been experimentally infected with LCMV such as rabbits, rats, dogs, cats, birds, ferrets, voles, cotton rats, horses, cows, and pigs (Lehmann-Grube, 1972; Skinner and Knight, 1979).

LCMV is found worldwide. Seroprevalence in feral mouse populations ranges from 2.5% to 9.0% in the United States, 6.8% in northern Italy, and 7.0% in Japan (Childs et al., 1992; Morita et al., 1991; Tagliapietra et al., 2009). Approximately 3% of pet hamsters from a single rodent distributor implicated in the 2005 LCMV solid organ transplant outbreak were found to be seropositive for the virus (Jay et al., 2005). In a 1993 survey of biological contaminants, LCMV was isolated from 28% of hamster transplantable tumors (Nicklas et al., 1993). Serologic surveys performed in the 1990s on healthy men and women living in Birmingham, Alabama and in Baltimore, Maryland found that 5.1% and 4.7%, respectively, possessed antibodies to LCMV (Childs et al., 1992; Stephenson et al., 1992).

High concentrations of virus have been identified in the blood, organs, urine, and feces of Syrian hamsters (Skinner and Knight, 1979; Smadel and Wall, 1942; Thacker et al., 1982). Viral shedding occurs primarily in the urine and saliva, but also in feces, milk, semen, and nasal secretions (Skinner and Knight, 1979; Traub, 1936). LCMV can be transmitted vertically or horizontally. Direct contact has been found to be the most efficient mode of horizontal transmission, specifically when traumatized epidermis or mucous membranes were exposed to infectious urine or saliva (Skinner and Knight, 1973, 1979). Indirect contact has been described in mice (Traub, 1936). Humans can be infected either by direct contact or inhalation of infectious aerosolized rodent excretions or secretions (Amman et al., 2007; Bowen et al., 1975; Skinner and Knight, 1979).

The pathogenesis of an LCMV infection in hamsters depends on the age of animal, the virus strain, dose, and route of inoculation. In one study 50% of hamsters inoculated parenterally as neonates developed

a persistent infection with lifelong viremia and viruria. The rest of the animals cleared the infection after 6 months of viremia and 12 months of viruria. Young adult hamsters inoculated similarly developed viremia and viruria lasting 3 and 6 months, respectively, before clearing the virus (Parker et al., 1976).

In immunocompetent adult mice experimentally inoculated with virus, the host immune response results in a CD8+ T-cell-mediated disease involving multiple organs. How severely each organ is affected by CD8+ T-cell-mediated disease depends on the route of inoculation. For example, intracerebral inoculation results in more notable brain lesions, while intraperitoneal inoculation results in more notable liver lesions (Hotchin et al., 1962).

Clinical Manifestations

Disease manifestation is ultimately dependent on a variety of factors including virus strain or variant, dose of virus administered, route of infection, age of the host, strain of the host, and host immunocompetence (Barthold and Smith, 2007). The clinical manifestations of natural disease also vary from what is seen clinically with experimental disease.

Natural LCMV infection in adult hamsters generally causes an acute short-term infection that rarely causes clinical signs of illness. Infections in perinatally exposed hamsters remain subclinical for at least 6 months even though the animals are shedding large amounts of virus during this period (Skinner and Knight, 1979; Skinner et al., 1976; Smadel and Wall, 1942). However, animals that remained persistently infected past this time developed a progressive wasting disease characterized by reduced activity, ruffled fur, hunched posture, blepharitis, and weight loss. These clinical signs can persist for weeks or months until the animals become moribund (Parker et al., 1976; Skinner et al., 1976). Studies have found that all hamsters, regardless of age or strain, are uniformly susceptible to the fatal wasting disease caused by LCMV when they are treated concurrently with immunosuppressive agents (Genovesi et al., 1988).

Pathology

Pathologic lesions of LCMV vary based on the animal's age, virus strain, virus dose, and the route of administration. Hamsters infected as adults or perinatally infected animals that are able to clear the virus develop minimal to moderate transient lymphocytic infiltration of the visceral organs (Parker et al., 1976). However, perinatally infected animals that are unable to clear the infection develop chronic disease characterized by lymphocytic infiltration of liver, lung, pancreas, kidney, spleen, meninges, and brain (Genovesi et al., 1988; Oldstone and Dixon, 1969; Parker et al., 1976;) as well as a widespread vasculitis and progressive

glomerulonephritis (Genovesi et al., 1988; Parker et al., 1976). The progressive glomerulonephritis can be attributed to antigen–antibody complex deposition in the arterioles and glomerular basement membranes of infected kidney (Buchmeier and Oldstone, 1978; Oldstone and Dixon, 1969). Pancreatic lesions can also be found with subacute and chronic interstitial pancreatitis, acinar atrophy, and interstitial fibrosis and have been associated with hyperglycemia and abnormal glucose tolerance (Oldstone et al., 1984).

Diagnosis

Care must be taken when using dirty-bedding sentinels to screen hamster colonies for LCMV as the virus is best transmitted via direct contact and viral transmission through dirty bedding is limited (Ike et al., 2007). Contact sentinels should be considered if LCMV is suspected to be endemic in a colony or if the colony is considered to be a high exposure risk. Serologic screening for LCMV in enzootically infected colonies may be difficult. Studies in persistently infected mice have yielded mixed results. Some found that circulating antibody to LCMV was difficult to detect presumably due to the formation of antigen–antibody complexes with the high number of viral particles present in the bloodstream (Oldstone and Dixon, 1969). Others have found that the detection of serum antibodies to LCMV was possible in most of the animals tested by both ELISA and IFA (Homberger et al., 1995). An investigation during a recent outbreak of LCMV in pet hamsters found that most hamsters where viral RNA was detected in the kidney were negative by ELISA, while some were positive by IFA (Amman et al., 2007). The efficacy of serologic testing is thus most likely assay-dependent and should not be used as the sole means to determine the status of a colony but a combination of screening tests should be used. Alternatively HAP (hamster antibody production) or PCR (polymerase chain reaction) could be used. LCMV infection in symptomatic hamsters can be readily diagnosed by serology using IFA, ELISA, or multiplexed bead-based immunoassays (Homberger et al., 1995; Thacker et al., 1982).

Prevention and Control

When populating a facility, it is important to purchase LCMV-free hamsters from reputable vendors and perform regular serologic surveillance of hamster colonies. It is also important to include in the regular surveillance any mouse colonies which could potentially be a source of exposure for hamster colonies. A pest control program needs to be established to prevent direct or indirect contact with feral mice. In addition, screening of transplantable tumors and hamster- or mouse-derived cell lines is strongly advised (Biggar et al., 1976). Studies that are utilizing LCMV or LCMV-infected animals require CDC Biosafety Level 3 containment

(Jay et al., 2005). If an LCMV outbreak were to occur, quarantine, depopulation, and thorough decontamination are recommended (Hankenson and Van Hoosier, 2002). If attempting to rederive a colony, embryos should be washed prior to transfer. Progeny should then be monitored using a combination of screening tests to confirm elimination of the virus (Ike et al., 2007).

Pneumonia Virus of Mice

Background

Pneumonia virus of mice (PVM) was discovered in 1938 during an attempt to isolate virus from human nasopharyngeal washes by serially passaging them through mice (Horsfall and Hahn, 1940). Although closely related to Sendai virus, PVM is less pathogenic and is only known to cause disease in immunocompromised mice (Brownstein, 2007). It has not been as extensively studied as Sendai virus, however, PVM infection in mice is an important model for human respiratory syncytial virus, a Pneumovirus pathogen in children (Cook et al., 1998; Rosenberg and Domachowske, 2008; Rosenberg et al., 2005).

Etiology

PVM is classified as a *Pneumovirus* of the family *Paramyxoviridae* (ICTV, 2009). PVM is pleomorphic, capable of forming both filaments and spheres, with a single-stranded negative-sense RNA genome (Compans et al., 1967). Pneumoviruses differ from other parainfluenza viruses because they lack neuraminidase. There are two primary glycosylated proteins associated with the virion envelope, the G protein and the fusion glycoprotein (F). The G protein mediates viral attachment and hemagglutination (Levine et al., 1987; Ling and Pringle, 1989). The F protein mediates fusion of the viral envelope with the host cell. As in Sendai virus, the F protein of PVM requires cleavage by host proteases in order to be biologically activated (Brownstein, 2007). PVM has been reported to grow in hamster kidney cell cultures and chick embryo cultures (Harter and Choppin, 1967; Tennant and Ward, 1962).

Epizootiology and Pathogenesis

The natural host range of PVM consists of mice, rats, and hamsters (Brownstein, 2007). However, it should be noted that the only documented isolation of PVM from hamsters was performed from animals inoculated with lung tissue suspension from mice (Pearson and Eaton, 1940). Antibody to PVM has been frequently isolated from hamsters in the past in North America, Europe, and Asia (Carthew et al., 1978; Gannon and Carthew, 1980; Lussier and Descoteaux, 1986). Early reported prevalence rates in hamster colonies have varied from

as high as 83% to as low as 10%, and were frequently found to be higher than prevalence rates reported in mouse colonies (Lussier and Descoteaux, 1986; Parker et al., 1987; Reed et al., 1974). There appeared to be a lower prevalence of PVM antibody among Chinese hamster (*Cricetus griseus*) colonies (Schiff et al., 1973). More recent surveys indicate that the prevalence of this pathogen has declined (Brownstein, 2007).

There are no documented reports of naturally occurring clinical disease associated with PVM in the hamster and the epizootiology of PVM in the hamster remains unknown. Studies done in mice indicate that PVM is not easily transmitted and that it is most likely spread through direct contact with respiratory secretions (Brownstein, 2007; Horsfall and Hahn, 1940). It has been shown that vertical transmission does not occur because antibody titers can be eliminated through cesarean derivation in successive generations of hamsters (Parker et al., 1987; Van Hoosier et al., 1970).

In pathogenesis studies performed in mice, PVM infection is restricted to the respiratory tract. Natural infection or intranasal dosing of immunocompetent mice with low viral loads appears to result in disease that is restricted to the nasal epithelium (Smith et al., 1984). Experimental inoculation of high viral loads has led to evidence of viral replication in the lower respiratory tract (Volkert and Horsfall, 1947).

Clinical Manifestations

There are no documented reports of naturally occurring clinical disease or mortality from PVM in hamsters (Parker et al., 1987). Hamsters inoculated with PVM intranasally by Horsfall and Hahn in 1939 did not display any signs of clinical disease (Horsfall and Hahn, 1940). Hamsters experimentally inoculated with mouse-passaged lung suspension showed signs of sneezing, dyspnea, and weakness with high mortality, however, retrospectively it is unclear whether PVM had been the only pathogen present (Pearson and Eaton, 1940).

Pathology

Experimental inoculation of hamsters with mouse lung suspension containing PVM has been shown to cause interstitial pneumonia with moderate to severe lung consolidation in a very early study (Pearson and Eaton, 1940). Swollen hyperemic nasal turbinates with a transient mild erosive rhinitis has been reported in both experimentally inoculated hamsters and mice (Pearson and Eaton, 1940; Smith et al., 1984).

Diagnosis

The detection of serum antibodies is the most commonly used diagnostic technique for routine monitoring. ELISA, IFA, and multiplexed bead-based immunoassays are available and show high specificity

and sensitivity. Viral isolation and RT-PCR have been described, however, due to the low prevalence of the virus and the absence of clinical signs in the infected animals these techniques are not useful as screening tools (Brownstein, 2007; Wagner et al., 2003).

Prevention and Control

The best form of control is prevention through the purchase of hamsters that are free of the virus and by performing regular serologic screening. Cesarean derivation and foster rearing eliminated infection in one hamster colony (Van Hoosier et al., 1970). Natural infection is thought to result in immunity (Tennant et al., 1966).

MISCELLANEOUS VIRUSES

A number of viruses have historically been associated with hamsters based on the detection of antibodies that cross-react with viral antigens used in mouse and rat serology. These agents include reovirus 3 (Reo-3), Theiler's meningoencephalitis virus of mice (TMEV), simian virus 5 (SV-5), and Toolan's H-1 virus (Parker et al., 1976; Percy and Barthold, 2007). Reo-3 is a virus with a broad host range infecting more than 60 animal species, however, the virus has never been isolated from a hamster and the presence of serum antibodies has never been correlated with clinical disease (Parker et al., 1987). The presence of TMEV and SV-5 antibodies could potentially be due to the hamsters being infected with closely related viruses. However, the presence of these viruses has never been confirmed in hamsters, the agents have not been isolated and again there is no clinical disease associated with them (Percy and Barthold, 2007). There is a single report of an enzootic outbreak of H-1 in a hamster breeding colony causing clinical disease in suckling and weanling hamsters (Gibson, 1983) but this is considered to be part of the hamster parvovirus cluster and is discussed there. Finally there is histological evidence of C-type particles associated with an endogenous retrovirus that was briefly thought to be involved in lymphoma formation during a hamster polyomavirus infection (Graffi et al., 1969). This is discussed in the polyomavirus section.

INTRODUCTION

There is a dearth of information on naturally occurring parasitism of the Syrian hamster (*Mesocricetus auratus*). This is somewhat surprising considering this species has never been successfully rederived by cesarean section. In this chapter, we provide information specific to the Syrian hamster when it is available. Information is also drawn from the literature pertaining to the same or similar parasites of other rodent species when it is applicable and relevant to the hamster, especially with respect to prevention, treatment, and

eradication. The limited available information on parasites of other hamster species is also presented.

Commercially reared Syrian hamsters available today for use in the laboratory harbor a plethora of non-pathogenic commensal protozoa and often *Demodex* spp. mites as they have never been successfully cesarian rederived. Interestingly, a protocol for generating protozoa-free hamsters using carbasone and quinacrine was reported by Saxe in the early 1950s (Wagner, 1987). Although there is limited literature pertaining to the indigenous parasites of the Syrian hamster, this species has historically and continues to serve as an important

model for a variety of diseases caused by various protozoal and helminth species including *Leishmania* spp., *Schistosoma* spp., *Fasciola* spp., and *Ancylostoma* spp., among others.

There are numerous treatment regimens published for eradication of parasitic diseases from laboratory rodents, each with associated challenges and the potential to confound research. Colony size, age, strain, and immune status may impact successful treatment. Inadequate treatment of all animals greatly increases the possibility of treatment failure. Dosing regimens extrapolated from other rodent species may also be inadequate and there is a potential for the development of resistance. Lastly, as with avermectins, treatment may present a health risk to the animal.

PROTOZOA

Microsporidia

Encephalitozoon cuniculi

BACKGROUND Minimal information is available regarding *Encephalitozoon cuniculi* infections in hamsters. Much debate over the correct taxonomy of this species has seen it classified at different times as either a fungus or a protozoan (Hankenson and Van Hoosier Jr., 2007). The current classification of this organism is, in fact, a fungal agent (Didier et al., 2000). Throughout the literature microsporidia are often referred to as protozoal species and thus are included in this section.

Microsporidia were first discovered in 1857 by Nägeli as the etiological agents responsible for pébrine disease in silkworms (Didier, 2005). *E. cuniculi* was subsequently recognized as infecting mammalian species by Wright and Craighead in 1922 when they discovered the infection in rabbits (Didier et al., 2000). Historically, the organism was commonly diagnosed in laboratory rodents and was a confounding factor in experimental models of infectious disease, altering immunological responses. As sanitary standards have improved within the laboratory setting, microsporidia no longer present a significant threat to laboratory rodents (Mathis, 2000). *E. cuniculi* is the microsporidial species most often associated with the Syrian hamster. It is an obligate intracellular parasite (Noble et al., 1989; Percy and Barthold, 2007).

ETIOLOGICAL AGENT The current classification of microsporidia as fungi is based on certain shared characteristics such as a chitinous spore wall, presence of the mitochondrial HSP70 gene, comparable gene sequences for α -tubulin, β -tubulin, large subunit RNA polymerase II, TATA box binding protein, glutamyl synthase, EF-1 α , and EF-2 (translocation elongation factors) (Didier, 2005).

EPIZOOTIOLOGY *E. cuniculi* infects an extensive range of mammalian hosts including mice, guinea pigs, squirrel monkeys, cats, dogs, and the "classical host" rabbit (Wagner, 1987). Studies in the 1970s analyzing the ultrastructural and serological properties of isolates from different animal species demonstrated that the isolates are identical (Pakes et al., 1975). This was confirmed by Shadduck et al. (1979) when they titrated rabbit, mouse, and hamster isolates of *E. cuniculi* in cultures of rabbit choroid plexus. They postulated that any differences in observed lesions caused by the organism are due to differences in host response to infection between animal species. In contrast, Didier et al. (1995) described the existence of three defined strains of *E. cuniculi*, strains I, II, and III using Western blot, PCR amplification and sequencing of the small subunit ribosomal RNA (SSU-rRNA) gene unique to microsporidial organisms. They suggested that strain variation may explain differences in host response. Strains I and III (the rabbit and dog strains, respectively) have been confirmed as zoonotic; however, strain II (the "mouse strain") is yet to be described as infecting humans (Mathis, 2000). The strain of *E. cuniculi* affecting hamsters remains "unclassified" (Didier et al., 2000).

CLINICAL MANIFESTATIONS *E. cuniculi* is not recognized as a significant cause of clinical disease in the hamster. Encephalitozoonosis tends to cause clinical disease in large animals such as non-human primates and canines (Percy and Barthold, 2007). Microsporidia cause opportunistic infections in people suffering from AIDS and manifest as a diarrheal and systemic disease (Didier, 2005). *E. cuniculi* has also been implicated as a cause of neurological disease in AIDS patients (Tosoni et al., 2002; Weber et al., 1997).

PATHOLOGY In mammals, *E. cuniculi* infections are generally localized to the brain and renal tubules. Infection can also occur within the liver, adrenal glands, myocardium, optic nerve, and retina (Noble et al., 1989). Minimal information is available regarding specific pathologic findings in the hamster.

PATHOGENESIS/LIFE CYCLE The spore wall is composed of three layers, the outermost being proteinaceous and the innermost comprised of chitin. The mature spore has a single coiled polar filament (Percy and Barthold, 2007) which is thought to play a role in infecting host cells by acting as a kind of "needle". An increase of internal pressure causes the filament to extrude and the sporoplasm is then expelled via the filament lumen, allowing it to penetrate the gut epithelium and travel to tissues elsewhere in the body via the blood stream (Noble et al., 1989; Percy and Barthold, 2007). Once within the gut epithelium, the sporoplasm matures into

a meront and enters the phase of merogony, undergoing two cycles to become a sporont. In a process called sporogony, the sporont undergoes meiotic division to form two mononucleate sporoblasts. The life cycle is complete when the sporoblasts undergo sporogenesis to become spores (Noble et al., 1989). The infective stage of the microsporidia spores is extremely small ($1.0\text{--}3.0\mu\text{M} \times 1.4\text{--}4.0\mu\text{M}$) (Didier, 2005). The host cell eventually ruptures, releasing the mature spores for spread to neighboring cells (Percy and Barthold, 2007).

Transmission is primarily via ingestion or inhalation of the spores. The initial tropism for the organism tends to be reflective of the mode of transmission and therefore commonly the epithelium of the gastrointestinal or respiratory tracts is affected (Didier et al., 2004). Later in the course of infection, the organism disseminates to other organs within the body, localizing in organs such as the brain and kidney (Didier et al., 2004).

DIAGNOSIS Definitive diagnosis of *E. cuniculi* may be achieved using transmission electron microscopy to detect microsporidia at any life stage in tissue biopsies, or spores in bodily fluids or feces (Didier et al., 2000). This method is not ideal due to the fact that tissue biopsy is invasive, testing bodily fluids or feces lacks sensitivity and the procedure is labor-intensive. Modified trichrome stain and fluorescent brighteners may be used to histochemically stain microsporidia in respiratory secretions, urine, and feces (Didier et al., 2000). Modified trichrome stains spores pink with a transparent posterior vacuole and a pink diagonal line is visualized within the spore against a blue-green background. Fluorescent staining of microsporidial spores binds chitin, resulting in the spores appearing as blue-green oval halos when visualized under ultraviolet light (Didier et al., 2000). Stained tissue sections reveal Gram-positive organisms. A Warthin-Starry silver stain may also be used to stain the organisms gray-black (Didier et al., 2000). The use of histological staining does not allow for speciation of the organism. Premortem diagnosis of *E. cuniculi* can be achieved via serological tests such as indirect fluorescent antibody and ELISA to detect anti-parasite antibody. These tests are fairly reliable in laboratory animals as they have limited environmental exposure (unlike humans, for example) and titers only remain high in chronically infected animals (Didier et al., 2000). Molecular techniques carried out on fecal samples, such as PCR amplification of primers complementary with the SSU-rRNA gene are gaining favor in the laboratory setting (Fedorko and Hijazi, 1996).

PREVENTION AND THERAPY As *E. cuniculi* rarely poses a clinical threat to hamsters, treatment has not been specifically described for this species. The latter, whilst effective against a greater spectrum of

microsporidial species, is toxic to mammals. Albendazole can be used as a treatment for affected animals and is part of the benzimidazole drug family and works by inhibiting tubulin polymerization (Didier et al., 2004). A dose of 400 mg of albendazole given twice daily for 2–4 weeks is described, however the paper does not specify whether this is a human or animal dose (Didier et al., 2000). Boiling water for a minimum of 5 minutes kills any spores present in water used for drinking or cleaning equipment/caging (Waller, 1979). A number of disinfectants, such as, quaternary ammonium, 70% ethanol, formaldehyde, phenolic derivatives, 1% hydrogen peroxide, sodium hydroxide or amphoteric surfactants applied for a period of 30 minutes at 22°C are also effectively sporicidal (Santillana-Hayat et al., 2002; Shadduck and Polley, 1978).

Flagellates

A plethora of flagellates have been identified in the hamster cecum. These protozoa are more often than not, non-pathogenic. The more commonly found and studied protozoa are described below.

SPIRONUCLEUS MURIS

BACKGROUND Historically this organism was referred to as *Hexamita muris*, but this non-host-specific flagellate has since been renamed. In general, immunocompetent adult animals are asymptomatic when infected with this parasite. Rats and hamsters seem to be particularly resistant to infection, whereas certain inbred mouse strains are more susceptible.

ETIOLOGIC AGENT *Spiroonucleus muris* are small, bilaterally symmetrical pyriform parasites ($7\text{--}9 \times 2\text{--}3\mu\text{m}$). The organism has two nuclei positioned at the anterior segment. Just anterior to this, six long flagella extend from the organism. Two additional flagella extend backwards parallel to two short axostyles. The organisms swim in a “torpedo-like” fashion. Binary fission of the organism results in the production of ovoid cysts measuring $7.4 \times 4.0\mu\text{m}$ (Owen, 1992).

EPIZOOTIOLOGY Schagemann et al. (1990) demonstrated that *Spiroonucleus* spp. isolates from the rat are highly host-specific and do not seem to cross-infect other rodent species. *S. muris* clones from mice, on the other hand are capable of infecting other mice and Syrian hamsters. *Spiroonucleus* spp. derived from Syrian hamsters also showed no host specificity, however cyst excretion was poor in rats and mice infected with the golden hamster isolate (Schagemann et al., 1990).

A study conducted by Kunstyr et al. (1993) demonstrated that *Spiroonucleus* spp. isolated from the European hamster (*Cricetus cricetus*) was ineffective at infecting rats and mice. Heterologous experimental

infection in the Syrian hamster was significantly less intense than spontaneously occurring infections in the European hamster (Kunstyr et al., 1993).

CLINICAL MANIFESTATIONS *S. muris* does not cause disease in the hamster (Barthold, 1985a).

PATHOLOGY Trophozoites may be observed extracellularly in between villi, within crypts and the central lumen but generally do not cause noticeable damage to the mucosa (Barthold, 1985a). On post-mortem, histological preparation of the intestine reveals mucoid hyperplasia of the mucosa and an inflammatory reaction characterized by mononuclear cells (Schmidt, 1995).

PATHOGENESIS/LIFE CYCLE *Spiroplasma* spp. cysts are ingested in contaminated water and/or feed (Schmidt, 1995). The prepatent period is generally 2–3 days but may take up to 6 days. Peak shedding of cysts occurs at 1–2 weeks (Barthold, 1985a).

DIAGNOSIS Trophozoites may be found in wet mounts of the duodenum and can be differentiated from *Giardia* by their smaller size and rapid, torpedo-like movement in comparison to *Giardia*'s slow, tumbling motion (Wagner, 1987).

PREVENTION AND THERAPY Prevention of *S. muris* outbreaks can be achieved by housing mice separately, as cross-contamination is known to occur between the species (Schagemann et al., 1990). Wagner suggests decontamination by pasteurization may be more effective than using disinfectants (Wagner, 1987). As this parasite does not cause clinical disease in the hamster, treatment may not be warranted. In mice, treatment of *S. muris* requires the addition of 0.1% dimetridazole to the drinking water for 2 weeks (Schmidt, 1995).

GIARDIA MURIS

BACKGROUND *Giardia muris* affect a wide host-range globally, including laboratory rodents, non-human primates, and man. The organism found in hamsters is morphologically indistinguishable from that found in mice (Hankenson and Van Hoosier Jr., 2007). *Giardia* is an opportunistic pathogen of the duodenum (Patterson et al., 2000).

ETIOLOGIC AGENT Trophozoites are the motile form of *Giardia* and are classically pear-shaped, possessing a flat ventral surface with an adhesive disc composed of microtubules and ribbons, allowing it to grasp onto the host's epithelial cells (Figure 32.1). Trophozoites range in size from $7\text{--}13 \times 5\text{--}10\mu\text{m}$ (Barthold, 1985b).

Four pairs of flagella confer motility to the organism. These flagella are classified as anterior, posterior,

FIGURE 32.1 A scanning electron micrograph (SEM) of the ventral surface of a *Giardia muris* trophozoite. The ventral adhesive disk resembles a suction cup, where overlapping microtubules in the cytoplasm form a number-6-shaped figure. *Giardia muris* has four pairs of flagella that are responsible for the organism's motility. The adhesive disk facilitates adherence of the protozoan to the intestinal surface. Reproduced from the Centers for Disease Control and Prevention/Dr. Stan Erlandsen (<http://phil.cdc.gov/phil/details.asp>) with permission.

ventral, and caudal pairs. The flagella originate from kinetosomes deep within the cytoplasm and extend extracellularly. The ventral flagella lie within a dark-staining ventral groove which is comprised of fibers called axonemes or axostyles. *Giardia* possess two nuclei with an eccentrically located endosome (Gardiner et al., 1988). Claw-like median bodies of unknown function are present within the organism, crossing the axonemes in the middle of the body (Noble et al., 1989). The cyst form of *Giardia* usually contains two or four nuclei and measures $8\text{--}11 \times 7\text{--}19\mu\text{m}$. The cysts do not possess an adhesive disc or exterior flagella. Cysts are also devoid of cellular machinery such as mitochondria, Golgi apparatus, lysosomes, and endoplasmic reticulum. Cysts require moist conditions to survive for a period of weeks to months (Noble et al., 1989).

EPIZOOTIOLOGY Host specificity of *G. muris* was analyzed by inoculating mice, rats, and hamsters with isolates from both naturally infected mice and hamsters (Kunstyr et al., 1992). The results showed that rats were not susceptible to infection from either isolate. Hamsters seemed to be more sensitive to infection from mouse isolates than homologous isolates. Mice were sensitive to heterologous isolates but to a lesser degree than hamsters. Kunstyr, Schoeneberg, and Friedhoff (1992) conclude that mice present a greater threat to hamsters in terms of infection with *Giardia* spp. than vice versa (Kunstyr et al., 1992).

CLINICAL MANIFESTATIONS While the prevalence of *G. muris* in the hamster is very high, the likelihood

that clinical signs or pathological lesions accompany the organism is very low (Barthold, 1985b). A self-limiting condition exists in weanling hamsters in which the animal presents with a pot belly and large numbers of both *G. muris* and *S. muris* (Owen, 1992). A number of hamsters with *Helicobacter aurati* infections culminating in gastritis and intestinal metaplasia were found to have *Giardia* and *Trichomonas* within the gastric pits (Figure 32.2) (Patterson et al., 2000). The authors suggest that decreased acidity may account for the migration of *Giardia* to the unusual location within the gastric mucosa.

PATHOLOGY Infections are most often subclinical (Schmidt, 1995). In animals clinically affected by giardiasis, the small intestine is often distended with yellow-white watery contents. Histologically, the parasite generally resides on the brush border of the small intestine but can also be found within the lumen. The oval cysts are found mostly within the large bowel (Barthold, 1985b). A lymphoplasmacytic infiltrate may be seen (Schmidt, 1995).

PATHOGENESIS/LIFE CYCLE Cysts represent the infective stage of the organism. Hosts are infected via the fecal-oral route. *Giardia* excysts in the duodenum to produce two trophozoites. In hamsters and other rodents, the organism may infiltrate the intestinal epithelium and submucosa traveling to the lungs and other organs via the lymphatics and blood stream. Gallbladder penetration may result in cholestasis (Noble et al., 1989). While tissue invasion in hamsters by *Giardia* is rare, it has been described within the duodenum and a renal blood vessel of mice (el-Shewy and Eid, 2003). The pre-patent period is generally 3–5 days and peak cyst excretion occurs at 7–14 days (Barthold, 1985b).

DIAGNOSIS Phosphate-buffered saline wet mount preparations from the duodenum can be examined to confirm the presence of *Giardia*. The characteristic tumbling motion of trophozoites can be visualized under a microscope ($\times 100$). Hematoxylin-eosin-stained sections of small intestine also reveal the organism adhered to the villous epithelium. The cystic form can be found in fecal smears stained with Lugol's iodine or in tissue sections of the large intestine stained with hematoxylin-eosin (Wagner, 1987). The identification of cysts using zinc-sulfate centrifugation flotation remains the gold standard for diagnosis. *Giardia* may be detected in pet cats and dogs using a SNAP Ag test (Payne and Artzer, 2009).

PREVENTION AND THERAPY Strict quarantine practices and testing of new animals coupled with high levels of sanitation can be used to prevent *Giardia* infection

FIGURE 32.2 Area of intestinal metaplasia in hamster antrum. Lumen of gastric pit contains many protozoa. HE stain. Bar = 50 μ m. Inset: Demonstrates ovoid shape and two nuclei consistent with *Giardia*. Warthin-Starry stain. Bar = 10 μ m. Reproduced from Patterson et al. 2000 with permission.

within a colony. Cleaning surfaces and equipment with boiling water is effective at killing cysts, however chlorination does not tend to destroy cysts successfully (Noble et al., 1989). Quinacrine, amodiaquin, and chlorocrine have been described as potentially effective drugs for the treatment of giardiasis (Schmidt, 1995). Metronidazole, while effective at eradicating *Giardia* in mice, is not useful in treatment of hamsters, even at doses 16 times higher than those used in mice (Hankenson and Van Hoosier Jr., 2007).

TRICHOMONAS MURIS

BACKGROUND The names *Trichomonas cricetus* and *T. criceti* were previously used to describe the trichomonads found in hamsters. These species are synonymous with *Tritrichomonas muris* (Hankenson and Van Hoosier Jr., 2007). Other trichomonads found in Syrian hamsters include *Trichomonas wenyoni*, *Tritrichomonas minuta*, *Tetratrichomonas microti*, and *Pentatrichomonas hominis* (Hankenson and Van Hoosier Jr., 2007). *Trichomonas* spp. are non-pathogenic and are commonly found in the cecum (Owen, 1992; Patterson et al., 2000).

ETIOLOGIC AGENT The morphologic characteristics of this protozoa include multiple anterior flagella conferring motility to the organism, a crescent-shaped shielding structure at the anterior margin of the body called the pelta (Tasca and De Carli, 2003), an undulating membrane at the base of which lies a deep staining ribbon-like structure called the costa which is thought to provide structural support (Gutierrez, 2000), an axostyle, and a single nucleus (Figure 32.3). The term trichomonad is a misnomer for the order as it was originally thought that this group of organisms had three flagella, when in fact various species possess from three to five flagella. *Trichomonas* actually possess four flagella, whereas *Tritrichomonas* possess three flagella.

FIGURE 32.3 Trophozoite of *Tritrichomonas muris* detected in cecal contents from a protozoa-free mouse transfaunated with Armenian hamster feces. Note its characteristic pyriform appearance, the undulating membrane, the three anterior flagella, recurrent flagellum and axostyle.

FIGURE 32.4 Round refractile body (*T. muris* pseudocyst) detected in the feces from an Armenian hamster. Lugol's iodine preparation. Reproduced from Lipman et al., 1999 with permission.

Trichomonads are anaerobic parasites that can grow under low oxygen tensions. They rely on the glycolytic pathway as a means of producing metabolic energy which involves the breakdown of glucose to either pyruvate or succinate. Pyruvate may also be used as an energy source to produce acetate within hydrogenosomes via hydrogen production (Noble et al., 1989). These organisms do not appear to encyst, rather they form pseudocysts (Figures 32.4 and 32.5). These structures are simply less-motile forms of the organism with internalized flagella. They appear like cysts but lack a true cyst wall, hence the name "pseudocyst". The organism is thought to transform into this shape as a survival mechanism in response to environmental stress (Martin, 2008).

Trichomonads have been implicated in barrier breaches within SPF mouse colonies established from

FIGURE 32.5 Electron micrograph of a *T. muris* pseudocyst. Notice the presence of the costa (C), recurrent flagellum (R), undulating membrane (U), and axostyle (Ax). Magnification, $\times 7500$. Reproduced from Lipman et al., 1999 with permission.

cesarean-derived stock. Because it has such a low infective dose (five pseudocysts) in mice (Stachan and Kunstyr, 1983), it is a good indicator of microisolation technique failure (Owen, 1992).

EPIZOOTIOLOGY *T. muris* was found to form pseudocysts in Armenian hamsters. Cross-infectivity was established when it was discovered that immunocompetent outbred mice were subsequently infected by the hamster (Lipman et al., 1999).

CLINICAL MANIFESTATIONS Trichomonads are not considered pathogenic in the hamster. They are often found in the presence of enteric disease as an incidental finding (Wagner, 1987).

PATHOLOGY This organism is found in the cecal lumen, however as it is non-pathogenic, no gross or microscopic pathology accompanies infection (Hankenson and Van Hoosier Jr., 2007).

PATHOGENESIS/LIFE CYCLE Trichomonads reproduce asexually by binary fission. They form pseudocysts which will eventually excyst to produce the motile trophozoite. Feco-oral transmission occurs via

ingestion of either the pseudocyst or trophozoite stage of this parasite (Wagner, 1987).

DIAGNOSIS Pseudocysts can be found microscopically in fecal flotations using Lugol's iodine staining (Lipman et al., 1999) or trichrome stain (Hankenson and Van Hoosier Jr., 2007). Both trophozoites and pseudocysts may be identified in the cecum and colon (Wagner, 1987).

PREVENTION AND THERAPY The glycolytic pathway is blocked by metronidazole and is therefore the treatment of choice for infections with trichomonads (Noble et al., 1989). Metronidazole may be administered intragastrically at 80 mg/day for 6 days (Hankenson and Van Hoosier Jr., 2007).

MISCELLANEOUS FLAGELLATES

The following organisms are mentioned as either examples of relatively common parasites or those which have, at the very least, been described over the years. Wantland (1955) examined numerous hamsters and found *Chilomastix bettencourti* in the cecum of approximately 9% of his subjects. These pyriform trophozoites measure 10–15 μm , are asymmetrical and possess a short, pointy tail. The organism has three anterior flagella which confer motility and a fourth flagellum which acts as a prehensile organ for feeding. *Chilomastix* move with jerky, spiral movements. The cystic form of this parasite is lemon-shaped and typically measures 6–9 μm (Wantland, 1955). Griffiths (1971) observed various cecal protozoa including *Monocercomonoides* sp. and *Octomitus* sp., both of unknown prevalence.

Sporozoa

Cryptosporidium spp.

BACKGROUND Numerous studies have proposed that *Cryptosporidium* spp. acts as an opportunistic pathogen in immunocompromised hosts. In general, cryptosporidial species are thought to play a minor to insignificant role in disease of hamsters.

ETIOLOGICAL AGENT It remains unclear which cryptosporidial species is responsible for naturally occurring infections in the hamster (Davis and Jenkins, 1986; Orr, 1988). The two most commonly discussed cryptosporidial species in hamsters are *C. parvum* (Rasmussen and Healey, 1992a, 1992b) and *C. muris* (Rhee et al., 1999). Both the sexual and asexual stages of these coccidia attach to the microvilli of epithelial cells (Gardiner et al., 1988). The oocysts typically measure $7 \times 5 \mu\text{m}$ and have a smooth wall (Owen, 1992).

EPIZOOTIOLOGY Rasmussen and Healey (1992a) evaluated whether a difference in susceptibility to *C. parvum*

FIGURE 32.6 Histologic section of ileum from aged hamster showing numerous *Cryptosporidium parvum* (arrowheads) associated with villous brush border. Bar = 70 μm . Reproduced from Rasmussen and Healey 1992 with permission.

exists between aged and young hamsters. Aged hamsters (20–24 months old) shed significantly more oocysts for a longer period of time than did young hamsters (8–12 weeks old). Histologically, the organism adhered to the villous enterocytes of the small intestine of aged hamsters (Figure 32.6), whereas no parasites were found in tissue sections of the juveniles. While there were no histologic lesions in young hamsters, widespread villous atrophy and hyperplastic crypts were seen in aged animals. The aged hamsters were found to have decreased T and B cell response to mitogens and reduced NK cell activity in contrast to the young hamsters. These findings supported the theory that immune competency is thought to be a significant factor in host susceptibility to cryptosporidiosis (Rasmussen and Healey, 1992a).

In a study conducted by Rhee et al. (1999), the prepatent period for *C. muris* (10–13 days) remained similar regardless of the animal's age at infection. However, an inverse relationship was found between age at infection and the length of the patent period. These authors also found that hamsters inoculated at 1 week of age shed higher oocyst numbers than did those infected at 5 and 10 weeks old. These findings suggested that innate immunity to *C. muris* is independent of age whereas acquired immunity is age-dependent (Rhee et al., 1999).

CLINICAL MANIFESTATIONS/PATHOLOGY Davis and Jenkins (1986) described a case of cryptosporidiosis (species unidentified) in a weanling male Syrian hamster with concomitant proliferative ileitis. Aside from poor body condition and a dehydrated state, the animal showed no clinical signs prior to death. On necropsy, the hamster was found to have gross lesions consistent with ileitis and colitis. Examination of the intestinal lesions via light microscopy revealed lesions consistent with proliferative ileitis. These lesions include significant hyperplasia of the enterocytes lining both crypts and villi, fusion of the villi, crypt abscessation, necrosis, hemorrhage, and granulomatous inflammation. In addition to the numerous bacteria infiltrating the enterocytes, many organisms identified as *Cryptosporidia* spp. were found along the microvillus borders of the enterocytes. While *Cryptosporidia* spp. were definitely present, it remained unclear whether the organism had contributed to the lesions as the prominent lesions were attributed to infection with the intracytoplasmic bacteria (subsequently recognized as *Lawsonia* spp.) (Davis and Jenkins, 1986). Similarly, Orr (1988) described several cases of enteritis in Syrian hamsters which on necropsy had histopathological lesions consistent with proliferative enteritis as well as various cryptosporidial stages within the epithelial brush border and intestinal crypts. The author did not draw any conclusions about the significance of the presence of cryptosporidia.

PATHOGENESIS/LIFE CYCLE Unsporulated oocysts are shed within feces where they eventually sporulate, becoming infective. Cryptosporidia are directly transmitted via the feco-oral route and occasionally via the respiratory route. Sporozoites are released upon entry into the body and invade the gastrointestinal epithelium. Rarely, invasion of the respiratory epithelium may occur, in hosts with a compromised immune system. The sporozoite matures to a trophozoite, which in turn forms into a meront. Several cycles of merogony result in the release of merozoites which become macrogametocytes and microgametocytes containing macrogametes and microgametes respectively. Once the macrogametes become fertilized, a thick-walled oocyst is formed (Gardiner et al., 1988; Owen, 1992).

PREVENTION AND THERAPY *Cryptosporidium* species are known to infect humans and, as such, represent a public health risk to laboratory personnel (Fayer et al., 2004; Xiao et al., 2004). Apart from adhering to hygienic practices such as hand washing and utilizing personal protective equipment, it is important to sanitize the laboratory environment. Unfortunately, *Cryptosporidium* spp. are notoriously resilient organisms and resistant to many commonly used disinfectants. Oocysts are

thought to be sensitive to heat shock (King and Monis, 2007); therefore cleaning surfaces and equipment with boiling water may be effective at rendering them incapable of infection. Cryptosporidia are transmitted via water sources and therefore water treatment is a critical control point. Recent studies indicate that UV disinfection may be effective at destroying cryptosporidial organisms (Le Goff et al., 2010; Xiao et al., 2004).

Very few studies discuss treatment of *Cryptosporidium* infections in hamsters. One study by Rasmussen and Healey (1992b) tested the hypothesis that pre-treatment of aged hamsters with exogenous dehydroepiandrosterone (DHEA) would lead to a reduction in susceptibility to *C. parvum* infection compared to aged hamsters that were left untreated. This hypothesis was based on a previous observation that the steroid hormone (naturally produced by the adrenal cortex) when administered exogenously was shown to increase lifespan and boost immunity in animals. Shedding of *C. parvum* oocysts was monitored and found to be significantly reduced by 75% in DHEA-treated hamsters when compared to the untreated group. They concluded that DHEA treatment prior to infection reduced susceptibility to cryptosporidiosis in aged Syrian hamsters. Presumably this is due to an increase in IL-2 production, which plays a critical role in clonal expansion of antigen-activated T cells and alteration of the intestinal flora, impairing the organism's ability to colonize the gut (Rasmussen and Healey, 1992b). It is questionable whether this treatment would have any practical application.

Amoebae

Entamoeba muris

BACKGROUND The most common species of amoebae found in hamsters, rats, and mice is *Entamoeba muris*. It is a non-pathogenic, large, slow-moving organism found in the lumen of the large intestine and its motility is conferred by pseudopodia. Pseudopodia also act as prehensile limbs for feeding on bacteria. The trophozoites are 8–30 μ m in diameter and the cysts are sizeable, measuring 9–20 μ m in diameter. Cross-infectivity between rats, mice, and hamsters can occur (Wagner, 1987).

ETIOLOGIC AGENT *Entamoeba* is an obligate parasite with a direct life cycle. The infective stage is a resistant cyst which is excreted in feces. The cyst is prone to desiccation yet it can withstand temperature extremes and is relatively resistant to disinfectants (Owen, 1992). Once ingested, development into a trophozoite occurs within the intestinal lumen. On rare occasions this stage can invade the intestinal wall and migrate to other organs (Gardiner et al., 1988).

EPIZOOTIOLOGY *E. muris* is a non-pathogenic organism, commonly found in the cecum of hamsters. The organism bears similarities to other amoebae affecting other laboratory animal species such as *E. caviae* in the guinea pig and *E. cuniculi* in rabbits.

CLINICAL MANIFESTATIONS/PATHOLOGY *E. muris* does not cause disease in hamsters.

PATHOGENESIS/LIFE CYCLE *E. muris* is directly transmitted via the feco-oral route. Resistant cysts are shed in feces and upon ingestion the nuclei of the cysts divide into eight, followed by the cytoplasm. As a result, eight trophozoites excyst into the small intestine where they can feed and travel to the large intestine where they can multiply by binary fission. Trophozoites may also migrate to other vital organs (Gardiner et al., 1988; Owen, 1992).

DIAGNOSIS Diagnosis of *E. muris* is by identification of the trophozoites within the intestinal lumen or feces or cysts in the feces. The cyst contains eight small nuclei that can be visualized in both unstained and iodine-stained fecal preparations. Other features of the *E. muris* cyst include chromatoid bodies described as having a "splinter-like appearance" and a distinct glycogen granule (Owen, 1992).

PREVENTION AND THERAPY Research on the treatment of this parasite is scarce and as this organism is not considered clinically significant in laboratory hamsters, its prevention and treatment are not discussed.

NEMATODES

Oxyuriasis

Syphacia spp., Aspiculuris spp., and Dentostomella spp.

BACKGROUND Oxyurids, or pinworms, are routinely detected in mice and rats from modern vivaria (Carty, 2008; Jacoby and Lindsey, 1998; Pritchett, 2007). There are far fewer reports of pinworm infection in hamsters, but an understanding of the disease is important due to potential research complications and transmission of infection to other rodents (Kellogg and Wagner, 1982; Ross et al., 1980). *Syphacia*, *Aspiculuris*, and *Dentostomella* are genera of nematode worms of the order Oxyurida, superfamily Oxyuroidea that parasitize rodents worldwide. *Syphacia* spp. belong to the family Oxyuridae and *Dentostomella* spp. and *Aspiculuris* spp. belong to the family Heteroxyematidae (Adamson, 1989; National Center for Biotechnology Information, 2009).

ETIOLOGY Hamsters have been reported to harbor many species of pinworms including *Syphacia mesocriceti*, *Syphacia criceti*, *Syphacia stroma*, *Syphacia peromysci*, *Syphacia obvelata*, *Syphacia muris*, *Aspiculuris tetraptera*, and *Dentostomella translucida* (Table 32.1). *S. mesocriceti* (Figures 32.7 and 32.8) is reported to be host-specific to the hamster and was originally described by Quentin (1971) from female worms collected from lab-reared Syrian hamsters in Anchorage, Alaska in 1953. The nematode was further described from specimens collected from Ontario, Canada and Japan (Dick et al., 1973; Hasegawa, 1981). Hosts include *Mesocricetus auratus* (Dick et al., 1973; Hasegawa, 1981; Quentin, 1971) and the desert (Roborovski) hamster, *Phodopus roborovskii* (Hasegawa et al., 2008).

Syphacia criceti (Figure 32.9) was originally described from nematodes collected from *Oryzomys subflavus* and *Calomys callosus* in Brazil (Quentin, 1971). The nematode was isolated from lab-reared Syrian hamsters in Brazil (Pinto et al., 2001), though a subsequent publication has questioned the identification suggesting that the pinworms were actually *Syphacia stroma* based on the morphology of the male's tail (Hasegawa et al., 2008). *S. stroma* infects *Apodemus* spp. in the Palaearctic region and *S. peromysci* is native to the deer mouse, *Peromyscus maniculatus*, in North America (Quentin, 1971). Both were recovered concomitantly with *S. mesocriceti* in Syrian hamsters that had been imported to Japan for the pet trade. It is believed that captive conditions provided a suitable environment for infection (Hasegawa et al., 2008).

Syphacia obvelata, the common mouse pinworm, has been reported in Syrian hamsters worldwide as early as 1946 (Watson, 1946) with transmission of infection possible from infected mice to hamsters (Kellogg and Wagner, 1982). *Syphacia muris*, the rat pinworm, has also been reported in Syrian hamsters with transmission of infection possible between Sprague-Dawley rats and hamsters (Ross et al., 1980). The mouse pinworm, *Aspiculuris tetraptera*, has been reported in pet desert (Roborovski) hamsters and Siberian dwarf hamsters (*Phodopus sungorus*) imported to Japan (Hasegawa et al., 2008), though infection in Syrian hamsters has not been reported (Wagner, 1987). Lastly, *Dentostomella translucida*, common to several cricetid rodents including *Meriones unguiculatus* (Mongolian gerbil), *M. meridanus*, *Rhombomys opimus*, *Dipus sagitta*, and *Mastomys fumatus*, has been isolated from the stomach of a Syrian hamster from a breeding colony in Minnesota, with an earlier suspect case reported in Iowa (Greve, 1985).

EPIZOOTIOLOGY Oxyurid nematodes are usually host-specific since the environmental phase in their monoxenous life cycle is reduced or absent (Hasegawa et al., 2008; Okamoto et al., 2007). Pinworm species

specificities are found to be predilections, not obligate associations (Pritchett and Johnston, 2002), as demonstrated by the various pinworm infections in hamsters. Analysis of mitochondrial CO1 gene sequences suggests that the co-evolutionary relationship between pinworms and rodent hosts may not be completely rigid and host switching has likely occurred during evolution (Okamoto et al., 2007).

Pinworm infections typically result from contact with fomites contaminated with embryonated eggs (Pritchett, 2007). *Syphacia* spp. can spread among rodents via grooming and ingestion of embryonated eggs directly from the perineum (Prince, 1950; Taffs, 1976). Since *Syphacia* spp. ova are rapidly infective within 5–20 hours (Chan, 1952; Taffs, 1976), retroinfection with larval migration into the colon via the anus

FIGURE 32.9 *Syphacia criceti*. (A) Male, whole body, lateral view. Bar = 0.08mm. (B) Cranial portion of male, lateral view. Bar = 0.02mm. (C) Head of female, en face view. Bar = 0.01mm. has been proposed (Prince, 1950). Retroinfection does not occur with *A. tetraptera* or *D. translucida* due to the location of egg release and the prolonged time to egg infectivity, approximately 5–10 days (Any, 1966b; Hsieh, 1952; Pritchett and Johnston, 2002).

CLINICAL MANIFESTATIONS In immunocompetent animals, pinworm infections are usually clinically silent (Taffs, 1976). Clinical signs are not observed following natural infection with *S. criceti* and *S. mesocriceti* in hamsters (Hankenson and Van Hoosier Jr., 2007). *D. translucida* infections typically are asymptomatic in Mongolian gerbils (Wightman et al., 1978; Wilkerson et al., 2001) and parasitism is considered incidental in Syrian hamsters (Greve, 1985). *S. obvelata*, *A. tetraptera*, and *S. muris* infections in mice and rats generally cause no clinical signs but may be associated with non-specific

signs of illness such as poor body condition, roughened hair coat, reduced exploratory behavior (McNair and Timmons, 1977), rectal prolapse (Hoag, 1961), and intestinal impaction or intussusception (Taffs, 1976). *Citrobacter rodentium* and *Helicobacter* spp., however, are known to cause similar signs in mice and may have contributed to these generalized conditions (Clifford and Watson, 2008; Pritchett and Johnston, 2002). *S. muris* has been found to have a shortened patent period in Syrian hamsters suggesting that the clinical effects would be minimal (Ross et al., 1980).

PATHOLOGY *S. criceti* and *S. mesocriceti* are considered non-pathogenic in hamsters (Hankenson and Van Hoosier Jr., 2007). *D. translucida* caused no pathological lesions in Mongolian gerbils (Wightman et al., 1978) and adults were found unattached to the stomach

mucosa of a Syrian hamster with no gastric lesions noted at necropsy (Greve, 1985). *S. muris* and *S. obvelata* infections in rats and mice are generally non-pathogenic, but infections may impact intestinal electrolyte transport (Lubcke et al., 1992), growth rate, and the hepatic enzyme system (Mohn and Philipp, 1981), and most well documented, the immunological response (Agersborg et al., 2001; Michels et al., 2006). In hamsters, *S. obvelata* is reported as non-pathogenic but the possibility of mild enteritis has been suggested (Unay and Davis, 1980) and immature forms of the nematode have also been isolated from the brain of an adult Syrian hamster (De Roeвер-Bonnet and Rijpstra, 1961).

PATHOGENESIS/LIFE CYCLE Pinworm infections are generally non-pathogenic in immunocompetent rodents (Taffs, 1976) and rarely penetrate the mucosa of the gastrointestinal tract (Anya, 1966a; Pritchett, 2007).

The life cycle of *S. mesocriceti* in hamsters is incompletely described, but information can be extrapolated from other species in the genus. *Syphacia* spp., *Aspiculuris tetraptera*, and *Dentostomella translucida* all have direct life cycles with varying prepatent periods (Anya, 1966a; Chan, 1952; Hsieh, 1952; Taffs, 1976; Wightman et al., 1978) (Table 32.1). Upon ingestion of infective embryonated eggs, *Syphacia* spp. larvae hatch in the small intestine and migrate to the cecum to feed on bacteria. In mice, *S. obvelata* reaches the cecum within 24 hours and within 6 days post-hatching, two-thirds of the females are fertilized and the males die (Chan, 1952). Similar to other *Syphacia* spp., gravid *S. obvelata* females then migrate to the anus to lay their eggs on the perineum of the host and die (Chan, 1952). In contrast, *A. tetraptera* ova hatch in the cecum and larvae reside in the crypts of Lieberkühn of the mid-colon for approximately 5 days before migrating to the proximal colon (Behnke, 1974; Chan, 1955). Adult females migrate to the distal colon to lay their eggs which are excreted in the mucus layer of the feces (Behnke, 1974; Taffs, 1976). Females live another 21–24 days after first egg release for a lifespan of 45–50 days (Hsieh, 1952). *D. translucida* resides in the proximal third of the small intestine and occasionally the stomach of gerbils. Like *A. tetraptera*, the eggs of *D. translucida* are shed in the fecal pellet (Wightman et al., 1978).

DIAGNOSIS Common diagnostic techniques in rodents include the perianal cellophane tape test, anal swab, fecal flotation, necropsy with microscopic examination of cecal and colonic contents, and histologic examination (Hill et al., 2009; Pritchett and Johnston, 2002). Demonstration of adult worms in cecal and colonic contents has been reported as the most sensitive diagnostic technique for the detection of pinworms in mice (West et al., 1992). *S. obvelata* ova have

been detected in Syrian hamsters with the perianal tape test technique (Taylor, 1992; Unay and Davis, 1980). This technique has a reported sensitivity of 100% for detection of *S. muris* in rats and 85.5% for detection of *S. obvelata* in mice (Hill et al., 2009). A modified anal swab technique has been used to detect *S. mesocriceti* and *S. criceti* in hamsters (Pinto et al., 2001). The technique involves inserting a plastic rod that is moistened in 0.85% NaCl into the anus; the rod is rotated and the collected feces are then transferred to a glass slide with saline and examined under light microscopy (Goncalves et al., 1998).

Due to shedding of ova in the feces, the perianal tape test will not detect *Aspiculuris* spp. and *Dentostomella* spp. infections (Pritchett and Johnston, 2002). As with other pinworms, evaluation of colonic and cecal contents for adult worms at necropsy is the most effective way to diagnose *A. tetraptera* and *D. translucida* infections (West et al., 1992; Wightman et al., 1978). Ova may also be found on fecal flotation and the anal swab technique described above has recovered *A. tetraptera* (Goncalves et al., 1998; Pritchett, 2007; Wightman et al., 1978).

A PCR-based method for identification of *S. muris*, *S. obvelata*, and *A. tetraptera* has also been described that differentiates the species based on their rDNA sequences and subsequent analysis of the amplicons with restriction endonucleases (Parel et al., 2008). A PCR assay to identify the three pinworm species is newly offered; the technique is reported to be more sensitive than either the tape test or fecal float and nearly as sensitive as post-mortem direct exam (University of Missouri Research Animal Diagnostic Laboratory, Columbia, MO, 2009).

PREVENTION AND THERAPY Preventive measures include exclusion of feral rodents from vivaria, the use of filter tops or microisolator caging, strict sanitation, and sterilization of feed and bedding (Farrar et al., 1994; Jacoby et al., 2002). Appropriate biosecurity measures should be employed when importing rodents, including the purchase of rodents from commercial vendors with well-established health monitoring programs that are free of parasites. Rodents imported from non-commercial research colonies should be quarantined and evaluated for parasite infection; preemptive treatment with an appropriate anthelmintic may also be employed.

Environmental decontamination of vivaria is often employed alongside anthelmintic treatment of rodents. Pinworm eggs are considered to be persistent environmental contaminants based on characteristics of the human pinworm, *Enterobius vermicularis*, including the ability to aerosolize (Pritchett and Johnston, 2002; Wantland, 1955). Pinworm eggs have been found in dust, on equipment, and in ventilation air-intake ducts

of animal-holding rooms housing infected mice (Hoag, 1961). *S. muris* eggs have been isolated from equipment and shelving in a room housing infected rats in individually ventilated cages (Huerkamp, 1993). Despite this, tape impressions from the interior surfaces of filter-top cages housing *S. obvelata*-infected mice failed to isolate eggs (Lipman et al., 1994). *S. muris* eggs remain infective in the laboratory environment for at least 4 weeks (Dix et al., 2004), while *S. obvelata* eggs may only remain viable for 42 hours at 30°C (Grice and Prociw, 1993). *A. tetraptera* is also thought to be long-lived in the environment (Clifford and Watson, 2008). With pinworm eggs resistant to most common disinfectants (Dix et al., 2004), physical methods such as scrubbing with detergent, steam cleaning, or painting are likely to be most effective for environmental decontamination (Clifford and Watson, 2008). In modern rodent vivaria with individually ventilated caging systems, failure to eradicate pinworm infections may be due less to environmental contamination than to ineffective anthelmintic regimens and compliance (Pritchett, 2007). Environmental decontamination may be unnecessary if all rodents are effectively treated to eradicate pinworm infection and for a duration that exceeds persistence of the eggs in the environment (Clifford and Watson, 2008).

Treatment strategies for pinworms in mice and rats are well documented (Pritchett and Johnston, 2002). Avermectins and benzimidazoles are currently the most widely used anthelmintics for pinworm eradication (Pritchett, 2007; Pritchett and Johnston, 2002). Avermectins, which include ivermectin, paralyze parasites by increasing chloride permeability in the cell membranes of peripheral nerve tissues and possibly potentiate gamma aminobutyric acid (GABA)-gated sites. Benzimidazoles, including fenbendazole, bind nematode B-tubulin and inhibit microtubule formation (Hill et al., 2006) and have adulticidal, larvicidal, and ovicidal actions (Pritchett and Johnston, 2002). Fenbendazole-medicated diet (150 ppm fenbendazole) fed for a total of 5–6 weeks in rats and mice has eradicated *S. muris* and *S. obvelata*, in some instances without environmental decontamination (Barlow et al., 2005; Hill et al., 2006; Huerkamp et al., 2004). Fenbendazole-medicated diet (150 ppm fenbendazole) fed for a total of 5 weeks with or without ivermectin-supplemented drinking water (ivermectin dose 0.005 mg/ml) has also been effective at eliminating *Dentostomella translucida* from Mongolian gerbils without additional husbandry measures (Wilkerson et al., 2001).

Studies detailing treatment strategies in Syrian hamsters are limited and strategies can be adapted from the treatment of other rodents. *S. obvelata* has been eradicated in Syrian hamsters via two treatment courses of 10 mg of piperazine citrate per ml of drinking water for 7 days each, separated by 5 days without treatment

(Unay and Davis, 1980). A combination of 0.1% thia-bendazole in the diet for 6 weeks and 0.6% piperazine hydrate in drinking water for 8 weeks, beginning 2 weeks before the thiabendazole, has eradicated *S. obvelata* from six Syrian hamsters that could not be transferred to a clean environment (Taylor, 1992).

Miscellaneous Nematodes

Trichosomoides nasalis

Adult *Trichosomoides* have been identified in decalcified parasagittal sections of the nose of an approximately 5-week-old male Syrian hamster. Ova with polar plugs were detected in the feces of hamsters (37/185) from the same colony. *Trichosomoides nasalis* was suspected (Chesterman, 1972; Chesterman and Buckley, 1965) and *T. nasalis* was subsequently reported in the nasal cavity of a golden hamster in Switzerland (Redha and Horning, 1980). *T. nasalis* was first described in the nasal cavities of *Rattus norvegicus* with infection spread via the ingestion of embryonated eggs (Biocca and Aurizi, 1961). Based on other Trichosomoidinae, the life cycle is direct and *T. nasalis* is presumed to have a migratory phase which is presently undetermined (Diagne et al., 2004) and may produce lesions in the lungs or other organs (Wagner, 1987).

A recent histological study of the nasal cavities of the African grass rat, *Arvicanthis niloticus*, naturally infected with *T. nasalis* shows female worms to reside in the nasal epithelium. Ova, mixed with mucus and polymorphonuclear cells, were found in the nasal lumen and one male was found within a female's uterus (Diagne et al., 2004) as is common for Trichosomoidinae (Wagner, 1987). Significant inflammatory lesions in the lamina propria resulted in rhinosinusitis with a lymphocytic infiltrate causing nasal obstruction (Diagne et al., 2004).

Mastophorus spp. and Protospirura spp.

Mastophorus muris has been reported in a variety of rodents, including *Graomys griseoflavus*, *Apodemus sylvaticus*, *Clethrionomys glareolus*, *Rattus* spp., and marsupials including *Trichosurus vulpecula* and *Hypsiprymnodon moschatus* (Pisanu et al., 2009; Rojas Mdel and Digiani, 2003). *Protospirura muricola* has also been isolated from many Muridae (Smales et al., 2009). Confusion regarding classification of *Mastophorus* spp. and *Protospirura* spp. is well documented (Smales et al., 2009). *Mastophorus muris* has also been cited as *Spiroptera obtusa* or *Protospirura muris* (Milazzo et al., 2003).

Reports specifically of *Mastophorus* spp. in hamsters are vague (Hankenson and Van Hoosier Jr., 2007; Wagner, 1987). *Protospirura muris* has been recovered from a single hamster exhibiting a heavy worm burden resulting in distention at the cardiac end of the esophagus and stomach (Mauer et al., 1953). The authors

suspected that the hamster ate a heavily infected insect which accounted for the parasitism (Wantland, 1955). Adults reside in the esophagus and stomach and infection is acquired through ingestion of the intermediate host, American and Madiera cockroaches (Brenner, 2002; Wagner, 1987; Wantland, 1955). Beetle larvae and meal worms can also serve as intermediate hosts (Pierce, 1921). Parasitism has not been reported as a natural occurrence in laboratory rodents (Hankenson and Van Hoosier Jr., 2007; Wagner, 1987).

Gongylonema neoplasticum

G. neoplasticum has been reported in rodents and lagomorphs worldwide. Infection is spread through ingestion of intermediate hosts, including cockroaches, mealworms, and fleas. The nematode occurs in the esophagus and stomach and can cause gastric ulcers. Natural infection has not been reported in laboratory rodents and there are only limited reports of the parasite in hamsters (Hankenson and Van Hoosier Jr., 2007; Wagner, 1987).

Heligmosomum juvenum

H. juvenum has been isolated from the small intestine of hamsters in western Asia. Infection is thought to occur through the ingestion of infectious larvae. Pathologic effects are unknown and zoonosis is not reported (Hankenson and Van Hoosier Jr., 2007; Wagner, 1987). Current infections in hamsters have not been reported.

CESTODES

Hymenolepiasis

BACKGROUND Hamsters are susceptible to a number of cestode infections of the family *Hymenolepididae*, including *Rodentolepis nana*, *Hymenolepis diminuta*, and *Rodentolepis microstoma*. Historically, *R. nana* (formerly *Hymenolepis nana*) was one of the most important internal parasites of hamsters (Renshaw et al., 1975; Soave, 1963). Recent infections have been detected in laboratory animal suppliers (Pinto et al., 2001). *R. nana* is also the most common cestode infecting humans world-wide (Macnish et al., 2003). It is frequently used in biologic research to study tapeworm biology and its pathologic effects.

ETIOLOGY/ETIOLOGIC AGENT *R. nana* is known as the dwarf tapeworm. Table 32.2 provides the average morphological measurements for this small, white tapeworm. The anterior portion has a rounded, inverted scolex with four unarmed suckers and a prominent rostellum (Habermann and Fletcher, 1958). This rostellum has a single layer of 20–27 hooks forming an anterior crown (Figure 32.10). The wider, posterior strobila

TABLE 32.2 Comparison of Cestode Physical Characteristics^a

	<i>Rodentolepis nana</i>	<i>Hymenolepis diminuta</i>	<i>Rodentolepis microstoma</i>
Body length	25–40 mm	20–60 cm	205 mm
Body width	1 mm	3–4 mm	2 mm
Scolex	4 unarmed suckers	4 unarmed suckers	
Rostellum	20–27 hooks	No hooks	<30 hooks
Ova	Oval, transparent	Spherical, transparent, yellow tint	Oval, transparent
Length (μm)	50–55	70–85	75–90
Width (μm)	37–47	60–80	51–75
Onco sphere	6 hooks	6 hooks	
Length (μm)	24–30	24–30	27–48
Width (μm)	16–25	16–23	29–54
Polar bodies	2 with 4–8 attached filaments	No polar filaments	Slight polar bodies, 3–5 polar filaments
Life cycle	Direct; indirect; autoreinfection	Indirect	Indirect
Location of adult worm in host	Ilium	Anterior small intestine	Duodenum; pancreatic ducts; biliary ducts; mesenteric lymph nodes

consists of numerous, transversely elongated proglottids (Pinto et al., 2001). Gravid proglottids release the transparent, ovoid eggs of *R. nana*. The ovum consists of an outer membrane encircling an enveloped

FIGURE 32.12 A photo of a *Hymenolepis diminuta* scolex. Note the lack of rostellar hooks. Reproduced from Centers for Disease Control and Prevention (http://phil.cdc.gov/PHIL/Images/370/370_lores.jpg) with permission.

oncosphere (hexacanth embryo). The oncosphere membrane has two polar thickenings from which 4–8 attached filaments arise. These are characteristic of *R. nana* and *R. microstoma* ova (Morrissey, 1996). These filaments extend into the space between the oncosphere and outer membranes. The oncosphere possesses three pairs of small hooks (Figure 32.11).

Hymenolepis diminuta is significantly larger than *R. nana* and has a pear-shaped scolex (Table 32.2). It has no rostellar hooks which further differentiates it from *R. nana* (Figure 32.12). The proglottids of *H. diminuta* are similar in shape to those of *R. nana*, but larger in size. The yellow-tinted, transparent ova of *H. diminuta* are spherical in shape, approximately twice the size of those of *R. nana* (Habermann and Fletcher, 1958) (Figure 32.13). These hardy ova are capable of

FIGURE 32.13 A photo of a *Hymenolepis diminuta* egg. Reproduced from Centers for Disease Control and Prevention/Dr. Mae Melvin (<http://phil.cdc.gov/phil/details.asp>) with permission.

surviving in feces for up to 6 months (Baker, 2007). The oncosphere of *H. diminuta* also contains three pairs of hooklets.

R. microstoma's developmental stages are similar in appearance to *R. nana* as adults possess rostellar hooks and the ova contain polar filaments (Table 32.2). Adult *R. microstoma* are generally larger in size, although an increased worm burden will negatively affect adult body length (Dvorak et al., 1961).

EPIZOOTIOLOGY The host specificity of *R. nana* is uncertain. Sources cite humans, wild or feral rodents, hamsters, and other lab rodents as definitive hosts (Larsh, 1946). *R. nana* may be found within non-human primates such as Rhesus macaques, squirrel monkeys, and chimpanzees (Wagner, 1987). Although *R. nana* is a prevalent human pathogen, a recent study indicates that the human strain of *R. nana* may be non-infective to rodents (Macnish et al., 2002). Attempts to infect rodent species such as rats with *R. nana* isolated from another rodent species have frequently failed, leading to the hypothesis that there are host-adapted strains of *R. nana* (Macnish et al., 2002; Vianna and de Melo, 2007). This is supported by evidence from experimental infections with *H. nana* which found the Syrian hamster to be the most permissive host when compared to experimental infections in other rodents (Larsh, 1946).

Definitive hosts for *H. diminuta* include hamsters, mice, and rats. Human infection with *H. diminuta* is rare and is most likely found in children (Macnish et al., 2002). These infections usually result from ingestion of dried fruits or cereals which are contaminated with infected intermediate hosts. The primary host of *R. microstoma* is the mouse, but cotton rats and hamsters

are also permissive hosts (Litchford, 1963). *R. microstoma* has also recently been detected as an infection in humans (Macnish et al., 2003).

CLINICAL MANIFESTATIONS Infection with *R. nana* rarely results in clinical signs (Morrisey, 1996). A small parasite load is relatively non-pathogenic, but increased intestinal burden may lead to clinical disease. In severe infections, decreased growth and emaciation have been observed (Wagner, 1987). Other sequelae include mechanical obstruction by worms leading to constipation, impaction, and eventually death (Soave, 1963). Infected young hamsters can have diarrhea and a pot-bellied appearance (Hankenson and Van Hoosier Jr., 2007). Poor husbandry has been cited as the major contributing factor in the development of clinical signs (Morrisey, 1996). *H. diminuta* causes clinical disease less frequently than *R. nana* (Morrisey, 1996). Experimental infections of Syrian hamsters with *R. microstoma* have resulted in significant clinical signs including emaciation, jaundice, and death (Dvorak et al., 1961).

PATHOLOGY Pathologic findings associated with *R. nana* infection include chronic catarrhal enteritis (Habermann and Fletcher, 1958). Severe cases may include the destruction of the intestinal mucosa. Abscesses of the mesenteric lymph nodes as well as hyperplasia of the Peyer's patches have been reported (Simmons et al., 1967; Wagner, 1987). One report demonstrated *Hymenolepis* in the duodenum, pancreatic ducts, bile ducts, and mesenteric lymph nodes, possibly contributing to liver cirrhosis in the infected animals (Chesterman, 1972; Chesterman and Pomerance, 1965). It is conceivable that these findings are due to a *R. microstoma* infection based on the location of the adult worm.

PATHOGENESIS/LIFE CYCLE *R. nana* is the only cestode with both direct and indirect lifecycles. The direct life cycle predominates for *R. nana*, lasting 14–16 days (Heyneman, 1963). The cycle begins with a definitive host's ingestion of embryonated eggs contained within feces. Eggs hatch in the anterior small intestine and the hexacanth larvae migrate into the local villi. Mucosal penetrance by the developing worm results in immunity which can prevent autoinfection (Heyneman, 1963). Once in the villi, the larvae develop into cysticercoids over the next 4–5 days. The developing worms exit the villi to attach to the lower ileal mucosa via the suckers and hooks of their scolices. Development into a mature worm takes 10–11 days. Adult worms survive for only a few weeks within the host. During this time, an adult worm may produce eggs which are expelled through the feces of its host.

Both *H. diminuta* and *R. microstoma* have obligate indirect lifecycles. Intermediate hosts are similar for

R. nana, *H. diminuta*, and *R. microstoma*. These include insects within the family Tenebrionidae, such as the confused flour beetle, *Tribolium confusum*. *R. nana* and *H. diminuta* can develop in other intermediate hosts such as moths, earwigs, fleas, and dung beetles. Intermediate hosts ingest cestode eggs within rodent feces. It takes approximately 2 weeks for the oncospheres to differentiate into cysticercoids within the hemocoel of *T. confusum* (Ito, 1997). However, the time to complete the indirect life cycle varies as the rate of larval development in intermediate hosts changes with environmental temperature (Wagner, 1987).

A definitive host is infected after ingesting an infected intermediate host. The indirect life cycle does not stimulate a protective immune response in the host due to the lack of a mucosal phase of parasite development (Heyneman, 1963). The ultimate locations of *H. diminuta* and *R. microstoma* adults within the final host vary from that of *R. nana*. *H. diminuta* adult worms are found predominantly within the upper small intestine. *R. microstoma* cysticercoids excyst within the duodenum and migrate to the bile duct within the next 5–7 days to mature. However, within hamsters they may remain solely within the duodenum (Macnish et al., 2003).

A unique feature of *R. nana* is the potential for autoreinfection. Autoreinfection occurs when eggs hatch within the host in which they were produced, rather than are excreted through the feces. Eggs then undergo development into mature worms within the intestinal tract of the original host. Evidence supports autoreinfection as a means for massive clinical infection in humans as well as potentially causing clinical disease in rodents (Heyneman, 1961). As stated above, induced immunity through the direct life cycle can prevent autoreinfection.

DIAGNOSIS There are several methods by which a cestode infection can be detected. Ova or proglottids (*H. diminuta*) can be observed directly in the feces or via crush preparations of intestinal contents. Adult worms may be visualized by inspection of the intestine at necropsy. Worm segments may also be seen on histologic preparations of host tissues. The ova of *R. microstoma* are very similar in appearance to *R. nana* and are not reliable for differentiation via light microscopy alone (Macnish et al., 2003). *R. microstoma* are also identifiable by finding adult worms within the bile duct (Baker, 2007). Molecular techniques such as PCR-RFLP or protein electrophoretic methods exist for species identification (Casanova et al., 2001; Macnish et al., 2003).

PREVENTION AND THERAPY There are several pharmaceutical and non-pharmaceutical methods for preventing and eliminating cestodes. The most effective method for control is maintaining a high level of

equipment and room sanitation along with wild rodent and arthropod control. Quarantine of incoming animals will aid in preventing the introduction of disease into animal facilities. Pet hamsters frequently carry *R. nana* and serve as a source of eggs which may be introduced into animal facilities by animal users (Pinto et al., 2001). Therapeutic measures to treat *R. nana* include the use of praziquantel, thiabendazole, and niclosamide (0.33% in feed for 7 days) (Ronald and Wagner, 1975). One study using *H. diminuta* as a model for testing anticestode medications derived oral, single administration doses for several agents, including praziquantel (3.125 mg/kg), bunamidine (100 mg/kg), niclosamide (200 mg/kg), cambendazole (50 mg/kg), and mebendazole (50 mg/kg) (Ostlind et al., 2004). It is reasonable to believe that these doses would be effective for treating *R. nana* and *R. microstoma*. One caveat exists regarding benzimidazole anthelmintics. *R. microstoma* is less susceptible to benzimidazole anthelmintics, such as albendazole and mebendazole, than other hymenolepidid tapeworms (McCracken et al., 1992).

Miscellaneous Cestodes

Taenia crassicollis

The cat cestode, *T. crassicollis* (= *Taenia taeniaeformis*) larval fragments were noted in hamster livers in one report (Chesterman and Negroni, 1961). Rodents are the intermediate host of this cestode, with its larval form previously known as *Cysticercus fasciolaris* (Irizarry-Rovira et al., 2007). Later experimental infections with this cestode failed to reproduce the reported natural infections (Olivier, 1962).

ARTHROPODS

Demodicosis

BACKGROUND *Demodex* spp. are in the class Arachnida along with ticks. These mites are further classified into the family Demodicidae within the suborder Prostigmata. *Demodex* mites are generally recognized to be host-specific. *Demodex* spp. have been reported in numerous species of hamsters including the Syrian hamster, the Siberian dwarf hamster, the Armenian hamster (*Cricetulus migratorius*), and the desert (Roborovski) hamster (*Phodopus roborovskii*) (Karaer et al., 2009; Tani et al., 2001). They are the most common ectoparasites of hamsters. Not all *Demodex* spp. have been definitively identified. Demodectic mites are still prevalent as health reports from a hamster vendor indicate an infection rate of approximately 5% (Charles River Laboratories International, Inc., 2009).

ETIOLOGY/ETIOLOGIC AGENT The identified mites include *Demodex criceti* and *D. aurati* of the Syrian hamster, *D. cricetuli* of the Armenian hamster, and *D. sinocricetuli* of the Chinese striped hamster (*Cricetulus griseus*). *D. criceti* has been described as the “stubby” mite due to its rounded body throughout all stages of development (Hasegawa, 1995) (Figure 32.14). There is sexual dimorphism for hamster *Demodex* spp. with the female mite typically being larger than the male (Table 32.3). In *D. criceti* the greater length of the female is due to a longer opisthosoma, the posterior portion of the body (Nutting and Rauch, 1958). The ova of *D. criceti* are thin-shelled and transparent. The larval form of *D. criceti* has six plates which appear similar to legs, though

FIGURE 32.14 A photo of *Demodex criceti*, a mite of hamsters and gerbils. Note that this mite has similar short stubby legs but its body is shorter than that of *D. aurati*. ^aFrom Bornstein and Iwarsson, 1980; Desch and Hurley, 1997; Hurley and Desch, 1994; Hurley et al., 1992; Nutting, 1961; Nutting and Rauch, 1958; Nutting and Rauch, 1963; Uzal et al., 2007; Watson, 2008.

*In engorged state.

they have no capability for movement. There is size and morphologic variation within larval and nymph forms because of the multiple molts. The early nymph stages have four pairs of plate legs which most likely serve to hold the mite in its location. During later nymph and adult stages these develop into eight functional legs with two terminal claws (Nutting and Rauch, 1958).

D. aurati differs from *D. criceti* as it has a thin, elongate body terminating in a sharp opisthosoma (Figure 32.15). Adult *D. aurati* average almost twice the length of adult *D. criceti* (Table 32.3). The transparent, thin-shelled ova of *D. aurati* are spindle-shaped, with the length being approximately four times the width. The acutely tapered end of the ovum will become the posterior end of the adult (Nutting, 1961). Larvae are variable in length and also have six plate legs with two small claws. There is no determination of the difference between deutonymphs from protonymphs (Nutting, 1961). Nymphs have eight plate legs with two small claws.

Originally identified as *D. aurati*, *D. cricetuli* is a separate species which infects the Armenian hamster (Hurley and Desch, 1994). It is similar in size and appearance to *D. aurati* (Table 32.3). The opisthosomal terminus of *D. cricetuli* adults is more rounded than that of *D. aurati* adults (Hurley and Desch, 1994). The ova are spindle-shaped. The larval and nymph stages are

FIGURE 32.15 A photo of *Demodex aurati*, the mange mite of hamsters and gerbils. Note the vermiform shape and 4 pairs of short stubby legs. Reproduced from University of Missouri Research Animal Diagnostic Laboratory (<http://www.radil.missouri.edu/ectoparasites.html>) with permission.

similar in appearance to those of *D. aurati*. The legs of the *D. cricetuli* larvae have only one small claw per leg.

D. sinocricetuli is also similar to *D. aurati* in appearance. The adult males are approximately two-thirds the length of *D. aurati* males, and adult females are approximately three-quarters the length of *D. aurati* females (Table 32.3). Differentiating it from the previous demodectic mites discussed, *D. sinocricetuli* does not have uniform spacing between its legs. The opisthosoma of the female is more rounded at the terminus than that of the

male. The eggs are ovoid, with a posterior tapering. The fusiform larvae lack ventral scutes, which the immature stages of *D. aurati* possess (Desch and Hurley, 1997).

EPIZOOTIOLOGY Most *Demodex* spp. are normal fauna, found in small numbers on healthy animals causing no overt disease. They may become pathologic under situations of high stress, illness, or immune suppression. Transmission of mites is by direct contact or vertical transmission at the time of suckling. Demodectic mites have been recovered from juvenile hamsters as young as 5 days of age (Nutting and Rauch, 1958). Due to host specificity, hamster *Demodex* mites are not zoonotic.

CLINICAL MANIFESTATIONS Even with high infestation numbers, *D. criceti* rarely causes clinical signs (Nutting and Rauch, 1958). *D. aurati* infections are more likely to result in clinical signs than *D. criceti*. Clinical signs vary from rough hair coats to dermatitis with moderate to severe dorsal alopecia extending from the neck to the hind quarters. Alopecic areas are dry with excoriations and scales (Estes et al., 1971; Heath and Bishop, 1984; Karaer et al., 2009). Abdominal skin may be affected (Tani et al., 2001). Pruritus is uncommon. *D. cricetuli* does produce a mild to moderate degree of pruritus along with a scaling dermatitis and alopecia (Hurley et al., 1992). Epidermal hyperemia may be seen along with a mild serous exudate. No clinical signs have been reported for *D. sinocricetuli*.

PATHOLOGY *D. criceti* is generally of low to no pathogenicity. Microscopically, *D. criceti* mites are found in epidermal pits which extend from the epidermal surface to the *stratum basale* (*stratum germinativum*), rarely entering into the dermis. All life stages of *D. criceti* lie within the pits with their mouth parts facing towards the dermis. They are not found within normal hair follicles.

D. aurati can distort the normal morphology of hair follicles. Normal-appearing or dilated hair follicles may contain up to five mites of either gender along with debris (Nutting, 1961). Hair shafts from infected hair follicles are variably lost. *D. aurati* causes little inflammation, but the *stratum corneum* may show mild to moderate hyperkeratosis (Estes et al., 1971).

D. cricetuli also dilate the lumen of hair follicles, as up to six mites may live within a single follicle (Hurley and Desch, 1994). Mite opisthosomas have been observed to protrude from hair follicles (Hurley and Desch, 1994). Histopathology may include hyperkeratosis, parakeratosis, epidermal hyperplasia with lengthening of the rete pegs, and some areas of suppurative inflammation (Hankenson and Van Hoosier Jr., 2007; Hurley et al., 1992). Pathologic effects are not reported for *D. sinocricetuli*.

PATHOGENESIS/LIFE CYCLE The direct life cycle of *Demodex* spp. requires approximately 24 days to complete. Following hatching, *Demodex* mites undergo several stages of development beginning with the larval stage and progressing through the protonymph and deutonymph stages to eventually molt into an adult. Research has not elucidated the number of molts undertaken by the larval and nymph forms (Nutting and Rauch, 1958).

D. criceti and *D. aurati* complete their life cycles within different ecological niches of the Syrian hamster's epidermis, permitting dual-species infection. *D. criceti* creates pits in the epidermis of its host. Eggs deposited into epidermal pits hatch and develop into larvae and nymphs. The mite spends its entire life within these pits, apparently feeding on epidermal cells (Nutting and Rauch, 1958). Rarely, *D. criceti* exist upon the host epidermis (Nutting, 1961).

All stages of *D. aurati* are found within the pilosebaceous system. There is no preference by the mite to hair type; mites were found in all hair follicle types or adherent to all hair types (Nutting and Rauch, 1963). Eggs are laid singly within the hair follicle at a level adjacent to the sebaceous canal. After hatching, larvae migrate deeper into the hair follicle below the sebaceous canal opening. Larvae and nymphs feed on epithelial cells as they molt. Following development into adults, the mites return to the level of the sebaceous canal to mate and lay eggs. Adult mites appear to eat follicular epithelial cells and sebaceous gland cells. *D. aurati* have also been found within Meibomian and perineal glands (Nutting and Rauch, 1963).

D. cricetuli are found within hair follicles throughout the body, but the greatest densities are found on the dorsum and face (Hurley and Desch, 1994). Similarly to *D. aurati*, adult *D. cricetuli* may feed on sebaceous gland cells along with follicular epithelium.

Clinical disease has been associated with immunosuppressive factors such as underlying disease, advanced age, malnutrition, and the presence of tumors (Estes et al., 1971; Tani et al., 2001). *Demodex* mites possess a lipase which hydrolyzes triglycerides in the sebum leading to the release of fatty acids which have an irritant quality (Jimenez-Acosta et al., 1989). This may explain why *D. aurati* has been reported as more pathogenic than *D. criceti*, as *D. aurati* are found within the pilosebaceous system. Gender differences possibly exist as male hamsters are reported to carry heavier infestations than female hamsters (Nutting and Rauch, 1963; Tani et al., 2001).

DIAGNOSIS Deep skin scrapes from the dorsum or from alopecic areas are the recommended method for detection of *D. criceti*, *D. cricetuli*, and *D. sinocricetuli* (Hurley and Desch, 1994; Nutting, 1961). Skin scrapes

and hair plucks are also useful for *D. aurati* detection; hair plucks will identify the adult form of *D. aurati* (Nutting and Rauch, 1963). Skin scrapes should be deep enough to cause erythema (Hankenson and Van Hoosier Jr., 2007). To increase the probability of mite detection, skin scrapings can be cleared with 5–10% sodium hydroxide or potassium hydroxide. Different life stages of mites may be seen in histologic preparations. By 16 hours after the death of the host, mites will move from their epidermal locations allowing for collection from the skin surface (Nutting and Rauch, 1963). Radiant heat applied to excised skin samples will also incite *Demodex* mites to leave the epidermis (Nutting and Rauch, 1963). Male hosts should be tested preferentially due to their higher mite burdens. Even if *Demodex* mites are noted, other causes of dermatitis such as bacterial infections, bite wounds, dermatophytes, or other ectoparasites need to be ruled out (Wagner, 1987). The presence of *Demodex* could be incidental within a lesion.

PREVENTION AND THERAPY Prevention of disease due to *Demodex* requires maintenance of high standards for animal health and well-being. Stressful situations should be minimized through proper husbandry techniques including appropriate housing and sanitation. Incoming animals should be properly quarantined and tested. Although treatment regimens exist as described below, identification and culling of infected animals is recommended (Hankenson and Van Hoosier Jr., 2007).

Application of topical miticidal amitraz (0.0013%) is a standard treatment for demodicosis. Treatment regimens vary from once weekly to once every 14 days. It is recommended that treatment continues for at least 4 weeks following a negative skin scraping (Hasegawa, 1995; Meredith, 2006). The efficacy of and tolerance to amitraz is animal-dependent; following the first dose the animal should be monitored carefully for adverse effects (Tani et al., 2001). Coumaphos (0.017%), another topical miticide, can be applied every 4 days for 2 weeks, then every 7 days for 2 weeks (Hasegawa, 1995). Repeated application of topical medications is necessary as immature mites hide deep within the epidermis where medication may not reach (Tani et al., 2001). Topical miticides should be applied with a cotton-tipped applicator or toothbrush. Once-weekly selenium sulfide or benzoyl peroxide shampooing can be used in conjunction with topical miticide treatment (Hasegawa, 1995). Oral ivermectin has proven efficacious at a dose of 0.3 mg/kg daily; however, the authors report that this may not be the optimal dosing regimen (Tani et al., 2001). For *D. cricetuli*, topical ivermectin at a dose of 0.3 mg/kg for 10 days has been recommended (Hankenson and Van Hoosier Jr., 2007). The above treatment regimens are assumed effective for *D. sinocricetuli* as adequate treatment information is not available.

Notoedric Acariasis

BACKGROUND Two species of *Notoedres* capable of infecting hamsters have been identified, *Notoedres cati*, the cat mange mite, and *Notoedres notoedres*. These mites fall within the family Sarcoptidae, along with *Sarcoptes scabiei*. These mites, causes of notoedric mange are no longer common parasites of laboratory animals. Literature of the 1940s and 1950s repeatedly reported cases within animal facilities (Wantland, 1955). Today it exists as a pet hamster disease, but without cumulative data on its true prevalence (Beco et al., 2001).

ETIOLOGY/ETIOLOGIC AGENT *Notoedres* spp. are small, round mites closely resembling *Sarcoptes* (Figure 32.16). Female mites are larger than male mites (Table 32.3). *Notoedres* adults have posterior limbs which do not protrude past the body margins (Leone, 2007). They also possess blunt dorsal spines and a dorsal anus which aids in differentiating them from *Sarcoptes* (Uzal et al., 2007). Males and females can be differentiated by the lack of a mid-dorsal shield in females.

EPIZOOTIOLOGY Transmission is by direct contact between animals and presumably by contact with infected bedding (Beco et al., 2001). The nymph and larval stages are the predominant transmissible stages of this highly contagious disease. It will spread rapidly within a colony if proper treatment strategies are not initiated. Unlike *Sarcoptes*, *Notoedres* appears to have limited zoonotic potential.

CLINICAL MANIFESTATIONS The clinical signs of *Notoedres* infections are severe pruritus, erythema, crusts, erosions, and hyperpigmentation (Beco et al., 2001). These lesions may be generalized, but are more often found on ear pinnae, face, genitalia, tail, and limbs (Beco et al., 2001) (Figure 32.17). These lesions may result in death within 2–3 months if left untreated (Wagner, 1987).

PATHOLOGY Infections with *N. cati* cause chronic inflammatory changes in the epidermis. Extrapolating from *N. cati* infections in other species, potential changes include hyperkeratosis and acanthosis along with inflammatory cells, cellular debris, and mites in the epidermis (Uzal et al., 2007). One or more mites are found within tunnels in the stratum corneum.

PATHOGENESIS/LIFE CYCLE The life cycle of *Notoedres* is not clearly understood (Uzal et al., 2007). Ova are deposited within epidermal tunnels. These ova hatch into six-legged larvae within 3–4 days. These larvae undergo several more molts, transforming into eight-legged nymphs in approximately a 3-day period. These nymphs continue to molt as they burrow within the skin,

FIGURE 32.16 A photo of *Notoedres* mite characterized by a dorsal anus. Skin scraping; chloral lactophenol. Reproduced from Beco et al. 2001 with permission.

FIGURE 32.17 A photo of a hamster with lesions of *Notoedres* infestation on its face and feet. Severe crusting can be observed on the muzzle, ears, and extremities. Reproduced from Beco et al. 2001 with permission.

eventually becoming adults. The entire cycle is estimated to take 10–20 days (Baker, 2007; Wantland, 1955). All three mobile life stages can be found on the skin.

Epidermal burrowing by mites causes pruritus and increases potential for secondary bacterial infections following mechanical damage to the skin by mites and the host's attempts to alleviate discomfort through scratching.

DIAGNOSIS Diagnosis is made by observation of mites and fecal pellets on skin scrapings using light microscopy (Beco et al., 2001).

PREVENTION AND THERAPY Along with proper sanitation and cage changing, several methods for elimination of *Notoedres* infections are reported. Whole body lime-sulfur dips can be done once a week and continued for 2 weeks after a negative skin scrape. One study compared treatment of infected hamsters using ivermectin and moxidectin (Beco et al., 2001). Once-weekly subcutaneous ivermectin (400 µg/kg) or once- or twice-weekly oral moxidectin (400 µg/kg) were each given for 8 weeks. Both reduced clinical signs dramatically, but neither treatment led to complete remission. Repeat skin scrapings are therefore necessary to ascertain the effectiveness of these drugs. Selamectin has also been used successfully to treat notoedric mange in cats (Itoh et al., 2004).

Ornithonyssus spp.

BACKGROUND *Ornithonyssus* spp. are mesostigmatid mites of the family Macronyssidae. The two *Ornithonyssus* species reported to infect hamsters are *Ornithonyssus bacoti*, the tropical rat mite or red mite, and *Ornithonyssus sylviarum*, the northern fowl mite. Although *O. bacoti* has a wide host range, the primary hosts are the brown Norway rat (*Rattus norvegicus*) and the black roof rat (*Rattus rattus*) (Fox, 1982). Its common name is also a misnomer, as it is found in tropical and moderate climates (Beck and Folster-Holst, 2009). Historical reports of severe *O. bacoti* infections in hamsters exist, and although no hamster-specific outbreaks have been reported in the last 10 years, outbreaks within animal facilities have occurred infrequently in this

FIGURE 32.18 A photo of ventral view of *Ornithonyssus bacoti* with anal (A), genital (B) and sternal (C) shields labeled. Reproduced from Hill et al. 2005 with permission.

time (Watson, 2008). *O. sylviarum* is a common mite of chickens in temperate climates. The hamster may serve as an incidental host (Miller and Price, 1977).

ETIOLOGY/ETIOLOGIC AGENT *O. bacoti* have dorsoventrally flattened bodies (Figure 32.18). It has four pairs of jointed legs arising from the cranial half of the body. Males and females can be distinguished by the number of chitinous thickenings on their ventrums, the ventral shields. Males have one ventral shield and females have three. *Ornithonyssus* appear white prior to feeding, when they then become a red-brown following engorgement (Watson, 2008). Female mites will double in size following engorgement (Table 32.3). The mite is visible to the naked eye at this time. *O. sylviarum* resembles *O. bacoti*. These can be differentiated as *O. bacoti* has a greater number of hairs and an anal plate with a cranial anus as compared to few hairs and an anal plate with a caudal anus of *O. sylviarum* (Beck and Folster-Holst, 2009).

EPIZOOTIOLOGY If it does not find a suitable rodent host, *O. bacoti* will feed upon humans causing pruritic papules on the skin. Pet hamsters are documented as sources of human disease (Creel et al., 2003). As well as causing discomfort, *O. bacoti* has the capability to carry pathogens such as *Litomosoides carinii*, a rodent filarial nematode, and other diseases such as *Francisella pestis*, *F. tularensis*, and *Trypanosoma cruzi*. Whether they serve as vectors for human infection is uncertain (Watson, 2008).

CLINICAL MANIFESTATIONS *O. bacoti* does not typically cause clinical signs in hamsters. Heavier

infestations may lead to severe anemia and death (Creel et al., 2003). In humans, cutaneous lesions such as pruritic papules result as a response to mite saliva (Fox, 1982).

PATHOGENESIS/LIFE CYCLE *O. bacoti* females will feed on a host for up to a day. Two to three days following this blood meal, females will lay 90–120 eggs in different environmental locations such as cage nesting material. These eggs hatch and undergo four more developmental stages (Fox, 1982). Non-feeding, six-legged larvae hatch within 1–4 days. These molt into an eight-legged protonymph which requires a blood meal. The nymph has up to 3 weeks to find a suitable host upon which to feed or it will die (Wagner, 1987). The nymph undergoes another molt to a non-feeding deutonymph stage 1–2 days prior to molting into an adult. The life cycle is generally completed within 11–16 days (Beck and Folster-Holst, 2009).

DIAGNOSIS Often detection of the mite results from laboratory animal facility staff complaining of insect bites (Watson, 2008). The mites can be visualized as small black to red dots moving upon the animals or with cages. Application of adhesive tape to the pelage of the animal followed by microscopic evaluation may reveal nymphs or adults (Beck and Folster-Holst, 2009).

PREVENTION AND THERAPY Repeated animal and facility treatments will be required to eliminate mites for several reasons. Mites are capable of surviving off of a host for extended periods of time, they may lay large numbers of eggs which are hidden throughout the laboratory environment and it has a rapid reproduction rate (Creel et al., 2003; Hill et al., 2005). *O. bacoti* can enter individually ventilated cages, making exclusion of this pest difficult once an infestation is present (Watson, 2008). Infestation can spread through the nocturnal journey of mites searching for new hosts. Environmental treatment should be the first action step followed by individual animal or cage treatments. Synthetic pyrethroids have been used successfully for environmental decontamination (Hill et al., 2005). Pest eradication professionals should be consulted to determine a proper treatment plan which will prevent unnecessary exposure of personnel to insecticides (Watson, 2008). At the cage and animal level, there are several medications which have shown efficacy. Permethrin-impregnated cotton balls (7.4%) were placed in cages weekly for 5 weeks to eliminate infection from mouse cages (Hill et al., 2005). Ivermectin has not been reported as a treatment for *O. bacoti*, but a single application of selamectin to infected gerbils eliminated infection within a week (Fisher et al., 2007).

Speleorodens clethrionomys

S. clethrionomys is a nasal mite. A single report details the infection of laboratory hamsters with this mite (Bornstein and Iwarsson, 1980). These mites do not appear to cause clinical signs. Mites are most readily identified living on the mucosa of the posterior nasal cavity (Bornstein and Iwarsson, 1980). Mites appear oval in shape and milky white in color. Only female mites of this species have been described (Table 32.3). Treatment suggestions have not been proposed, however ivermectin and other types of avermectins may be effective.

Radfordia cricetuliphila

The identification of fur mites in laboratory hamsters is not well documented. The importance of these reported mites in a laboratory animal setting is undetermined at this time. Several species of Myobiid mites are reported in feral hamsters. Subspecies of *Radfordia cricetulus* have been collected from *Cricetulus migratorius* in Iran (Fain and Hyland, 1980). A myobiid mite, *Radfordia cricetuliphila* sp. n., has been identified on the striped hamster, *Cricetulus barabensis*, in a Russian Republic (Bochkov, 1999).

INTRODUCTION

Hamsters are generally hardy animals when housed under optimal conditions. As with many species, however, even animals free of infectious pathogens develop disease associated with conditions such as advancing age, heredity, and environment. This chapter summarizes such conditions as recorded in the published literature.

DISEASES ASSOCIATED WITH AGING

Amyloidosis

Background

Amyloidosis is the non-infectious disease of primary importance in the aging Syrian hamster (Franks and Chesterman, 1957). The incidence of amyloidosis varies

by hamster colony (Pour et al., 1976a, 1979), and there is a higher incidence of amyloidosis in females compared to males (Coe and Ross, 1990; Tennent et al., 1993). Amyloidosis results from the extracellular deposition of highly ordered proteinaceous material in tissues (Eanes and Glenner, 1968; Gruys et al., 1979; Kisilevsky and Young, 1994; Mezza et al., 1984).

Etiology

The amyloid fibril is the major component of amyloid. Amyloid forms from the straight, non-branching arrangement of fibrils which contain a high amount of beta-pleated sheet secondary structure (Eanes and Glenner, 1968; Glenner, 1980a, 1980b). Amyloid fibrils are derived from precursor proteins, and other proteins that can be transformed into fibrils (Kisilevsky and Young, 1994). In the Syrian hamster, amyloid fibrils are typically composed of Amyloid A and Amyloid P proteins (Coe et al., 1981; Linke et al., 1984). As in other species, there is a growing list of other distinct proteins that can be recruited into amyloid fibrils.

Epizootiology and Clinical Manifestations

Spontaneous age-related systemic amyloidosis is associated with early mortality in Syrian hamsters (Anderson et al., 1978; Chesterman and Pomerance, 1972; Gleiser et al., 1971; McMartin, 1979; Pour et al., 1976a, 1979; Redman et al., 1979; Schmidt, 1983). Amyloidosis can be detected in hamsters as early as 5 months of age, but there was a documented increase in mortality in 15–20-month-old hamsters when the incidence of amyloidosis of the liver and kidney was the highest (Schmidt, 1983).

The occurrence of amyloidosis differs by sex. There is a higher incidence, increased severity, and earlier onset of amyloidosis of the liver, kidney, stomach, adrenal, thyroid, and spleen of female hamsters (Coe and Ross, 1990; Schmidt, 1983; Tennent et al., 1993). The increased incidence is related to a higher expression of “Female Protein” compared to males. The “Female Protein” is a plasma protein with similar biochemical and functional characteristics compared to Amyloid P, and is under sex hormone control (Coe and Ross, 1990; Coe et al., 1977, 1981, 1997; Pepys et al. 1982; Tennent et al., 1993).

Pathology and Pathogenesis

Amyloid may be diagnosed in histological sections using characteristic colors imparted by special stains: green birefringence when stained with Congo red, metachromasia when stained with crystal or methyl violet, and secondary fluorescence when stained with thioflavin S and thioflavin T (Glenner, 1980a, 1980b; Husby and Sletten, 1986; Jakob, 1971). As seen with the electron microscope, amyloid is composed of non-branching fibrils approximately 100 Å in diameter, which are

composed of two or more twisted subfilaments about 40 Å diameter and separated by a 20-Å gap, forming a double helix of 100-Å periodicity (Jones et al., 1997).

Hepatic amyloidosis was detected as early as 5 months of age in one Syrian hamster colony (Schmidt, 1983). Eosinophilic, homogeneous deposits appear to develop first in the vascular walls and portal triads. With advanced disease, the portal areas and adjacent parenchyma fill with amyloid. The accumulation of amyloid accentuates the lobular architecture of the liver. These histologic changes typically promote the appearance of a swollen liver with accentuated lobes.

Renal amyloidosis typically presents primarily as glomerular depositions; but interstitial and combined amyloidosis can also occur (Schmidt, 1983). Kidneys often appear pale tan, enlarged, and/or misshapen. Amyloid deposition occurs in the glomerular and tubule basement membranes, but with advanced disease amyloid can disrupt the ultrastructure of the kidney (Percy and Barthold, 2007). Glomerular amyloidosis was reported to be the main cause of death in Syrian hamsters (Redman et al., 1979), and has been associated with atrial thrombosis (McMartin and Dodds, 1982). In another study, amyloidosis was observed in the liver, kidney, and adrenal gland, with 88% of hamsters greater than 18 months of age experiencing amyloidosis (Gleiser et al., 1970). In that study, amyloidosis was first detected in the kidneys and was accompanied by a rise in serum globulins.

Adrenal amyloid was observed to deposit initially in the zona fasciculata and zona reticularis, with eventual collection throughout the cortex. This deposition was seen as early as 5 months of age and became more frequent after 15 months (Schmidt, 1983).

Amyloid deposition may also occur in the salivary glands, stomach, small intestine, thyroid gland, parathyroid gland, spleen, meninges, trachea, lung, gallbladder, and pancreas (Chesterman, 1972; Frenkel, 1958; McMartin, 1979; Percy and Barthold, 2007; Pour et al., 1976b; Schmidt, 1983).

Diagnosis

Microscopic examination of affected tissues is the most reliable method of diagnosis. Special histochemical staining procedures as described above are useful for verifying the presence of amyloid in tissues. Use of the potassium permanganate method with Congo red stain can be used to distinguish types of amyloid fibrils in tissues (Mezza et al., 1984).

Prevention and Therapy

Amyloidosis occurs spontaneously in the aged Syrian hamster and there is no treatment for this disease (Anderson et al., 1978; Schmidt, 1983). The incidence of amyloidosis in female hamsters may be reduced through

feeding a diet high in fat and protein, but this does not completely prevent the disease (Birt and Pour, 1985). Since the incidence of amyloidosis varies based on colony source (Pour et al., 1976a, 1979), selecting the appropriate source of hamsters may be another approach to reducing the occurrence of amyloidosis when establishing a colony.

Glomerulonephropathy

Epizootiology and Pathogenesis

Among those diseases associated with the aging hamster, glomerulonephropathy remains an important cause of morbidity and mortality. Schmidt (1983) described progressive and degenerative kidney disease affecting both the tubules and connective tissue. In severe cases, areas of tubular collapse and connective tissue proliferation resulted in gross manifestations, visible on the capsular surface. The etiology and pathogenesis of this disease process remains unclear (Schmidt, 1983).

Doi et al. (1987) described a systematic pathological study comparing age-related, non-neoplastic lesions in the heart and kidneys of APA strain Syrian hamsters. This colony was developed and maintained as a closed breeding colony in Japan. In this colony, renal lesions developed more rapidly in females and were found more frequently and with greater severity than in males. In general, the renal lesions closely resembled glomerulonephropathy (chronic progressive nephrosis) of aged rats. Further characterization using electron microscopy of the same colony of APA strain Syrian hamsters revealed the lesion to be progressive and associated with advancing age (Han et al., 1992).

Pathology

Schmidt et al. (1983) described early kidney lesions as minimal and displaying areas of radial tubular atrophy, with minimal amounts of connective tissue. Severe lesions had variable numbers of linear or wedge-shaped areas of tubular collapse and increased amounts of connective tissue, which resulted in gross changes to the renal capsule. Most glomeruli in affected areas appeared normal, while tubular dilatation was common throughout much of the kidney. Most of the tubular luminae were empty, indicating functional nephrons, though some contained proteinaceous fluid and the glomeruli had changes to the mesangium and basement membranes but did not stain positive for amyloid. Inflammatory cells in affected kidneys were minimal or absent, and vascular lesions were not observed.

Doi et al. (1987) graded renal lesions in APA strain hamsters as mild, moderate, or severe based on the number of nephrons involved in each cross-section of tissue. Mild cases demonstrated focal changes consistent with tubular atrophy and/or tubular dilatation with proteinaceous casts scattered throughout

the tissue section. Segmental thickening of the basement membrane, mesangium, and Bowman's capsule was also observed in some nephrons. Moderately diseased kidneys demonstrated more injured nephrons and wedge-shaped or linear lesions extending from the subcapsular zone to the inner medulla. Injured nephrons were characterized by tubular dilation and thickening of peritubular basement membranes with a mild increase in interstitial connective tissue. Dilated tubules commonly contained proteinaceous material, while glomeruli demonstrated, on occasion, eosinophilic and PAS-positive deposits in the capillary walls and mesangium, resulting in segmental thickening. Severely affected kidneys, in which over half of the nephrons were involved, typically had large numbers of proteinaceous casts. The presence of interstitial connective tissue around the atrophied tubules was also a common finding. Despite many of the glomeruli showing increased intercapillary PAS-positive deposits and other glomerular changes, no amyloid deposits were detected.

Kamino et al. (2001) investigated age-related spontaneous non-neoplastic processes in a colony of Han:AURA hamsters. Interestingly, calcification, cystic change, and infarction, were frequently found as concurrent lesions in the kidneys and were considered as evidence of chronic progressive nephropathy.

Atrial Thrombosis

Background and Epizootiology

Thrombosis of the heart chambers is a common finding in aged Syrian hamsters but the incidence varies widely by colony. Pour et al. (1976a) reported an incidence of 16% in one colony versus 35% in another. McMartin (1977) reported a 73% incidence in yet a different colony of aged hamsters. Males and females were equally affected but females developed the condition at an earlier age. In a study of 750 control, male hamsters on long-term carcinogenicity studies, atrial thrombosis was the most frequently observed cardiovascular lesion (Schmidt, 1983). The condition was first seen at 13 months of age, with a peak incidence at 27 months of age. According to Doi et al. (1987), cardiac thrombosis was commonly seen in the APA strain of Syrian hamsters. It affected primarily the left atrium and was diagnosed in 71% of males and 50% of females over 16 months of age that died spontaneously. Of interest is that of the 16 male hamsters that were euthanized per protocol at 18 or 24 months, only three showed evidence of cardiac thrombosis.

Clinical Signs

Clinical signs, when reported, were consistent with heart failure, including hyperpnea, tachycardia, and cyanosis (Sichuk et al., 1965).

Pathogenesis

Changes in coagulation and fibrinolytic parameters suggest a consumption coagulopathy (McMartin and Dodds, 1982). The authors theorized the thrombi occurred as a result of local blood stasis, secondary to heart failure.

Pathology

Grossly, thrombi were present primarily in the left atrium, and usually filled the atrium (McMartin and Dodds, 1982). The authors also noted bilateral ventricular hypertrophy in thrombosed hearts and myxomatous thickening of the atrioventricular valves. However the AV valve lesions were found in most aged hamsters, regardless of whether or not thrombi were present. Myocardial degeneration was also a common finding in aged hamsters (McMartin and Dodds, 1982). Doi et al. (1987) reported that the absolute and relative heart weights increased with age, suggesting cardiac hypertrophy in older APA hamsters.

Prevention

In one study, the incidence of cardiac thrombosis was reduced to zero when hamsters were fed a low-fat/high-protein diet during the first 3–7 weeks of life (Birt and Pour, 1985). However, the incidence in hamsters fed other diets (control and varying levels of fat and protein) was only 6%, which is significantly less than seen in other colonies of Syrian hamsters.

Polycystic Disease

Background

Polycystic disease is an incidental finding typically affecting the liver in older Syrian hamsters (Gleiser et al., 1970).

Etiology

The cause of polycystic disease in hamsters is not fully understood. There appears to be a genetic predisposition for cyst formation since the incidence of cysts varies based on the colony under study (Gleiser et al., 1970; Kaup et al., 1990; Somvanshi et al., 1987). Congenital abnormalities of hepatic or bile duct development have also been implicated in polycystic disease (Somvanshi et al., 1987).

Epizootiology

Polycystic disease is a common postmortem finding in Syrian hamsters between 6–24 months of age (Gleiser et al., 1970; Kaup et al., 1990; Pour et al., 1976a; Schmidt, 1983; Somvanshi et al., 1987). Cysts are typically found in the liver, but cystic dilations may also be present on the epididymis, seminal vesicle, pancreas, endometrium, ovary, esophagus, and adrenal gland.

Clinical Manifestations

Polycystic disease is an incidental finding, and Syrian hamsters typically do not develop clinical signs associated with this condition. However, one study reported abdominal enlargement in an affected hamster due to ascites (Somvanshi et al., 1987).

Pathology

On gross examination, cysts vary in size, but may be as large as 3 cm in diameter (Somvanshi et al., 1987). Hepatic cysts have thin walls and contain clear to straw-colored fluid, and may occupy the parenchyma or be located on the capsule (Gleiser et al., 1970; Kaup et al., 1990; Pour et al., 1976c; Somvanshi et al., 1987).

Microscopically, cysts are present as small unilocular or large multilocular cystic areas. Low cuboidal or flattened epithelial cells line the cysts, and these thin-walled structures contain homogeneous eosinophilic material (Gleiser et al., 1970; Kaup, 1990; Somvanshi et al., 1987). Pressure necrosis of the adjacent liver parenchyma, hemosiderin deposition, and lymphocytic infiltrations are variable pathologic changes associated with polycystic disease of the liver (Somvanshi, 1987).

Pathogenesis

The exact mechanism of cyst formation in the hamster is unknown. Histopathology and epidemiology suggest a congenital condition resulting from abnormal hepatic and bile duct development (Somvanshi et al., 1987). Further investigation is necessary to substantiate these findings.

Diagnosis

Polycystic liver disease of the Syrian hamster is an incidental finding that is easily diagnosed on necropsy and confirmed with histopathology.

Prevention and Therapy

There is no treatment or proven method of prevention for polycystic disease.

Hepatic Cirrhosis

Epizootiology and Pathogenesis

Pathological lesions in the liver including hepatic cirrhosis have been reported as incidental findings (Fortner, 1957; Frenkel, 1963; Galton, 1964; Ising, 1956; Klement and Svoboda, 1963). Chesterman and Pomerance (1965) reported finding pathological features of hepatic cirrhosis and liver tumors affecting mostly their inbred breeding stock and experimental study animals. The incidental finding of cirrhosis increased from less than 1% to greater than 20% during a 5-year period. Interestingly, the increased incidence

in cirrhosis was mirrored by an increased incidence of hepatic tumors. Both of these findings were more common in female hamsters and the number of lesions in both sexes increased as the hamsters aged. Of the experimental animals identified as having cirrhosis and hepatic tumors, most were over 6 months of age. It was speculated that dietary contamination, infectious agents, and/or genetics could have played a role in the development of these diseases; however, the etiology is still unknown (Chesterman and Pomerance, 1965).

Pathology

The dominant microscopic feature of the cirrhotic livers was periportal fibrosis and bile duct proliferation (Chesterman and Pomerance, 1965). Also noted were small groups of hepatic lobules separated by broad bands of tightly arranged regular acini and bile duct proliferation. Most of the hepatic tumors seen were cholangiocarcinomas, described as groups of firm gray nodules distributed in the subcapsular surface of the liver.

NUTRITIONAL DISORDERS

Spontaneous Hemorrhagic Necrosis (SHN) of the Central Nervous System

Spontaneous hemorrhagic necrosis has been reported in neonatal hamsters and fetuses during the last trimester of pregnancy. While the etiology is unknown, vitamin E deficiency has been implicated in this condition. In one study, supplementing the dam on day 7 of gestation with low levels of vitamin E significantly decreased the incidence and severity of lesions, while supplementation with high levels of vitamin E eliminated the condition entirely (Keeler and Young, 1979). In affected hamsters, hemorrhage and edema are seen initially in the forebrain, progressing to intraventricular hemorrhage and necrosis of portions of the axial nervous system (Young and Keeler, 1978). Clinical signs include stillbirths and/or weak neonates that fail to survive.

GENETIC, TRAUMATIC, ENVIRONMENTAL AND OTHER NON-INFECTIOUS DISEASES

Hereditary Hydrocephalus

Epizootiology and Pathogenesis

The prevalence of hereditary hydrocephalus in the Syrian hamster varies based on the colony under study. Yoon et al. (1972) reported a sporadic and lethal case of hydrocephalus, which resulted in the death of most

of the affected animals prior to reaching breeding age. All of the affected animals had a characteristic dome-shaped head. A more recent report described a high incidence of hydrocephalic animals in a colony of Swiss golden hamsters (Edwards et al., 2006). In contrast to the first report, these hamsters did not have the characteristic phenotype or the behavioral or neurological deficits despite 71% of the animals having severe gross lesions and 81% showing both gross and microscopic evidence of hydrocephalus.

Pathology

Hydrocephalic features included greatly distended lateral ventricles, which were fused together forming a large space filled with cerebral fluid. The third ventricle was less affected, but combined with the weight of the lateral ventricles compressed the fourth ventricle. Massive degeneration of the ependyma in the lateral ventricles was also described (Yoon et al., 1972).

Edwards reported that affected study animals only had dilation of the lateral ventricles, and further histologic examination revealed the third and fourth ventricles were not affected. This suggests the condition is caused by aqueductal stenosis (Edwards et al., 2006).

Congenital Heart Valve Anomalies

A family of Syrian hamsters, subjected to systematic inbreeding for over 25 generations, was noted to have a high incidence of aortic and pulmonary valve anomalies (Fernandez et al., 1998; Sans-Coma et al., 1996). Bicuspid aortic valves as well as bicuspid and quadricuspid pulmonary valves are common in this line. In addition, cartilaginous foci were commonly found in the aortic valves of these hamsters (Sans-Coma et al., 2005). These anomalies have no apparent clinical implications.

Spontaneous Seizures

Spontaneous motor seizures were reported in a colony of BIO[®] 86.93 Syrian hamsters, which had been inbred for 23 generations (Yoon et al., 1976). The seizures were manifested as tonic muscle spasms and severe paralysis, and which were distinct from audiogenic seizures. The seizures occurred in animals between 30–60 days of age, lasted from 2–5 hours, and were easily precipitated by mild stress. Breeding tests confirmed a simple recessive gene (*sz*) which was proposed as the symbol for this condition.

More recent studies using this colony described a condition more similar to dystonia (Loscher et al., 1989). Placement of the hamsters in a novel environment resulted in immobility lasting for hours. Based on these studies and the nature of disease, the authors proposed

that the hamster mutation be renamed “dystonic,” and designated using the new gene symbol, *dt^{sz}*.

Traumatic Disease

Syrian hamsters avoid social interactions and prefer a private existence unless breeding. Hamsters are easily agitated and have a tendency to fight (Harkness and Wagner, 1995). Cannibalism is a problem in stressed or young hamsters and is best prevented through improved husbandry (clean bedding, proper nutrition, and noise reduction) (Magalhaes, 1968; Ponsford and Whyley, 1954; Pour et al., 1976a). In one retrospective study, 97.5% of total preweaning mortality was due to cannibalism (Renshaw et al., 1975). The frequency of maternal cannibalism is more severe with malformed hamsters (Harkness and Wagner, 1995). Hamsters that destroy all or parts of a litter should not be used as breeding stock (Magalhaes, 1968).

NEOPLASMS

Spontaneous neoplasms are uncommon in the Syrian hamster, especially when compared to mice and rats. There have been a number of papers published documenting the tumor rates and types (Homburger and Russfield, 1970; Pour et al., 1976a; Schmidt, 1983; Van Hoosier and Trentin, 1979). There are differences in the reported frequencies of certain tumors. This is likely due to a number of factors including genetic differences in hamster colonies; different methods of tumor detection; and gender and age differences. In general, there is agreement that tumors occur more frequently in females than males (Homburger and Russfield, 1970; Pour et al., 1976a; Van Hoosier and Trentin, 1979).

Van Hoosier reported an overall incidence of spontaneous malignant neoplasms in the Syrian hamster as 3.7%. Pour et al. (1976c) studied two different colonies and noted an overall incidence for all tumors as 32% in one colony versus 42% in another. The most commonly reported group of primary tumors in hamsters are lymphomas. Endocrine tumors, especially adrenal gland tumors, are also very common (Homburger and Russfield, 1970; Pour et al., 1976a; Schmidt, 1983; Van Hoosier and Trentin, 1979). Intestinal tumors, both benign (polyps) and malignant (adenocarcinomas) are commonly reported (Van Hoosier and Trentin, 1979). However, to underscore differences between hamster colonies, Pour et al. (1976a) reported no tumors, either benign nor malignant, in the intestines of one hamster colony, while a different colony developed a significant number of malignant intestinal neoplasms. Melanomas are also reported with some frequency. Tumors of the nervous system, thymus, and the mammary glands are uncommon.

INTRODUCTION

The Syrian hamster (*Mesocricetus auratus*) is a widely used experimental animal model. A recent fiscal-year report from the USDA indicates that 172498 hamsters were used in 2007. Although the hamster still makes a significant contribution to research and teaching, the number of hamsters utilized currently is well below their peak usage of over 500000 achieved during the 1980s (Hankenson and Van Hoosier, 2002). Much of this decline is likely attributable to the availability and widespread use of genetically engineered mice. Despite this decline, the hamster still provides key data for a variety of research areas. As such, this chapter will focus primarily on the most current research uses of the hamster. More classical uses will be covered only as they pertain to these current uses.

Hamsters possess unique anatomical and physiological features which make them desirable research models. Unlike other commonly used laboratory rodents, hamsters possess a cheek pouch which can be easily everted and examined in situ at both the gross and microscopic level (Hankenson and Van Hoosier, 2002). The hamster's relative size also allows for better visualization of certain biological systems including the respiratory and reproductive systems when compared to the mouse (Magers et al., 1995). Additionally, hamsters are relatively free of pathogens yet they are naturally susceptible to a wide range of experimental pathogens (Hankenson and Van Hoosier, 2002). Further, laboratory hamsters develop a variety of inherited diseases which display similarities to human conditions. Hamsters possessing some of these inherited traits are commercially available (Biobreeders Inc. Watertown, MA; Table 34.1). In addition to these benefits, hamsters are susceptible to a variety of carcinogens and develop tumors that other research animals less commonly develop. Furthermore, hamsters are susceptible to the induction of a variety of metabolic disorders through the use of dietary manipulations. Finally, the antagonistic nature of hamsters is utilized to study the effect of treatment on male aggressive and defensive behaviors.

CANCER RESEARCH

Syrian hamsters display several unique characteristics that make them desired models for carcinogenesis studies. Specifically, they develop tumor types that other models, particularly the mouse, are less apt to develop. Further, they can be reliably infected with oncogenic and oncolytic viruses. This section details the most commonly used hamster models of cancer and carcinogenesis and highlights the key findings discovered in these models.

Pancreatic Adenocarcinoma

Pancreatic tumors of non-endocrine origin are particularly aggressive tumors with a poor prognosis in humans (Uchida et al., 2008). The most common anatomic form of this tumor is ductular adenocarcinoma. The Syrian hamster is used extensively to study this tumor. Most commonly, the tumors are induced by the administration of nitrosamines (particularly *N*-nitrosobis amine) as a single subcutaneous injection. The resulting tumor is both morphologically and biologically similar to human pancreatic ductal adenocarcinoma (Uchida et al., 2008). One of the limitations of this model is the prolonged time-course for tumor induction (as long as 51 weeks). This time-course can be expedited by giving multiple nitrosamine injections (Konishi et al., 1998). Additional limiting factors of the model are the incomplete penetrance of tumor formation even with multiple injections and the low rate of tumor metastasis (Konishi et al., 1998; Mizumoto et al., 1990). Environmental factors, including a choline-deficient diet, given in combination with nitrosamines produce tumors more rapidly and with a greater prevalence in both male and female hamsters (Mizumoto et al. 1988, 1989a, 1989b).

Current studies utilizing the carcinogen injection model focus on treatment and reduction of tumor development. Specifically, chemicals and biologics with the potential to prevent cancer can be given synchronously or shortly after carcinogen administration, and effectiveness in cancer reduction (both tumor size and prevalence) can be assessed phenotypically at specified time points. Utilizing this general scheme several potential anti-cancer compounds were identified, including dimethylamino-parthenolide, celecoxib, iNOS inhibitors, and melatonin (Ruiz-Rabelo et al., 2007; Takahashi et al., 2008; Yip-Schneider et al., 2008). Alternatively, studies can be carried out after induction to determine the efficacy of tumor treatment and metastasis prevention. This approach recently demonstrated that somatostatin analogs are able to decrease metastasis of pancreatic cancers (Kilian et al., 2009).

More recently, a transplantable cell line, PGHAM-1, was isolated from the pancreata of hamsters with

induced pancreatic cancer (Fukuhara et al., 2005). A variety of other biological behaviors can be induced with this transplantable model. Specifically, if the cell line is injected into the pancreas, hamsters develop pancreatic cancer which metastasizes to the liver whereas splenic injection induces direct metastasis to the liver, and intraperitoneal injection induces dissemination to the entire peritoneal cavity (Uchida et al., 2008). Therefore, this model can be used to study the primary disease, metastasis, and dissemination in a rapid fashion. An additional benefit of the transplant model is that it is characterized molecularly and is known to contain mutations of *k-ras*, *Vegf*, and matrix metalloproteinases similar to human pancreatic adenocarcinoma cells (Matsushita et al., 2001).

Respiratory Tract Tumors

Primary Lung Tumors

The two predominant types of lung cancer in humans are small cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC) (Koletsis et al., 2009; Powell et al., 2009). NSCLC are lung tumors which originate from diverse cell types but behave and are treated in similar fashions. In contrast, SCLC originates primarily from neuroendocrine cells of the respiratory tract (Lee et al., 1992). Both tumor types are associated with tobacco smoking in humans.

In hamsters, lung tumors are induced by carcinogen treatment and typically result in NSCLC. One method to induce lung tumors is to inject the carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) subcutaneously (Sunday et al., 1995). Multiple injections must be given over a prolonged (6 months or longer) time course. Modifications to this induction protocol include the use of hyperoxia in conjunction with the carcinogen treatment (Oreffo et al., 1993). Presumably, the addition of hyperoxia increases the potential for free-radical damage to DNA of the lung tissue. The NNK model displays molecular characteristics of human NSCLC including mutations in the *k-ras* gene (Oreffo et al., 1992, 1993). A thorough immunohistochemical characterization of both the chemical model and the chemical plus hyperoxia model indicates that both experimental paradigms induce similar lung lesions that display strong similarity to human NSCLC at the protein level (Sunday et al., 1995).

Upper Airway Tumors

Upper airway tumors occur in the larynx, trachea, or pharynx. The primary risk factors for development of these tumors are smoking and chronic alcohol consumption; however, other environmental and genetic factors may contribute to the disease (Spitz, 1994).

The hamster is susceptible to tumors of the upper airways. These tumors are induced by inhalation or topical application of carcinogens with or without the addition of co-carcinogenic stimuli (Estensen et al., 2007; Homburger et al., 1979; Moon et al., 1992a, 1992b). A reported limitation of topical carcinogen application models is the lack of reproducibility among different labs (Estensen et al., 2007). It is unclear why various labs are unable to faithfully reproduce the cancer phenotype using the same protocols; however, one possibility is that because the hamsters came from different sources, they may be genetically different. To overcome this limitation, a recent publication describes combining the administration of N-methylnitrosourea (MNU) with direct wounding of the tissue (Estensen et al., 2007). The experimental design includes two tracheal wounding procedures done under general anesthesia. The trachea is gently abraded using a curette and this abrasion is coupled with six applications of MNU using a gavage needle. The induction of the wound induces epithelial proliferation which acts epigenetically in conjunction with the genotoxic mutagen to promote carcinogenesis. A benefit of this model is the coinduction of esophageal tumors which mimics the epidemiological linkage of these two tumor types in human smokers (Wattenberg et al., 2004). The model can be altered to incorporate preventative and post-induction treatments. Utilizing this paradigm, difluoromethylornithine (DFMO; a mitosis inhibitor) and 5-fluorouracil (5-FU; a DNA replication inhibitor) treatments were both found to reduce the prevalence of tumor formation in hamsters (Wattenberg et al., 2004).

Oral Carcinogenesis

Oral squamous cell carcinoma (OSCC) is a common cancer of humans and generally carries a poor prognosis (Vairaktaris et al., 2008a, 2008b). Primary risk factors for the development of OSCC include tobacco and alcohol use, but other genetic and environmental factors contribute as well (Williams, 2000). The hamster cheek-pouch carcinogenesis model is one of the most accepted animal models to study oral tumor formation and progression (Vairaktaris et al., 2007, 2008a, 2008b). Carcinogens, most notably 7,12-dimethylbenz(a)anthracene (DMBA), administered by repeated topical application to the buccal pouch, induces carcinomas rapidly (~14 weeks) (Vairaktaris et al., 2008b). The DMBA administration technique is simple and involves anesthetizing the hamsters and brushing the desired carcinogen onto the buccal surface of the cheek pouch. Importantly, oncogenesis can be assayed in vivo or the transformed cells can be grown ex vivo (Wong et al., 1988).

Tumor formation and progression in the hamster cheek pouch occurs in a predictable, reproducible stepwise fashion. First, hyperkeratosis develops followed

rapidly by hyperplasia and dysplasia. Finally, these lesions progress to invasive carcinomas (Vairaktaris et al., 2008b). Cellular and molecular alterations that occur during these predictable stages of tumorigenesis are extensively characterized (Vairaktaris et al., 2007, 2008b). The cellular and molecular alterations in the hamster display many similarities to human OSCC. Early in the disease, tyrosine kinase receptors are highly expressed in hamsters similar to the increase of the ErbB2 tyrosine kinase noted in humans (Werkmeister et al., 2000). Additionally, the oncogenes p53 and c-myc are highly expressed early in hamster tumorigenesis and there is a loss of expression of the p16 tumor suppressor gene during the early dysplastic stage (Papakosta et al., 2006; Vairaktaris et al., 2007). More recently, the microRNA expression profile of the DMBA-treated hamster cheek pouch has been analyzed and compared to normal cells. Treated cells display a unique microRNA profile distinct from normal tissue (Yu et al., 2009). These data imply that microRNA may play a role in the formation and progression of hamster cheek pouch tumors. The similarities of these new data to the human disease are not yet known.

A key advantage of the hamster cheek pouch carcinogenesis model is the predictable nature of tumor progression. Because of this predictability, the hamster model is also utilized to analyze various treatments and preventatives which may be given either concurrently with induction or at specified points during tumorigenesis (Shklar, 1999; Sood et al., 2005). Since the hamster cheek pouch undergoes a predictable pathway of induced oncogenesis, these studies can be accurately timed to the appropriate tumor stage or pre-cancerous lesion. A more recently described advantage of the hamster model is the isolation of buccal pouch stem cells, which can be studied in vitro and may provide data on novel treatments (Huang et al., 2009).

SV40 Tumor Induction

Simian vacuolating virus 40 (SV40) is a polyoma-virus naturally occurring in macaques that was introduced into humans via contaminated polio vaccines (Pershouse et al., 2006; Rollison et al., 2004). The role of SV40 in human cancers has a long and controversial history. Large epidemiological studies tracking infected humans indicate no link between the agent and cancer (Rollison et al., 2004). Proponents of the link between SV40 and cancer state that the true prevalence of SV40 in the human population is not known, and therefore, an accurate epidemiological assessment cannot be made (Pershouse et al., 2006). Detailing the controversies surrounding the role of the SV40 virus in human tumors is beyond the scope of the current chapter. However, the hamster figures prominently into the data detailing the oncogenic potential of SV40.

Hamsters injected with SV40 develop a variety of different tumors depending on the route of inoculation and the age of hamsters at the time of inoculation. Tumor formation is highest in newborn hamsters and decreases progressively with age (Cicala et al., 1993). Local fibrosarcomas develop with subcutaneous injection of virus, even when given at a low dose in newborn hamsters. In contrast, adults develop fibrosarcomas only when given a high dose of virus (Allison et al., 1967; Cicala et al., 1993). Intravenous inoculation of young hamsters produces a variety of tumors including leukemia, lymphoma, and a variety of sarcomas (Cicala et al., 1993; Diamandopoulos and McLane, 1972). Finally, mesotheliomas develop when hamsters are injected with virus into the heart, peritoneum, or pericardium (Cicala et al., 1993). SV40 viral infection can therefore be utilized to analyze a variety of tumor types using the hamster model.

Recent studies utilizing the hamster lend further evidence to support the hypothesis that SV40 may play a role in human carcinogenesis. Hamsters that are infected with a non-oncogenic SV40 virus strain or a low dose of asbestos, fail to develop tumors. In contrast, when sub-oncogenic doses of the two agents are given together a large percentage of hamsters (90%) develop tumors (Kroczyńska et al., 2006). Additionally, these results are reproducible in in vitro cell-culture systems. These data imply that, at least in the hamster, SV40 and asbestos can act as co-carcinogens.

The role of SV40 in human cancers remains highly controversial. However, the hamster model provides an excellent way to prospectively test these hypotheses. Even if SV40 plays no role in human tumorigenesis, much can still be learned from the hamster model regarding how viral agents transform mammalian cells. For example, a recent study demonstrates that differences in the SV40 regulatory region lead to differences in tumor induction in the hamster model (Sroller et al., 2008). These new data provide evidence that various strains of virus possess pro-oncogenic factors and these data argue that epidemiological studies in humans should account not merely for the presence or absence of SV40, but rather for the type of SV40 present.

Estrogen-Dependent Renal Tumors

Exogenous estrogen therapy in post-menopausal women decreases the risk of developing both osteoporosis and coronary artery disease; however, it also increases the risk for development of breast cancer and endometrial adenocarcinoma in this population (Sartwell et al., 1977; Stampfer et al., 1991). The benefits and limitations of the use of estrogen therapy in postmenopausal women remains an active area of research and debate. Animal models of estrogen-induced tumorigenesis

provide valuable mechanistic data to optimize estrogen therapy.

The Syrian hamster is a valuable model to study the effects of exogenous estrogenic compounds on tumor development. The administration of estrogens induces renal tumors in 100% of male hamsters in a predictable fashion (Li and Li, 1996; Liehr, 1997). Most commonly, estrogens are administered to hamsters in the form of slow-release subcutaneous implants which maintain constant levels in the blood (Debauve et al., 2006). In addition to *in vivo* studies utilizing the estrogen injection or implantation hamster model, HKT-1097 cell-lines generated from this model can be studied *in vitro* (Laurent et al., 1999).

A wealth of mechanistic data on the tumorigenic potential of estrogenic compounds has been generated utilizing the hamster model. Specifically, administration of a variety of natural and synthetic estrogenic compounds demonstrates that tumorigenesis occurs with some estrogenic compounds but not others (Liehr, 1997; Liehr et al., 1983, 1987a, 1987b). These data led to the hypothesis that tumorigenic estrogens mediate carcinogenicity, at least in part, through their metabolic breakdown products (Liehr, 1997). In particular, estrogen is broken down to 4-hydroxyestrogen, a catecholesterogen, in the hamster kidney (Dwivedy et al., 1992; Liehr, 1997). This intermediate can be further broken down into quinones which cause DNA damage by forming DNA adducts. This pathway, initially characterized in the hamster, was later identified in women with breast cancer. Specifically, the "normal" breast tissue of women with breast cancer displays higher levels of quinones when compared to unaffected controls (Li et al., 1994; Rogan et al., 2003). The estrogen receptor may be actively involved in tumor formation by shuttling quinone directly to nuclear DNA (Bolton and Thatcher, 2008).

Aside from the ability of quinones to directly damage DNA, quinine production results in the formation of reactive oxygen which can also cause DNA damage (Li et al., 1994; Liehr, 1997). Since the breakdown products of estrogen can damage DNA (mutation), and estrogen itself can promote cell growth (proliferation), all of the necessary components of carcinogenesis are present in the estrogen-treated hamster kidney (Liehr, 1997). The administration of some estrogenic compounds does not damage DNA because toxic metabolic byproducts are not generated (Bhat et al., 2003). Cancer induction with these compounds can be rescued by inducing oxidative stress while administering these normally non-oncogenic estrogens. This finding highlights the need for both the proliferative and the DNA-damaging aspects of estrogen to produce tumors. The hamster model may facilitate development of novel, non-DNA-damaging, estrogens which could provide the benefits of estrogenic therapy without the increased risk of cancer.

Oncolytic Viruses

The use of oncolytic adenoviruses holds promise as a future cancer treatment in humans. These adenoviruses kill tumor cells as part of their normal lytic replication cycle (Thomas et al., 2006a). The prospective *in vivo* study of these viruses is hampered by the lack of animal models that permit the replication of human adenoviruses (Hjorth et al., 1988; Thomas et al., 2006a). However, the hamster can be infected with human adenoviruses via intranasal instillation (Hjorth et al., 1988). In addition, permissive hamster cancer cell lines are available for assessing tumor suppression (Bortolanza et al., 2007; Thomas et al., 2006a). Notably, the Syrian hamster pancreatic carcinoma cell line (SHPC6) is highly permissive for human adenovirus replication (Spencer et al., 2009).

Thomas and colleagues recently developed a step-wise, reproducible hamster model to study the efficacy of adenoviral vectors in tumor therapy (Thomas et al., 2006b). The investigators injected immortalized tumor cells into the flanks of hamsters. After tumors developed, hamsters were inoculated with adenovirus into the respiratory tract. Tumor reduction at both the primary site, and the site of metastasis, was then analyzed. The investigators found that adenovirus inhibits primary tumor growth and metastasis and may promote survival (depending on tumor type injected). The virus is capable of replicating in the liver, lungs, and tumor tissues of the hamster following instillation and distribution in the blood (Thomas et al., 2006b). This experimental paradigm can be expanded to examine the treatment of a variety of tumors in the hamster and potential toxicities associated with the use of these viruses (Dhar et al., 2009; Lichtenstein et al., 2009). A further modification of this method is immunosuppression of hamsters with cyclophosphamide which allows for sustained adenoviral replication and oncolysis (Thomas et al., 2008). The hamster provides a valuable experimental model to evaluate the potential benefits, limitations, and strategies of this novel treatment modality.

METABOLIC DISEASES

Metabolic diseases are an area of great biomedical concern. Although all these diseases may occur independently of one another, they often present with a variety of overlapping clinical signs. Like humans, the hamster is highly susceptible to metabolic diseases and there are similar overlaps in the signs that they develop (Ginsberg, 1996; Gotto, 1992; Laakso, 1996; Lamarche and Lewis, 1998). Therefore, the hamster is an excellent animal model to study metabolic diseases of humans.

Cholesterol Gallstones

Cholesterol cholelithiasis is a significant health problem worldwide. The prevalence of this condition is three times higher in women than in men and increases regularly with age (Capron, 1994). The Syrian hamster is commonly used as a model for this condition which can be induced by excess dietary cholesterol (Cohen et al., 1989; Trautwein et al., 1999) or sucrose (Khallou et al., 1991a). The metabolism of cholesterol in the hamster is similar to humans (Khallou et al., 1991b). The nature and composition of hydrophobic bile salts and the ratio of taurine- and glycine-conjugated bile salts are similar in hamsters and humans (Figure 34.1) (Combettes-Souverain et al., 2002; Hardison, 1983; Singhal et al., 1983). In earlier studies, gallstones were induced in Syrian hamsters by feeding a fat-free glucose-rich diet (Dam, 1971). Diet models have evolved to include elevated levels of butterfat (Cohen et al., 1992; Hayes et al., 1992; Holzbach, 1984). In hamsters, the butterfat-diet induces a high cholesterol/phospholipid ratio in bile which promotes cholesterol cholelithiasis. In contrast, diets rich in safflower oil induce phospholipid secretion and reduce the lithogenicity of bile, thereby inhibiting cholesterol gallstones (Ohshima et al., 1996a).

The Syrian hamster displays significant gender differences in the basal rate of hepatic sterol synthesis which is several-fold higher in females fed a regular chow diet as compared to age-matched males on the same diet (Spady et al., 1983). In contrast to humans, female hamsters are less susceptible to gallstones because they maintain more favorable biliary lipid and bile acid profiles (predominantly glycocholate) characterized by lower molar percentages of cholesterol and chenodeoxycholate (Ayyad et al., 1993; Trautwein et al., 1999). Dietary administration of androgens to female hamsters on a lithogenic diet (0.3% cholesterol) induces

cholesterol gallstones at a comparable rate to induction in males fed a similar diet. In these androgen-treated, cholesterol-fed female hamsters, chenodeoxycholate increases while cholate decreases (Ayyad et al., 1995). Furthermore, castrated male hamsters on the lithogenic diet do not form cholesterol gallstones, and maintain a higher ratio of biliary cholate to chenodeoxycholate as compared to uncastrated males (Ohshima et al., 1996b).

Male LPN hamsters (bred at Laboratoire de Physiologie et de la Nutrition, France) are highly susceptible to cholesterol gallstones (~70%) induced by a low-fat high-sucrose diet, whereas commercial Janvier (JAN) hamsters on a similar diet do not develop gallstones (Boehler et al., 1999; Combettes-Souverain et al., 2002; Ferezou et al., 2000). In LPN hamsters, the sucrose-rich lithogenic diet causes an increase in biliary cholesterol and phospholipid. A cholesterol-enriched diet results in hypercholesterolemia, increased liver cholesterol, and reduced cholesterologenesis along with expression of the LDL receptor in both LPN and JAN hamsters (Souidi et al., 2001). In both strains, the cholesterol-enriched diet increases the cholesterol content in both the LDL and HDL fractions of sera (Souidi et al., 2001; Woollett et al., 1997). Further, excess dietary cholesterol leads to a reduction of CYP7A (the rate-limiting enzyme in the classical pathway of cholesterol breakdown to bile salts) activity and transcription in both LPN and JAN hamsters (Souidi et al., 2001). There is a concurrent stimulation of sterol 27-hydroxylase (CYP27) and oxysterol 7 α -hydroxylase (CYP7B), enzymes involved in the alternative bile-salt pathway of cholesterol conversion to bile salts in both LPN and JAN hamsters. Compared with LPN hamsters, hypercholesterolemia in JAN hamsters is associated with hepatomegaly and fatty liver but only modest hypertriglyceridemia. Interestingly, after cholesterol feeding for 5 weeks, neither LPN nor JAN hamsters develop cholesterol gallstones, perhaps because of the upregulation of the alternative pathway of bile-salt synthesis (Souidi et al., 2001).

Differences in gallstone formation also exist between commercially available hamsters. Charles River Laboratory hamsters display the highest cholesterol saturation of bile on low-cholesterol diets and display a correspondingly high prevalence of stones (64%) when challenged with a high-cholesterol diet (Trautwein et al., 1993). Biobreeder F1 hamsters also commonly form gallstones (58%) when challenged with cholesterol-enriched diets. In contrast, Harlan Sprague-Dawley hamsters display a low prevalence (23%) of gallstones when fed the same diet (Trautwein et al., 1993). These findings highlight the role of genetics in both hamsters and humans in this complex polygenic disease. One drawback of this study is that the sex of these animals was not described and therefore the data are difficult to evaluate thoroughly.

Diabetes Mellitus

Diabetes mellitus is a disease of metabolic dysregulation including abnormal glucose metabolism due to derangement of insulin secretion and development of insulin resistance. Diabetes is often accompanied by dyslipidemia (high LDL, VLDL, and chylomicron levels, and a low level of HDL) and elevated risk for the development of atherosclerosis (Ginsberg, 1996; Gotto, 1992; Laakso, 1996; Lamarche and Lewis, 1998).

An animal model of pre-diabetic insulin resistance, the fructose-fed Syrian hamster, is employed to investigate mechanisms mediating overproduction of VLDL in the insulin-resistant state. Feeding fructose for 7 days causes hyperinsulinemia and hyperlipidemia in hamsters with absence of overt hyperglycemia (Taghibiglou et al., 2002). Fructose feeding for a 2-week period induces significant hypertriglyceridemia and hyperinsulinemia (Taghibiglou et al., 2000). Plasma hepatic lipase activity, and hepatocyte hepatic lipase concentration and mRNA levels are increased in these hamsters (Lewis et al., 2004). Activation of farnesoid X receptor (FXR) by the addition of chenodeoxycholic acid in high-fructose-diet-fed hamsters reduces plasma triglyceride and cholesterol concentrations, mainly by decreasing de novo lipogenesis and hepatic secretion of triglyceride-rich lipoproteins (Bilz et al., 2006). These studies provide evidence that stimulation of FXR could decrease the risk of hyperlipidemia in the diabetic state.

Diabetes can be experimentally induced in hamsters by different approaches, such as dietary modifications or use of chemical agents. Chemical agents such as alloxan or streptozotocin (STZ) are commonly used to induce diabetes in animal models. To induce chronic diabetes in hamsters, STZ is more effective and reliable when compared to alloxan (Phares, 1980). STZ depletes nicotinamide adenine dinucleotide (NAD) in pancreatic β -cells leading to necrosis (Ar'Rajab and Ahren, 1993). Furthermore, type 2 diabetes can be induced by administration of STZ to hamsters on a high-fat diet, resulting in an increase in serum lipid profile, fasting blood glucose, and fasting plasma insulin level (Zhu et al., 2007). Another described method to induce type 2 diabetes in hamsters is to inject nicotinamide intraperitoneally 15 minutes before administration of STZ (Fararh et al., 2002). Nicotinamide provides partial protection against the beta-cytotoxic effect of STZ resulting in partial (40%) preservation of pancreatic insulin stores (Masiello et al., 1998). Dietary modifications alone, such as feeding high-fat (15%) diets containing modest cholesterol (0.12%) to hamsters, induce type 2 diabetes as well as obesity, hyperinsulinemia, hyperleptinemia, hypercholesterolemia, and hypertriglyceridemia (van Heek et al., 2001). A combined hyperlipidemia and diabetes hamster model is induced by feeding a fat-rich diet (3% cholesterol and

FIGURE 34.2 Displayed is the pancreas and common bile duct. Cellophane (black) is wrapped around the head of the pancreas to induce islet neogenesis. Modified from Rosenberg 1998, with permission from Wiley InterScience.

15% butter fat) and a single IP injection of STZ. These animals exhibit pathobiochemical changes characteristic of both diabetes and hyperlipemia and show an earlier and more severe induction of diabetic and hyperlipidemic changes compared to either STZ or high-fat diet alone (Simionescu et al., 1996).

Albino-panda-albino (APA) hamsters develop diabetes with nephropathy following STZ injections (Inenaga et al., 2002). The STZ-induced diabetic APA hamster is a good model of human diabetic nephropathy because progressive renal lesions are a common component of this model. In addition to renal lesions, the diabetic APA hamster also develops coronary lesions and is an excellent model to investigate the etiology and pathogenesis of aortic dissection accompanying diabetes mellitus in humans (Horiuchi et al., 2005).

Hamsters can be utilized to study islet neogenesis, which is the new formation and differentiation of pancreatic islets. This process is induced in Syrian hamsters by wrapping the head of the pancreas with cellophane tape and is efficient in reversing induced diabetes in hamsters (Figure 34.2) (Rosenberg et al., 1983, 1988). Islet neogenesis-associated protein (INGAP) is involved in the control of islet development and growth (Pittenger et al., 1992). INGAP is identified in both endocrine and exocrine pancreatic cells of normal hamsters, consistent with findings in humans (Flores et al., 2003). The hamster provides a model to understand the potential therapeutic application of islet neogenesis in the treatment of diabetes in humans.

Atherosclerosis

Atherosclerosis is a fibroproliferative disease of the arterial intima caused by the retention of modified

FIGURE 34.3 Distribution of lipoproteins (by FPLC system) in fasting plasma samples from F1B (A) and Syrian (B) hamsters. The low-density fractions of plasma cholesterol in F1B hamsters on a fish oil diet (–) was significantly higher than the Syrian hamsters on a similar diet. Both groups of hamsters had a comparable lipoprotein profile when fed monounsaturated-fatty-acid-rich (---) and N6:N3 fatty acid ratio of ~5 (...) diets. From Cheema and Cornish, 2007, with permission from BioMed Central.

low-density lipoproteins and by hemodynamic and redox stresses (Hayden and Tyagi, 1998, 2000). Hamsters are a good animal model to investigate cholesterol metabolism and atherosclerosis because they possess similar lipid metabolism to humans (Asami et al., 1999; Foxall et al., 1992). As in humans, the main plasma cholesterol carrier in hamsters is LDL (Sullivan et al., 1993). The hamster LDL receptor gene shows strong sequence and structural similarities to the human gene (Bishop, 1992). Unlike mice and rats, which lack cholesterol ester transfer protein, hamsters exhibit all enzymatic pathways in lipoprotein and bile metabolism that are present in humans (Bishop, 1992). The low basal rates of bile acid and cholesterol synthesis, coupled with a lack of CYP7A induction by cholesterol, render the hamster much more sensitive than the rat or mouse to the cholesterolemic effects of excess dietary cholesterol (Horton et al., 1995). In contrast to mice and rats, apolipoprotein (apo) B-48 is exclusively of intestinal origin in hamsters and humans and apoB-100 is exclusively of hepatic origin (Arbeen et al., 1992; Ebara et al., 1994).

Hamsters develop atherosclerosis in a predictive manner in response to dietary manipulation and the vascular changes accompanying the development of atherosclerotic plaques are similar to those encountered in humans (Mitchell and McLeod, 2008; Simionescu et al., 1993; Wissler, 1991). Hypercholesterolemic (0.05% cholesterol and 10% coconut oil) diet-induced atherosclerosis in susceptible hamsters is confined initially to the inner curvature of the aortic arch. Atherogenesis in this region is characterized by the infiltration of monocytes, which become lipid-filled foam cells (Kowala et al., 1991a). Male hamsters on a hyperlipidemic diet (3% cholesterol and 15% butter fat) develop coronary atherosclerotic lesions which are very similar to lesions seen in humans (Sima et al., 1990). Interestingly, hyperglycemia alone in hamsters induces atherosclerotic

lesions in the coronary arteries, aortic arch, and aortic valves, implying that the hyperglycemic hamster could provide a model of diabetes-induced atherosclerosis (Sima et al., 1997).

Albino-panda-albino (APA) hamsters (previously described in the diabetes section of this chapter) develop atheromatous lesions in the aortic arches and show signs of hypercholesterolemia and hypertriglyceridemia with an increased LDL fraction and a decreased HDL fraction following injection of STZ (Han et al., 1992; Kume et al., 1995; O'Brien et al., 1994). The deposition of ApoE and advanced glycation end-products in the atheromatous lesions of these hamsters are similar to humans with atherosclerosis (Kume et al., 1995; O'Brien et al., 1994). The APA hamster, therefore, is a good animal model to study both diabetes and atherosclerosis. Since these conditions are often co-morbidities in humans, this model could provide valuable data to understand the pathogenesis of these diseases and test novel treatments.

The Bio F1B hamster is highly susceptible to diet-induced atherosclerosis. This strain develops aortic atherosclerotic lesions even at low (0.05%) dietary cholesterol concentrations (Kowala et al., 1991b). F1B hamsters on a 20% fish oil diet developed markedly elevated plasma cholesterol and cholesterol ester concentrations compared to wild-type Syrian hamsters (Figure 34.3) (Cheema and Cornish, 2007). Wild-type Syrian hamsters typically display increases in both LDL and HDL cholesterol in response to an atherogenic diet (Hayes et al., 1992). In contrast, F1B hamsters develop highly elevated LDL-cholesterol concentrations without appreciable alterations of HDL-cholesterol (Kowala et al., 1991a).

Ovariectomized hamsters are used to study postmenopausal hypercholesterolemia (Sohn et al., 1999). In humans, there is an association between postmenopausal hormone deficiency and the increased risk for

cardiovascular disease (Sohn et al., 1999). Similar to postmenopausal women, ovariectomized hamsters experience an increase in serum cholesterol and atherosclerosis. This increase occurs even without feeding a high-cholesterol or high-fat diet (Lucas et al., 2003; Sohn et al., 1999).

Hypercholesterolemic hamsters are also a good model of peripheral arterial disease. Angiogenesis in response to femoral artery-induced hindlimb ischemia is reduced in hypercholesterolemic hamsters (Caron et al., 2004). Feeding a cholesterol-rich diet to hamster causes a chronic angiogenic disorder both at the macro- and micro-vascular levels, mimicking the conditions seen in humans with peripheral arterial disease (Caron et al., 2004). This model is also utilized to study the potency of therapeutic gene transfer to overcome revascularization defects in these patients (Caron et al., 2004).

NON-CANCEROUS RESPIRATORY DISEASES

Syrian hamsters possess characteristics that make them ideal models for studying human non-cancerous respiratory diseases. Specifically, researchers can induce respiratory diseases in hamsters that closely resemble similar human diseases. This section outlines common inducible hamster models for human non-cancerous respiratory disease and describes scientific and medical advances made using these models.

Smoke Inhalation

The negative effects of cigarette smoking on the cardiovascular and respiratory systems in humans are well known (Alberg, 2008; Fagerstrom, 2002). Over the past 10 years, an active area of research focuses on the consequences of smoking on the female reproductive tract (Rogers, 2008, 2009). Epidemiological studies demonstrate that women who smoke cigarettes experience increased rates of reproductive problems, including delay to conception, ectopic pregnancies, lower birth weights, and spontaneous abortions (DiCarlantonio and Talbot, 1999; Magers et al., 1995). Syrian hamsters are a prominent rodent used in female reproductive toxicology inhalation studies including mainstream (MS) smoke (active inhalation of a bolus of smoke) and side-stream (SS) smoke (passive inhalation of smoke). Advantages of hamsters in these studies are that they adapt well to smoking machines and they have reproductive tracts that are large enough to allow thorough evaluation (Magers et al., 1995).

To test the effects of smoke inhalation on reproductive parameters, female Syrian hamsters in various stages of estrous or pregnancy are anesthetized, placed in dorsal

recumbency, and exposed through a nose cone to smoke released from the burning end of a cigarette (SS smoke) or to a puff of MS smoke with a puffer box (Magers et al., 1995). A machine of equivalent design that pumps fresh air is used for control animals. Exposure to doses of MS and SS smoke equivalent to those in women who smoke actively or passively (second-hand smoke) is ensured by quantifying serum levels of cotinine, a metabolite of nicotine (DiCarlantonio and Talbot, 1999). The major downfall of this technique is that it exposes females to either MS or SS smoke, but not to both, as would be the case for an active human smoker (Magers et al., 1995). Female hamsters that inhale either MS or SS smoke twice per day for 7 days, starting 1 month prior to mating and ending at day 7 of pregnancy, develop fewer corpus lutea (CL) with accompanying decreases in CL vascularity (Magers et al., 1995). Additional changes in these hamsters include blebbing of ciliated epithelial cells in oviducts, increases in secretory cells of the ampulla, decreases in the ability of the uterus to stretch, and crowding of fetuses. Functionally, the transport of pre-implantation embryos through the oviduct is retarded, and oviduct muscle contraction rate is greatly decreased by smoke inhalation (DiCarlantonio and Talbot, 1999). Transport rate is more significantly retarded in the SS exposure group, suggesting that SS smoke exposure is more detrimental than MS smoke exposure with regard to embryo transport. Inappropriate transport and implantation could explain the increase in ectopic pregnancy in human smokers. Interestingly, when mating is delayed for 1 month following smoke inhalation, all deleterious effects of MS and SS exposure are ablated (Magers et al., 1995). This indicates that the female reproductive tract can quickly recover from the negative effects of smoke inhalation.

COPD and Emphysema

Chronic obstructive pulmonary disease (COPD) is a chronic, progressive airflow obstruction with concurrent inflammation of the small airways and emphysema of lung parenchyma (Cosio Piqueras and Cosio, 2001; Petty, 2006). Emphysema contributes to airflow obstruction by reducing the elasticity of the lung, increasing alveolar size, and increasing airway resistance (Cosio Piqueras and Cosio, 2001). COPD is the fourth most common cause of death in the United States, with a prevalence of approximately 16 million (Petty, 2006). Animal models yield clues to the pathophysiology and therapeutic approaches for COPD (Petty, 2006).

The Syrian hamster is a useful model to study the emphysema component of COPD because hamsters develop severe diffuse emphysema resembling human panacinar emphysema following a single intratracheal dose of porcine pancreatic elastase (Borzone et al., 2007;

Hayes et al., 1977; Snider and Sherter, 1977). Elastase is used as an induction agent because it destroys or impairs the formation of elastin, resulting in emphysema (Soskel et al., 1984). The elastase induction model reproducibly results in alveolar damage and destruction of alveolar septa resulting in airway enlargement, and causes lung hyper-inflation, all of which are seen in humans with COPD (Borzone et al., 2007; Hayes et al., 1977). Additionally, elastase-treated hamsters do not gain weight at a normal rate, which is analogous to the weight loss seen in humans with emphysema (Snider and Sherter, 1977). Syrian hamsters are also used as a model for emphysema treatment. Intratracheal instillation of hyaluronic acid in hamsters with elastase-induced emphysema reduces emphysema by binding with and protecting elastic fibers from elastase-induced injury, and may be useful in preventing emphysema (Cantor et al., 1997, 2002).

Emphysema can also be induced in hamsters by feeding diets deficient in copper (Soskel et al., 1984). This model requires chronicity (8–10 weeks), thereby resembling the time course of human emphysema development (Soskel et al., 1984). Copper deficiency results in the inhibition of lysyl oxidase-mediated elastin cross-linking, causing impaired elastin formation and emphysema (Soskel et al., 1984). Also, since superoxide dismutase requires copper, copper deficiency leads to free radical accumulation which can cleave elastin bonds and attract inflammatory cells to the lung exacerbating emphysema.

A popular hypothesis regarding the pathogenesis of emphysema is that an imbalance between proteases and antiproteases plays a major role in disease development (Borzone et al., 2007). When compared to Syrian hamsters, rats develop only mild emphysema when given similar doses of elastin. This could be due to a 60% reduction in serum levels of the antiprotease α_1 -antitrypsin in Syrian hamsters compared to rats, which leads to low elastase inhibitory capacity, thereby predisposing hamsters to elastase-induced emphysema.

Pulmonary Fibrosis

Interstitial pulmonary fibrosis (IPF) is a debilitating disease characterized by proliferation of lung fibroblasts, collagen accumulation, loss of alveolar space, reduction in lung volume and compliance, and impairment of gas exchange (Giri et al., 1994, 1997; Lazo et al., 1990; Wang et al., 2002). These changes cause hypoxemia and, if the fibrosis is severe, pulmonary insufficiency and fatal hypoxemia (Lazo et al., 1990). Currently, there are no adequate treatments for IPF and mortality in humans is high (Giri et al., 1994; Iyer et al., 1999; Wang et al., 2002). Bleomycin, a DNA-interactive antineoplastic drug is a known cause of dose-dependent pneumonitis that progresses to IPF in humans (Giri et al., 1994, 1997; Lazo

et al., 1990; Thrall et al., 1979). The prevalence of bleomycin-induced toxicity is reported to be 10%, with many of these cases resulting in death (Lazo et al., 1990).

Bleomycin is one of the most commonly used agents to induce IPF because it causes a similar, reproducible condition in the Syrian hamster (Lazo et al., 1990). A single intratracheal installation of approximately 5mg/kg body weight produces pulmonary fibrosis within 7 days (Lazo et al., 1990). Importantly, other organs are unaffected by this treatment and the treatment induces biochemical, inflammatory, and histological changes similar to those seen in the lungs of humans with IPF (Giri et al., 1994; Thrall et al., 1979; Wang et al., 2002). The bleomycin model of IPF involves an initial injury to the lung, followed by an influx of inflammatory cells that release cytokines (i.e. IL-1, TNF- α , PDGF, and TGF- β), leading to increased collagen synthesis and deposition (Iyer et al., 1999). A drawback of this model is that it produces high mortality in Syrian hamsters (Giri et al., 1994; Lazo et al., 1990). A refinement is the three-dose bleomycin hamster model where IPF is produced by the intratracheal instillation of three lower doses of bleomycin into the lungs of anesthetized hamsters at weekly intervals (Giri et al., 1994; Wang et al., 2002). This model uses repeated insults on the lung to initiate and sustain the fibroproliferative stage of fibrosis, and is the closest model to human IPF because it provides a multi-hit stimulus for lung injury, causing the slow development of IPF (Wang et al., 2002). There is age-selective resistance to bleomycin in young hamsters due to enhanced antioxidant defenses and bleomycin hydrolase activity in neonates (Lazo et al., 1990).

After induction, the hamster model can be used to study antifibrotic compounds (Giri et al., 1994, 1997; Iyer et al., 1999; Wang et al., 2002). Transforming growth factor- β (TGF- β) plays a central role in the pathophysiology of excessive extracellular matrix (i.e. collagen) production resulting in IPF (Iyer et al., 1999; Lazo et al., 1990). TGF- β mRNA and protein levels are increased in fibrotic hamster lungs; therefore, suppressing its production constitutes a rational therapeutic approach (Iyer et al., 1999; Lazo et al., 1990; Wang et al., 2002). Decorin, a proteoglycan component of collagen fibrils, binds and inactivates all isoforms of TGF- β , offering a potential treatment for IPF (Giri et al., 1997). The antifibrotic drug pirfenidone down-regulates the bleomycin-induced overexpression of TGF- β in the lungs, and pirfenidone is now a clinical therapeutic agent for IPF in humans (Antoniou, 2006; Bhatt et al., 2006; Iyer et al., 1999). Further, a TGF- β antagonist, TGF- β chimeric soluble receptor, causes significant reductions in fibrosis in the hamster model (Wang et al., 2002).

Another area of IPF treatment research focuses on the elimination of reactive oxygen species (ROS) and increasing NAD and ATP needed for the repair

of injured pulmonary tissue (Giri et al., 1994). Dietary supplementation with taurine and niacin inhibits lung fibrosis in the bleomycin induced hamster model (Giri et al., 1994). This defense is provided by the ability of taurine to scavenge ROS and the ability of niacin to replenish NAD and ATP levels (Giri et al., 1994).

CARDIOVASCULAR

Syrian hamsters exhibit characteristics that make them desirable models for cardiovascular research. Specifically, spontaneous genetic mutations cause diseases that closely resemble human cardiovascular disease. Further, Syrian hamsters display unique anatomical characteristics, most notably a readily evertible cheek pouch, that facilitate cardiovascular studies.

Cardiomyopathy

Cardiomyopathy is a primary degenerative disease of the myocardium and is characterized as various forms, such as hypertrophic or dilated, based on gross appearance (Sakamoto et al., 1997). Dilated cardiomyopathy (DCM) is characterized by atrial and ventricular dilation with ventricular wall thinning, severe systolic and diastolic left ventricular dysfunction, and heart failure (Ikeda and Ross, 2000). DCM is one of the main causes of congestive heart failure in humans, is the leading cause of hospitalization of older patients in the United States, and is hereditary in 25% of affected patients (Ikeda and Ross, 2000). Hypertrophic cardiomyopathy (HCM) is characterized by increased ventricular wall thickness, generally involving the interventricular septum, and normal or reduced left ventricular volume (Richardson et al., 1996; Rodriguez et al., 2009). HCM is the most common, heritable cardiovascular disease in humans, affecting one in 500 people (Bos et al., 2009; Rodriguez et al., 2009). Approximately 10% of humans with HCM eventually develop left ventricular dilation and DCM (Ikeda and Ross, 2000). The cardiomyopathic Syrian hamster is a naturally occurring, inherited, established animal model for both dilated and hypertrophic cardiomyopathy. In the hamster, both DCM and HCM are caused by a defect in the δ -sarcoglycan gene, a component of the dystrophin complex, which is inherited in an autosomal recessive fashion (Bajusz et al., 1969; Escobales and Crespo, 2006, 2008; Goineau et al., 2001; Ikeda and Ross, 2000; Lipskaia et al., 2007; Ryoike et al., 1999; Sakamoto et al., 1997). The Syrian hamster model shares many features with human DCM and HCM and is used to study the pathophysiology, prevention, and treatment of cardiomyopathy (Escobales and Crespo, 2008; Ryoike et al., 1999).

All cardiomyopathic Syrian hamsters were originally derived from the polymyopathic line 1.50, providing an

example of a single mutation causing different types of cardiomyopathy (Goineau et al., 2001; Sakamoto et al., 1997). Hamster strains Bio 14.6, UM-X7.1, CHF 146, and CHF 147 are characterized by significant hypertrophy of cardiac muscle, while strains 53.58 and Bio TO-2 are characterized by ventricular dilation without hypertrophy (Goineau et al., 2001; Ikeda and Ross, 2000). Some strains, such as the Bio 14.6, exhibit compensatory hypertrophy progressing to left ventricular dilation, thinning and impaired function, while strains such as TO-2 develop dilated cardiomyopathy without an initial hypertrophic response (Goineau et al., 2001; Ikeda and Ross, 2000). These various strains provide diverse models which can be used to study various aspects of pathogenesis.

Many features of the TO-2 dilated cardiomyopathy strain closely resemble those of human DCM so this strain is used commonly to characterize the pathophysiology and hemodynamic profiles of DCM in humans (Escobales and Crespo, 2006; Goineau et al., 2001). TO-2 strain cardiomyopathy is progressive, beginning with myolysis, then developing fibrosis followed by hypertrophy and dilation, and culminating in congestive heart failure (Cruz et al., 2007; Escobales and Crespo, 2006). These stages represent the majority of phases seen in humans with cardiomyopathy, including heart dilation, ventricular hypertrophy, fluid congestion, and death (Cruz et al., 2007; Escobales and Crespo, 2006). Acute myocarditis is also observed in humans and hamsters (Escobales and Crespo, 2006). The common hemodynamic features include low cardiac output, elevated left ventricular end-diastolic pressure, delayed left ventricular relaxation rate, increased peripheral resistance, and reduced renal blood flow.

In the TO-2 Syrian hamster, abnormal sarcoplasmic reticulum function results in calcium sequestration and overload, and high ATPase activity results in decreased contractility. These features are partially responsible for decreased cardiac function in this strain, and these abnormalities are hypothesized to be a pathogenic mechanism in human DCM (Goineau et al., 2001). Deficiency of the δ -sarcoglycan gene also affects peripheral and coronary vasculature, ultimately contributing to heart failure in cardiomyopathic hamster models (Escobales and Crespo, 2006, 2008; Lipskaia et al., 2007). Angiotensin II promotes increased oxidative stress and decreased peripheral vasorelaxation, leading to high systemic blood pressure and increased cardiac work load in cardiomyopathic prone TO-2 hamsters (Escobales and Crespo, 2006). Angiotensin-II-dependent oxidative stress influences coronary vasculature by causing endothelial dysfunction which predisposes hamsters to the development of ischemic heart disease and cardiomyopathy (Escobales and Crespo, 2008). Based on the similarities between cardiomyopathic Syrian hamsters and humans,

these results associate angiotensin II with the development of cardiomyopathy in humans with hereditary sarcoglycanopathies (Escobales and Crespo, 2008).

Current medical treatment for human dilated and hypertrophic cardiomyopathy is only palliative (Sakamoto et al., 1997). Syrian hamster cardiomyopathic strains are used in research targeting prevention and treatment of the condition. The treatment of cardiomyopathic hamsters with angiotensin-converting enzyme (ACE) inhibitors improves left ventricular contractility and coronary flow, providing evidence that Syrian hamsters are useful models in studying drug treatment interventions. Coronary vasculature renin-angiotensin system (RAS) plays a role in generating increased coronary reactivity and resistance in young Syrian hamsters that have yet to develop cardiomyopathy. Early RAS blockade may prevent and improve the clinical signs of cardiomyopathy (Escobales and Crespo, 2008). Finally, the administration of carvedilol, a non-selective β -blocker with α_1 -blocker properties, to 6-month-old TO-2 hamsters, improves cardiac function due to decreased peripheral resistance (Cruz et al., 2007).

Microcirculation

The bilateral cheek pouches of the Syrian hamster are invaginations of the oral mucosa which extend to the shoulder region and possess a retractor muscle (Svensjo, 1990). These anatomical structures are highly vascular, thin, easily transilluminated, and can be everted with blood flow intact, making the hamster cheek pouch ideal for intravital microscopy and microcirculation research (Davis and Gore, 1985; Kerger et al., 1995; Klitzman et al., 1983; Svensjo, 1990). Numerous preparations are described in the literature to observe the hamster cheek pouch microscopically. These methods perfuse the tissue with a bicarbonate-buffered saline solution and maintain physiological temperature, oxygen tension, and pH in an anesthetized hamster (Davis and Gore, 1985; Greenblatt et al., 1969; Svensjo, 1990; Yamaki and Kritchman, 1981).

With the everted method, the cheek pouch is grasped with forceps, pulled through the mouth, and pinned over a specialized Lucite support pedestal (Davis and Gore, 1985; Persson et al., 1985). Longitudinal and transverse incisions allow exposure of the pouch in a single-layer preparation with high optical clarity, making this method one of the standards for microcirculation studies (Davis and Gore, 1985; Svensjo, 1990). The disadvantages of the everted preparation are restricted blood flow due to tension on the retractor muscle, and the requirement of pouch incisions. Refined everted techniques eliminate the disadvantage of restricted blood flow. Following a skin incision to expose the pouch the retractor muscle is removed and a thin glass

support plate is positioned in the cheek pouch which allows unrestricted blood flow. The everted pouch can then be observed in a chamber attached over the microscope condenser system. This preparation decreases surgical trauma and preserves the entire cheek pouch vascular supply (Davis and Gore, 1985).

An alternative method is the use of a skin incision in the neck followed by ligation and cutting of the retractor muscle at the point of insertion and retraction of the cheek pouch through the skin incision (Yamaki and Kritchman, 1981). This preparation eliminates tension on the retractor muscle, but requires more surgical manipulation than the everted technique.

A third method, the chamber method, involves incising the skin over the cheek pouch, inserting a translucent chamber through the hamster's mouth into two cheek pouch incisions, and illuminating the chamber with a Lucite rod inserted into the mouth (Greenblatt et al., 1969). This method can be used for acute and chronic experimentation, and does not place excessive tension on the retractor muscle. The primary disadvantage of this method is limited transillumination (Davis and Gore, 1985).

A detailed three-dimensional intravital microscopic view of hamster microcirculation can be visualized using one of the above-described preparations, and intravenous injection of fluorescein-labeled dextran (Endrich et al., 1980; Svensjo, 1990). Intravital microscopy is also used for observation of the microcirculation of non-anesthetized Syrian hamsters using the dorsal skinfold chamber method (Endrich et al., 1980; Lehr et al., 1991; Menger et al., 2002; Nolte et al., 1995). After implantation of two catheters into the jugular vein and carotid artery, two titanium frames are implanted into the dorsal skinfold to extend the double layer of skin. One layer is completely removed and the remaining layer is covered with a cover slip. This preparation allows for chronic studies of microcirculation (Menger et al., 2002).

Ischemia Reperfusion

The hamster cheek pouch is used to study ischemia-reperfusion injury. Ischemia-reperfusion injury is important because it contributes to tissue damage during myocardial and cerebral infarction, and following surgical manipulations that interrupt and then restore blood flow, such as during vascular and organ transplantation and reconstructive surgery (de With et al., 2005; Nolte et al., 1995). Ischemia-reperfusion injury is caused by several factors including the generation of reactive oxygen and nitrogen species and the resulting lipid peroxidation; cytokine production following leukocyte margination, adherence, and infiltration; and activation of the complement system (de Groot and Rauen, 2007; de With et al., 2005; Kaminski et al., 2002;

Yasuhara et al., 1991). The Syrian hamster is extensively used to reveal the pathophysiological mechanisms of ischemia–reperfusion injury, as well as therapeutic options to preserve tissue and vascular viability.

Numerous models of ischemia–reperfusion injury are described using the Syrian hamster cheek pouch. In the model of pressure-induced ischemia a translucent pressure chamber is pressed against the cheek pouch for variable amounts of time and then released to produce reperfusion (Romanus et al., 1977; Yasuhara et al., 1991). The disadvantage of this model is that the results are influenced by the pressure applied to the tissue. In a second model, ischemia is produced by tightening a latex cuff around the neck of an everted cheek pouch for up to an hour followed by cuff release (Persson et al., 1985; Yasuhara et al., 1991). The disadvantage of this model is that tension on the retractor muscle is produced by the everted preparation. Alternatively, ischemia can be induced by compressing the feed arteries and collecting veins of the pouch with a piece of silastic tubing or atraumatic microvascular clips (Bertuglia and Reiter, 2007; de With et al., 2005).

In the incomplete ischemia model, ischemia of the cheek pouch is produced by occluding the ipsilateral common carotid artery, its external branch, and the contralateral external carotid artery (Erlansson et al., 1987; Yasuhara et al., 1991). Partial ischemia better reproduces ischemia as seen in the clinical setting, when compared to models of global ischemia. The disadvantages of this model are that the degree of ischemia is not easily evaluated, and occlusion of the carotid arteries reduces cerebral blood flow (Yasuhara et al., 1991). A further refinement of the incomplete ischemia model is produced by selecting two sections of cheek pouch and placing a triangular chamber made of polyester/plastic film in each area. Ischemia is induced by applying a set amount of pressure to a cover slip over one of the chambers, while the other area acts as a control. Increased pressure is avoided by using a 1.0-mm aperture at one of the chamber corners. Reperfusion is produced when pressure is released after 1 hour (Yasuhara et al., 1991). The advantages of this method include decreased trauma to the pouch microcirculation, the ability to select various sizes of tissue, the maintenance of blood flow in surrounding microvasculature, and the ability to study both ischemic and non-ischemic areas simultaneously. In addition to the cheek pouch, the dorsal skin-fold chamber method can be used in ischemia reperfusion research utilizing an O-shaped silicone ring pressed into the tissue with an adjustable screw clamp, leading to cessation of blood flow into and out of the chamber (Pickelmann et al., 1999).

While Syrian hamster ischemia–reperfusion models are broadly used for elucidating the pathophysiology of the condition, the models are also utilized in the

development of prevention and treatment (Bertuglia and Reiter, 2007; Pickelmann et al., 1999). Melatonin, a potent antioxidant, effectively preserves microcirculation in the hamster cheek pouch during ischemia reperfusion, making melatonin administration a possible preventative measure during situations when ischemia reperfusion injury is a possibility (Bertuglia and Reiter, 2007). Another possible preventative intervention is daflon, a highly purified flavonoid with anti-inflammatory and antioxidative properties. Daflon blocks immigration and accumulation of leukocytes in perivascular tissue during ischemia reperfusion in the Syrian hamster (Pickelmann et al., 1999).

INFECTIOUS DISEASE RESEARCH

Syrian hamsters were introduced as a laboratory animal species in 1930 due to their susceptibility to *Leishmania* spp. and ease of breeding in captivity (Adler, 1948). Prior to the use of Syrian hamsters, Chinese hamsters were the only suitable models for *Leishmania* research but they did not breed well in captivity and had to be imported from the Far East (Adler, 1948). Early on, Syrian hamsters were also found to be useful models for tuberculosis and brucellosis. Syrian hamsters remain a valuable tool for studying many infectious diseases due to their relative lack of spontaneous diseases compared to other rodent models, and their susceptibility to many experimentally induced infectious diseases (Hankenson and Van Hoosier, 2002).

Viruses

Hantavirus

Hantavirus pulmonary syndrome (HPS) is a severe infectious disease caused by numerous members of the *Bunyaviridae* family (Jonsson et al., 2008; Wahl-Jensen et al., 2007). HPS can range from a typical flu-like disease with fever to fatal pneumonia. Unlike other diseases caused by Hantavirus, HPS is transmitted by aerosol and wild rodents in the family *Cricetidae* are the natural hosts of these infectious agents (Hooper et al., 2001). Research conducted on HPS agents must be conducted at ABSL-4 facilities.

The hamster serves as an experimental model to study the pathogenesis of HPS. Specifically, the Syrian hamster is highly susceptible to Andes and Maporal viruses which cause fatal pneumonia and edema in experimentally infected hamsters (McElroy et al., 2004; Milazzo et al., 2002; Wahl-Jensen et al., 2007). In contrast, Sin Nombre virus readily infects the hamster but does not cause disease. Further, Choclo virus is not fatal in the hamster (Eyzaguirre et al., 2008). These varying

results create an understanding of how these agents produce disease. Specifically, Choclo virus damages the endothelium of the lung without significantly inciting inflammation (Eyzaguirre et al., 2008). In contrast, Andes virus targets endothelium and induces a proinflammatory response (Eyzaguirre et al., 2008; Hooper et al., 2001, 2008). This same proinflammatory response is noted in humans with severe HPS. It therefore seems likely that more pathogenic viruses produce disease by both directly damaging lung endothelium and inducing a potent proinflammatory response (Eyzaguirre et al., 2008; Hooper et al., 2001, 2008). Based upon these data a potential treatment of HPS would be the initiation of anti-inflammatory therapy.

Coronavirus (SARS)

In 2003, an outbreak of a previously unknown condition, severe acute respiratory syndrome (SARS), affected more than 8000 people and resulted in 774 deaths across 30 countries (Schaecher et al., 2008). The etiological agent of SARS was identified as a novel coronavirus, SARS-CoV (Drosten et al., 2003). The outbreak was controlled through quarantine of infected individuals and travel advisories (Subbarao and Roberts, 2006). The possibility of future SARS outbreaks has led to the search for an appropriate animal model to study the pathogenesis and potential therapeutics for SARS (Subbarao and Roberts, 2006).

In the hamster model, a high virus titer develops in the respiratory tract following intranasal inoculation of SARS-CoV (Roberts et al., 2005). In the lungs, peak viral replication occurs two days post-infection and is cleared by day 7; however, low levels of virus are present in the nasal turbinates for up to 14 days (Roberts et al., 2005). SARS-CoV elicits a robust neutralizing antibody response in the hamster which can be detected in sera at day 7 post infection and hamsters are protected from re-challenge by 28 days after initial infection (Roberts et al., 2005). In hamsters, viral replication occurs in epithelial cells of the respiratory tract and causes interstitial pneumonia, pulmonary consolidation, and diffuse alveolar damage. A positive correlation exists between pulmonary viral titer and the extent of pneumonia, making the hamster an excellent model for studying the efficacy of potential vaccines and immunotherapy for SARS (Subbarao and Roberts, 2006). Despite the high level of viral replication and associated histopathological lesions, hamsters exhibit no overt clinical signs (Roberts et al., 2005).

Immunotherapy with anti-SARS-CoV monoclonal antibodies (MAbs) has been tested in the hamster model (Roberts et al., 2006). In these studies, the virus is administered intranasally and 24 hours post-infection hamsters are treated with MAbs by intraperitoneal injection. Treatment with MAb 201, a SARS-CoV-specific MAb,

significantly reduces viral replication and the severity of pulmonary lesions in hamsters (Roberts et al., 2006). There is a 1000-fold reduction in viral titer when MAb 201 is given at a dose of 40mg/kg and a 10000-fold reduction when given at a dose of 80mg/kg.

Cyclophosphamide-induced immunosuppression increases the severity of SARS in hamsters when given prior to and during infection (Schaecher et al., 2008). In these studies, hamsters are first given a loading dose of cyclophosphamide (140mg/kg) 2–5 days prior to infection, and then a maintenance dose (100mg/kg) every 3–4 days throughout the course of the study. In treated animals the virus displays a more expansive tissue tropism and high titers are present in the lung, liver, spleen, kidney, and heart and treated animals exhibit weight loss and mortality. This condition is similar to humans with SARS who develop extrapulmonary lesions including splenic atrophy, acute tubular necrosis in the kidneys, neuronal edema and degeneration, heart edema, and myocardial fiber atrophy (Gu and Korteweg, 2007). While the immunosuppressed hamster model does not replicate all of the extrapulmonary lesions in humans it more closely mimics the human disease presentation when compared to the immunocompetent hamster model (Schaecher et al., 2008).

Bacteria

Leptospira spp.

Leptospirosis, caused by organisms in the genus *Leptospira*, is a potentially fatal disease affecting humans and animals worldwide (Guerra, 2009). In humans, clinical signs range from asymptomatic to high fever, severe headache, chills, muscle aches, vomiting, diarrhea, jaundice, abdominal pain, and a rash (Arean, 1962). If the disease is left untreated, kidney damage, meningitis, liver failure, respiratory distress, and death are possible. Leptospirosis is contracted by ingestion or contact with contaminated water, food, or soil (Guerra, 2009).

Two strains of *Leptospira interrogans* (L1–130, Kito) and three strains of *Leptospira noguchii* (Cascata, Hook, and Bonito) produce an acute lethal infection when inoculated intraperitoneally into Syrian hamsters (Silva et al., 2008). Leptospirosis in hamsters is characterized by hepatic and renal complications similar to those seen in acute lethal infection in humans (Silva et al., 2008). Clinical signs that may be observed by the fourth day post-infection include hemorrhage, dehydration, ruffled fur, decreased activity, and isolation from cohorts. Hamsters infected with L1–130 or Kito strains die 7–14 days after inoculation, while hamsters infected with Cascata, Hook, or Bonito die 7–22 days after inoculation. The reproducible lethal nature of these isolates in hamsters, coupled with lesions in target organs that

resemble leptospirosis in humans, provides a useful animal model.

Through the use of this model, new treatment and prophylactic modalities can be tested. For example, azithromycin is an effective treatment for acute leptospirosis in hamsters, with 100% survival, following only two doses initiated 2–4 days post infection (Moon et al., 2007). Azithromycin provides an alternative to the standard doxycycline or penicillin treatment because it lacks contraindications in young children and pregnant women (Jain and Danziger, 2004; Moon et al., 2007).

Clostridium difficile

Clostridium difficile, a Gram-positive spore-forming bacillus, is the leading cause of antibiotic-associated diarrhea in humans (Poutanen and Simor, 2004). Disease occurs when the normal colonic flora is disrupted typically due to clindamycin, ampicillin, or cephalosporin administration and overgrowth of toxin-producing strains of *C. difficile* (Poutanen and Simor, 2004). Pathogenic strains of *C. difficile* produce two toxins, enterotoxin A and cytotoxin B, which are the major virulence factors for *C. difficile* (Razaq et al., 2007). Outbreaks of *C. difficile*, beginning in 2000, are attributed to a newly recognized strain, known as the BI strain (McDonald et al., 2005). In addition to the other toxins mentioned the BI strain of *C. difficile* produces a binary toxin, has an 18-bp deletion in the *tcdC* locus (a negative regulator of toxin A and B), and is resistant to fluoroquinolone antibiotics (McDonald et al., 2005). Patients that acquire *C. difficile* may remain asymptomatic carriers or develop diarrhea, pseudomembranous colitis, or toxic megacolon (Al-Eidan et al., 2000). Treatment consists of stopping the initiating antibiotics and beginning treatment with metronidazole or vancomycin for 10 days. Relapse after completion of treatment occurs in about 20% of cases (Pepin et al., 2005).

The Syrian hamster model for *C. difficile* closely mimics several important aspects of human infection (Kokkotou et al., 2008). Hamsters are orally gavaged with clindamycin followed by gastric inoculation of *C. difficile* 24 hours later (Kokkotou et al., 2008). Hamsters exposed to this experimental paradigm develop hemorrhagic typhlitis, similar to antibiotic-associated pseudomembranous colitis in humans, followed by death within 3 days of infection (Kokkotou et al., 2008). Clinical signs of infection may include diarrhea, weight loss, ataxia, dyspnea, and death (Babcock et al., 2006). Highly virulent strains may cause death without any premonitory signs (Razaq et al., 2007).

Hamsters, like humans, may succumb to a relapse after completing treatment of the primary disease (Kokkotou et al., 2008). Hamsters receiving vancomycin, the historical treatment for human *C. difficile*-associated colitis, display a 75% recurrence rate by 28 days post-initial-infection (Kokkotou et al., 2008).

However, treatment with Rifaximin, a non-absorbable oral antibiotic, results in a 0% recurrence rate, potentially providing refinement to therapy in humans (Kokkotou et al., 2008).

The hamster model of *C. difficile* is also used to test the use of human monoclonal antibodies (HuMAbs) directed against either toxin A (CDA1) or toxin B (MDX-1388) (Babcock et al., 2006). Intraperitoneal administration of CDA1 and MDX1388 daily for 4 days prior to inoculation with *C. difficile* protects against mortality both in the primary disease and in the relapse model of infection (Babcock et al., 2006). The use of HuMAbs may provide a useful therapeutic option either alone or in combination with antibiotics for treatment of humans with *C. difficile* colitis (Babcock et al., 2006).

Mycoplasma pneumoniae

Mycoplasma pneumoniae is the leading cause of pneumonia in children and young adults (Denny et al., 1971). A majority of the cases result in upper respiratory tract infections, with fever, cough, sore throat, headache, and malaise, but some cases may progress to tracheobronchitis or pneumonia (Denny et al., 1971). Antibiotics may reduce the severity of disease, but do not eliminate the infection (Ford et al., 1980). Recovery from *M. pneumoniae* infection protects the individual from reinfection, suggesting that the development of a vaccine is the most promising approach to controlling *M. pneumoniae* infections (Barile et al., 1988).

Syrian hamsters, which do not harbor *Mycoplasma* spp. as part of their indigenous microbiota, provided an early model for studying *Mycoplasma* and potential vaccines and therapeutics (Barile et al., 1988). In this model, *M. pneumoniae* is inoculated into hamsters via either the aerosol, intranasal, or intratracheal routes, and infection results in changes that are consistent with natural human disease (Clyde, 1971). The intratracheal route consistently produces pulmonary disease of greater severity with greater colonization than the other routes of exposure (Barile et al., 1988). In general, peak disease severity occurs 2 weeks post inoculation with hamsters over 6 weeks of age becoming most severely affected (Barile et al., 1988). Assessment of experimental vaccines and other therapeutics can be accomplished by assessment of lung lesion scores. Specifically, lung lesions are scored microscopically by evaluating the degree of leukocyte cell infiltrates, luminal exudate, and parenchymal pneumonia in three cross-sections of the entire lung (Barile et al., 1988). Alternatively, following treatment with a potential chemotherapy agent, viable mycoplasmas in the lung can be quantitated by homogenizing the lungs in mycoplasma liquid medium and plating serial dilutions on agar medium. The use of the hamster in *M. pneumoniae* research has decreased in recent years (2000 and beyond). This reduction

likely stems from the wide availability of mice free of *Mycoplasma* spp.

Treponema pallidum

Two forms of syphilis occur in humans: the venereal form with primary, secondary, and tertiary manifestations and possible congenital transmission, and the endemic form that is usually seen in childhood and is transmitted between children by close contact. In humans, *Treponema pallidum* subsp. *pallidum* is the etiologic agent for venereal syphilis and *T. pallidum* subsp. *endemicum* is the etiologic agent for the endemic form (Kajdacsy-Balla et al., 1993). In the venereal form, primary lesions present as small painless firm raised sores at the site of contact that heal in 3–6 weeks (McAdam and Sharpe, 2010). Secondary lesions occur about 2–10 weeks after the primary lesions and are characterized by widespread cutaneous and mucocutaneous lesions with lymphadenopathy that lasts for several weeks (McAdam and Sharpe, 2010). The tertiary stage occurs in about a third of people that do not receive treatment and appears after a latent period of 5 or more years. Internal organs are the target for the tertiary stage of syphilis, primarily causing cardiovascular or neurologic damage.

When Syrian hamsters are infected with *T. pallidum* subspecies *endemicum*, a disease process similar to

human venereal syphilis develops (Kajdacsy-Balla et al., 1993). Intradermal injection of *T. pallidum* into the inguinal regions of hamsters results in primary lesions at the site of inoculation. The primary lesions form about 3 weeks after inoculation as erythematous papules, which enlarge and become ulcerated by 4 weeks (Figure 34.4A). The lesions continue to expand until the sixth to eighth week post-inoculation when they begin to heal slowly (Kajdacsy-Balla et al., 1993). Around 24 weeks post-infection, secondary lesions develop as perioral ulcers (Figure 34.4B) and an erythematous rash on the paws and cranial trunk (Kajdacsy-Balla et al., 1993). Most infected hamsters die within 28–32 weeks following inoculation due to malnutrition from the presence of severe perioral ulcers. If the hamster survives, the perioral ulcers will resolve. Tertiary lesions in hamsters are not documented; however, this could be due to the rarity of survival past the secondary stage.

Gross pathologic features of hamster syphilis include lymphadenopathy and thymic atrophy (Kajdacsy-Balla et al., 1993). Histologic features include generalized follicular hyperplasia of lymph nodes, hepatic periportal foci of mononuclear cells, and a diffuse increase in mononuclear cells in the sinusoids. The perioral ulcers are characterized by an intense polymorphonuclear infiltrate at their base. Treponemes are visualized in the lymph nodes and perioral ulcers by dark-field

FIGURE 34.4 Hamster with syphilitic lesions. (A) Primary cutaneous lesions form at the site of inoculation as erythematous papules which enlarge and become ulcerated with raised indurated borders. (B) Secondary lesions spontaneously develop approximately 24 weeks after infection in the form of perioral ulceration. From Kajdacsy-Balla et al. 1993 with permission from the American Society for Investigative Pathology.

microscopy. Persistent latent infection is demonstrated in these animals by transfer of lymph node material into naïve hamsters.

Hamsters infected prior to pregnancy transmit syphilis to their offspring congenitally. A majority of the offspring exhibit rhinitis, about a third develop perianal and perigenital lesions, and a quarter are stillborn or die shortly after birth (Kajdacsy-Balla et al., 1993). Human congenital syphilis also results in about 25% of prenatal infections resulting in stillbirth, while 25–30% of newborn infants die shortly after birth and 40% develop syphilis later in life (Crissey and Denenholz, 1984).

Experimental infection of hamsters with *T. pallidum* provides a model to study syphilis infection and drug therapy. Daily clarithromycin given over 7 days successfully eliminates infection in hamsters (Alder et al., 1993). Success is confirmed by failure to infect susceptible hamsters following inoculation with lymph node material from treated hamsters (Alder et al., 1993). These findings may prove useful in establishing alternatives to penicillin treatment, which is the drug of choice for treating human infections.

Hamsters infected with *T. pallidum* for 8 weeks then treated with 4000 IU of penicillin to clear the infection are susceptible to reinfection (Schell et al., 1980). However, hamsters infected with *T. pallidum* for 10–16 weeks and treated with 4000 IU of penicillin are resistant to reinfection (Schell et al., 1980). Following re-inoculation with *T. pallidum*, hamsters do not develop lesions and treponemes are not detectable in the lymph material. The hamster's ability to develop resistance to *T. pallidum* may prove useful in studying human syphilis vaccine development.

While many features of the hamster *T. pallidum* subsp. *endemicum* model make it an excellent model for studying congenital syphilis, it does not utilize *T. pallidum* subsp. *pallidum*, which is the agent that causes congenital syphilis in humans. Hamsters do not develop any lesions in response to *T. pallidum* subsp. *pallidum*. In contrast guinea pigs do develop congenital syphilis in response to *T. pallidum* subsp. *pallidum*, and are therefore more popular current models in the study of congenital syphilis.

Parasites

Toxoplasma gondii

Toxoplasma gondii is an intracellular parasitic protozoan widely distributed in nature. Cats are the definitive host, but all mammals may serve as intermediate hosts. In all hosts, the parasite forms cysts within various tissues (Kean, 1972). Approximately 23% of adolescents and adults in the United States have anti-*T. gondii* antibodies (National Center for Health Statistics, 1994). In some areas of the world, up to 97%

of people are positive for *T. gondii* antibodies (Santos et al., 2009). Infection is usually asymptomatic; however, infection during pregnancy may lead to abortions or to offspring that develop mental retardation, epilepsy, or toxoplasmic retinochoroiditis (Lopez et al., 2000). Ocular disease resolves spontaneously, but reoccurs frequently, and may result in episodic blindness (Pavesio et al., 1995).

The hamster is a reliable model of toxoplasmic retinochoroiditis. Hamsters inoculated intraperitoneally with cysts of *T. gondii* strain ME 49 develop ocular disease without systemic illness (Pavesio et al., 1995). Retinal lesions develop in both eyes by 2–3 weeks after inoculation and cysts form as white pinpoint to optic disc-sized lesions, primarily at the posterior pole of the inner retina. Four weeks post-infection, the lesions enlarge and develop diffuse indistinct edges with vasculitis and occasionally vitritis. Regression typically occurs by 8–9 weeks, but retinal atrophy may persist (Pavesio et al., 1995).

Oral administration of *T. gondii* ME 49 results in a comparable outcome with no systemic signs of illness, and similar but less severe ocular lesions (Gormley et al., 1999). The lesions appear similar in color and position in the retina, however, they are smaller in size, fewer in number, associated with a milder inflammatory reaction, and first appear approximately 1 week later than with the intraperitoneal route.

During the past decade, mice have replaced hamsters as the model of choice for studying ocular toxoplasmosis. Mouse models offer the advantages of a completed genome, the wide availability of knock-out strains, and the ability to reproduce many features of human ocular toxoplasmosis.

Babesia microti

Babesia spp. are protozoal pathogens that infect red blood cells. Many *Babesia* spp. are found in animals, but *Babesia microti* is the main cause of infection in humans and is transmitted by *Ixodes scapularis* ticks (Vannier et al., 2008). Babesiosis in humans can range from asymptomatic to life-threatening. Hemolytic anemia and flu-like symptoms are possible, especially in people without a functional spleen or in people that are otherwise immunocompromised (Vannier et al., 2008).

Syrian hamsters provide a reliable model of babesiosis through intraperitoneal inoculation with *B. microti*-infected red blood cells (Wozniak et al., 1996). Without treatment, infection is patent for 3–5 weeks, and hamsters develop severe anemia and marked parasitemia with low mortality. Parasitemia is evident by day 7 post-inoculation, with a peak parasitemia occurring by day 14. This is followed by a carrier state with low or undetectable levels of parasites.

Because Syrian hamsters are highly susceptible to *B. microti* infection they are commonly utilized to

maintain *B. microti* within the laboratory. *B. microti*-infected hamster blood can be used to infect other animals or they may be used for in vitro studies of *Babesia* during infection of erythrocytes.

The hamster model also provides a valuable tool for assessing new therapeutic options for human babesiosis. Drug treatments are initiated once parasitemia reaches 3–7% of the total red blood cell population (Marley et al., 1997). To determine whether a treatment elicits a complete cure, blood is drawn from a treated hamster 14 days after the last drug dose and administered by intraperitoneal injection into a naïve sentinel hamster. The sentinel hamster is then monitored weekly for 6 weeks for development of parasitemia by examination of thin blood smears (Marley et al., 1997).

Utilizing this experimental approach, clindamycin consistently eradicates *B. microti* in hamsters (Rowin et al., 1982). The combination of quinine and clindamycin results in a more significant and faster therapeutic response and is now the treatment of choice for severely ill human patients with babesiosis (Rowin et al., 1982; Wittner et al., 1996). The combination of atovaquone and azithromycin also eliminates *B. microti* in hamsters and is an alternate therapy for human cases of babesiosis that are resistant to clindamycin and quinine (Falagas and Klemperer, 1996; Wittner et al., 1996).

Leishmania donovani

Visceral leishmaniasis is caused by *Leishmania donovani*, an intracellular protozoan transmitted by sandflies (Chappuis et al., 2007). Visceral leishmaniasis is a progressive disease characterized by prolonged fever, hepatosplenomegaly, anemia, leukopenia, severe weight loss, and ultimately death (McAdam and Sharpe, 2010). Pentavalent antimonial drugs, such as sodium stibogluconate, are the treatment of choice, despite harmful side effects and significant levels of drug resistance (Sundar et al., 2000). Identifying more effective chemotherapeutics is the focus of research for this disease (Wyllie and Fairlamb, 2006).

Hamsters can be experimentally infected with *L. donovani* by intracardiac injection under anesthesia or intraperitoneal injection of amastigotes (Dea-Ayuela et al., 2007; Wyllie and Fairlamb, 2006). Intracardiac injection results in a more rapid infection than the intraperitoneal route; however, the intraperitoneal route results in a greater parasite burden in the spleen (Wyllie and Fairlamb, 2006). Systemic *L. donovani* infection results in clinicopathological features that closely mimic the human disease (Melby et al., 2001). Infection of the hamster results in a persistent increase in parasite burden, progressive cachexia, hepatosplenomegaly, pancytopenia, hypergammaglobulinemia, and ultimately death (Melby et al., 2001).

Early detection of infection can be accomplished using a latex agglutination test developed to diagnose

visceral leishmaniasis in dogs (Wyllie and Fairlamb, 2006). The assay is based on detection of a low-molecular-weight glycoconjugate in the urine. Hamster urine must be diluted 1:10 in phosphate-buffered saline before testing due to its concentrated nature, which creates a vast excess of antigen in the test sample that can result in false-negative results.

Weight loss is the most commonly used ante-mortem indicator of infection in live hamsters (Wyllie and Fairlamb, 2006). Early detection of infection can be accomplished by comparing body weights between inoculated and control juvenile hamsters where control hamsters gain weight significantly faster than age-matched infected hamsters (Wyllie and Fairlamb, 2006). Weight loss of 25% is used as the end-point for tissue collection and post-mortem analysis and parasite burden can be purified and quantified from a homogenate of the spleen at this endpoint (Dea-Ayuela et al., 2007).

Trypanosoma cruzi

Chagas disease is caused by the flagellate protozoan *Trypanosoma cruzi* (Kirchhoff, 1993). In Chagas-endemic areas of Central and South America, the most common route of infection is from the triatomine insect, which shed *T. cruzi* in their feces. Chagas disease is comprised of two phases, acute and chronic. The acute phase lasts for the first few weeks or months following infection and symptoms include fever, fatigue, body aches, headache, rash, anorexia, diarrhea, and vomiting (Kirchhoff, 1993). Gross lesions may include splenomegaly, hepatomegaly, lymphadenopathy, and local swelling at the site of parasite entry. Rarely, young children or immunocompromised people develop fatal myocarditis or meningoencephalitis (Kirchhoff, 1993). During the chronic phase, infection may remain dormant for decades; however, up to 30% of infected people will develop life-threatening inflammatory cardiomyopathy 15–30 years following infection (Koberle, 1968).

Syrian hamsters, following intraperitoneal injection of *T. cruzi*, develop a *T. cruzi*-induced cardiomyopathy resembling human Chagas cardiomyopathy, and display high levels of anti-*T. cruzi* IgG antibodies (Bilate et al., 2003). *T. cruzi* infection results in the death of some hamsters during the acute phase, within the first 4 months of infection, and during the chronic phase, after 8 months of infection (Bilate et al., 2003). All infected animals develop myocarditis, interstitial fibrosis, and mild-to-severe left ventricular dysfunction (Bilate et al., 2003). In the chronic phase, hamsters also develop ventricular dilation and a decrease in ventricle wall thickness (Bilate et al., 2003). Hamsters do not develop apical or segmental wall hypcontractility, which are additional features of human Chagas cardiomyopathy (Bilate et al., 2003).

The Chagas disease hamster model allows quantitative evaluation of left ventricular function and

myocardial lesions throughout progression of the disease. Novel therapeutics and their effect on the progression of cardiac disease can therefore be evaluated rapidly using the acute and chronic hamster model (Bilate et al., 2003).

Opisthorchis viverrini

Epidemiological studies reveal a high prevalence of cholangiocarcinoma in northeast Thailand (Sriamporn et al., 2004). In this region, the traditional diet exposes the local population to infection with the liver fluke *Opisthorchis viverrini* and nitrosamines through consumption of contaminated water and salt-fermented fish (Pairojkul et al., 1991). The use of a Syrian hamster model established a connection between *O. viverrini* infection, consumption of nitrosamine, and the development of cholangiocarcinoma (Pairojkul et al., 1991).

Syrian hamsters can be readily infected with *O. viverrini* by oral administration of metacercariae. Infection results in inflammation and fibrosis in the periductular region of the liver, similar to human infection (Chaimuangraj et al., 2003; Pairojkul et al., 1991). Feeding *O. viverrini*-infected hamsters subcarcinogenic doses of dimethylnitrosamine results in the development of cholangiocarcinomas in up to 93% of hamsters (Thamavit et al., 1987). In contrast, administration of subcarcinogenic doses of dimethylnitrosamine alone or infection with *O. viverrini* alone does not cause cancer in this animal model, suggesting that these factors interact to produce cholangiocarcinoma (Thamavit et al., 1987, 1996).

After experimental infection with *O. viverrini*, liver procollagen prolyl hydroxylase activity increases, reflecting increased collagen synthesis that is proportional to the intensity of liver fluke infection (Hutadilok et al., 1983). Liver fluke infestation likely acts as an epigenetic promotor of tumor formation, rather than a frank genomic mutagen, by inducing inflammatory and fibrotic changes in the liver (Pairojkul et al., 1991). This is supported by similar studies that utilize complete bile duct ligation in hamsters which results in biliary inflammation and proliferation. If this procedure is performed in hamsters treated with subcarcinogenic doses of dimethylnitrosamine, promotion of cholangiocellular lesions develop similar to the findings in *O. viverrini* infection (Thamavit et al., 1993).

Taenia spp.

Humans are the natural definitive host for *Taenia solium* and *Taenia saginata* (Avila et al., 2002). Human taeniosis is acquired by ingestion of cysticerci in raw or undercooked pork or beef. In the human small intestine, the cysticerci attach to the intestinal wall and develop into adult tapeworms which become gravid approximately 4 months after infection (Avila et al., 2002; McAdam and Sharpe, 2010). Taeniosis is usually

asymptomatic but may result in mild gastrointestinal disturbances (McAdam and Sharpe, 2010). In contrast, when humans ingest embryonated eggs through ingestion of food or water contaminated with human feces, they may serve as intermediate hosts (cysticercosis) (McAdam and Sharpe, 2010). The larvae hatch, penetrate the intestinal wall and disseminate to other organs where they encyst (McAdam and Sharpe, 2010). Cysticerci develop in the central nervous system, heart, eyes, subcutaneous tissue, and skeletal muscle. Clinical manifestations depend on where the cysticerci develop and may include neurologic, cardiac, or ocular deficits, or even death (Avila et al., 2002, 2006).

Hamsters can successfully become infected with adult *Taenia* spp. by being fed cysticerci encysted in rodent muscle (Wang et al., 1999). Oral gavage of cysticerci without muscle encasement results in digestion of the cysticerci and no colonization with adult tapeworms (Wang et al., 1999). Tapeworms grow better in hamsters that are immunosuppressed with steroids; however, it is unclear if this is due to a direct effect of the steroids on the tapeworm or due to depression of the host immune response (Avila, 2006). Tapeworms reach lengths in excess of 30 cm after 30 days, but do not form gravid proglottids in the hamster model (Allan et al., 1991).

Utilizing the hamster model, an ELISA, which detects a *Taenia* spp.-specific fecal antigen, was developed and standardized (Allan et al., 1990). In contrast to identification of eggs in the feces, this test can be used to diagnose infection even during the prepatent period. Additionally, the hamster model can be used to study the morphological and ultrastructural attachment of adult tapeworms to the intestinal wall, the results of which may contribute to a better understanding of the biology of tapeworm infections (Merchant et al., 1998).

Ancylostoma ceylanicum

Hookworm infection affects hundreds of millions of people living in tropical and subtropical climates around the world. Adult hookworms attach to the intestinal mucosa and feed on blood from lacerated capillaries. Chronic hemorrhage from the site of attachment leads to iron-deficiency anemia, serum protein loss, and intestinal inflammation (Held et al., 2006).

Unlike mice, Syrian hamsters are fully permissive hosts for the development of adult *Ancylostoma ceylanicum* hookworms (Bungiro et al., 2003; Carroll et al., 1983). Hamsters can be inoculated with infective *A. ceylanicum* third-stage larvae via oral gavage (Mendez et al., 2005). Hookworm eggs can be detected in the feces 14 days following infection and live adult hookworms can be recovered from the small intestine and colon (Mendez et al., 2005). Infected hamsters experience anemia, weight loss, growth delay, and chronicity of infection, just like children that are infected with

hookworms, making them an excellent model for the study of human hookworm infection (Held et al., 2006; Mendez et al., 2005).

Hamsters can also be orally inoculated with adult *A. ceylanicum* (Bungiro et al., 2003). This method allows for the specific study of host responses to bloodfeeding adult hookworms without the confounding influence of prior larval exposure. This model provides the added benefits of allowing for manipulation of adult hookworms by immunologic, genetic, or pharmacologic methods prior to inoculation into the hamsters and for the study of single-sex infections.

Schistosoma spp.

Schistosomiasis is one of the most prevalent parasitic diseases affecting humans in tropical and subtropical climates, with an estimated 779 million people at risk and over 200 million infected (Steinmann et al., 2006). Following percutaneous invasion flukes mature and lay eggs within hepatic or pelvic blood vessels and eggs migrate to the liver, intestine, or bladder, causing inflammation and scarring possibly leading to hepatic cirrhosis.

Syrian hamsters can be readily infected with *Schistosoma* spp. cercariae via percutaneous or subcutaneous inoculation (Botros et al., 2004). Chemotherapeutic agents can be tested for effectiveness against the juvenile stage of infection by administration at 21 days post inoculation and against adult worms by administration at 49 days post inoculation.

Prion Diseases

Transmissible spongiform encephalopathies (TSE), such as Creutzfeldt-Jakob disease in humans, bovine spongiform encephalopathy in cattle, or scrapie in sheep are fatal neurodegenerative diseases of the central nervous system (Kratzel et al., 2007a, 2007b). A common feature of TSE is that normal host cellular prion protein (PrP^c), which is strongly expressed by cells of the nervous and lymphoreticular systems, converts into an abnormal disease-specific prion protein (e.g. PrP^{Sc} in scrapie) (Kratzel et al., 2007b). This abnormal prion protein is a biochemical marker for TSE and is linked with infectivity.

TSE can be transmitted by oral, intracerebral, intravenous, intraperitoneal, and subcutaneous routes, but the most common route is through ingestion (Kratzel et al., 2007b). To study the course of disease following the oral route of infection, hamsters can be infected with scrapie by housing them with other hamsters that were intracerebrally inoculated with scrapie prions as weanlings (Prusiner et al., 1985). The experimental hamsters cannibalize the infected hamsters when they become terminally ill. Approximately 120 days after

consuming scrapie-infected brain, progressive neurologic signs including ataxia, tremors, and head bobbing develop, and death occurs about 20 days later (Prusiner et al., 1985).

Injection of scrapie-infected brain homogenate into the foot pad using a 27-gauge needle provides an alternative route of experimental infection (Kratzel et al., 2007b). Clinical signs, starting with muscle tremors, begin approximately 78 days following unilateral foot pad injection (Kratzel et al., 2007b). This method of inoculation provides a shorter incubation time than oral inoculation and allows the distribution of scrapie prion protein in nerve tissue to be assessed at various time points. Utilizing this method, scrapie prion protein is detected in the ipsilateral sciatic nerve 60 days post infection and 80 days post infection in the contralateral nerve (Kratzel et al., 2007b). Within the brain, the red nucleus correlating with the ipsilateral sciatic nerve produces stronger prion protein immunoreactivity compared to the contralateral nucleus. These findings suggest centripetal propagation to the CNS and subsequent centrifugal spread to other nerve projections (Kratzel et al., 2007b).

The role of the lymphoreticular system on the pathogenesis of TSE is also studied using the unilateral footpad infection model (Kratzel et al., 2007a). Scrapie prion protein is consistently detected in the ipsilateral popliteal lymph node as early as 2 days post-inoculation. In contrast, the contralateral popliteal lymph node remains negative throughout the study, indicating that systemic spread of scrapie prion protein through the lymphoreticular system does not occur (Kratzel et al., 2007a). Removal of the ipsilateral popliteal lymph node 4 weeks prior to infection with scrapie does not affect the incubation period or mean survival time at high or medium doses; however, at low doses, hamsters remain free of clinical symptoms for 314 days post inoculation (duration of experiment) (Kratzel et al., 2007a). These data suggest that very low doses of scrapie may require replication in the lymphoreticular system prior to invasion of the nervous system (Kratzel et al., 2007a).

OTHER MODELS

Amyloidosis

Amyloidosis is an abnormal deposition of highly ordered proteinaceous material in various organ systems of humans and animals (Coe and Ross, 1990). There are currently 20 clinical syndromes in humans associated with amyloid deposition and each syndrome is classified into primary or secondary amyloidosis based on chemical composition (Hukkanen et al., 2006). Primary amyloidosis is the result of overproduction of immunoglobulin light chains and is principally of

neoplastic or genetic origin. Reactive or secondary amyloidosis is the result of the accumulation of β -pleated fibrils composed of serum amyloid A (SAA), an acute-phase protein associated with inflammation (Hukkanen et al., 2006). In addition to SAA, in reactive amyloidosis, amyloid deposits contain a minor protein component called amyloid P (AP) derived from serum AP (SAP) (Coe and Ross, 1990). Amyloidosis occurs both spontaneously and after induction with amyloid-inducing substances in Syrian hamsters. The spontaneous disease is more prevalent in females compared to males and spontaneous occurrence is promoted by fight wounds, stress, high-protein diets, and various infectious agents (Gruys and Snel, 1994). Syrian hamsters are commonly used as a model of induced amyloidosis, using casein or lipopolysaccharide (LPS) subcutaneous injections (Hol et al., 1986; Niewold et al., 1987). The lag or pre-amyloid phase associated with these amyloid-inducing substances can be accelerated by intraperitoneal or subcutaneous injection with amyloid-enhancing factors (AEF), which are small fragments of amyloid fibrils (Hol et al., 1986; Niewold et al., 1987). AEF injection shortens the pre-amyloid phase for splenic, hepatic, and renal amyloid deposition (Hol et al., 1986).

Syrian hamsters are unique when compared to other animal models of secondary amyloidosis because they have an SAP homolog called female protein (FP) which is under estrogenic control (Coe and Ross, 1990). The hamster amyloid model provides the unique opportunity to hormonally manipulate the synthesis of FP and study concurrent amyloid deposition. Female hamsters, when compared to males, possess higher serum concentrations of FP, acquire more amyloid at an earlier age and die at an earlier age due to amyloid accumulation (Coe and Ross, 1990). In the Syrian hamster, FP rather than amyloid fibril, plays a predominant role in the sex-limited expression of amyloidosis (Coe and Ross, 1990). Male Syrian hamsters that are deprived of testosterone by castration or administered diethylstilbestrol (DES) acquire amyloid deposition at an earlier age similar to female hamsters (Coe and Ross, 1990). The amyloidogenic effect of DES in male hamsters is inhibited by testosterone injections, and female hamsters given testosterone are also protected from amyloid deposition (Coe and Ross, 1990). These studies established the importance of FP in this disease and it is hypothesized that FP undergoes calcium-dependent binding of amyloid fibrils which stabilizes and protects the amyloid fibrils after formation (Coe and Ross, 1990).

Sex Behavior and Steroids

Sexual behavior of male humans and most other male mammals is dependent upon gonadal androgen secretion (Meisel and Sachs, 1994). Using a hamster

model, Schulz and colleagues described the two-stage model of sexual behavior development (Schulz and Sisk, 2006). The first stage is the perinatal period when neural circuits become sexually differentiated and the initial programming of adult responses to hormones occurs. The second stage is adolescence, when the structural and functional organization of behavioral circuits are refined and completed, resulting in the expression of sex-typical social behaviors. The presence of testosterone during adolescence results in adults who more readily display male-typical social behaviors compared to adults that matured in the absence of testosterone (Schulz and Sisk, 2006). The testosterone exposure during adolescence defeminizes the brain and behavioral responses to estradiol and progesterone (Schulz and Sisk, 2006).

Castrated male Syrian hamsters that are treated daily with 1000 μ g of dihydrotestosterone (DHT) do not display copulatory behavior or interest in female hamsters in estrus (Arteaga-Silva et al., 2005). In contrast, castrated males treated with 50 μ g of estradiol (E2) show sexual motivation but do not display the ejaculation reflex (Arteaga-Silva et al., 2005). Combined treatment with DHT and E2 restores all components of male sexual behavior in castrated males (Arteaga-Silva et al., 2005). Castrated male Syrian hamsters that receive brief infrequent elevations of testosterone display male sexual behavior (Piekariski et al., 2009). This provides a useful model to assess the neuroendocrine basis of male sexual behavior and raises the possibility that infrequent low-dose androgen replacement may restore sexual behavior in hypogonadal men without inducing negative side-effects.

Flank marking, like reproductive behavior, is activated by testosterone in adulthood (Albers et al., 2002; Johnston, 1981). In contrast, attack behavior toward another male in a resident-intruder paradigm is significantly higher prior to puberty when compared to adulthood, indicating that attack behavior is not under the influence of physiologic testosterone (Romeo et al., 2003). Therefore, exposure to gonadal hormones during adolescence and adulthood facilitates aggression towards an intruder and flank-marking behavior, respectively (Romeo et al., 2003).

Anabolic steroids are abused by humans for their tissue-building potency and performance-enhancing effects. These steroids induce a variety of negative effects including heightened aggression, changes in sexual libido, testicular atrophy, baldness, cancer, and cardiovascular disease (Leshner, 2000). Hamsters are used to study the deleterious behavioral effects of exogenous steroid administration. Specifically adolescent (post-pubertal) male hamsters exposed to anabolic steroids for 2–4 weeks show an increase in aggression (DeLeon et al., 2002; Grimes and Melloni, 2002; Melloni and

Ferris, 1996). In addition, when adolescent hamsters are given exogenous anabolic steroids they do not express submissive behaviors such as defensive posturing, escape dashes, or tail-up walking (Salas-Ramirez et al., 2008). Both adolescent male and adult male hamsters treated with anabolic steroids display increased flank marking. In adolescent hamsters, exposure to anabolic steroids results in levels of sexual behavior comparable to adult hamsters. In contrast, steroid administration in adult hamsters results in decreased sexual behavior compared to untreated controls. These studies suggest that the adolescent brain is more vulnerable than the adult brain to the adverse behavioral consequences of exogenous steroids (DeLeon et al., 2002; Grimes and Melloni, 2002; Melloni and Ferris, 1996; Salas-Ramirez et al., 2008).

The addiction potential of anabolic steroids is evaluated using a classical self-administration paradigm of drug abuse (Madden et al., 1980; Panlilio et al., 2003). Castrated male hamsters that are supplemented with testosterone self-administer additional testosterone at all doses tested (DiMeo and Wood, 2004). In contrast, when testosterone is not exogenously administered, castrated males do not self-administer testosterone (DiMeo and Wood, 2004). These findings indicate that circulating androgens enhance the desire to self-administer testosterone. This study also provides strong evidence that exogenous testosterone administration, particularly in individuals that possess endogenous testosterone, poses a strong potential for addiction.

Nutritional Infertility

Limited food availability diminishes fertility in mammals, particularly in females (Bronson, 1989). The hamster provides a model to evaluate the deleterious effects of inadequate nutrition on fertility. A negative energy balance in hamsters suppresses ovulatory cycles and estrus behavior (Wade et al., 1996). Food deprivation decreases estrogen receptor immunoreactivity in the ventromedial hypothalamus, implying a direct neurological effect of food deprivation in sexual behavior. Treatment with leptin promotes female sexual behavior in ad libitum-fed hamsters; however, in food-deprived hamsters, leptin treatment fails to overcome the loss of estrus behavior associated with poor nutrition. Interestingly, leptin-induced changes in female sexual behavior are not accompanied by changes in estrogen receptor immunoreactivity of the hypothalamus, implying that leptin acts via another mechanism (Wade et al., 1997). Neuropeptide Y (NPY) may play a role in nutritional infertility. Injections of NPY into the central nervous system stimulate robust and long-lasting increases in food intake in hamsters while simultaneously reducing estrus behavior (Corp et al., 2001; Kulkosky et al.,

1988). These studies provide strong evidence that multiple pathways (leptin and NPY) control alterations in female nutrition-associated fertility.

Generalized Dystonia

Dystonia, characterized by involuntary twisting movements and abnormal postures caused by co-contractions of antagonistic muscle groups, is the third most common movement disorder in humans (Raike et al., 2005). The disease is a heterogeneous disorder because patients display clinical signs associated with many different brain regions. Primary dystonia is inherited or arises spontaneously, and secondary dystonia follows brain trauma or insult. These disorders can be further classified, based on affected muscle groups, as focal (involving a small number of muscles) or generalized dystonia (involving all of the muscles throughout the body). The dt^{sz} disorder exhibited in the Bio 86.93 inbred line of Syrian hamsters is an animal model of generalized dystonia (Loscher et al., 1989; Raike et al., 2005). The disorder in hamsters, originally designated sz because of the seizure-like presentation, is inherited in an autosomal recessive fashion (Loscher et al., 1989). The mutation was later renamed dystonic and symbolized as dt^{sz} . In hamsters, dystonic attacks last several hours, vary in severity, progress from the head to the extremities, and are partially age-dependent with signs mostly disappearing after 8 weeks of age (Raike et al., 2005). The dt^{sz} phenotype is modified by hormonal fluctuations and late-term pregnant and nursing dt^{sz} hamsters experience attacks (Raike et al., 2005). Attacks begin with rapid vibrissae twitching, flattening of the ears, and facial contortions, followed by stiffening of the hindlimbs, gait abnormalities, and falling episodes, ending with limb hyperextension, severe truncal torsion, and immobility (Loscher et al., 1989; Raike et al., 2005). The dystonic attacks are stress-induced and initiated by placing the hamsters in a new environment. The motor disturbances can also be pharmacologically initiated with subconvulsant doses of pentylenetetrazol (PTZ), picrotoxin, or inverse benzodiazepine receptor agonists (Gernert et al., 1999; Loscher et al., 1989). The generalized syndrome in humans shares many phenotypic features with hamster dystonia including prolonged attacks lasting up to 4 hours, onset in infancy or childhood, and attacks initiated by stress or excitement (Loscher et al., 1989).

Wound Healing

Traumatic damage to tissue is followed by a complex cascade of tissue-repair events that involve overlapping inflammatory, proliferative, and remodeling phases. Research into understanding the process of tissue repair

focuses on the role of epithelial cells, fibroblasts, endothelial cells, and inflammatory cells (Wong et al., 1993).

Hamsters provide an excellent model for elucidating the role of eosinophils in wound healing (Wong et al., 1993). The induced model involves creating a circular transdermal wound between the shoulder blades and leaving the wound open to heal by secondary intention (Wong et al., 1993). In normal hamster skin, eosinophils are rarely found; however, a prominent eosinophilic infiltrate occurs during cutaneous wound healing. The eosinophils, and other inflammatory cells, provide a cellular source of two cytokines, transforming growth factor- α (TGF- α) and TGF- β_1 , both important regulators of wound healing.

These two cytokines are expressed from eosinophils in a temporal fashion. Eosinophil expression of TGF- α peaks 5 days after cutaneous injury (Wong et al., 1993) followed by a gradual decline. In contrast, expression of TGF- β_1 gradually increases throughout wound healing. The early expression of TGF- α is implicated in epithelial migration, proliferation, and angiogenesis (Barrandon and Green, 1987; Schreiber et al., 1986). Later expression of TGF- β_1 is believed to contribute to the down-regulation of epithelial migration and proliferation, as well as to granulation tissue formation (Quaglini et al., 1990).

Yang et al. (1997) developed an eosinophil-deficient hamster model by treating with anti-interleukin-5 monoclonal antibody (TRFK-5), which inhibits the IL-5-dependent pathway of eosinophil differentiation and maturation. TRFK-5 is injected intraperitoneally 7 and 4 days before and on the same day as wound creation. An absence of eosinophils results in accelerated re-epithelialization of cutaneous wounds, with wound closure occurring 4 days faster than in non-TRFK-5-treated animals. One mechanism which could explain the accelerated wound healing is a reduction in TGF- β_1 , which is antiproliferative for keratinocytes. Eosinophil depletion may be clinically relevant for the treatment of wounds to accelerate wound closure.

Due to the hamster's relatively large oral cavity, an 8-mm circular wound can be created in the oral mucosa overlying the masseter muscle and allowed to heal by secondary intention, providing an excellent model for comparing oral and cutaneous wounds. Similar to cutaneous wounds, eosinophils infiltrate oral wounds and express TGF- β_1 , however, they do not express TGF- α (Yang et al., 1996). The lack of TGF- α expression by eosinophils in oral wounds may reflect the presence of TGF- α and epidermal growth factor (EGF) in hamster saliva. Oral eosinophils can be induced to express TGF- α by first performing sialoadenectomy of the submaxillary and sublingual complex to knock-out the salivary-associated TGF- α and epidermal growth factor (EGF) (Yang et al., 1996). Furthermore, oral eosinophils cease producing TGF- α when EGF is supplemented in

the drinking water. This suggests that EGF and TGF- α in the saliva are responsible for the decreased production of eosinophil-associated TGF- α in oral wounds.

NSAID Gastropathy

Non-steroidal anti-inflammatory drugs (NSAIDs) are the most frequently used group of drugs in medicine (Roth, 1988). Although these drugs are extensively utilized, they may result in significant gastrointestinal injury (Tamblyn et al., 1997). The ability of NSAIDs to inhibit prostaglandin synthesis leads to anti-inflammatory and pain reduction, but also compromises the protective properties of the gastric mucosa, potentially leading to gastric mucosal erosions and ulcers (Roth, 1996).

The hamster model of NSAID-induced gastric ulceration is created by subcutaneously injecting indometacin into hamsters (Kolbasa et al., 1988). Indometacin produces gastric antral ulcers in hamsters within 1–5 hours post-administration in a dose-dependent fashion. With repeated administration of indometacin, the gastric lesions become more severe and most hamsters die with perforated antral ulcers after 2–5 days. Indometacin reduces the antral mucosa production of prostaglandin E₂, prostaglandin F_{2 α} , and 6-keto prostaglandin F_{1 α} and increases gastric acid output more than twofold. The ulcers created in this model may be prevented by anti-secretory agents such as cimetidine, methscopolamine bromide, and omeprazole (Kolbasa et al., 1988).

To create a chronic NSAID-induced gastropathy model in hamsters which more closely mimics the disease process in humans, naproxen can be administered twice daily by oral gavage (Fitzpatrick et al., 1999). Gastric ulceration occurs almost exclusively in the antrum and increases in size as a function of dose and time for the first 3 days of naproxen treatment. At a dose of 80 mg/kg given twice a day, naproxen can be used for chronic anti-ulcer drug studies with a low (<5%) mortality rate (Fitzpatrick et al., 1999). Gastric ulcer area decreases in naproxen-treated hamsters by the fourth day of administration, suggesting adaptation of the gastric mucosa. The process of adaptation involves stimulation of gastric mucosal healing and the creation of a gastric mucosa that is more resistant to future injurious agents (Levi and Shaw-Smith, 1994).

The naproxen-induced model provides a useful system to study anti-ulcer drugs. Misoprostol, a prostaglandin analog, when administered in conjunction with naproxen, results in a significant reduction in number and size of gastric ulcers without modifying gastric acid secretion (Fitzpatrick et al., 1999). This same protection is noted in humans (Dajani and Agrawal, 1995). Famotidine, an H₂-receptor antagonist that inhibits stomach acid production, does not reduce the prevalence or number of gastric ulcers in the hamster

(Fitzpatrick et al., 1999). Similarly, H₂-receptor antagonists do not consistently reduce NSAID-induced gastric ulceration in humans (Dajani and Agrawal, 1995). These results suggest that gastric acid secretion is not the primary mechanism of naproxen-induced ulceration in hamsters or humans and that the naproxen hamster model accurately models NSAID-induced antral ulceration in humans (Fitzpatrick et al., 1999).

Gastric ulcer models have also been developed in rats and rabbits using subcutaneous administration of indometacin. Limitations of the rat model include the addition of profound intestinal ulceration and high mortality (Satoh et al., 1981). The rabbit antral ulcer model displays ulcers that are morphologically similar to human ulcers without the high mortality or intestinal injury noted in rats (Wallace and McKnight, 1993); however, the relatively large size of rabbits may make them less desirable when compared to hamsters.

Human Fertility

The hamster zona-free oocyte penetration assay is used to examine human male fertility (Aitken, 2006). This assay was first described in 1980 and involves the incubation of human sperm with hamster eggs that have undergone zona removal (Overstreet et al., 1980). The assay can be utilized both clinically and experimentally to determine human sperm fertility and it analyzes the ability of sperm to capacitate eggs, undergo the acrosome reaction, and fuse with the oocyte. Limitations of the assay are that it is labor-intensive, and difficult to standardize. Despite these limitations, results obtained in the hamster assay correlate well with human in vitro fertilization. Since intracytoplasmic sperm injection (ICSI) is replacing standard IVF in many settings the utility of the zona-free hamster assay from a clinical perspective may be waning.

INTRODUCTION

The Chinese hamster used in biomedical research is traditionally classified as *Cricetulus griseus* (Honacki et al., 1982), but some taxonomists (Nowack and Paradiso, 1983) do not recognize this species and classify these animals as *Cricetulus barabensis*. For the purpose of this chapter, the Chinese hamster will be

referred to as *Cricetulus griseus* the classification used by most authors. The Chinese hamster, also known as the striped-back hamster (Figure 35.1), is indigenous to Northern Asia, with a range extending from southern Siberia, Mongolia, and northeastern China, to the northern regions of North Korea. The Chinese hamster has had an important and much storied role in biomedical research. However in recent years, this hamster's

FIGURE 35.1 An adult Chinese hamster, *Cricetus griseus*. Note the dark stripe on the dorsal midline. Photo courtesy of Dr. Don Holmes, Department of Veteran Affairs.

contributions as a laboratory animal have been largely overshadowed by the focus on its cell lines and the role they play in scientific research and biotechnology.

The Chinese hamster has several biological features that have helped promote its use in biomedical research. These attributes include its small size, polyestrous cycle, short gestation period and low chromosome number (Chang et al., 1987). In addition, the Chinese hamster has a low incidence of spontaneous and endogenous viral infections. This species has been shown to be susceptible to a number of experimentally induced viral, bacterial, and parasitic infections (Diani and Gerritsen, 1987).

The Chinese hamster was first used as a laboratory animal to type pneumococci obtained from human patients (Hsieh, 1919). Subsequently, the Chinese hamster became a valuable animal model in other infectious disease and epidemiology research studies. This hamster is a known carrier of the protozoal parasite *Leishmania* that causes the often deadly human disease leishmaniasis, also known as Kala-azar or black fever.

Efforts at domestication, in the mid-20th century, resulted in the serendipitous finding that some inbred lines of Chinese hamsters develop spontaneous hereditary diabetes mellitus. This finding fostered interest in the Chinese hamster as an animal model for diabetes and helped spur research interest in hamster genetics (Yerganian, 1959, 1985).

The Chinese hamster has been used as an animal model in radiobiological research and has been shown to be more resistant to the effects of radiation exposure than many other common laboratory rodents (Corbascio et al., 1962). In addition, the Chinese hamster has been utilized for the experimental induction of gastric and esophageal tumors (Baker et al., 1974).

Tijo and Puck (1958) isolated Chinese hamster ovary (CHO) cells (Figure 35.2) which have since been commonly used as an in vitro research tool for mutagenesis and carcinogenesis studies. Subsequent laboratory investigations have led to a series of elegant research studies directed at utilizing CHO cells for the

FIGURE 35.2 Chinese hamster ovary cell culture, phase contrast (positive) microscopy. Photo courtesy of Wikimedia Commons and User Alcibindes.

production of recombinant therapeutic proteins (Oka and Rupp, 1990). During the past 20 years, CHO cells have been used to synthesize a wide array of recombinant proteins that have found clinical application in the treatment of a variety of human diseases (Chin, 2007; Jayapal et al., 2007).

BIOLOGY

General

Chinese hamsters are small rodents with a grayish black coat and a black dorsal stripe. Adult animals weigh approximately 39–46 grams, and measure approximately 9 cm in length. The average gestation length is 20.5 days, with a litter size of approximately 4–5 offspring. Newborn pups weigh approximately 1.5–2.5 grams. The average life span under laboratory conditions is 2.5–3.0 years (Harkness, 1984; Harkness and Wagner, 1985). An overview of physiological reproductive data is provided in Table 35.1.

The Chinese hamster, like the Syrian hamster, has a cheek pouch that can be used as an immunologically privileged site. Normal hematological parameters for the Chinese hamster are shown in Table 35.2. In terms of distinctive anatomical features that have been quantitatively assessed, the brain and spleen in both sexes are relatively larger, with respect to body size, than those of the Syrian hamster (Festing, 1972). In addition, adult male Chinese hamsters have exceptionally large testicles.

Behavior

Chinese hamsters, particularly sexually mature females, are bellicose and frequently fight with one

TABLE 35.1 Normal Hemogram of the Chinese Hamster^{a,b}

Parameter	Mean $\pm$ SD

another. Fights erupt frequently between females, and least often among males. The presence of females usually suppresses fighting behavior in males, whereas the presence of males has no effect on female aggression and fighting behavior.

The marking pattern used by the Chinese hamster involves vigorous scratching of the flank gland with a hindfoot, followed by pressing the anogenital region onto a substrate to transfer the scent-bearing secretion of the flank gland onto the substrate. In female–female encounters, marking frequency correlates with behavioral dominance. In female–male interactions, the male marks more frequently although the females are usually dominant in fights or chases. In typical female–female and male–male encounters, marking behavior follows

rather than precedes engagement in fighting behavior. The lack of warning behaviors and the high level of food caching behavior observed in the Chinese hamster are suggestive that in their natural habitat this species lives a relatively solitary existence with infrequent encounters with conspecifics (Skirrow and Rysan, 1976).

CARE AND HUSBANDRY

Housing

The Chinese hamster can be purchased commercially or bred under laboratory conditions. It does well under standard laboratory animal housing conditions. Since the Chinese hamster is comparable in size to the mouse, a similar type of caging and husbandry practices are commonly used, and have proven adequate for general housing. Hamsters with metabolic disorders such as diabetes are more susceptible to stress and special precautions must be taken in the provision of routine husbandry to optimize colony management for diabetic animals.

Feeding

There are no unique dietary requirements for the Chinese hamster. A standard, commercially available laboratory rodent diet provides adequate nutrition. Wheat germ may be used as a dietary supplement for breeders. Average daily water intake is 11.4 ml and 12.9 ml per 100 g body weight for male and female hamsters, respectively (Thompson, 1971).

Breeding

Early attempts to breed Chinese hamsters under laboratory conditions were unsuccessful. However, a reversed illumination schedule has been used to successfully establish a production colony for research purposes (Yerganian, 1958). Subsequently, several other schemes have been utilized to manage Chinese hamster breeding colonies due to the aggressiveness of the animals, particularly the females. Consequently, females with non-aggressive behavior (Calland, 1986) or sexually aggressive males (Moore, 1965) are selected as breeders. Modified test mating and monogamous mating schemes are used to breed the Chinese hamster (Camden et al., 1968, 1969). In one approach, a female is placed with a male for 7 days or longer, but the female is removed prior to delivery of the litter. In a second scheme, the male and female are left together during the entire reproductive life of the pair. Hand-mating and artificial insemination have been used with moderate success (Avery, 1968). A more practical and efficient

approach to produce Chinese hamsters on a commercial scale has been reported (Cisar et al., 1972). In this system, three males are placed in a breeding cage with three to five female littermates at weaning; the authors reported a 3.5% loss of males per month.

Progesterone levels are markedly different during estrus and pregnancy. During the Chinese hamster's 4-day estrous cycle, maximal progesterone synthesis occurs on day 3, in contrast to the low levels observed on day 3 of the Syrian hamster estrous cycle (Sato et al., 1984). During pregnancy, progesterone blood levels increase through day 12, with a general stabilization through day 18 of gestation. Progesterone blood levels peak on day 19 with a dramatic drop immediately prior to parturition (Sato et al., 1984). Breeding is confirmed by the presence of a vaginal plug. Pregnancy is indicated by a closed vagina, with dry, pale, and scaly perineal tissue at 4 days post-mating. In one study, an increase in ambient room temperature (above 82°F) has been shown to increase the number of runts in a litter (Yerganian, 1958).

CYTOGENETICS AND FETAL DEVELOPMENT

The Chinese hamster has been frequently selected for studies of chromosomal abnormalities because of a low spontaneous mutation rate and a low diploid chromosome number ($2N = 22$). The ten large pairs of autosomes and the two sex chromosomes can be readily differentiated. Chinese hamster chromosomes can be divided into four morphologically distinct subgroups (Vistorin et al., 1977). Research investigations suggest that cleavage of embryos with chromosome abnormalities is delayed compared with karyotypically normal zygotes (Sonta et al., 1984). A survey of 226 Chinese hamster preimplantation embryos indicates a low incidence (0.9%) of genome mutations (Binkert and Schmid, 1977). The low spontaneous chromosome mutation rate has made the Chinese hamster a good animal model for mutagen testing.

Characterization of the gametes and in vivo fertilization of the Chinese hamster have been reported (Yanagimachi et al., 1983). Fertilization begins approximately 2–3 hours after ovulation and is completed within the next 4–5 hours. At 20–26 hours following ovulation, the first three cleavages occur. Four days post-ovulation, the fertilized egg reaches the blastocyst stage and enters the uterus. Implantation occurs at approximately day 5 or 6 post-ovulation (Pickworth et al., 1968). Embryonic and fetal development of the Chinese hamster have been extensively characterized. Prenatal developmental stages are similar to the developmental stages in the mouse (ten-Donkelaar et al., 1979).

DISEASES

Infectious Diseases

A Chinese hamster colony was evaluated for the presence of murine viral antibodies and intestinal/cecal microflora by Schiff et al. (1973). The presence of antibodies against several murine viruses was reported including: Pneumonia virus of mice (RNA virus, family *Paramyxoviridae*), Kilham rat virus (DNA, family *Parvoviridae*), Theiler's murine encephalomyelitis virus (GDVII; RNA virus, family *Picornaviridae*), H-1 (DNA virus; family *Parvoviridae*), and Reovirus-3 (RNA virus, family *Reoviridae*). No animals were found to have detectable antibody levels to Sendai virus (RNA virus, family *Paramyxoviridae*), Polyoma virus (DNA virus; family *Papovaviridae*), mouse adenovirus (DNA virus; family *Adenoviridae*), mouse hepatitis virus (RNA virus, family *Coronaviridae*), or lymphocytic choriomeningitis virus (RNA virus, family *Arenaviridae*). On assessment of 30 Chinese hamsters aged 2, 3, or 4 months from a colony of 200, *Lactobacillus* predominates as the major bacterial group identified following quantitative recovery from the intestinal tract. On examination of the ceca, several bacterial genera have been routinely identified including: *Bacillus*, *Bacteroides*, *Escherchia*, *Lactobacillus*, *Micrococcus*, and *Streptococcus*.

A *Mycoplasma* species (*M. cricetula*) was isolated from the conjunctiva and nasopharynx of 55 animals in one Chinese hamster colony by Hill (1974). The pathogenic significance of this organism has not been determined.

Zook et al. (1977) diagnosed Tyzzer's disease in a colony of Chinese hamsters. Affected animals exhibit clinical signs of lethargy, diarrhea, rough hair coat, and hunched posture. Gross necropsy findings include multiple, disseminated white foci in the liver and distension of the large intestine with semi-liquid yellow feces. On microscopic examination, there is focal necrosis of hepatic cells with no significant cellular inflammatory response. Giemsa, toluidine blue, and methenamine silver stains reveal clusters of pleomorphic bacilli in the cytoplasm of hepatic cells adjacent to necrotic foci. The histopathological lesions are consistent with a diagnosis of Tyzzer's disease (*Clostridium piliformis*).

There are few reports of spontaneous parasitic diseases in the Chinese hamster. In one survey, Schiff et al. (1973) consistently found *Trichomonas* spp. in 2-, 3-, and 4-month-old animals from a group of 200. An investigation by Benjamin and Brooks (1977) suggests a low incidence of demodectic mange in the Chinese hamster. Desch and Hurley (1997) identified a new species of mite, *Demodex sinocricetuli*, in the Chinese hamster. In their study, histopathologic evidence of demodectic mange is found in only two of 157 animals. The clinical significance of this organism has not been determined.

Neoplastic Diseases

Chinese hamsters have a low incidence of spontaneous tumors; when tumors occur the most common association is involvement with the liver or reproductive tract. The rarity of spontaneous and induced tumors has been postulated to be attributable to the absence of tumor-associated viruses in this species.

Uterine and Ovarian Tumors

Ward and Moore (1969) described spontaneous uterine adenocarcinomas in 30 of 120 aged female Chinese hamsters; approximately 10% of the affected hamsters had lung metastases. Benjamin and Brooks (1977) found similar uterine neoplastic lesions in 11 of 77 animals, however, no pulmonary metastases were observed. Brownstein and Brooks (1980) characterized and classified uterine neoplasms in 21 of 93 multiparous, non-inbred Chinese hamsters ranging in age from 3 to 4 years.

Animals with malignant uterine neoplasms frequently exhibit clinical signs of vaginal hemorrhage. Gross necropsy findings include hemorrhage within the peritoneal cavity and tumor spread by direct extension to other organs. On gross examination, the tumor tissue is usually white to yellow with a nodular firm surface. Brownstein and Brooks (1980) developed a histological classification system for uterine neoplasms of the Chinese hamster (Table 35.3). The most frequently observed uterine tumor in the aged Chinese hamster is endometrial adenocarcinoma. The Chinese hamster might be a useful model for studying endomyometrial neoplasms of women since the relative frequency and classification of uterine tumors in the two species is similar.

Kohn and Guttman (1964) report that the incidence of ovarian tumors is significantly increased following X-ray irradiation under several different exposure regimens, however tumors are rarely observed in control animals.

Hepatocellular Hyperplasia and Adenoma

Kohn and Guttman (1964) describe a benign liver lesion, hepatocellular adenoma, in five of 112 non-irradiated control animals but did not report any non-neoplastic liver lesions. Ward and Moore (1969) observed hepatocellular adenoma in 18 of 50 non-irradiated control animals; they found a similar incidence in animals receiving ^{131}I . They also reported hepatocellular hyperplasia in some animals which they postulate might be a pre-neoplastic lesion. Nodular hepatic hyperplasia, a non-neoplastic lesion, is reported in 111 of 157 aging animals in a survey conducted by Benjamin and Brooks (1977). They found evidence

TABLE 35.3 Classification of Endomyometrial Neoplasms in 21 Chinese Hamsters^a

Site	Type	Occurrence ^b	Metastasis
Endomyometrium	Adenocarcinoma	13	Abdominal spread (10)
	Mixed adeno-squamous carcinoma	3	Abdominal spread (3)
	Mixed Mullerian carcinosarcoma	2	Abdominal spread (1) Lung metastasis (1)
	Mixed mesodermal	1	Abdominal spread
Myometrium	Leiomyoma	1	
	Leiomyosarcoma	1	Abdominal spread

^bFrom a group of 93 nulliparous non-inbred females with a median survival time of 1040 days.

of hepatic adenoma in only one of the 157 animals. Grossly, the two conditions appear similar with multiple nodules ranging in size from less than 1 mm to greater than 1 cm in diameter, and lighter in color than the surrounding tissue. Histologically, these are nodular hyperplastic lesions ranging from small nodules with normal sinusoid and central vein structure to coalescing masses with disrupted tissue architecture. Parenchymal cells are often enlarged with increased eosinophilic and sometimes vacuolated cytoplasm. Cell nuclei are enlarged but otherwise had a benign appearance. Nodular hyperplasia was distinguished from hepatocellular adenoma by the appearance of abundant hyperchromatic nuclei containing multiple nucleoli. Ward and Moore (1969) also distinguished between nodular hyperplasia and hepatic adenomas. In their investigation they found a much higher incidence of hepatic adenomas. Since the Chinese hamster is used in toxicology studies, it is important to distinguish spontaneous hepatic lesions from experimentally induced lesions.

Myeloproliferative Disease and Leukemia

Benjamin and Brooks (1977) report hematopoietic hyperplasia in 49 of 157 Chinese hamsters. Bone marrow hyperplasia occurred in 36 animals. In most cases, the hyperplasia is granulocytic. In approximately half the cases, the hematopoietic hyperplasia is associated with degenerative or inflammatory changes; in the other cases no underlying lesions are observed. Splenomegaly and a pale bone marrow are observed grossly in all clinical cases. On microscopic examination, the marrow is

hypercellular and granulocytic cells replace erythroid cells. A diagnosis of leukemia is made in three cases; myelocytes and myeloblasts with leukemic infiltrates are found in liver, kidney, brain, spinal cord, and spleen. The Chinese hamster might provide a useful model for the study of myelogenous leukemia.

Other Neoplasms

Table 35.4 provides a summary of some infrequently occurring, spontaneous malignancies that have been reported for the Chinese hamster.

Metabolic and Genetic Disease

Spontaneous Diabetes Mellitus

Spontaneous diabetes mellitus was observed in Chinese hamsters during early attempts to establish inbred breeding colonies. This metabolic condition is a suitable model for studying various aspects of the human disease, and will be discussed in more detail in the section on research uses. Since diabetes is a spontaneous disease in the Chinese hamster, the occurrence of this metabolic disorder might potentially confound experimental results in animals used for research protocols unrelated to diabetes. In addition, the use of Chinese hamsters with spontaneous diabetes mellitus in cytogenetic experiments might have a confounding influence on experimental results due to metabolic aberrations associated with the diabetic state.

TABLE 35.4 Infrequently Occurring Spontaneous Malignancies of the Chinese Hamster^a

Tumor type	Occurrence	Reference
Adrenal cortical carcinoma	1/157	Benjamin and Brooks (1977)
Pancreatic adenocarcinoma	4/112	Kohn and Guttman (1964)

^aFrom Ladiges (1987); reprinted with permission from Elsevier.

^bKohn and Guttman (1964) reported the occurrence of ovarian tumors in 18 of 74 irradiated females, but none in 69 control animals.

Primary Chromosomal Abnormalities

Mikamo and Kamiguchi (1983) studied the occurrence of spontaneous chromosomal aberrations in Chinese hamster oocytes and zygotes, and classified the lesions according to their causal mechanism. A summary of this classification is provided in Table 35.5. The overall incidence of chromosomal anomalies has been determined to be 8%. This incidence is lower than that estimated for the human population; the lower incidence has been postulated to be due to the lack of mutagen influence in a controlled laboratory environment. Since the Chinese hamster is frequently used as an animal model for cytogenetic studies, it is important to be cognizant of the incidence of spontaneous chromosomal defects in this species.

Traumatic Diseases

Female littermates can become very aggressive as they reach sexual maturity. Fighting and severe bite wounds may lead to death. In addition, females can be very aggressive following mating with resultant death of male breeders. Separation of litters before fighting occurs, and removal of the male following mating are among the strategies used to prevent serious injury and death. Selection of non-aggressive female breeders through genetic selection has also been utilized as a strategy to reduce fighting and traumatic injuries in Chinese hamster breeding colonies.

TABLE 35.5 Primary Incidence of Spontaneous Chromosomal Anomalies, Classified According to Their Origins and Causal Mechanisms in the Chinese Hamster^a

Chromosomal Anomaly	Origin and Causal Mechanism	Incidence (%)
Aneuploidy	Non-disjunction and anaphase lagging	
	During oogenesis	2.1
	During spermatogenesis	0.7
Mosaic	Non-disjunction and anaphase lagging	
	During first somatic division	0.5
Triploidy	Diandry	0.9
	Digyny	0.3
	Uncertain	0.3
Haploidy	Parthenogenesis	0.5
Structural anomaly	Breakage during oogenesis	1.3
	Breakage during spermatogenesis	1.4
Total		8.0

Reproductive Disorders

Avery (1968) reported infertility in young female Chinese hamsters housed in open-bottom cages. Infertility was believed to be attributable to excess hair growth around the vulva that prevented penile penetration during copulation. Infertility has also been associated with diabetic females in inbred colonies. Parkening (1982) studied aging changes and the effect on reproductive performance. Clinical signs include failure to conceive or decreased conception rates. Cage type and colony health status have been shown to have an impact on conception rates. Progesterone administration, immediately following mating, has been used with some success to increase conception in inbred and/or diabetic breeders, and in aged animals (Avery, 1968; Parkening, 1982). Testicular degeneration and atrophy has been observed in 14 of 80 male Chinese hamsters in an aging colony of outbred hamsters (Benjamin and Brooks, 1977).

Miscellaneous Diseases

Pulmonary Granulomas

Pulmonary granulomas have been observed in 54 of 157 aging Chinese hamsters (Benjamin and Brooks, 1977). On gross examination, the lesions are subpleural, 1–3-mm yellow-gray foci with variable degrees of lung involvement. Histologically, mild lesions consist of lipid-filled macrophages, while more severe lesions include well-developed granulomas containing lipid-filled macrophages, inflammatory cells, focal septal fibrosis, and occasional cholesterol clefts. Several animals exhibit severe alveolar and bronchiolar epithelial hyperplasia. The cause of the pulmonary granulomas has not been determined. The significance of this spontaneous lesion should be differentiated from pathology attributable to experimentally induced causes.

Cerebral Hemorrhage

Cerebral hemorrhage is observed in 20% of both control and experimental animals in a ¹³¹I chronic toxicity study (Ward and Moore, 1969). Sporadic deaths are observed in 1–2-year-old animals. The cause of the cerebral hemorrhage has not been determined but is postulated to involve an inflammatory or degenerative change in the anterior cerebral artery. On gross examination, hemorrhage is observed between the cerebral hemispheres with blood often present in the lateral ventricles. On histological examination, the lesions are restricted to the anterior cerebral artery. In acute cases, the vascular changes include an increased arterial lumen diameter, and thickened arterial wall with the presence of inflammatory cells. An amorphous eosinophilic material is often present in the media of the arterial wall. The eosinophilic material is periodic

acid-Schiff (PAS)-reagent-positive but fibrin-negative. In chronic cases, the arterial wall is greatly thickened with numerous macrophages surrounding the lesions. In affected animals, no vascular changes are found elsewhere in the brain or in other organs. The incidence of cerebral hemorrhage is not known since this clinical condition has not been reported in other Chinese hamster colonies.

Degenerative Renal Disease

INTERCAPILLARY GLOMERULOSCLEROSIS

Intercapillary glomerulosclerosis has been reported in Chinese hamsters in association with diabetes mellitus (Meier and Yerganian, 1961). It has also been reported as a progressive condition associated with aging (Guttman and Kohn, 1960; Kohn and Guttman, 1964).

NEPHROSCLEROSIS

Nephrosclerosis is described in 46 of 157 Chinese hamsters in one colony of animals older than 600 days (Benjamin and Brooks, 1977). Incidence and severity of the condition are age-dependent. Early changes include tubule degeneration, mild interstitial fibrosis, and cortical atrophic foci. Progressive pathologic changes consist of glomerular sclerosis, severe interstitial fibrosis, and severe tubular degeneration and atrophy. Severely affected kidneys are small in size, pale tan, and have a pitted surface.

Periodontitis

Cohen et al. (1961) describe periodontitis in an inbred strain of Chinese hamsters with hereditary diabetes mellitus. Incidence correlate with the presence and severity of the underlying metabolic disorder. The periodontitis in the Chinese hamster corresponds closely to the development of the clinical condition in humans affected by diabetes mellitus.

Spondylosis

Silberberg and Gerritsen (1976) report an increased incidence of spondylosis in an inbred strain of Chinese hamsters with spontaneous diabetes mellitus compared to non-diabetic control animals.

RESEARCH USES

Infectious Diseases

There are few reports of spontaneously occurring infectious diseases in Chinese hamsters. However, this species has been experimentally shown to be susceptible to a variety of different infectious agents and has been used extensively in viral, bacterial, and parasitological disease investigations. Table 35.6 provides a list of some

infectious disease agents that have been studied experimentally using the Chinese hamster as an animal model.

Metabolic Disorders

Spontaneous Diabetes Mellitus

Spontaneous hereditary diabetes mellitus, with similarities to the human disease, was first described in Chinese hamster inbred lines by Meier and Yerganian (1959). The diabetic Chinese hamster has been studied extensively to elucidate the pathophysiology associated with the disease and to develop effective clinical therapies for treatment of the human disease. Numerous reviews of the spontaneously diabetic Chinese hamster model have been published (Chang, 1978, 1981; Diani and Gerritsen, 1987; Gerritsen, 1982; Hunt et al., 1976; Sirek and Sirek, 1967, 1971; Wappler and Fiedler, 1972).

PATHOPHYSIOLOGY

The diabetic Chinese hamster has been described as an inbred, lean animal that exhibits glucose intolerance, mild to severe hyperglycemia, hypoinsulinemia, polyuria, glycosuria, possible ketonuria, and high free fatty acid levels (Dulin and Gerritsen, 1967; Dulin and Soret, 1972; Gerritsen and Blanks, 1974; Gerritsen and Dulin, 1967).

Several genetic and environmental factors have been demonstrated to play a role in this metabolic disturbance in the hamster and influence the extent of beta cell death. These factors include the amount of food consumed, dietary composition, and uterine environment of the dam (Dulin and Gerritsen, 1967, 1972; Gerritsen and Dulin, 1967, 1972; Gerritsen et al., 1970, 1974, 1976, 1981). Plasma insulin and glucagon levels have been shown to be altered in chronically diabetic animals. In general, diabetic Chinese hamsters exhibit low, non-fasting plasma insulin levels (Gerritsen, 1982; Gerritsen and Blanks, 1974; Gerritsen and Dulin, 1967). Plasma insulin levels of newly diagnosed diabetic Chinese hamsters are usually within normal limits or slightly elevated (Gerritsen, 1982; Gerritsen and Blanks, 1974). Plasma glucagon levels are usually elevated with chronic disease (Chang et al., 1977a). The chronic absolute deficiency of plasma insulin and the high plasma glucagon levels in the diabetic Chinese hamster are similar to endocrinologic changes observed for human type I diabetes. Pancreatic hormone levels are markedly altered in the chronic diabetic state. Pancreatic insulin levels are decreased, whereas pancreatic glucagon levels are generally elevated, particularly with chronic disease. Pancreatic somatostatin concentrations are significantly decreased in diabetic Chinese hamsters (Petersson et al., 1977).

PATHOLOGY

A number of studies using the Chinese hamster have focused on structural changes in the islets of Langerhans. Primary morphological alterations are observed in the β cells, which degranulate as the disease progresses (Boquist, 1969; Like et al., 1974a, 1974b; Malaisse et al., 1967). The defective β cells in the Chinese hamster are characterized by proliferation of rough endoplasmic reticulum, expansion of the Golgi apparatus, and glycogen deposition (Boquist, 1969; Luse et al., 1967; Soret et al., 1974). The islets are reduced in size due to β -cell death (Carpenter et al., 1967, 1970). Some peripheral tissues and organs have been studied by light and/or electron microscopy, to better characterize the diabetic Chinese hamster. Glycogen deposition in the renal tubules is the most consistent change in the kidney (Soret et al., 1973, 1974). Examination of the eyes of diabetic Chinese hamsters documents the presence of retinal lesions. The most consistent finding involves glycogen deposition within Müller cells of the outer nuclear layer (Soret et al., 1973, 1974). Structural changes have been identified in the central, peripheral, and autonomic nervous systems of diabetic Chinese hamsters. Alterations of the hypothalamic-hypophyseal axis may provide the basis for the development of diabetic syndrome in this animal model (Bestetti and Rossi, 1982; Deslex and Rossi, 1976; Luse et al., 1970). Extensive studies of the autonomic nervous

system, including both qualitative and morphometric, have been conducted in the diabetic Chinese hamster. Aberrant myelination and axonal degeneration of pelvic viscera may contribute to urinary bladder distension in the diabetic Chinese hamster (Dail et al., 1977). Reduction of myelinated and unmyelinated fiber size in the abdominal sympathetic trunk and ventral abdominal vagus nerve might be a causative factor underlying gastrointestinal malfunction in the diabetic Chinese hamster (Diani et al., 1981, 1984).

GENETICS

The original hypothesis for diabetes in the Chinese hamster proposed that a single recessive gene and certain modifier genes are responsible for the syndrome (Meier and Yerganian, 1959, 1961a, 1961b; Yerganian, 1964). However, based upon epidemiologic examination of diabetic animals from other colonies, a polygenic hypothesis has been proposed for the disease. This hypothesis states that the Chinese hamster possesses a minimum of four recessive diabetogenic genes. In the homozygous state, any two of the genes produce a glycosuric hamster. Extensive genetic studies involving backcrosses have now shown that certain sublines of hamsters possess a single recessive gene for diabetes, whereas other sublines possess two recessive genes (Gerritsen et al., 1984). The onset of glycosuria in the diabetic hamsters is regulated by a multi-gene system. Inbred non-diabetic Chinese hamsters appear to lack any recessive genes for diabetes.

EFFECT OF DIET

Dietary modification has been shown to have a pronounced effect on diabetes development in this animal model. In prediabetic hamsters, hyperphagia is often observed. By limiting feed consumption to that of a non-diabetic hamster, a delayed onset of glycosuria and prevention of urinary ketones is achieved (Gerritsen, 1974, 1975; Gerritsen and Dulin, 1972). In another study, dietary restriction was shown to delay the development of glycosuria and hyperglycemia. Hyperinsulinemia is typically not observed in non-hyperphagic prediabetic animals (Gerritsen et al., 1981). Metabolic complications associated with diabetes are reduced or prevented by changes in dietary composition. A reduction in dietary fat and replacement of animal fat with vegetable fat in the diet ameliorates or prevents ketonuria (Gerritsen et al., 1981; Grodsky et al., 1974).

THERAPY

The diabetic Chinese hamster is an insulin-deficient model of diabetes mellitus. Treatment with exogenous insulin has a beneficial effect on the metabolic alterations. Severely diabetic animals treated with Neutral Protamine Hagedorn (NPH) insulin exhibit

a substantial reduction in glycosuria (Gerritsen and Dulin, 1966). In other investigations, continuous insulin infusion for 7 or 14 days was demonstrated to elicit improvements in blood glucose levels and endogenous insulin release from diabetic animals (Bringer et al., 1981; Frankel et al., 1979). However, insulin treatment of prediabetic Chinese hamsters does not delay the onset or the severity of glycosuria or hyperglycemia (Frankel and Grodsky, 1979).

Chemically Induced Diabetes Mellitus

Several chemical agents have been used to induce the metabolic and pathologic complications of diabetes mellitus in hamsters which do not possess the genes for diabetes. Experimentally induced clinical abnormalities include hyperglycemia, glucosuria, abnormal plasma insulin levels, and β cell abnormalities. These abnormalities are similar to those observed in chemically induced diabetic rats and mice. Diabetogenic substances include: streptozotocin, N-nitrosomethylurea, alloxan, monosodium glutamate, cortisone, and zinc deficiency.

STREPTOZOTOCIN

Streptozotocin, an antibiotic derived from *Streptomyces achromogenes*, has a direct cytotoxic effect on pancreatic islet β cells of the Chinese hamster. A single intravenous streptozotocin injection (75 mg/kg) into fasted animals causes a decrease in insulin levels, hyperglycemia, an increase in serum free fatty acids, and an elevation in hepatic glucose-6-phosphatase activity. There is no observed concurrent degranulation and degeneration of islet β cells (Losert et al., 1971; Richter et al., 1971). A transient glycosuria is produced with low-dose streptozotocin (25 mg/kg) administered in concert with NPH insulin therapy (Berman et al., 1973). In several studies, streptozotocin was administered to adult animals as a single dose (175 or 200 mg/kg). Changes indicative of diabetogenesis included hyperglycemia, glycosuria, and pancreatic islet changes affecting both α and β cells. Further, pancreatic insulin and glucagon levels were significantly reduced (Dulin and Soret, 1977). Others have shown that, following treatment with streptozotocin, the β cells undergo severe degeneration characterized by cytoplasmic vacuolization, nuclear pyknosis, and cell necrosis (Wilander and Boquist, 1972).

ALLOXAN

Alloxan, a pyrimidine nucleic acid, has a cytotoxic effect on cells and has been used to induce diabetes in the Chinese hamster. Intramuscular or intraperitoneal injection of a single alloxan dose (300 mg/kg) is shown to cause a temporary, modest rise in blood glucose levels in the Chinese hamster (Boquist, 1967). Alloxan is considered a transitory diabetogenic agent in the

Chinese hamster (Boquist, 1968; Boquist and Falkmer, 1970). Normalization of blood glucose and regeneration of islet β cells are shown to occur within several weeks of alloxan administration.

MONOSODIUM GLUTAMATE

A single subcutaneous injection of monosodium glutamate (4mg/kg) into newborn Chinese hamsters causes a marked change in the hypothalamus including severe necrosis and loss of nerve cell bodies in the arcuate and ventromedial hypothalamic nuclei (Komeda et al., 1980). These pathological changes are suggestive that the hypothalamus plays a central role in the development of monosodium glutamate-induced diabetes.

General Toxicology

The non-diabetic Chinese hamster has received considerable attention as a rodent model for the toxicological evaluation of a wide range of agents. Its usefulness is attributable to its small size, relatively long lifespan, and ease of care and handling. The Chinese hamster has been utilized to evaluate a wide range of chemicals and physical agents including radioisotopes, X-irradiation, microwaves, environmental pollutants, therapeutic drugs, pesticides, and potent tumorigenic agents. Table 35.7 provides an overview of some select general toxicology studies conducted in the Chinese hamster.

Genetic Toxicology

The Chinese hamster has been widely used for cytogenetic testing. It is an ideal candidate for genetic toxicology studies, due to its well-defined, stable karyotype, short gestation period, large chromosomes, and low chromosome number. Cytogenetic testing requires careful attention to a number of factors including: growth conditions, controls, doses, treatment conditions, and the time interval between treatment and sample analysis. In vivo assays for chromosomal aberrations involve treatment of intact animals and later collection of intact cells for cytogenetic analysis (Kirkland et al., 1990; Tice et al., 1994). The main advantage of an in vivo cytogenetic assay is that mammalian metabolism, DNA repair, and pharmacodynamics can be evaluated. The target is tissue from which large dividing cells can be easily prepared. Bone marrow from rats, mice, or Chinese hamsters has been most commonly used.

Cytogenetic assays have been developed utilizing mammalian cell lines to identify cells that have experienced genetic damage (e.g., chromosomal aberrations, micronuclei, sister chromatid exchanges, or changes in chromosome number). A large body of literature

TABLE 35.7 Chemical Agents (Environmental Pollutants and Therapeutic Drugs) Which have been Tested for their Ability to Produce Genetic Aberrations in Chinese Hamsters

exists on the effects of a variety of chemical insults on chromosome composition in Chinese hamster cells. These insults include radiation, environmental pollutants, therapeutic drugs, pesticides, mycotoxins, and other agents. Metaphase analysis is used in conventional cytogenetics to detect chromosomal anomalies, especially unstable chromosomes or chromosomal aberrations.

Two in vitro assays for chromosomal damage have been developed in cloned Chinese hamster ovary cells to identify chemicals capable of inducing chromosomal aberrations or sister chromatid exchanges in mammalian cells. Both assays are described in detail by Galloway et al. (1985, 1987).

Chromosomal Aberration (CA) Test

Since many birth defects and most cancers are associated with abnormal chromosome complements, it is important to identify chemicals that can induce chromosome damage. To assess induction of chromosomal aberrations, cells are harvested during the first mitotic division after initiation of chemical exposure. The CA assay only detects structural chromosomal damage; it does not detect changes in chromosome number (aneuploidy) induced by chemical exposure.

Sister Chromatid Exchange (SCE) Test

Sister chromatid exchanges are a measure of DNA damage. Increased levels of DNA damage are associated with mutation induction and cancer. Sister chromatid exchange assays require examination of cells that have entered their second mitotic division following the initiation of chemical exposure, and assessment of the number of chromatid exchanges that have occurred.

Cytogenetics of Germ and Somatic Cells

A large body of cytogenetic literature exists for the Chinese hamster due to the small number of chromosomes present in this rodent species as well as a low rate of spontaneous chromosomal anomalies. The Chinese hamster has a small number of chromosomes compared with humans and other vertebrates, which has permitted in-depth analysis of banding patterns and systematic analysis of mitosis, meiosis, spermatogenesis, and oogenesis. [Tables 35.8 and 35.9](#) summarize select cytogenetic studies performed on germ and somatic cells of the Chinese hamster.

Cell Lines Derived from Chinese Hamster Tissues and Organs

Puck et al. (1958) obtained a female Chinese hamster from Yerganian's laboratory and used it to derive the original Chinese hamster ovary (CHO) cell line. Cell lines derived from Chinese hamster tissues and organs have been utilized for in vitro experimentation in a wide range of scientific disciplines including cytogenetics, toxicology, immunology, and cell physiology. The Chinese hamster ovary (CHO) and V-79 lung fibroblast are two cell lines derived from the Chinese hamster that have been used extensively in biomedical research (Bradley et al., 1981).

The adaptive ability of CHO cells and their ease of maintenance have been utilized in many basic biomedical research disciplines. G-coupled protein receptors and their signaling pathways have been studied by stable expression in CHO cells, and have contributed to advances in the fields of anesthesiology and

pharmacology, and ultimately to patient therapy (Figler et al., 2003; Hornigold et al., 2003; Schulte and Fredholm, 2003). CHO cells serve as a tool for understanding cytoskeletal structure, adhesion, and motility, and have provided a better understanding of cancer biology and treatment (Hari et al., 2003; Zeng et al., 2003). CHO cells are relatively easy to synchronize, which has facilitated their use in cell cycle studies (Fiore et al., 2002). In addition, CHO cells are used for studies to assess the effects of various agents on mammalian cells (Cai et al., 2001; Fernandez et al., 2003; Soloneski et al., 2002). CHO cell mutants have been utilized in DNA repair and radiation research studies (Batista et al., 2006; Dunkern and Kaina, 2002).

Some early cell biology studies conducted in CHO cells involved mutagenesis and isolation of certain auxotrophs (Puck and Kao, 1967) that facilitate cell growth and viability in cell culture. Cell mutants with deficiencies in metabolic enzymes such as adenosine

phosphoribosyl transferase (APRT) and dihydrofolate reductase (DHFR) have been isolated and utilized as research tools (Taylor et al., 1977; Urlaub and Chasin, 1980). In addition, mutants defective in transcription, translation, and amino acid/polyamine biosynthesis have been isolated. The isolation of cells deficient in DHFR enzyme has led to an effective means for selection of stable clones and amplification of genes (Puck, 1985). DHFR is an enzyme that catalyzes the conversion of folic acid to tetrahydrofolate (THF). THF is a carrier for one-carbon molecules required in the biosynthesis of glycine, purine, and thymidine. In the early 1980s, Chasin et al. isolated two DHFR-deficient mutants (DXB11 and DG44), that are common parent cell lines used today (Graf and Chasin, 1982; Urlaub and Chasin, 1980; Urlaub et al., 1983). Both DHFR-deficient mutants are derivatives of a proline-requiring auxotroph established by Kao and Puck (1968).

SUMMARY

The Chinese hamster has played an invaluable role in biomedical research from rigorous in vivo scientific investigations of its unique biological features to cell-culture-based experimentation. With the advent of cell culture techniques developed within the past 50 years, Chinese hamster-derived cells have played a major role in cytogenetic toxicity assays and the production of glycosylated therapeutic proteins. Numerous recombinant cell lines have been produced using Chinese hamster cells transfected with genes derived from human or other mammalian cells. Advances in cell culture techniques have obviated the need for performing many in vivo studies, and Chinese hamster cell culture research has led to the prolific production of recombinant proteins through bioengineering. During the past 20 years, CHO cells have been utilized to produce numerous

TABLE 35.10 Selected List of Biologics Produced in Chinese Hamster Ovary (CHO) Cell Lines^a

Product	Type	Therapeutic Use	Manufacturer	FDA Approval
Vectibix	Anti-EGFR mAb	Metastatic colorectal cancer	Amgen	2006
Myozyme	α -Glucosidase	Pompe disease	Genzyme	2006
Aldurazyme	Laronidase	Mucopolysaccharidosis I	Genzyme	2006
Orencia	Ig-CTLA4 fusion	Rheumatoid arthritis	Bristol-Myers Squibb	2005
Naglazyme	N-AGA-4-sulfatase	Mucopolysaccharidosis VI	Biomarin Pharm	2005
Luveris	Luteinizing hormone	Infertility	Serono	2004
Avastin	Anti-VEGF mAb	Metastatic colorectal & lung cancer	Genentech	2004
Advate	Factor VIII	Hemophilia A	Baxter	2003
Xolair	Anti-IgE mAb	Moderate/severe asthma	Genentech	2003
Raptiva	Anti-CD11a mAb	Chronic psoriasis	Genentech	2003
Fabrazyme	α -galactosidase	Fabray disease	Genzyme	2003
Rebif	Interferon- β	Relapsing multiple sclerosis	Serono	2002
Humira	Anti-TNF α mAb	Rheumatoid arthritis	Abbott	2002
Aranesp	Erythropoietin	Anemia	Amgen	2001
Campath	Anti-CD52 mAb	Chronic lymphocytic leukemia	Genzyme, Bayer	2001
ReFacto	Factor VIII	Hemophilia A	Wyeth	2000
Tenectaplast	Tissue plasminogen activator	Myocardial infarction	Genentech	2000
Herceptin	Anti-HER2 mAb	Metastatic breast cancer	Genentech	1998
Enbrel	TNF α receptor fusion	Rheumatoid arthritis	Amgen, Wyeth	1998
Benefix	Factor IX	Hemophilia B	Wyeth	1997
Follistim/Gonal-F	Follicle stimulating hormone	Infertility	Serono/NV Organon	1997
Rituxan	Anti-CD20 mAb	Non-Hodgkin's lymphoma	Genentech, Biogen Idec	1997
Avonex	Interferon- β	Relapsing multiple sclerosis	Biogen Idec	1996
Cerezyme	β -glucocerebrosidase	Gaucher's disease	Genzyme	1994
Pulmozyme	Deoxyribonuclease I	Cystic fibrosis	Genentech	1993
Epogen/Procrit	Erythropoietin	Anemia	Amgen/Ortho	1989
Activase	Tissue plasminogen activator	Acute myocardial infarction	Genentech	1987

recombinant therapeutic proteins to treat a wide array of human diseases. A list is provided in Table 35.10 of some select therapeutic proteins derived from Chinese hamster cell cultures. Currently, greater than 50% of all recombinant therapeutic proteins are derived from cells of Chinese hamster origin, with annual world-wide revenues exceeding 30 billion dollars (Jayapal et al., 2007). The current focus on the use of Chinese hamster cells in cell culture research exemplifies animal welfare initiatives to refine, reduce, and replace the use of animals in research. The history of the Chinese hamster as a laboratory animal is replete with studies clearly demonstrating its value as a unique animal model in biomedical research.

TAXONOMY

Cricetus cricetus is officially known as either the European or Common hamster, though it may be less commonly referred to as the European field hamster, black-bellied hamster, or the Alsace hamster. It belongs to the family Cricetidae and subfamily Cricetinae of the order Rodentia (Mohr and Ernst, 1987). Like the Chinese hamster, the European hamster has a chromosome diploid number 22 (Hankenson and Van Hoosier, 2002).

HISTORY

The wild European hamster was originally found in large numbers across the lowlands in much of Eurasia from Belgium to eastern Russia. They favored rural areas

bordering industrialized regions, especially in the grain and root crop areas (Mohr and Ernst, 1987; Neumann et al., 2004; Reznik et al., 1979). As the species thrived and populations expanded, it was considered a pest by farmers, as they caused extensive damage and hoarded the farmers' crops. Hamster trappers and rodenticides were used to control the population (Nechay et al., 1977; Ziomek and Banaszek, 2007). In some years, the numbers of hamsters caught were extremely high, from 1.5 million in 1973 and 2.4 million in 1974 in Hungary, or 1.3 million annually between 1953 and 1966 in Germany (Nechay et al., 1977). In the 1970s, these mass outbreaks quickly turned to the other end of the spectrum – dramatic population decline that has continued since. Since the 1979 Bern Convention, this species is listed in Appendix II as a strictly protected species (Figure 36.1). It later became listed in Appendix IV of the Habitats Directive,

Bern Convention.

At the 1979 Bern (Bern Switzerland) Convention, which was sponsored by the Council of Europe, a set of procedures were established to protect Europe's wild flora and fauna and their habitat. The European hamster is one species covered. Each country that signed the agreement agreed to submit a report every six years on how the country is doing following the Convention guidelines. According to the Convention and procedures established, man was prohibited from collection, killing or deliberate disturbance or destruction of resting or breeding sites- especially during breeding, rearing and hibernation seasons. No possession or internal trade of live or dead animals is allowed.

and is therefore provided with strict legal protection in all European countries (Ziomek and Banaszek, 2007). In some countries of Western Europe, such as France, Belgium, and the Netherlands, this hamster is now threatened with extinction (Nechay, 2000). Despite their protected status, the conservation efforts to include breeding and release programs, and improvements in their natural agricultural habitat, the wild European hamster population continues to decline, as does their distribution range across western and central Europe (Neumann et al., 2004).

The European hamster is not a widely used research laboratory animal. In the first half of the twentieth century, it was used in the study of thermoregulation and hibernation (Kayser, 1939). It was later developed as a research model when several wild-caught animals from a West German industrial area were found to have bronchogenic squamous cell carcinoma (Reznik et al., 1979). A closed institutional breeding colony was established in the early 1970s from 50 wild-caught hamsters in Hannover, Germany (Mohr and Ernst, 1987). Method sections from the total published literature cited herein indicate that prior to the early 1990s, either wild-caught or institutionally bred hamsters were used in research; however, since the mid-1990s, the source of the European hamster for research is only from European institutional research breeding colonies. As of 2010, there is a single institution with an active breeding colony – the University of Strasbourg in France (Monecke, 2010). There is no breeding colony or active research using this species in the United States. The current research efforts, based on topics of recent publications, are on circadian/circannual biology, hibernation, and species conservation.

BIOLOGY

Appearance

The European hamster is the largest of all hamsters, bearing a size resemblance to the guinea pig (three

FIGURE 36.1 Convention on the Conservation of European Wildlife and Natural Habitats, 1979.

FIGURE 36.2 The adult European hamster (rear) is approximately three times the size of the Syrian hamster (fore).

FIGURE 36.3 Coloration of the ventral surface of an adult European hamster.

times the size of the Syrian hamster) (Reznik et al., 1979) (Figure 36.2). Its coloration is similar to the Syrian hamster. Their bodies are yellow-red brown to grayish brown on the dorsal and lateral surfaces, and the cranioventral areas are completely black, except for a small white patch on the chest (Figure 36.3) (Monecke, 2010).

FIGURE 36.4 Changes in body weight and testis size over time in European hamsters. Parameters increased during the reproductive season and decreased during hibernation. (from Masson-Pévet *et al.*, 1994.)

TABLE 36.1 Body Weight of European Hamsters in the Laboratory Setting (Reznik *et al.*, 1979)

	Males	Females
Summer	451 ± 49 g	359 ± 63 g
Winter (4°C, 90% RH)	245 ± 92 g	174 ± 49 g

In the summer, the fur is lighter than in the winter. The adult body conformation is stocky with a short tail. Its eyes are an intense deep, black color, its nose is non-haired, and the brown or white facial whiskers extend laterally. Their prominent relatively avascular external ears are directed dorsomedially.

The males are larger than the females. The body weight of both the male and female is heaviest in the reproductive season (spring and summer) and lightest during hibernation (fall and winter) (Figure 36.4 and Table 36.1). In addition, the maximum body weight of an individual from year to year continues to increase over time (Masson-Pévet *et al.*, 1994). It is important to note, there are dramatic body weight changes in individuals between the reproductive and non-reproductive seasons (e.g., individual body weight with losses of ~200g in a 500-g animal). The weight gain after food deprivation/hibernation is faster in the spring and summer than the decrease in the autumn and winter (Canguilhem and Marx, 1973). They maintain large subcutaneous fat pad depots throughout the year. The more impressive fat pads are seen on the abdomen (Figure 36.5) (Reznik *et al.*, 1979). The average body length of the adult male is between 27–32cm and adult female is 22–25cm, excluding the tail (Mohr and Ernst, 1987).

Males and females have a sac-like cutaneous organ in the umbilical region, called the umbilical glandular organ. At the level of the anterior process of the ilium, there are bilateral flank organs that appear as dark cutaneous stripes, 2cm long by 2mm wide. The flank organs are sebaceous glands and active in sexually mature males. These glands are used to mark the male's territory.

FIGURE 36.5 Subcutaneous fat pads (indicated by arrows) in an adult European hamster.

Life Cycle

Animals in the wild are currently reported to live up to 4 years of age, although there are older published references (e.g., Reznik *et al.*, 1979) indicating a life span

TABLE 36.2 Reproductive Data for the European Hamster

Sexual maturity	Females, 80–90 days
	Males, 60 days
Estrus cycle	4–6 days
Gestation	18–21 days (wild caught) 15–17 days (laboratory-born) 17–18 days (Monecke and Wollnik, 2008; Vohralik, 1974)
Litter size	7–9 7–8 (Vohralik, 1974; Monecke and Wollnik, 2008)
Weaning	25–28 days

up to 6–8 years in the wild. It is not known if the lifespan has actually significantly shortened or if the older information was incorrect.

The average lifespan of the research-bred European hamster is reported to be 31 months for females and 28 months for males (Ernst et al., 1989), attributing changes from the wild due to loss in hibernation pattern (Mohr and Ernst, 1987), dental lesions (Althoff et al., 1986), and higher incidence of neoplasia (Brandes et al., 2004; Ernst et al., 1987). The University of Strasbourg reports the average lifespan in captivity is slightly shorter, 2.5 years for females and 2.0 years for males (Monecke 2010).

Similar to other rodents, the male has a large, round prepuce and the space between the anus and prepuce is larger than in the female (2 and 1 cm, respectively) (Mohr and Ernst, 1987). The female clitoris has a pointed shape with a very small urinary opening. Females have eight teats, obvious by 10–14 days of age (Mohr and Ernst, 1987). Only during the reproductive season are the testes located within the scrotum (Reznik et al., 1979). During hibernation, the testes are smaller and situated in the abdominal cavity (Reznik et al., 1979). Before sexual maturity and during hibernation, the vagina is closed by a layer of squamous epithelium (Mohr and Ernst, 1987). The females reach sexual maturity around 200 g (Reznik et al., 1979). During the reproductive season, the vaginal orifice opens and the epithelial layer disappears (Reznik et al., 1979).

The reproductive indices are noted in Table 36.2. In the wild and in natural conditions simulated in the laboratory setting, they are reproductively active from spring to early summer (Masson-Pévet et al., 1994; Monecke et al., 2009; Nechay, 2000; Reznik et al., 1979; Vohralik, 1974). European hamsters become reproductively quiescent in the non-reproductive season when gonadal regression occurs (Canguilhem et al., 1988). Even if maintained under constant photoperiods in a laboratory setting, there are annual rhythms in body weight and the reproductive state due to the circannual endogenous reproductive cycle (Monecke and Wollnik, 2004; Masson-Pévet et al., 1994). Some animals may remain reproductively active for a longer period, depending upon the

individual period length of its circannual clock, which drives the reproductive cycle (Monecke and Wollnik, 2004).

Laboratory studies of breeding females show that they have a regular four-stage estrus cycle of 4–6 days (Reznik et al., 1979) during the ~4-month reproductive season. The female is responsive to the male for a short period during estrus (Reznik-Schüller et al., 1974). Females are markedly aggressive toward the male in the other three stages of the cycle. The four-stage estrus cycle is characterized by a proestrus stage lasting a few hours, an estrus of 1–2 days, a metestrus of 6 hours, and a diestrus stage lasting 2–4 days (Reznik-Schüller et al., 1974). Monecke and Wollnik (2004) reported a regular estrous cycle of 4–5 days at the University of Stuttgart. Male acceptance is indicated by reduced aggression of the female toward the male and interest in each other. When receptive, the female is followed closely behind by the male uttering a mating call, which is a loud “ffff” sound (Monecke, 2010) that increases in volume when the female is ready to mate (Mohr and Ernst, 1987). Copulation occurs several times during mating. Pregnancy lasts 17–18 days in the laboratory setting (Vohralik, 1974).

The average litter size is 7–8 (range 1–13) young, with 1–3 litters being produced per year (Monecke and Wollnik, 2008; Vohralik, 1974), with the smaller number of litters (two/year) occurring in a semi-natural laboratory setting or natural (wild) environment, and the larger annual litter number occurring under a constant photoperiod cycle in the laboratory setting throughout the year. Fecundity is reduced after 14 weeks under a long photoperiod (Monecke, 2010).

Incisors are the first teeth to erupt on day 4–5 post-partum. The young remain sucklings for about 28–30 days post-partum. Dental eruption is complete at 35 days of age, with only one set of permanent teeth (Reznik et al., 1979).

Anatomical and Histological Characteristics

Reznik et al. (1979) provide a very comprehensive description of pathology of the European hamster and include gross anatomy and histopathology illustrations and descriptions. Table 36.3 is intended to be a brief anatomic description of major organ systems in the European hamster.

Hematology and Clinical Chemistry

The normal blood values of the laboratory-bred European hamster show seasonal and lifecycle changes (Mohr and Ernst, 1987). There are no significant differences between the sexes for most hematology parameters. Normal hematology and clinico-chemical parameters for the non-hibernating hamster are briefly

TABLE 36.3 Summary of Anatomic Information for Adult European Hamsters (Reznik et al., 1979)

Organ	Characteristics
Salivary glands	Parotid, mandibular, sublingual, and zygomatic glands
Brain	2.85 g; well-developed cerebral hemispheres without sulci; large olfactory bulbs; cerebellum about half size of cerebrum
Cheeks	Cheek pouches – nonkeratinizing epithelium
Teeth	Continuously growing incisors (4) and molars (12); canines and premolars are lacking; one set of permanent teeth
Lungs	Right lung divided into five lobes (cranial, middle, diaphragmatic, accessory, and intermediate accessory); left lung has only one lobe
Heart	Four chambers with two atria and ventricles; average heart rate 175 beats/minute
Stomach	Divided by a distinct constriction into the larger forestomach lined with squamous cell epithelium and a smaller glandular stomach lined with typical gastric mucosa
Duodenum	120 mm long and 3.5 mm wide; common duct, a combination of bile and major pancreatic ducts, enter into the duodenum about 30 mm from pylorus
Jejunum	510 mm long and 5 mm wide; similar histology to duodenum, with fewer and smaller villi
Ileum	25–35 mm long and 3 mm wide; goblet cells found frequently and at the base of the broad based villi
Cecum	120 mm long and 15 mm wide; distinct apex, body and freely mobile base
Colon	370 mm long and 4 mm wide; crypts are deeper than small intestine; epithelium consists of mostly goblet cells; lymphatic tissue diffuse; folds of colon occur at 1–2 mm intervals
Rectum	Longer in male (40–60 mm) than female (35–45 mm); many lymph nodes along the lamina propria and submucosa; increased thickening of tunica muscularis; fewer goblet cells than colon
Liver	15 g; usually brown; divided into six parts (bipartite left portion, left lateral lobe, caudate and papillary processes of the caudal lobe, quadrate lobe, and right medial lobe)
Pancreas	Three well-defined, elongated lobes (gastric, duodenal, and splenic); light in color similar to fat; main pancreatic duct forms a common duct with the bile duct 15 mm before it reaches the duodenum
Kidneys	930 mg each; smooth surface, reddish brown; adrenal gland at cranial pole; cortex and medulla have no distinct border; glomerula and tubules not visible macroscopically
Urinary bladder	4–20 mm in diameter; transitional epithelium; urethra discharges urine separately from the vagina and anus in females and via penis in the males
Male genital organs	Testes external during breeding season; all organs involute during hibernation; epididymis firmly attached to testes; paired vesicular glands; prostate gland
Female genital organs	Ovaries – 5 mm, 26 mg each; bipartite uterus – undivided body and paired horns ~59 mm long; firm cervix ~10 mm long; epithelium closing the vagina disappears in the spring

summarized in [Tables 36.4 and 36.5](#), respectively. During hibernation, the entire metabolism of the European hamster is reduced to a minimum. The most notable changes occur in leucocyte and thrombocyte indices. Leukopenia occurs during hibernation with a decrease of leucocytes from an average of 5350 to 740 cells/mm³ ([Mohr and Ernst, 1987](#)). The lowest counts appear around 16 weeks into the hibernation cycle. Thrombocytes decrease from 226000 to 24170 cells/mm³. Within 1 day of awakening from hibernation, leucocyte and thrombocyte levels rebound to average levels recorded in the summer. Hamsters kept in a non-hibernating state during the winter show no seasonal changes in hematology parameters ([Mohr and Ernst, 1987](#)).

Hibernation Cycle

In the wild and in natural to semi-natural environmental conditions in the laboratory setting, the European hamster is a hibernator during the cooler, shorter months of the year. Less than 15.5 hours of light will induce gonadal regression for animals previously

exposed to long photoperiods ([Canguilhem et al., 1988; Saboureau et al., 1999](#)). The short days induce testicular regressions; a reduction in food intake and body weight; and hibernation when the ambient temperature is lowered ([Canguilhem, 1989](#)). On average, hibernation lasts 104.2 ± 23.8 hours ([Wollnik and Schmidt, 1995](#)), and the animals arouse at 5–7-day intervals to feed on feed stored in the burrow. The entry into hibernation typically occurs around midnight, reported between 00:00–08:00 hours ([Canguilhem et al., 1994](#)) or a mean time of day 01:48 hours ± 3.4 h ([Wollnik and Schmidt, 1995](#)). Spontaneous arousal is less predictable, scattered throughout the day and night ([Canguilhem et al., 1994; Wollnik and Schmidt, 1995](#)).

Body temperature of the European hamster during the active, reproductive period is approximately 36.1–37.9°C ([Wollnik and Schmidt, 1995](#)). During hibernation, body temperature and metabolism are reduced to save energy. Like all other hibernators, they run through rhythmical succession of torpor episodes characterized by low body temperature alternating with

TABLE 36.4 Normal Hemogram of the European Hamster

Hemogram	Silverman and Chavannes (1977)		Emminger et al. (1975)

Blood pH	7.4 ± 0.02	–	

short periods of eutheria in which the body temperature returns to 37°C (Waßmer and Wollnik, 1997). The lower body temperature is correlated with ambient temperature, following a lag time of 3–5 hours. Body temperature in the European hamster as low as 4.0°C has been recorded during hibernation (Wollnik and Schmidt, 1995).

A photoperiod of approximately 13 hours or more is required to stimulate gonadal regrowth in animals previously exposed to short photoperiods (Monecke and Wollnik, 2004; Monecke et al., 2009). As hibernation ends, there are spontaneous, light-independent increases in body weight and food intake; and gonadal regrowth occurs (Canguilhem, 1989).

BEHAVIOR

The European hamster is well acclimated to the laboratory setting. Though historically reported to be very aggressive, those in captivity have shown slightly reduced aggression to their kind and to man (Mohr

and Ernst, 1987); however, they continue to be aggressive toward each other and are typically singly housed (Canguilhem et al., 1988; Monecke et al., 2009; Tournier et al., 2007; Waßmer and Wollnik, 1997).

European hamsters are not a typical nocturnal rodent, as they are active only during the dark cycle with limited or no seasonal differences in activity. In 2 months of reproductive season (May to July), they are most active from the few hours before sunset to the few hours before dawn. They have an arrhythmic cycle, with no clear rest or activity phase, during the other 10 months of the year (Monecke and Wollnik, 2005; Wollnik and Schmidt, 1995; Wollnik et al., 1991).

In the wild, the solitary male travels over a large territory and does not occupy a single burrow (Bartlett, 2003). They are prodigious collectors of food, with as much as 180 lb of food reported to be stored in a burrow. The male mates with many females and his territory may cover the ranges of three or more females. Females have a smaller territory and spend less time out of the burrow than males and more time with her young (Bartlett, 2003). The species prefers to burrow in dry clay or loess soil. They

inhabit grassy steppes, plowed land, cultivated fields, and areas along riverbanks, ranging from lowlands to 2000-foot elevation (Bartlett 2003; Mohr and Ernst, 1987). The burrows are shallow (30–60 cm) in summer and deeper (up to 2 meters) in the winter; and each burrow has several exits in winter (Mohr and Ernst, 1987; Reznik et al., 1979). The European hamster maintains the same burrow for winter and summer. The burrow becomes more complex as the animal grows older (Eisentraut, 1928; Kayser, 1961). Within the adult burrows, there are separate areas for food, sleeping, and excreta (Bartlett, 2003; Eisentraut, 1928; Mohr and Ernst, 1987). The diet of the European hamster includes cereal seeds, cabbage, peas, potatoes, and roots and green parts of plants, insect larvae, small mice, and frogs (Bartlett, 2003).

DISEASES

Viruses

Little is reported in the literature with respect to the health profile of wild or laboratory-reared European hamsters. According to Svrcek et al. (1980), rabies virus was identified in five out of 266 free-living hamsters in Eastern Slovakia in 1972 and 1973. Hannoun et al. (1974) described a spontaneous and subclinical infection with papovavirus in European hamsters captured in France.

Bacteria

Secondary bacteria infections with *Corynebacteria*, *Staphylococcus*, *Pasteurella pneumotropica*, and *Pasteurella multocida* have been associated with pathological processes of the jaw and head (Kunstyr et al., 1976). These occasionally appeared as fistulating abscesses in both captured and laboratory-bred European hamsters.

Protozoan and Metazoan Parasites

Matthiesen et al. (1976) reported an outbreak of chronic enteritis associated with *Spironucleus muris* in seven newly captured European hamsters. The main pathological findings were hepatic swelling and edema of the intestinal wall, pancreas, and mesenteric lymph nodes. There was histological evidence of hepatic necrosis, cysts, and bile duct proliferation. In the intestine, the villi were shortened and the dilated Lieberkühn's crypts contained necrotic debris and inflammatory cells. There were large numbers of *Spironucleus muris* seen intra- and extracellularly in the small intestine. Co-infections with *Hymenolepis diminuta* and trichomonads were also seen in some of the hamsters.

Spontaneous, clinically inapparent infections with *Sarcocystis*, *Trypanosoma*, *Taenia*, *Cysticercus*, *Metastrongyles*, and *Capillaria* have also been described (Kunstyr et al., 1976; Meszaros, 1977; Murai, 1970; Tenora and Murai, 1970).

Spontaneous Tumors and Other Pathologies

Spontaneous benign and malignant tumors in older European hamsters are very common. The tumor incidence is up to 70% in those reaching 2 years of age. The most common tumors found in European hamsters at the Hannover Medical School were lymphatic in origin (Mohr and Ernst, 1987). Another report indicated that spontaneous neoplasia occurs more frequently in males than in females (overall frequency of 57.9% and 47.2%, respectively). Malignant tumors were more frequent than benign neoplasias. The most frequent tumors in descending order are leukemias and lymphomas, adrenal pheochromocytomas, and granulosa cell tumors in females (Ernst et al., 1989). Bronchogenic squamous cell carcinomas were found in the wild-caught hamsters from an industrialized area of West Germany, though it could not be determined whether these were spontaneous or due to environmental pollution (Mohr et al., 1973).

Thymomas have been reported in wild European hamsters (Ghadially and Illman, 1965). Brandes et al. (2004) reported a large number of spontaneously occurring thymomas in a laboratory colony of European hamsters. Of the 40 hamsters evaluated, 22 (55%) presented clinically with masses of variable diameter in the cranial mediastinum. The thymomas were characterized according to the World Health Organization (WHO) human classification to be type B1 thymomas, predominantly cortical or organoid low-grade malignant tumors. Typically, thymomas are rare neoplasms compared to other spontaneously occurring tumors in the European hamster. These tumors were evaluated for viral particles by electron microscopy and polymerase chain reaction, but none were identified.

The European hamster is prone to development of peritoneal cysts, particularly in the liver, with a higher incidence in females than males. Peritoneal cysts may also be found in the cecum, ovaries, spleen, kidneys, and colon (Kaup et al., 1990).

Spontaneous pathological processes may occur in the head, particularly the jaw. These include malocclusion, osteomyelitis, and dysplasia. There is evidence to suggest that the European hamster may be useful in dental research, as the lesions increase with age (Althoff et al., 1986; Kunstyr et al., 1987). These spontaneous pathologies may become complicated by secondary bacterial infections that may be fatal (Ernst et al., 1989).

MANAGEMENT, HUSBANDRY, AND COLONY HEALTH

The housing conditions for the European hamster vary depending upon the type of research being conducted and the location in which it is conducted. Conditions vary and range from natural conditions to semi-natural conditions (Canguilhem et al., 1994), or constant photoperiod (Wollnik and Schmidt, 1995) laboratory conditions. In the summer, animals have been maintained in light: dark (LD) 16: 8 photoperiod, temperature $20 \pm 2^\circ\text{C}$, and $55 \pm 5\%$ relative humidity. In winter, some investigators have moved them into a cold room with LD 8: 16 photoperiod and decreasing temperature gradually lowered to $8 \pm 1^\circ\text{C}$. They are typically housed individually (Canguilhem et al., 1988; Monecke et al., 2009; Tournier et al., 2007; Waßmer and Wollnik, 1997). The cages used for non-hibernating European hamster containers have included Makrolon cages (type III, 800cm^2) (Mohr and Ernst, 1987; Monecke et al., 2009) and Macrolon type IV cages (Monecke and Wollnik, 2004, 2005; Monecke et al., 2006; Wollnik et al., 1991). These same cages can be used during the hibernation season (Revel et al., 2007). However, a larger cage may also be used for winter housing (reported as 1m^3). The cages may contain soil and/or hay to be used as burrowing material and various nests boxes. During the hibernation period caging changes may be suspended to prevent interruption to the normal cycle (Wollnik and Schmidt, 1995).

Standard rodent chow may be fed to European hamsters. Food pellets and water are given *ad libitum*, supplemented with fruit (apples, bananas) and nuts (Wollnik and Schmidt, 1995). For gestating or lactating females, additional protein-rich food (white cheese, milk pudding, baby nutrition) may be used (Monecke, 2010). The average water consumption is $5\text{ml}/100\text{g BW}$, and food consumption is $2.9\text{g}/100\text{g BW}$ in summer and $1.8\text{g}/100\text{g BW}$ in winter (Silverman and Chavannes, 1977).

EXPERIMENTAL METHODOLOGY

Reproductive assessment is an important data point used in hibernation or circadian/circannual research. Under anesthesia, testis size is measured externally with a caliper square to measure the reproductive status of male hamsters. When the length of the testis is $\geq 1.8\text{cm}$, they are considered fully developed and reproductive, and the levels of testosterone are maximal (Monecke and Wollnik, 2004; Monecke et al., 2006). Gonadal regression begins when the testis length falls below 1.8cm . Gonadal regression is completed when the testes are no longer palpable, as they have ascended

into the peritoneal cavity (Monecke et al., 2006). The female reproductive state is determined by the opening of the vagina which correlates well with ovarian cyclicity (Monecke and Wollnik, 2004). Vaginal smears are no longer considered appropriate for determining estrus due to significant stress effect on the animal (Monecke et al., 2006). Rather than rely on smears, estrus is determined by animal behavior and male acceptance.

Parameters typically evaluated in hibernation or circadian/circannual research include body temperature; body weight; activity; cardiac and respiratory function; oxygen consumption; and blood parameters such as clinical chemistry, complete blood count, and measurement of testosterone, melatonin, and neuropeptides (Canguilhem and Masson-Pévet, 1988; Kayser, 1961). Light: dark cycle and room temperature modifications to emulate or control the natural seasonal changes are often manipulated as variables. Body temperature is typically monitored using surgically implanted temperature-sensitive radio transponders (Wollnik and Schmidt, 1995). Surgical procedures commonly employed in studies related to hibernation/circadian rhythm include pinealectomy (Garidou et al., 2003; Masson-Pévet et al., 1994); castration (Canguilhem et al., 1988); cerebral ventricular (lateral septal) cannulation (Hermes et al., 1989); telemetry or transponder implantation; and silastic capsule or osmotic pump implantation for infusion (Hermes et al., 1989). Inhalant gases, such as ether, halothane, enflurane, and isoflurane, have been used for anesthesia (Canguilhem et al., 1988; Monecke and Wollnik, 2004). Injectable anesthetics have included ketamine/xylazine ($50/10\text{mg}/\text{kg}$ body weight (bw)) (Waßmer and Wollnik, 1997; Wollnik and Schmidt, 1995); pentobarbital $1\text{mg}/\text{kg}$ bw IP (Hermes et al., 1989); and zoletil $20/\text{xylazine}$ ($80/10\text{mg}/\text{kg}$ bw) (Monecke, 2010).

USE IN BIOMEDICAL RESEARCH

Carcinogenicity

There are several publications evaluating the organ distribution of experimentally induced tumors in the European hamster following administration with nitroso-compounds (e.g., Althoff et al., 1974; Mohr et al., 1972, 1974; Reznik-Schüller, 1978; Reznik-Schüller and Lijinsky, 1979), as well as tumors from concentrated smoke inhalation (Reznik et al., 1975). Reznik et al. (1979) stated that their goal was to find a sensitive experimental animal that would fulfill the following criteria for carcinogenicity in vivo studies: (1) the lesions are induced in a reasonable time period after administration of known carcinogens; (2) development of well-differentiated tumors (adenoma and squamous cell carcinomas) originating from the respiratory tract; and (3) lack of infectious respiratory

tract diseases that might interfere with the experimental results. Mohr et al. (1972) found European hamsters to be susceptible to development of pulmonary tumors following administration of N-diethyl nitrosamine. Reznik-Schüller and Lijinski (1979) determined that respiratory tract tumors would develop within 13 weeks following exposure to nitroso-compounds. The incidence of pulmonary tumors in this study approached 100% with no tumor induction in the liver. The tumors were found to be well-differentiated and included adenomas, adenocarcinomas, squamous carcinomas, and mixed tumors. The authors further advocated for the use of European hamsters over other hamsters due to their size which (1) facilitated clinical evaluations such as radiology, bronchography, cytology; (2) facilitated administration of compounds by the intratracheal and intrabronchial routes; and (3) a larger respiratory tidal volume than the Syrian hamster. Lastly, the laboratory-bred European hamsters examined were determined to be free of infectious diseases of the respiratory tract. Thus, the European hamster met key criteria and the species was determined to be a better animal model for carcinogenicity than other hamsters.

Hibernation, Circadian and Circannual Rhythm

The majority of biomedical research using the European hamster is in the field of chronobiology and involves study of hibernation, circadian rhythm and circannual cycles.

Hibernation is considered to be a form of survival adaptation for animals that live in areas with striking seasonal changes in their environment. Offspring are born in the most favorable season for survival, while the harsh conditions of winter are survived by hibernation (Garidou et al., 2003; Kayser, 1961; Monecke et al., 2006, 2009; Waßmer and Wollnik, 1997). The European hamster is a well-characterized hibernator and especially interesting due to its large seasonal variations in physiological processes relative to other rodents (Kayser, 1961; Monecke et al., 2004). There are seasonal variations in body weight, food intake, gonadal activity, gonadal hormone levels, body temperature, and locomotion for the hibernating animal. Physiological processes such as heart and respiratory rates, immune and renal functions, and neural activity all run at greatly reduced levels during hibernation (Revel et al., 2007).

Circadian rhythms are endogenously driven patterns that have a period length of 1 day and are synchronized to the environmental cycle by the light: dark cycles. The suprachiasmatic nucleus (SCN) of the hypothalamus controls the master circadian clock. During hibernation, the SCN is metabolically very active (Monecke and Wollnik, 2004). The entry into, but not the arousal from, a torpor bout is coupled to a certain time of day (Waßmer

and Wollnik, 1997) indicating that the circadian clock which drives the daily activity and rest cycle is involved only in the former. During hibernation, the circadian clock seems also to be inactive (Revel et al., 2007).

Circannual rhythms are endogenously driven patterns that have a period length of approximately 1 year. The seasonal timing of the hibernation phase is driven by a circannual clock (Masson-Pévet et al., 1994) which is synchronized by changes in photoperiod (Monecke and Wollnik, 2004; Monecke et al., 2009; Saboureau et al., 1999). With the help of the circannual clock, the upcoming seasons can be predicted such that all the necessary changes in physiology can be initiated before they are needed. If perfectly timed, the animals will survive the harsh conditions of the winter through hibernation (Monecke et al., 2009). Rhythms that are under the control of an endogenous circannual clock include reproduction (Masson-Pévet et al., 1994); hibernation and body mass (Canguilhem et al., 1973); seasonal activity pattern changes (Tournier et al., 2007; Wollnik et al., 1991); serotonin and noradrenaline levels and turnover rates (Kempf et al., 1978); urinary sodium excretion (Haberey et al., 1967); and aldosterone excretion (Bloch and Canguilhem, 1966). Additional seasonal physiological changes occur in the European hamster that affect the melatonin binding sites of the pars tuberalis (Skene et al., 1993); pineal melatonin secretion (Garidou et al., 2003; Revel et al., 2007; Tournier et al., 2007; Vivien-Roels et al., 1992, 1997, 1998); daily body temperature patterns (Wollnik and Schmidt, 1995); vasopressin release (Buijs et al., 1986); and cortisol and progesterone secretions (Franceschini et al., 2007).

Gonadal regrowth in the spring is controlled by an endogenous timer rather than through a direct photoperiod effect. The gonadal regrowth begins prior to leaving the hibernation burrow and at a time when the animal has no information about the photoperiod from the outside world. There also appears to be a period of sensitivity to long photoperiods, which is unique to the European hamster compared to other hamster species. Sensitivity to long photoperiods following a shortening photoperiod does not induce gonadal regrowth until mid-November to March/April, as it does in other hamster species (Monecke and Wollnik, 2004).

INTRODUCTION

The hamsters described in this chapter have served over the last 40 years as important animals models in biological and biomedical research, but they are used less often than *Mesocricetus auratus*. Not all of these hamsters are commercially available from North American research rodent vendors, so research programs that use these hamsters generally maintain their own breeding colonies, acquire these animals from other research laboratories with breeding colonies, or trap hamsters from their native habitat to establish intramural colonies. As interest in use of these hamsters in research increased, the sharing of hamsters between laboratories and use of common names to describe the species has caused confusion as to which species of hamster was actually used in the published research. More recently, information about the taxonomy or genetics of these species is included in

descriptions of the hamster models to accurately reflect the species.

PHODOPUS SUNGORUS (DJUNGARIAN HAMSTER)

Taxonomy, History, and Genetics

There are three species in the genus *Phodopus*: *Phodopus sungorus*, *Phodopus campbelli*, and *Phodopus roborovski*. The most studied species, *Phodopus sungorus*, is called by many common names, including the hairy-footed hamster, Siberian hamster, and the Djungarian (or Dzungarian) hamster. *Phodopus campbelli*, once considered a subspecies of *P. sungorus*, was recognized as a separate species in 1993 (Carelton and Musser, 1993). *Phodopus campbelli*, often referred to as Campbell's hamster, shares many of the same common names as *P. sungorus*, which has caused

confusion in the life sciences literature. The most obvious phenotypic feature that distinguishes *P. campbelli* from *P. sungorus* is the lack of dramatic coat color change in response to a short photoperiod. *P. sungorus* molts to pure white haircoat, while *P. campbelli* retains a gray haircoat. In reviewing literature about dwarf hamsters, it might be advised to critically evaluate the species under discussion by evaluating the supplier, the geographic region of origin and whether the haircoat is pure white in short photoperiods (Ross, 1998). Information in this section will be focused on *P. sungorus*, with relevant comparisons to *P. campbelli*.

Phodopus sungorus is found in dry mountain steppes and semi-deserts of southwest Siberia, and eastern Kazakhstan, and in one isolated area in Khakassia, near the Yenisey River in Russia (IUCN, 2008; Ross, 1998). The first colony was established at the Max Planck Institute for Behavioral Physiology in Andechs, Germany from four hamsters captured in western Siberia (Figala et al., 1973; Hoffman, 1973). Colonies of *P. sungorus* have been established worldwide, and there are experimental data that suggest there are genetic differences between colonies from Germany and the United States with respect to photoresponsiveness (Lynch et al., 1989). In the United States, colonies of these hamsters molt later, have more photo-unresponsive animals and lose weight more slowly than those in German colonies. It was unclear whether these differences were due to genetic drift, or from inadvertent selection for photoresponsiveness.

P. sungorus has a diploid number (2N) of 28 chromosomes, all of which are metacentric except for chromosomes 12, 14, 15, 16, and Y, which are acrocentric (Schmid et al., 1986). Karyotype analysis using G-banding and chromosomal painting with probes from the golden hamster *Mesocricetus auratus* and the Chinese hamster *Cricetulus griseus* has confirmed close phylogenetic relationship between *P. sungorus* and *P. campbelli* (Romanenko et al., 2007). Analysis of partial DNA sequences from mitochondrial genes cytochrome b and either the 12S rRNA gene (Neumann 2006) or the tRNA-Thr gene (Meshchersky et al. 2009) characterize *Phodopus* as a distinct clade, and the oldest in the subfamily Cricetinae. The data suggest *P. sungorus* and *P. campbelli* separated about 0.8–1.0 million years ago, and are well separated from the other dwarf hamster, *P. roborovski*. Unique C-banding patterns in *P. sungorus* chromosomes also distinguish the karyotype from that of *P. campbelli* (as described in Ross, 1998). Interspecies mating produced females with reduced fertility and subfertile to sterile males (as described in Ross, 1998; Safronova et al., 1999).

Anatomy, Physiology, Husbandry, and Breeding

Phodopus sungorus is a small hamster with a unique characteristic of dense fur on the footpads, which

accounts for the common name of “hairy-footed hamster”. Adult males are about 11 cm long while mature females are about 9 cm long. Body weights vary with length of photoperiod, with the heaviest weights noted during the longest daylight hours that correspond to summer months. At peak body mass, males weigh from 40–50 grams while females weigh about 30 grams. In winter months, hamsters can lose from 40–50% of their body weight (Figala et al., 1973; Hoffmann, 1973). Hamsters have short tails, 5–15 mm in length, which are partially covered with white hair (Ross, 1998). The dorsal pelage is dense and gray with a wide, black-brown mid-dorsal stripe that extends from a dark black-brown patch on the crown of the head to the base of the tail (Figure 37.1). Black patches on the shoulders and flanks are connected with a line of black hairs that demarcate the dorsal from the ventral fur. The ventral pelage is white with a few black hairs. In contrast, *P. campbelli* has a yellow-brown tinge to gray haircoat with a gray underside; blackish fur patches on the shoulder only; narrow mid-dorsal stripe; and lack of dramatic coat color change in response to a short photoperiod. Winter molt under natural conditions begins in September and is complete in 2 months. The summer molt begins in late January and is complete by March (Figala et al., 1973). For either seasonal change, the molt begins on the head and the rump, and proceeds to the sides and ventrum. *P. sungorus* has lateral and midventral sebaceous marking glands. The glands are responsive to testosterone, vitamin D, and possibly estradiol and so are larger in males, especially in the breeding season (Stumpf et al., 1993). Like other hamsters, *Phodopus* has cheek pouches that are extensive for storing food. In contrast to other hamsters, *Phodopus* has an epidermal pocket between the skin of the cheek and the opening of the cheek pouch. This pouch is lined by stratified squamous epithelium that exfoliates into the center of the pouch, forming a whitish material with a pungent odor (Sokolov et al., 1994). The amount of secretion is greatest in females during the breeding season, and may be important in communicating age and sex, and for marking pelage and food stores (Sokolov et al., 1994). Females have four pair of mammary glands. The dental formula is: incisor 1/1 and molar 3/3, with continuously growing incisors as in other rodents. Detailed anatomical descriptions of the gastrointestinal tract (Vorontsov, 1979) and microscopic descriptions of the salivary glands (Suziki et al., 1983, 1984) and cecum (Snipes, 1979) have been published. Light and electron microscopic evaluations of the Harderian gland documented the similarities in glands between male and female hamsters collected during long and short photoperiods (Schreckenberger and Reuss, 1993). The body temperature ranges from 36.1°C to 37°C (Heldmaier and Ruf, 1992).

FIGURE 37.1 *Phodopus sungorus* (Djungarian hamster).

Phodopus are reported to be more docile and less aggressive than Syrian hamsters (Hoffmann, 1981). These hamsters can be housed in same-sex groups, and breeding pairs can stay together for the duration of their breeding life (Lerchl, 1995). Solid-floored cages with various kinds of bedding have been used for *Phodopus*. Material for nest building can be provided as enrichment, and is important in cages of breeding hamsters. Room temperature (20–25°C) and humidity levels (>50% RH) typical for rodent housing are acceptable conditions for colonies of *Phodopus* (Lerchl, 1995).

P. sungorus is nocturnal, crepuscular, and active year round in the wild (Ross, 1995). In captivity, the daily light cycles will influence the reproductive performance and body weight of *P. sungorus*. Puberty in male is influenced by the photoperiod exposure of the mother during gestation (Gündüz and Stetson, 2003; Stetson et al., 1986) and the postnatal photoperiod exposure (Gorman and Zucker, 1997; Shaw and Goldman, 1995). Male hamsters born and raised in 16h light and 8h dark photoperiodic cycles initiate spermatogenesis on postnatal day 11. Elongated spermatids are in seminiferous tubules by day 31 (Bergmann et al., 1991). Under these conditions, male hamsters reach puberty by 35–40 days of age. Puberty is delayed to around 150 days of age in male hamsters raised under short day conditions (8h light and 18h dark) (Hoffmann, 1979, 1981). Females kept in 15–16h daylight photoperiod have a 4-day estrous cycle (Schlatt et al., 1993; Scribner and Wynne-Edwards, 1994), and can be paired with males as adults.

P. sungorus are seasonal breeders, with the breeding season in the wild beginning in April to May and extending through September (Ross, 1998). Breeding colonies use stable photoperiods of 15–16h light with 8–9h darkness to match the photoperiod of the hamster's breeding season. Hamsters can breed year round with a constant long-day photoperiod, but may become obese (Jordan, 1971). Gestation length for the first litter is around 18–19 days (Figala et al., 1973; Scribner and Wynne-Edwards,

1994). Litters are typically born about 12 weeks after pairing, so females generally produce their first litter at about 4 or 5 months of age (Lerchl, 1995). Mean litter size is from 5–6, with litter size peaking at the third litter. Females have a fertile post-partum estrus, and the interbirth interval is from 18–25 days (Lerchl, 1995). The interbirth interval delay of over 19 days may be the result of post-implantation embryonic diapause (Newkirk and McMillan, 1997). Male *P. sungorus* do not participate in the rearing of offspring. In contrast, male *P. campbelli* are integral for the successful raising of litters (Wynne-Edwards, 1987). The breeding life of a pair of hamsters is about 1 year, and up to 13 litters can be produced (Lerchl, 1995). A dip in reproductive rates has been described in summer and winter in captive hamsters maintained under long day photoperiod (Jordan, 1971). However this seasonal variation was not observed in a 5-year study of breeding records from a *P. sungorus* colony that had been in captivity for 30 years, suggesting that selection over time may have influenced the loss of seasonal variation. While reproductive abnormalities are infrequent in *Phodopus*, there is one report of abdominal pregnancies in a breeding colony of hamsters used for mutagenesis experiments (Buckley and Caine, 1979). Affected hamsters were multiparous dams who all had previously delivered normal litters. Macerated fetuses were found in the abdomen, some attached by placentas to the abdominal wall, but most were free in the abdominal cavity which was often inflamed. There was no macroscopic or microscopic evidence of rupture of the uterus or oviduct, and the majority of affected dams were either stock or control animals, so the experimental procedures were not considered causative.

Young are born hairless except for vibrissae and weigh 1–2 grams. Incisors and claws are present at birth. The dorsal stripe is first recognized by day 3 and separation of the pinna from the head occurs by day 4. Pups are fully haired by day 8. When the eyes open around day 10, pups leave the nest and chew on food. Young can be weaned at 16–18 days, but commonly are weaned at 21–23 days of age (Lerchl, 1995). Weaned young can be housed with same-sex littermates. Weaned weight at 20 days averages 17.4 grams (range of 11.7–21.5 grams) (Jordan, 1971), and adult weight is achieved by 4 weeks of age.

Diseases and Veterinary Care

P. sungorus is a robust animal with few reports of serious contagious diseases. A report of *Trichophyton mentagrophytes* causing alopecia and hyperkeratosis of the extremities and ventrum was reported from a captive colony (Young, 1973). Other infectious diseases noted in this colony included fur mite infestation with *Myocoptes musculinus* and infected wounds. Bacterial pseudomycetomas

or cutaneous botryomycotic lesions were described in the forelimb of a solitary pet *P. sungorus*. The etiology of the pseudomycetomas was interpreted to be *Staphylococcus aureus* based on the Gram staining and histologic appearance of the bacteria in the lesion (Martorell et al., 2006). The majority of reports of diseases in *Phodopus* describe spontaneous neoplasia, and the mean age at diagnosis ranged from 12–28 months (Cooper et al., 1991; Kondo et al., 2008; Pogosianz and Sokova, 1996). The incidence of spontaneous neoplasia in captive research and domestic colonies ranged from 1–10%, and cancers included mammary adenomas and adenocarcinomas, cutaneous papillomas and squamous cell carcinoma and basal cell tumors, integumentary sarcomas, pulmonary adenomas and carcinomas, renal cell carcinoma, various mesenchymal tumors and endocrine neoplasia, including thyroid parafollicular or C-cell adenocarcinomas and adrenal pheochromocytoma (Cooper et al., 1991; Kondo et al., 2008; Li et al., 1995; Pogosianz and Sokova, 1996; Quimby et al., 1982).

Experimental Models

Seasonal-induced changes in morphology, physiology, and behavior in *P. sungorus* have made the hamster a popular model for the study of circadian rhythm and pineal gland activity. These changes include molting to the pure white winter pelage, loss of gonadal function, and weight loss. The neuroendocrine response to shorter days when seasons shift from summer to winter is an increase in nocturnal pineal secretion of melatonin (Illnerova et al., 1984). Melatonin secretion is proportional to the length of dark phase, and is extended in the winter months with longer dark cycles and compressed in summer months with shorter dark periods (Illnerova and Sumova, 1997). The melatonin signal is further enhanced by exposure to cold and reduced food (Stieglitz et al., 1991). The physiologic response to decreasing day length and increasing melatonin secretion is a molt to the pure white winter pelage. A decrease in serum prolactin is thought to initiate the growth of the unpigmented winter coat (Duncan and Goldman, 1984). In male hamsters, testicular weight drops to 10% of adult testicular weight. Histologic changes include reduction in seminiferous tubular diameter, loss of spermatids with arrest of spermatogenesis, and retention of primary spermatogonia. Decreases in circulating follicle-stimulating hormone (FSH) occur within 5 days of short day cycles, and at this time, testicular apoptosis is increased almost five-fold (Furuta et al., 1994). Serum and testicular testosterone levels subsequently drop and the rate of apoptosis is correlative with rate of hormone decline. In females, drops in FSH levels lead to ovarian involution with no progression in oogenesis past the secondary follicular stage (Schlatt et al., 1993). Hamsters lose up to 30% of body weight (Figala et al., 1973; Hoffmann, 1973, 1979). The loss of

body mass is due to a dramatic reduction in white fat from melatonin-stimulated, norepinephrine-induced lipolysis of white adipose (Bowers, 2005). Brown fat stores remain relatively constant (Hoffmann, 1981). In short days and temperatures <20°C, hamsters do not hibernate, but rather enter torpor. Their metabolic rate decreases and the body temperature drops to 17–23°C depending on the ambient temperature (Figala et al., 1973). Hamsters will hunch over, and hide their heads and forepaws in the fur of the ventral abdomen, fluff up their fur and will stay in this position with sporadic feeding activity (Heldmaier, 1975). The ability of *Phodopus* to withstand cold temperatures in torpor is from norepinephrine-induced non-shivering thermogenesis (Heldmaier and Buchberger, 1985; Heldmaier and Ruf, 1992). In short photoperiod and cold temperatures, brown fat respiration increases, as measured by increases in mitochondrial protein and GDP-binding of mitochondria. Additionally, there is activation of brown fat lipoprotein lipase and an increase in brown fat lipolysis providing the substrate for non-shivering thermogenesis (Klingenspor et al., 1989).

Change from short (8-h day) to long photoperiod (16-h day) results in recrudescence or stimulation of weight gain, gonadal function, and molt to the summer pelage (Hoffmann, 1981). A short burst of light for 1 or 5 minutes was shown to have the same effect on reinitiating spermatogenesis as did a 16-h daily exposure to light (Hoffmann, 1982). Response to photostimulation is the release of FSH, with increased levels measured by the third day in intact male hamsters (Furuta et al., 1994). By day 5 of long days, there was a 65% reduction in testicular apoptosis, increase in testicular weight and increases in serum testosterone levels (Futura et al., 1994; Wolfe et al., 1995). Female hamsters also show a rise in FSH that results in reinitiation of oogenesis (Schlatt et al., 1993). Interestingly, FSH administered exogenously to photo-inhibited male hamsters can reinitiate spermatogenesis when testicular testosterone levels are still low (Schlatt et al., 1995), suggesting this hormone, and not testosterone, was responsible for initiation of spermatogenesis.

Phodopus that remain in prolonged short photoperiods will undergo spontaneous recrudescence (Hoffmann, 1981). Nocturnal melatonin synthesis is disrupted (Lerchl 1992) and hamsters gain weight, regain normal gonadal function, and the molt to the summer pelage (Hoffmann, 1975). In spontaneous recrudescence, serum FSH levels return to normal levels 6 weeks before a rise in serum testosterone levels was detected (Schlatt et al., 1995), confirming the role of FSH in initiating gonadal function in spontaneous recrudescence.

Photoperiod also influences puberty in the male and female *P. sungorus*. Young males born in the long day length (16-h daylight) will develop active spermatogenesis and show increased testicular weight by 35 days

of age. However, *Phodopus* males and females raised in short day length (8-h daylight) will have delayed puberty. Testicular growth is sensitive to photoperiod stimulation at around 15 days of age and will stop developing in short daylengths. Testicular growth can be delayed for months (up to 150 days) and then proceed to full development by 5–7 months of age (Hoffmann, 1981, Stetson et al., 1986). Female hamsters raised in short days will also experience delayed puberty and gonadal development (Hoffman, 1981). Juvenile males raised in short day exposures have lower serum FSH, luteinizing hormone, and prolactin levels as compared to cohorts raised in 16-h daylight (Yellon and Goldman, 1984).

Seasonal changes in the immune system also occur in *Phodopus* as well as other mammals, and are linked to changes in day length (Yellon et al., 1999). Immunologic changes in immune cells from hamsters exposed to short day length include decreased circulating granulocytes and increases in circulating B-lymphocytes (Prendergast et al., 2002), reduced phagocytosis, and oxidative burst activities of macrophages and enhanced natural killer cell activity (Yellon et al., 1999), and diminished IgM production in T-cell-dependent adaptive immune responsiveness (Yellon, 2007). The mechanisms by which immune competence is diminished in response to short day photoperiod are not well understood, however, melatonin and sex hormones have been shown to have some influence on immune function in these hamsters. Pinealectomized male hamsters exposed to short days had serum IgM responses comparable to those of intact hamsters exposed to long days, suggesting that melatonin plays an inhibitory role in adaptive immunity (Yellon, 2007). The low granulocyte, high B-lymphocyte leukograms in *Phodopus* exposed to short day length were not observed in leukograms from castrated hamsters that were exposed to short days (Prendergast et al., 2002), and that sex hormones may also be involved. *Phodopus* offers a unique model system to continue to evaluate the responsiveness of immune cells to hormonal changes associated with photoperiod.

Phodopus are used in behavioral studies on separation anxiety and aggression. When a mated pair of *Phodopus* is separated, male hamsters display increase in body mass and altered behaviors, including increased food consumption, inactivity, decreased testicular and seminal vesicular weights, and increased serum cortisol levels. These responses to separation mimic some of the patterns observed in atypical human depression, and allow opportunities to evaluate the neuroendocrine influence on this induced behavior (Castro and Matt, 1997). *P. sungorus* are also considered ideal animal models for studies on aggression. Male hamsters display increased territorial aggression during the non-breeding season as compared to hamsters in the breeding season even though non-breeding hamsters have lower levels of testosterone (Jasnow

et al., 2000). Interestingly, aggressive encounters at night did result in increased serum testosterone levels, suggesting a possible role of melatonin (Scotti et al., 2009). Female *P. sungorus* display more maternal aggression when males are removed after birth of the litter than when the male stays postpartum (Gammie and Nelson, 2005). Female *P. sungorus* are more aggressive compared to female *P. campbelli* in maternal aggression experiments, and may prove useful in future studies needed to dissect the neurobiological correlates of maternal aggression.

P. sungorus is not often used in infectious disease studies. However, the recognition of the susceptibility of the Syrian hamster (*Mesocricetus auratus*) to prion disease prompted the investigation of the susceptibility of other rodents, including *P. sungorus* and *P. campbelli*, to the prion responsible for cervid chronic wasting disease or CWD (Raymond et al., 2007). Of the nine *P. sungorus* inoculated with various CWD inocula, two hamsters developed disease after prolonged incubations, and were considered to have limited susceptibility. In contrast, of the 15 *P. campbelli* inoculated, none developed disease and were considered resistant. The authors concluded that transmissibility of CWD to rodents might be useful for further comparison of strains of prion agents or for testing potential therapies.

MESOCRICETUS BRANDTI (TURKISH HAMSTER)

Taxonomy, History, and Genetics

Mesocricetus brandti is commonly referred to as the Turkish hamster or Brandt's hamster and is closely related to *Mesocricetus newtoni* (Romanian hamster) and *Mesocricetus auratus* (Syrian hamster). In the wild, the Turkish hamster is found in dry open steppe habitat at 1000–2200 meters above sea level over a large range including Turkey, Georgia, Armenia, and Iran (IUCN, 2008).

Research colonies have been established in the United States from animals trapped in Turkey and Iran. Chromosomal number varies among *M. brandti* populations with most populations having a diploid number (2N) of 42 chromosomes. However, one population trapped near Ankara Turkey has a diploid number of 44 chromosomes. Hybrid animals, produced from mating these two populations, are viable and fertile and contain a diploid number of 43 chromosomes. Chromosomal analysis suggests that chromosome pair #19 in the Ankara population is absent in Mayla populations (Lyman and O'Brien, 1977; Shimada, 2007). Breeding experiments crossing *M. auratus*, which also has a diploid number of 44, with *M. brandti* has not resulted in offspring (Lyman and O'Brien, 1977) indicating that *M. brandti* is a separate

FIGURE 37.2 *Mesocricetus brandti* (Turkish hamster).

species from the Syrian hamster. Reproductive crosses between *M. brandti* and *M. newtoni* have resulted in viable offspring but they are sterile with underdeveloped reproductive organs also indicating that *M. brandti* is a separate species from the Romanian hamster (Lyman and O'Brien, 1977). Recent molecular characterization of subfamily *Cricetinae* shows that hamsters from the genus *Mesocricetus* are a distinct phylogenetic group of hamster species. Within this group *M. brandti* is most closely related to *M. newtoni* and these two species comprise a subclade which is well separated from the other subclade comprised of *M. auratus* and *M. raddei* (Neumann et al., 2006).

Anatomy, Physiology, Husbandry, and Breeding

M. brandti has a slightly rougher hair coat and a dark subaruricular band, otherwise it is very similar in appearance to *M. auratus* (Figure 37.2). *M. brandti* is larger than *M. auratus* and averages 163 grams (range 137–258 grams). Median lifespan is 670 days and animals have a tendency to become obese after the first year of life (Lyman and O'Brien, 1977). *M. brandti* hibernates when exposed to cold and is considered a more consistent hibernating species when compared to *M. auratus*. Longevity in *M. brandti* has been linked to hibernation (Lyman et al., 1981). Animals categorized as good or moderate hibernators showed a statistically significant increase in longevity compared to animals not exposed to cold. However, poor hibernators had a decreased longevity compared to animals not exposed to cold and aged animals, which were apparently healthy when exposed to cold for a third season, died within a short time frame after cold exposure. This study shows that many animals within a colony have an increased longevity when exposed to hibernation temperatures for part of the year, but this benefit may not occur in all individuals. In particular, aged animals may die within a short time period when exposed to hibernation conditions.

Husbandry and management of *M. brandti* is the same as that of *M. auratus*. They can be raised in shoebox-type cages with wood shavings. Young are born blind and hairless, but hair coat quickly comes in and eyes are open around 12–13 days. Young can be weaned around 20 days and can be group housed until about 6 weeks of age. After 6–7 weeks of age the animals become aggressive and must be singly housed (Lyman and O'Brien, 1977). Puberty occurs around 7–8 weeks of age but can be delayed particularly if animals are born in late summer and exposed to a natural light cycle. Peak fecundity occurs around 1 year of age (Lyman and O'Brien, 1977). Female estrous cycle is 4 days in duration. Males are placed with females during estrus and can be left for 3–4 days after which time the incidence of fighting increases and males should be removed (Lyman and O'Brien, 1977). Gestation is 15 days and litter size averages six pups. Cannibalism is common especially if females are disturbed. Ample bedding and darkness may help prevent cannibalism of newborn litters. *M. brandti* are photoperiodic seasonal breeders. Light cycle is critical for testicular and ovarian function. Light cycles of 15–17 hours of light are associated with normal reproduction. Light cycles less than 15 hours light or greater than 17 hours light are associated with testicular regression in males and anestrus cycles in females (Hong and Stetson, 1986; Ogilvie et al., 1992).

Diseases and Veterinary Care

Very little has been published regarding naturally occurring diseases of *M. brandti*. Fighting and traumatic injury are common in group housed hamsters older than 7 weeks of age and in males co-housed with females for longer than 4 days (Lyman and O'Brien, 1977). Other reported diseases included “wet tail” diarrhea which was controlled with tetracycline added to the drinking water and resolved over time with diet modification and dental malocclusion with upper and lower incisor overgrowth (Lyman and O'Brien, 1977).

Experimental Models

M. brandti is used as a model animal for hibernation studies (Bartness, 1990; Bartness et al., 1991; Darrow et al., 1987; Giedke and Pohl, 1985; Goldman and Darrow, 1987; Hall and Goldman, 1982; Hall et al., 1982; Okulicz et al., 1988; Papafrangos and Lyman, 1982; Spangenberg et al., 1995). *M. brandti* is easily bred and reared in research facilities and is a more reliable hibernator than *M. auratus* and it hibernates readily when exposed to cold temperatures (Lyman and O'Brien, 1977). Hibernation is characterized by 2–7 day bouts of torpor followed by 1–2 days of activity. Unlike marmot species which acquire large fat stores prior to hibernation, *M. brandti* stores food which

is consumed during periods of activity. *M. brandti* is a seasonally breeding mammal that is a photoperiodic long-day breeder so many research studies focus on the photoperiodic control of reproduction and the interplay of the photoperiodic control, hibernation, and gonadal regression (Badura and Goldman, 1992; Butler et al., 2008; Carter et al., 1982; Darrow et al., 1986; Fang and Jagiello, 1991; Gunduz and Stetson, 1998; Hong and Stetson, 1987, 1988; Hong et al., 1993; Jagiello et al., 1992; Myoga et al., 1991; Ogilvie and Stetson, 1990; Pevet, 1988; Stetson and Watson-Whitmyer, 1986). Other photoperiodic research study focus areas include circadian rhythm studies and retinal studies (Albers et al., 1983; Pohl 1985, 1987; Williams and Jacobs, 2008; Youngstrom and Nunez, 1986).

Another major research focus for *M. brandti* relates to behavioral studies (delBarco-Trillo et al., 2009a, 2009b; Heth et al., 1999; O'Connell, 1983). *M. brandti* in the wild are solitary nocturnal animals and in captivity fighting is common in adult animals requiring single-animal housing. Behavior studies tend to focus on odor cues that allow animals to distinguish kin, species, and even familiar animal exposure. Other areas of use include infectious disease studies in which it was found that *M. brandti* can harbor *Yersinia pestis* (Karimi, 1980). *M. brandti* has also been used as a model for transmissible spongiform encephalopathy when inoculated intracranially with 263K scrapie agent (Meade-White et al., 2009). Other research studies with *M. brandti* examine estrogen-induced hepatic injury, estrogen-initiated renal carcinogenesis, and amyloidosis (Coe and Ross, 1988; Coe et al., 1997).

CRICETULUS MIGRATORIUS (ARMENIAN HAMSTER)

Taxonomy, History, and Genetics

Cricetulus migratorius is also known as the Armenian hamster, gray hamster or gray dwarf hamster. The Armenian hamster can be found in regions that overlap with the habitat of the Chinese hamster (*Cricetulus griseus*), but its geographic distribution is quite broad, extending from Balkan regions in western Europe through the middle of Asia, including southern Russia, Turkey, Iraq, Iran, and Afghanistan to western China (IUCN, 2008). This hamster prefers a semidesert environment, inhabiting the steppes, dry grasslands, and desert regions with limited vegetation. However, it is also been found in the foothills of south-east Bulgaria where the habitat includes field crops and pastures (Milchev, 2009).

This species was brought to the United States from the former Soviet Union and first used in cytogenetic studies in the mid 1960s as a complement to ongoing studies in the Chinese hamster, *C. griseus* (Yerganian and Papoyan,

FIGURE 37.3 *Cricetulus migratorius* (Armenian hamster).

1964). The Armenian hamster has a diploid chromosome number of $2N = 22$, and cytogenetic analysis revealed the X and Y chromosomes are isomorphic, sub-telocentric, and practically indistinguishable from each other (Gharkheloo, 2006; Yerganian and Papoyan, 1964). Even though the karyological data of the Armenian hamster are similar to those of the Chinese hamster, recent DNA-based phylogeny of the subfamily Cricitinae revealed a lack of monophyly within the genus *Cricetulus* (Neumann et al., 2006). Analysis of DNA sequences from two mitochondrial genes and one nuclear gene places *C. migratorius* outside of the genus *Cricetulus* and within a separate but related group that includes *Tscherskia*, *Cricetus*, and *Allocricetulus*. Multiple inbred strains of the Armenian hamster had been developed for genetic and genotoxic investigations. A characteristic of some of the inbred strains was a late-onset, progressive autoimmune disease without neoplasia (Yerganian et al., 1978). Outbred stocks and some inbred strains are currently available commercially.

Anatomy, Physiology, Husbandry, and Breeding

C. migratorius weighs from 33–80g (average 45 grams), has gray dense fur with a cream belly and a short tail (Figure 37.3). The husbandry for this species is similar to that used to care for Syrian and Chinese hamsters. Armenian hamsters reach sexual maturity at about 50 days of age. The estrous cycle, like that of other hamsters, is from 4–4.5 days. Males and females are paired prior to weaning, and males are removed from the cage prior to parturition. Gestation averages 19 days (range from 16–21 days) and litter size ranges from 5–7 pups. The reproductive life of females is about 1½ years and that of the male is about 2 years.

Diseases and Veterinary Care

Armenian hamsters are hardy and spontaneous diseases are uncommon. *Demodex cricetuli* is a mite found in the hair follicles that can induce clinical signs of alopecia and dermatitis (Hurley, and Desch, 1994). Armenian hamsters carry a myriad of intestinal protozoa, including trichomonads, which are likely commensals for the hamster, but have been documented to be transmissible to sentinel mice that were housed on soiled bedding from hamster cages (Lipman et al., 1999).

Experimental Models

Use of the Armenian hamster in biomedical research is primarily in studies of cytogenetics and infectious disease. This hamster is susceptible to many mutagens, carcinogens, and oncogenic viruses. Cells from *C. migratorius*, when recovered for primary in vitro cultures, frequently remain in euploidy, a feature that enhances use for mutagenic studies (Yerganian, 1972). The low diploid number ($2N = 22$) and large chromosome size facilitated analysis of insults from genotoxic agents. Much of the toxicological literature compares the relative susceptibility and resistance of the Chinese as well as the Armenian hamster to mutagens (Gad, 2007). Limited studies have demonstrated that Armenian hamsters develop hepatocellular injury and carcinoma from chronic exogenous estrogen exposure (Coe et al., 1990, 1998).

With the recognition of the susceptibility of the Syrian hamster to experimental infection with prion agents from ruminant diseases (scrapie and cervid wasting disease), there are several studies that compare the susceptibility of *C. migratorius* to wild-type and hamster-passaged prion strains. These studies were performed to not only develop new rodent models of disease (Raymond et al., 2007), but also to investigate the molecular events associated with cross-species transmission of the prion protein, that is transmission of the prion protein from the natural ruminant host to another mammalian species. In the latter study, six hamster species, including the Armenian hamster and the Chinese hamster were infected with a Syrian-hamster-passaged scrapie prion (Meade-White et al., 2009). The authors used these two *Cricetulus* species because of apparent taxonomic relatedness, but many characteristics of the induced disease and protein profiles of the prions recovered from infected hamsters were quite different.

Interspecies mouse:Armenian hamster hybridoma clones that produced hamster monoclonal immunoglobulins were first described by Sanchez-Madrid et al. (1983). Armenian hamster monoclonal antibodies are now common reagents for immunologic assays.

MESOCRICETUS NEWTONI (ROMANIAN HAMSTER)

Taxonomy, Physiology, and Genetics

Mesocricetus newtoni is known by its common name, the Romanian hamster. This hamster has a small range in the lowlands of northern Bulgaria and Romania where scrubby, rocky steppes and dry grassland make up the habitat. Recent surveys conclude that the wild populations are vulnerable and likely declining (IUCN, 2008). This hamster has been highlighted as a small European mammal that should be targeted for conservation efforts such as habitat improvement and local captive breeding for re-introduction (Gippoliti and Amoru, 2007).

Morphologic and physiologic similarities between *M. newtoni* and *M. auratus* resulted in early genetic studies, including karyotypic analysis as well as intercross breeding experiments. *M. newtoni* has a diploid number of chromosomes $2N = 38$, while *M. auratus* has $2N = 42$ (Yigit et al., 2000). Breeding *M. newtoni* males with *M. auratus* females resulted in hybrids with a $2N$ of 41 (Raicu et al., 1969; Todd et al., 1972). Hybrid males were infertile, but hybrid females ranged from expressing behavioral estrus with no conception to fertile matings with *M. auratus* male hamsters. Successful production of hybrids was also accomplished with mating of male *M. brandti* (the Turkish hamster) with *M. newtoni* females. When given choices of male hamsters of different species, female *M. newtoni* preferred *M. brandti* males over *M. auratus* males (Murphy, 1977). Not only did these studies help evaluate behavior related to sympatric evolution, but also outcomes of mixed mitochondrial populations in cells from hybrid hamsters.

More recent studies verify the genetic separation demonstrated by behavioral preferences between *M. newtoni* and *M. auratus*. DNA sequence data from two mitochondrial genes and one nuclear gene reveal greater genetic separation from *Mesocricetus auratus* than anticipated by morphologic data. *M. newtoni* and *M. brandti* are in a subclade separate from that of *M. auratus* and *M. raddei*. Their habitat is geographically separated as well, and the split from *M. auratus* likely happened in the upper Pliocene epoch (Neumann et al., 2006).

Anatomy, Husbandry, and Breeding

The Romanian hamster has brown fur on the dorsal side and a white belly. There is a dark stripe that extends from the top of the head to the neck. Dark stripes also start along each cheek and above the forearms and extend to the shoulder. The head has a pointier nose than the closely related *M. auratus* even though the shape of the nasal portion of the skull is not narrower. The length

from nose to rump is 180 mm and its weight ranges from 80–115 grams (Musser and Carleton, 2005). Like other members of the *Mesocricetus* genera, *M. newtoni* has cheek pouches for carriage of food, bedding, and offspring. Hamsters reach puberty when about 56–70 days of age. Management of breeding colonies is similar to the husbandry practices for *M. auratus*. The Romanian hamster has a 15–16-day gestation and gives birth to litters that range from one to 11 pups.

INTRODUCTION

Chinchillas are a recent and relatively specialized addition to the biomedical research armamentarium. Considering use of the species in Pubmed-published articles as a reasonable reflection of all biomedical research use, their representation can be followed through the years.

Articles from the 1940s through the early 1960s focused on basic descriptive biology and clinical medical conditions, especially spontaneous infectious diseases. One of the earliest listed prospective studies using chinchillas appeared in 1952. That study assessed vitamin requirements and referenced only four pertinent articles involving chinchillas (King and Orcutt, 1952). Of those articles, two related to breeding and the others reflected captive management and anatomy. The King and Orcutt article also provided situational perspective on chinchilla research by explaining that breeding pairs cost over \$1000 and thus limited their use. Adjusted for inflation, this equates to over \$8000 a pair in 2009 prices.

Chinchillas appear in a variety of studies in the later 1960s and early 1970s with research related to the auditory system appearing among vaccine, radiologic, reproductive, and other studies. Late in the 1970s, chinchillas appear to have become established as an important model in acoustic research based on the rapid increase in frequency and numbers of published papers involving their use. Research related to the auditory system remains as the primary field utilizing chinchillas as experimental models.

TAXONOMY

Evolutionary History

As members of the Order Rodentia, the family Chinchillidae is represented in the fossil record from early in the Oligocene epoch, nearly 34 million years ago (Hartenberger, 1985; Patterson and Pascual, 1968). The group arose in the Patagonian region of the South American continent and while having once expanded

in species diversity and geographic distribution, the evolutionary record suggests that both decreased by the Pliocene epoch approximately 5 million years ago (Patterson and Pascual, 1968).

Classification

The Chinchillidae are hystricomorphous rodents. Anatomical adaptations within Rodentia accommodating bite force and jaw mobility have followed several paths of masseter muscle modification. The hystricomorphous condition is characterized by a portion of the masseter muscle passing through greatly enlarged infraorbital foramina. Other well-known hystricognath rodents include the guinea pig (*Cavia porcellus*) and the Old World and New World porcupines (e.g. *Erethizon dorsatum*, the North American porcupine) (Animal Diversity, 2009).

Modern examples of Chinchillidae were first scientifically described as *Mus laniger* by Molina in 1782 (Osgood, 1941; Sanborn, 1926; Woods and Kilpatrick, 2005). Osgood's review suggested that Molina based this speciation on a composite of non-living material from several species (Osgood, 1941). The genus was changed to *Chinchilla* by Bennett following study of skins and living specimens in London Zoo. Bennett also adapted Molina's species terminology as *C. lanigera* and further recognized that the species group belonged in a unique Family and coined the name Chinchillidae in 1833 (Osgood, 1941).

The species representatives within this Family and Genus have a long history of uncertainty (Bennett, 1835; Bidlingmaier, 1937; Bowen and Jenkins, 1988; Partington, 1836; Spotorno et al., 2004b). In 1937, Bidlingmaier condensed what had previously been described as four chinchilla species into three (Bidlingmaier, 1937). Less than 10 years later, Osgood supported a single species (Woods and Kilpatrick, 2005); yet, some authors were describing three species as late as 1969 (Bowen and Jenkins, 1988). A recent effort to resolve the chinchilla species number examined mitochondrial DNA of both wild and domestic representatives. While the number of individuals sampled was limited, there was clear evidence for there being two rather distantly related chinchilla species. (Spotorno et al., 2004b). The two species of chinchilla are the long-tailed chinchilla, *Chinchilla lanigera*, and the short-tailed chinchilla, *Chinchilla chinchilla* (Woods and Kilpatrick, 2005) (Figure 38.1). Unfortunately these are still frequently designated as *C. laniger* and *C. brevicaudata*, respectively.

It is currently believed that the Family Chinchillidae consists of six species in three genera. In addition to *Chinchilla* with two representatives, Chinchillidae has living specimens of *Lagidium* and *Lagostomus* which are the mountain vaschacha with three species and the

plains vaschacha with a single species, respectively (Animal Diversity, 2009; ITIS, 2009; Vanderlip, 2006). This is surprisingly consistent with the earliest descriptions of the group (Bennett, 1835; Partington, 1836).

Geographical Distribution

The Chinchillidae developed in and are currently limited to the western reaches of South America. The historical range of chinchilla was arid, rocky, and sandy areas of the Andean mountains of modern countries Chile, Bolivia, and Peru. The evidence indicates that the short-tailed chinchilla occupied the more northerly areas from central Chile to Peru, the long-tailed chinchilla occupied central Chile, with some overlap of the two ranges near present-day Potrerillos, Chile. The precise ranges are not well characterized as the populations were severely decimated prior to ecological study and persistent disagreement about how many different species existed (Jiménez, 1996).

Both chinchilla species are "critically endangered" in the wild, the last step before extinction (IUCN, 2009). Both species are listed in the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) Appendix 1 (CITES, 2009). The short-tailed chinchilla was recently believed to be extinct having not been seen in the wild after 1953 (Jiménez, 1996). However, tissue samples collected from wild representatives for a recent genetic study indicate that some still survive (Spotorno et al., 2004b). A survey of wild long-tailed chinchillas in 1996 located 42 colonies in two areas of Chile (IUCN, 2009). Despite legal protection since 1929, wild populations continue to decline even in a Chilean national park created specifically for their protection (Spotorno et al., 2004a). While the pressures on chinchilla populations are not fully understood, continued trafficking in pelts is reportedly involved (Spotorno et al., 2004b; Vanderlip, 2006).

HISTORY

Origin

Early Spanish explorers noted that the Chincha Indians used chinchilla meat and fur (Vanderlip, 2006). This association is believed to have been the origin of the Genus name. In the Chincha Quechaun language, the words for silent, *chin*, and courageous or strong, *sinchi*, formed the basis for the name. The Spanish diminutive word suffix, *lla*, was added to complete it (Bowen and Jenkins, 1988; Vanderlip, 2006). The genus name may have actually originated as a derivative of the country of origin as that is the explanation given just 3 years after the fact (Partington, 1836).

The fur industry has been both bane and salvation for the chinchilla. The Spaniards took furs to Spain in the 18th century and commercial harvest began in earnest in 1828 (Jiménez, 1996). Early in the 19th century, chinchilla were described as “very abundant” (Partington, 1836); however, further expansion of the fur trade late in that century decimated the chinchilla populations. Fur exports decreased from about 700 000 in 1900 to 24 600 in 1910 despite rapidly increasing fur prices, demonstrating the disappearance of the chinchilla (Bowen and Jenkins, 1988; Jiménez, 1996). A regional agreement in 1910 was enacted to protect the chinchilla. Further legislation followed in 1929 but there was no practical enforcement of these protections prior to the 1970s (Jiménez, 1996).

Domestication

Practical continuation of a fur trade required domestic cultivation. A popular-press natural history article written by a curator of the Field Museum of Natural History indicated that Chilean efforts to raise them in captivity were not going well. Chinchillas fought and killed each other during breeding, litters were killed by parents, and young were attacked by unrelated adults (Sanborn, 1926). Mathias F. Chapman, a US mining engineer working in Chile, contracted for the collection of a few animals from the wild. Chinchilla were so scarce in the early 1920s that it required several years to acquire a small group of individuals (Bowen and Jenkins, 1988). Chapman imported 12 chinchillas (11 wild-caught and one born in transit) into southern California in 1923. Chinchillas were protected in Chile at that time and an exportation permit does appear to have been secured (Bowen and Jenkins, 1988; Parker, 1975).

While not a furrier himself, Chapman’s nascent chinchilla colony was supported by the US fur industry from its origin. However, domestic maintenance was again confronted with extensive challenges. Basic feeding and housing methods had to be developed

and no offspring were produced for several years. Domestic cultivation was further hindered by the Great Depression and Chapman’s death in 1934 (Bowen and Jenkins, 1988). Continued production by Chapman’s family was extremely poor with colony size increases of only about 37% per year in the late 1920s, 65% per year in the early 1930s and only doubling by the late 1930s in the absence of any production for furs (Parker, 1975).

Through the 1940s and early 1950s domestic colonies could not support a chinchilla fur industry. That period represented a speculative market of breeding stock; breeding pairs were so expensive they were often purchased by owner conglomerates. The first organized sale of chinchilla pelts occurred on June 21, 1954. Prices were far below expectation and the ensuing collapse of the breeder market led to dispersion of chinchillas to other parts of the world (Bowen and Jenkins, 1988).

Following the shake up, chinchilla farming entered into a period of slow development of fur quality and colony management for productive cultivation. There is no recorded history describing the process of chinchillas becoming available for biomedical research. One prominent vendor’s experience is probably typical (Moulton, 2010). In that case, after approximately 10 years as a fur farm, the facility was contacted in 1975 by a research organization seeking chinchillas. Over time, the business slowly converted from fur farming to that of a research vendor, based on demand. That vendor development process seems to reflect the current state of affairs, as well.

Genetics

Genetic information commonly associated with research rodents does not exist for chinchillas. No genetic information related to chinchillas could be found in the biomedical research literature in preparation of this chapter. There are no chinchilla “breeds” as the term is usually applied but color varieties are now common. Sporadic color mutations were reported in the 1940s but none were commercially developed. The first persistent color variety was with white fur in the mid-1950s, followed by black and brown fur types in the late 1950s. There was a wide expansion of color varieties in the 1960s but none were commercially viable by late in that decade (Bowen and Jenkins, 1988). Coat color genetics are not well-described in the scientific literature. Popular press sources indicate that the basis of color is in five dominant and four recessive mutations each with various phenotypic and genotypic designations (Trochinchillas, 2009).

While no specific genetic features of chinchillas are noted in biomedical research, there are issues related to domestication that could impact this species’ application to some types of research. Although these issues

are not scientifically well-documented, biomedical researchers should not discount them without due consideration. These issues are: first, the readily available and widely reported story about the domestic chinchilla industry says that it was founded on only 12 animals (three female and nine male) and this tightly restricted gene pool could have importance; and second, the domestic chinchilla may be an interspecies hybrid.

Clearly the original introduction of chinchillas into the US was of 12 individuals (Bowen and Jenkins, 1988; Parker, 1975; Spotorno et al., 2004a, 2004b; Vanderlip, 2006). Sources routinely state that these were the only introductions and that all current chinchillas are descendants of those 12 (e.g., Spotorno et al., 2004a; Vanderlip, 2006; and routinely in pet chinchilla popular press). However, two books describing the early domestication, by those close to the events, fail to note this limited source (Bowen and Jenkins, 1988; Parker, 1975). While such an omission is weak evidence, Parker further indicates his own association with efforts to capture wild chinchillas near Lampa, Chile in the 1960s (Parker, 1975). Although not indicating any collection success, the author does not indicate that the effort was out of the ordinary. One source that says all chinchillas are derived from the Chapman group also indicates that 10–50 chinchillas were imported per year up until the 1950s, although without attribution (Vanderlip, 2006). In all likelihood, domestic chinchillas were derived from a reasonably large pool of individuals captured and imported over many years and the story about them all being derived from the Chapman group is a widely reported quaint story perpetuated due to a lack of readily available contradicting evidence.

The second problem of domesticated chinchillas potentially being an interspecies hybrid may have validity. Statements to that effect appear in both popular press and scientific literature (Chincare, 2009; Jiménez, 1996), while other sources express doubts (Spotorno et al., 2004a). It is generally believed that the Chapman animals were all long-tailed chinchillas (Vanderlip, 2006); however, they were captured in the region of Chile where the species may have had overlapping ranges (Spotorno et al., 2004a). Indeed, early breeders believed they were dealing with multiple species (Bowen and Jenkins, 1988) and a recent book indicates that the US population currently includes both species (Vanderlip, 2006). On the basis of the short-tailed chinchilla having a number of advantageous characteristics over the predominant long-tailed chinchilla, there are clear descriptions of cross-breeding efforts. This was an arduous process complicated by male F1 sterility and 25% sterility of male offspring when F1 females were bred to males of either species. Bowen indicates that while body size, fur quality, and disposition were desirable, smaller litter sizes and general difficulty in

generating the hybrid rendered the idea unsustainable (Bowen and Jenkins, 1988). Hybridization was not commercially successful; however, it was biologically successful. Given the high economic value of chinchillas, the positive attributes of the hybrids, and the general confusion about speciation, if the hybrids were capable of contributing to the growth of the industry, they certainly did so. Both early and recent authors indicate phenotypic differences between domestic and wild chinchillas (Bowen and Jenkins, 1988; Spotorno et al., 2004a). While active selection for production would likely account for differences, Bowen attributes some of the difference to residual effects of the active hybridization programs (Bowen and Jenkins, 1988). A recent genetic study was conducted to clarify chinchilla speciation and the authors concluded that there was no evidence for either domestic long-tailed or short-tailed chinchillas being hybrids (Spotorno et al., 2004b). However, the study had several limitations to an authoritative conclusion to that question. All chinchillas sampled were from Chile and may not have been representative of stocks typically used in biomedical research. Also, the study sampled two short-tailed and five long-tailed chinchillas from single breeders and the limited sample size may have been insufficient to detect genetic contamination. Further, the study analyzed mitochondrial *Cytochrome b* sequences as the basis for comparison and the maternal lineage of mitochondrial DNA would support a further need for larger sample sizes in such a study. While evidence of interspecies hybridization remains sparse, biomedical researchers should remain cognizant that residue genetic contamination may persist and maintain awareness of this potential complication.

INTRODUCTION

Chinchillas possess several key anatomic, physiologic, and behavioral characteristics which in many ways are adaptations derived from their evolution in the high Andean mountains of South America. As a consequence, chinchillas are useful animal models for a number of human diseases. This chapter discusses certain features in detail, while treating other attributes only briefly, so that key differences can be explored in sufficient detail while leaving other sources to discuss systems in common with other mammals.

EXTERNAL FEATURES

Chinchillas weigh an average of 400–600 grams (Hillyer and Quesenberry, 1997; Hoefer 1994), although they can weigh up to 800 grams (Riggs and Mitchell, 2009). Females generally weigh more than males of the same age (Hillyer and Quesenberry, 1997; Johnson-Delaney, 1998; Strake et al., 1996; Williams, 1976). Their bodies, about 12–14 inches long (Medow, 1969), are short, stocky, and compact (Hillyer and Quesenberry, 1997; Riggs and Mitchell, 2009), with comparatively long, delicate limbs (Hillyer and Quesenberry, 1997;

Riggs and Mitchell, 2009). The front limbs are shorter than the longer, more muscular, powerful back limbs (Donnelly and Quimby, 2002; Lyon, 2003; Nowak, 1999). The front feet possess four digits (digits 2, 3, 4, and 5) as digit 1 is not present. The hind feet possess three normal digits (digits 2, 3, and 4), with digits 1 and 5 being small and rudimentary (Kraft, 1987; Lyon, 2003). Each toe has a small, short claw (Hillyer and Quesenberry, 1997; Hrapkiewicz and Medina, 2007; Williams, 1976). There are stiff bristles on the digits of the rear feet, which may be used for grooming (Nowak, 1999). The palmar and plantar surfaces of their feet are furless (Hillyer and Quesenberry, 1997; Hoefer 1994; Hrapkiewicz and Medina, 2007; Nowak, 1999). The toe pads are irregularly shaped, prominent, and extend to the hock on the rear feet (Williams, 1976). The tail is about 4–5 inches long (Medow, 1969), and bushy, with coarse fur (Hillyer and Quesenberry, 1997; Hrapkiewicz and Medina, 2007; Riggs and Mitchell, 2009; Williams, 1976). It curls towards the body, and is normally carried high (Hillyer and Quesenberry, 1997) and erect (Lightfoot, 1999).

Chinchilla fur is soft and thick (Hillyer and Quesenberry, 1997; Hrapkiewicz and Medina, 2007). The density of the body fur is due to the large number of hairs which emerge from one opening. There are an average of 50–60 hairs, with a maximum of 75 (Hoefer and Crossley, 2002; Wilcox, 1950), emerging as a cluster from each opening. In each cluster there is one central “guard hair” approximately 12–15 μm in diameter. Surrounding the “guard hair” are two lateral bunches of “wool hairs”, each approximately 5–11 μm in diameter. The “guard” and “wool” hairs have no bulb at their base. There is a single erector pili muscle attached to each cluster. For each cluster, 3–4 sebaceous glands serve the “wool hairs” and one sebaceous gland serves the “guard hair” (Wilcox, 1950). On the tail, hairs all emerge separately, although they are arranged in groups of 3–8 hairs. On the pinna, hairs also emerge separately, and are not grouped (Wilcox, 1950). Each hair is approximately 2–4 cm long (Bennet, 1835), and has three color areas. The tip is black, and the longer the tip, the darker the animal’s appearance. Proximal to the tip is a clear/unpigmented bar, about 1/8–3/8 inch long. From the bar to the root is the rest of the hair, which has the animal’s undercoloring (Medow, 1969). In the wild, the original coloring was mottled yellow-gray. Through selective breeding, the natural color is now blue-gray (Donnelly and Brown, 2004) or silver gray with black ticking (Hillyer and Quesenberry, 1997; Riggs and Mitchell, 2009) and yellow under parts (Hillyer and Quesenberry, 1997). There are color mutations of white, silver, black, and beige, and the fur and pet trades have led to the development of more colors and variations (Hillyer and Quesenberry, 1997). Beige, white, and ebony are inherited via dominant genes, and sapphire,

violet, and velvet are inherited via recessive genes (Donnelly and Brown, 2004). The fur colors are beige (blond, pearl, pastel); white (Wilson white, white mosaic, silver, platinum, pink white, apricot); violet (Afro violet, Rhodesian violet, German violet); sapphire; charcoal (pastel charcoal, sapphire charcoal, violet charcoal); ebony (brown ebony, chocolate ebony, pastel ebony); and velvet (black velvet, brown velvet, pastel velvet, blond velvet) (Donnelly and Brown, 2004). Coulton (1989) provides a detailed explanation of chinchilla coat color heredity. The fur coat grows in waves from the head caudally, and a pale bar line in the fur indicates its stage of growth (Hrapkiewicz and Medina, 2007; Williams, 1976).

The head of the chinchilla is large relative to its body (Donnelly and Quimby, 2002; Hrapkiewicz and Medina, 2007; Riggs and Mitchell, 2009). Interestingly, one study found that the average skull size of captive-bred chinchillas was significantly larger (16% longer and 6% wider) than the average skull size of wild-caught chinchillas (Crossley and del Mar, 2001). The eyes are large (Donnelly and Quimby, 2002; Hillyer and Quesenberry, 1997; Hrapkiewicz and Medina, 2007), within a shallow bony orbit (Hillyer and Quesenberry, 1997; Hoefer and Crossley, 2002; Williams and Kern, 2008). The cornea is also large relative to the size of the globe and palpebral fissure (Peiffer and Johnson, 1980), which is characteristic of a nocturnal animal (Donnelly and Brown, 2004). There are fine cilia on the upper and lower lids, and the medial canthus has a fleshy caruncle (Peiffer and Johnson, 1980). The eye also has a poorly developed nictitating membrane (Peiffer and Johnson, 1980; Williams and Kern, 2008). The pupil is a vertical slit (Hoefer and Crossley, 2002; Peiffer and Johnson, 1980; Williams and Kern, 2008). When relaxed, the pupil is a vertical ellipse, which contracts to a fine slit with a teardrop end, and then finally to complete closure (Donnelly and Brown, 2004). The iris is heavily pigmented (Donnelly and Brown, 2004; Hoefer and Crossley, 2002; Williams and Kern, 2008), appearing dark brown (Peiffer and Johnson, 1980). The dark iris and slit-like pupil help the animal cope with their behavior of basking in bright sunlight at their natural high altitudes (Donnelly and Brown, 2004). The chinchilla also has large ears (Donnelly and Quimby, 2002; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007; Riggs and Mitchell, 2009; Strake et al., 1996; Williams, 1976), which have been described as “bat-like” (Hoefer 1994; Strake et al., 1996; Williams, 1976). The pinnae are thin (Hoefer 1994; Hoefer and Crossley, 2002; Strake et al., 1996; Williams, 1976) and pigmented (Williams, 1976), with sparse fur. The chinchilla has long vibrissae (Hillyer and Quesenberry, 1997; Hrapkiewicz and Medina, 2007; Williams, 1976) on either side of the upper lip (Hoefer and Crossley, 2002). The vibrissae are independent sensory hairs, with a

bulb and papilla, which resemble a typical hair follicle. They are approximately 100–130 mm long, strong, and abundant (Wilcox, 1950). The chinchilla, being nocturnal, uses these to find its way in the dark (Hoefer and Crossley, 2002). The chinchilla mouth is small (Riggs and Mitchell, 2009).

Only the female chinchilla has mammary glands and teats, with three pairs (Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007). There are two thoracic pairs and one inguinal pair (Donnelly and Brown, 2004; Johnson, 2006; Nowak, 1999; Weir, 1974), although the caudal thoracic pair has been referred to as an abdominal pair (Yu and Anderson, 1975). The number of galactophores per teat varies. The cranial thoracic pair has two per teat, the inguinal pair has one per teat, and the caudal thoracic (or abdominal) pair can have one or two per teat (Yu and Anderson, 1975). During lactation, the area around the teats loses fur (Spotorno et al., 2004).

The female chinchilla has a large, prominent cone-shaped urogenital papilla (clitoris/urethral cone/urinary papilla) (Hillyer and Quesenberry, 1997; Hoefer 1994; Hrapkiewicz and Medina, 2007; Strake et al., 1996; Williams, 1976). It can be manually extruded through the urethral orifice (Donnelly and Brown, 2004), and, due to its size, may be mistaken for the prepuce/penis (Donnelly and Brown, 2004; Hillyer and Quesenberry, 1997; Hoefer 1994; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007). The urethral orifice sits within the urogenital papilla (Hoefer and Crossley, 2002), but the chinchilla female has a separate vaginal opening between the urethra and the anus (Hrapkiewicz and Medina, 2007; Kraft, 1987; Strake et al., 1996). The vulva is immediately caudal to the urogenital papilla (Hillyer and Quesenberry, 1997; Hoefer 1994; Strake et al., 1996; Williams, 1976). It is slit-like, but oriented transversely/horizontally to the body's craniocaudal axis (Hillyer and Quesenberry, 1997; Kraft, 1987). The vulva has no labial folds (Kraft, 1987; Lyon, 2003). There is a vaginal closure membrane present except during estrus and parturition (Hoefer 1994; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007; Johnson-Delaney, 1998; Strake et al., 1996; Williams, 1976). The vaginal closure membrane is sturdy, and the opening and the perforation and sealing are distinct. The perforation and sealing usually take 2–4 days, but can occur over 12 hours (Weir, 1974). When the vaginal closure membrane is present, the urethral orifice can be mistaken for the vulva. The membrane-covered vaginal orifice can be distinguished by a slightly raised semicircular area (Hillyer and Quesenberry, 1997). When the vaginal closure membrane is absent close to parturition, the vagina takes on a bluish hue (Strake et al., 1996).

Because the external genitalia of females and males appears similar (Hrapkiewicz and Medina, 2007),

the anogenital distance is the best criterion for sexing chinchillas (Brower, 2006; Hillyer and Quesenberry, 1997; Strake et al., 1996). The male's anogenital distance, between the penis and the anus, is approximately 1–1.5 cm (Hillyer and Quesenberry, 1997), which is about twice the anogenital distance in females (Hrapkiewicz and Medina, 2007; Johnson-Delaney, 1998; Strake et al., 1996; Williams, 1976). An additional distinguishing feature is that the penis is larger than the clitoris. Also, the extruded penis can be separated and distinguished from the prepuce, while the extruded clitoris tends to evaginate and the prepuce is not apparent (Donnelly and Brown, 2004). Also, compared to the female, the male chinchilla has a larger genital papilla (Hrapkiewicz and Medina, 2007; Merry, 1990).

The penis normally sits in an s-shape when in the retracted position (Kraft, 1987; Lyon, 2003; Weir, 1974). It originates with two supports in the pelvic region which fuse together to point caudally; and it then bends in a cranial and ventral direction, then turns again to point posteriorly (Kraft, 1987). The glans penis terminates just below the anus, and the prepuce/foreskin extends nearly to the anus (Kraft, 1987; Lyon, 2003). The glans is partially covered with small horny spines, which point backwards, towards the body (Kraft, 1987; Spotorno, 1979). There is also a supporting bone/baculum (Strake et al., 1996), approximately 1 cm long within the penis (Kraft, 1987; Lyon, 2003). The penis may be manually extruded (Strake et al., 1996), and measures 1–2 cm (Hillyer and Quesenberry, 1997). There is no true scrotum (Brower, 2006; Donnelly and Brown, 2004; Hoefer 1994; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007; Johnson-Delaney, 1998; Merry, 1990; Strake et al., 1996; Weir, 1974; Williams, 1976), and the genital papilla is separated from the anus by bare skin (Hillyer and Quesenberry, 1997; Weir, 1974). The inguinal canal is open, and the testes remain in the abdomen or are subcutaneous in the anal region (Brower, 2006; Donnelly and Brown, 2004; Hoefer 1994; Hrapkiewicz and Medina, 2007; Johnson-Delaney, 1998; Strake et al., 1996; Williams, 1976). The caudal epididymus can drop into two small external sacs (postanal sacs) (Donnelly and Brown, 2004; Weir, 1974). However, if the male is close to a female in estrus, his testes swell and become easier to observe (Strake et al., 1996).

UNIQUE BIOLOGICAL CHARACTERISTICS

The organ systems of the chinchilla are essentially similar to those of most other mammals. They do, however, have unique biological attributes which may either influence approaches to their medical care or demonstrate their value as research animals.

Reproductive System

Anatomy

The chinchilla's ovaries are 6–8 mm long (Riggs and Mitchell, 2009), approximately 0.3 g each (Kraft, 1987), and located lateral and caudal to the kidneys (Bennett and Mullen, 2003). The ovaries are smooth in the immature chinchilla, but as she reaches sexual maturity, small lumps form on the ovary surface, due to eggs migrating to the surface (Kraft, 1987; Lyon, 2003). The oviduct has an ampule-like enlargement with a strongly developed longitudinal fold where the eggs are fertilized after ovulation (Kraft, 1987). The chinchilla has two uterine horns, each with a separate internal os (Hoefer 1994; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007; Strake et al., 1996; Williams, 1976), and two cervixes (Spotorno, 2004). Each uterine horn is approximately 6 cm long (Kraft, 1987), and the vagina is approximately 1.5 cm long (Kraft, 1987).

The chinchilla's testes are approximately 2.0–2.5 cm long (Kraft, 1987; Strake et al., 1996) $\times$ 1 cm, and approximately 2.6 g each (Kraft, 1987). The epididymus is lateral to the testis (Kraft, 1987). The testes are relatively large (Weir, 1974), and the gonadosomatic index (testes mass/body weight) in the adult chinchilla is relatively high compared to most mammals, but is similar to rats and mice (Leal and França, 2008). The chinchilla testis has a high seminiferous tubule volume and density (Leal and França, 2008). There is also a seasonal variation in testis volume, with a reduced volume in the summer (Busso et al., 2005). The male accessory sex glands include seminal vesicles (Williams, 1976), prostate gland, and bulbourethral glands (Kraft, 1987). The seminal vesicles/spermatocystic glands/deferentio-vesical glands are long (Kraft, 1987; Weir, 1974), tubular (Williams, 1976), and branched (Kraft, 1987). The ducts from the seminal vesicles enter the urethra along with the vas deferens from the testes/epididymus (Kraft, 1987; Weir, 1974). The prostate's presence is variable (Adaro et al., 1999). When present, it consists of two triangular reddish brown lobes approximately 1–2 cm $\times$ 0.5 cm. The lobes are lateral and dorsal to the urinary bladder and proximal urethra. The ducts open into the urethra close to the vas deferens (Kraft, 1987). The bulbourethral glands/Cowper's glands/bulb of urethra glands are reddish, round (Kraft, 1987), and approximately 5–6 mm diameter (Cepeda et al., 1999; Kraft, 1987). They are covered by a capsule consisting of dense connective tissue and striated muscle (Cepeda et al., 1999). They are located below the root of the tail, lateral to the rectum and dorsal to the urethra (Kraft, 1987).

Physiology

Females are seasonally polyestrous (Donnelly and Quimby, 2002; Hrapkiewicz and Medina, 2007; Webb,

1991), even in captivity (Weir, 1974), but males produce spermatozoa of similar quality continuously (Busso et al., 2005) and are fertile throughout the year (Weir, 1967). The breeding season in the southern hemisphere is May to November (Nowak, 1999), and in the northern hemisphere, it is November to May (Donnelly and Quimby, 2002; Webb, 1991). Estrous cycles may be irregular (Williams, 1976), with a range of 30–50 days (Donnelly and Quimby, 2002; Hoefer 1994; Hrapkiewicz and Medina, 2007; Kuroiwa and Imamichi, 1977; Webb, 1991; Weir 1967; Williams, 1976). Estrus is 2–3 days long (Weir, 1967), and ovulation is usually spontaneous (Hrapkiewicz and Medina, 2007). Several eggs mature and are ovulated simultaneously (Kraft, 1987; Lyon, 2003). The age at which chinchillas reach sexual maturity varies, depending on when they are born (Weir, 1974). Chinchillas born in spring breed in the fall of the same year. Those born in the fall first breed a year or more later (Williams, 1976). Thus, they reach puberty at 4–12 (Hoefer, 1994), or 18 months (Williams, 1976). Hence, the age of vaginal opening in the female ranges from 71–308 days (Kuroiwa and Imamichi, 1977). The placentation type is hemoendothelial (Williams, 1976).

Urinary System

Anatomy

The kidneys are approximately 18 $\times$ 13 $\times$ 5 mm, and 1 g (Kraft, 1987). They have a relatively thick medulla compared to the cortex (Prong et al., 1969), and the ratio has been measured as 5.6: 1 (Díaz and Cortés, 2003). The kidneys have elongated renal papillae (Díaz and Cortés, 2003; Prong et al., 1969), which protrudes into the ureter (Gutman and Beyeth, 1970; Prong et al., 1969). This thick medulla, with its long renal papilla, resembles that of some desert rodents (Prong et al., 1969). The ureters empty into the urinary bladder near its neck (Kraft, 1987).

Physiology

Chinchillas produce a wide (100-fold) range of urine concentrations, from diuresis at 60 mOsm/kg to a highly concentrated 6000 mOsm/kg (Prong et al., 1969). They are able to excrete a concentrated urine (Weisser et al., 1970), and can survive without drinking water from 8 days (Weisser et al., 1970) to 2 weeks (Prong et al., 1969). In general, mammals from arid and semiarid habitats tend to have a thick medulla relative to their kidney size, and long loops of Henle when compared to mammals from mesic habitats (Sperber, 1944). The chinchilla's urine-concentrating ability has been an object of study, as the kidneys have a thick medulla (Díaz and Cortés, 2003; Prong et al., 1969), thus the species can withstand long periods of water deprivation (Ness,

1999). Several studies have demonstrated that chinchillas can indeed efficiently concentrate urine. Weissner et al. (1970) observed that chinchillas were able to maintain a positive water balance (water loss did not exceed intake) when drinking a salt solution up to 0.6 Molarity NaCl. Further, chinchillas deprived of water up to 8 days had urine osmolality up to 7599 mOsm/kg with an average of 3505 mOsm/kg (Weisser et al., 1970), and chinchillas deprived of water for 2 weeks had urine concentrations of up to 6000 mOsm/kg (Prong et al., 1969). These high concentrations are comparable to those of desert rodents (Schmidt-Nielson and O'Dell, 1961). Chinchilla urine often has a specific gravity greater than 1.045 (Hrapkiewicz and Medina, 2007). Chinchillas also have high serum osmolality (Weisser et al., 1970), which is similar to other rodents in arid climates (Sakai et al., 1965).

Cardiovascular and Pulmonary Systems

Anatomy

Although there is a relative dearth of information on the cardiovascular and pulmonary systems in this species, recent studies on the cardiovascular system of chinchillas have revealed several features worth mentioning. Two arterial branches, the brachiocephalic trunk and left subclavian artery, originate from the aortic arch in a manner similar to rabbits and guinea pigs. The left common carotid branches from the brachiocephalic trunk; this trunk then divides into the right subclavian artery and the right common carotid artery (Ozdemir et al., 2008a). Internal carotid arteries are absent, as the blood to the brain is supplied solely by a vertebral-basilar artery system (Sportorno et al., 2004). Further, the chinchilla has only a left coronary artery. The left coronary artery arises from the aorta at the sinus of the aorta and courses towards the coronary groove, eventually dividing into paraconal, interventricular, and circumflex branches (Ozdemir et al., 2008b). Cardiac musculature in the chinchilla is distributed in both large-sized and medium-sized intrapulmonary venous walls (Endo et al., 1992). Eken and coworkers (2005) determined that the course of the chinchilla femoral artery and its branches are similar to the rat. The left lung has three lobes, whereas the right has four (Sportorno et al., 2004).

The cerebral arterial system is described in conjunction with the nervous system later in this chapter.

Musculoskeletal System (Figures 39.1–39.3)

Anatomy

The dental formula of the chinchilla is $2(I \ 1/1 \ C \ 0/0 \ P \ 1/1 \ M \ 3/3)$, and all teeth are open-rooted and grow continuously throughout life. Various authors cite different

FIGURE 39.1 Dorsal view of the chinchilla skull (mandible not included). (A) Tympanic bulla; (B) infraorbital foramen.

FIGURE 39.2 Ventral view of the chinchilla skull (mandible not included). (A) Tympanic bulla; (B) infraorbital foramen; (C) zygomatic bone; (D) lacrimal bone.

FIGURE 39.3 Right lateral view of the chinchilla skull (mandible not included). (A) Tympanic bulla; (C) zygomatic bone; (D) lacrimal bone; (E) paraoccipital process; (F) incisors; (M1) first molar; (M2) second molar; (M3) third molar; (P) premolar.

growth patterns for the yellow incisors of this species. Strake et al. (1996) and Hoefer (1994) indicate that incisors grow 4–6 cm per year; Sportorno et al. (2004) report that the incisors grow 5–7.5 cm per year. In contrast, Sulik et al. (2007) cite that incisors grow only 1.5–3 cm per year. The teeth are considered “aradicular hypsodont” (Crossley et al., 1998) and have long crowns with no anatomic roots (Brenner et al., 2005). The occlusal planes of premolar and molar teeth are slightly angled from buccal to lingual (Brenner et al., 2005). As chinchilla teeth do not form a true anatomic root, some authors refer to the portion of the root below the alveolar margin as the “reserve crown” (Brenner et al., 2005; Crossley et al., 2001). Chinchillas demonstrate an anisognathism whereby the mandible is wider than the maxilla (Brenner et al., 2005).

The skeletal system of chinchillas has several features worth mentioning. The skulls of male and female chinchillas are visually indistinguishable, and there is minimal skull growth beyond maturity (Crossley et al., 2001). The tympanic bullae are large, with three vesicular protuberances, and the mean total volume of the middle ear is $1.52 \text{ ml} \pm 0.26 \text{ SD}$ (Sportorno et al., 2004; Vrettakos et al., 1988). Further distinctive features of the chinchilla skull include large infraorbital foraminae, reduced zygomatic arches, an absence of a masseteric crest of the mandibles, large lacrimal bones, and lacrimal canals that open in the side of the rostrum (Brenner et al., 2005). The vertebral formula is C7, T13, L6, S2, Ca23, for a total of 51 vertebrae, with 13 pairs of ribs.

Studies of the anatomy of the chinchilla nasal cavity revealed that the naso- and maxilloturbinates of the chinchilla nasal cavity more closely resemble the simple turbinates found in other rodents, rather than the branched or complex turbinates found in canids and felids. The nasal mucosa of the chinchilla also has numerous lymphoid aggregates (nasal-associated lymphoid tissue, or NALT) similar to other rodents. The NALT is responsible for induction of both secretory and systemic immune responses in the upper respiratory tract (Jurcisek et al., 2003).

Digestive System

The digestive system of chinchillas presents a number of interesting characteristics which might influence a clinician's approach to their veterinary medical care.

Anatomy

Chinchillas possess a palatal ostium, an opening in the soft palate through which the oropharynx communicates with the rest of the pharynx (Hillyer et al., 1997; Sportorno et al., 2004). Martinez et al. (2000) report that the posterior third of the tongue's dorsal surface has a

pair of vallate papillae, which is similar to that seen in insectivores and armadillos. The gallbladder is located between the right and median sides of the four-lobed liver. In the chinchilla liver, there is little lobulation which is grossly visible at the surface (Lyon et al., 2003; Sportorno et al., 2004). Hopkins and Whidden (1959) reported observing “sex chromatin” bodies in hepatocytes of most female chinchillas, a finding which has not been reported elsewhere.

The stomach is pyriform-shaped (Sportorno et al., 2004), similar to that of a horse or pig (Lyon et al., 2003). The gastrointestinal tract itself is very long, and the length of the small and large intestine together often exceeds 3 m in adult animals (Hoefer, 1994; Johnson-Delaney, 2006; Sportorno et al., 2004). The large intestine is 1.5 times longer than the small intestine (Chen-Pan and Fujiwara, 1989), although the jejunum nearly fills the entire abdominal cavity (Hoefer, 1994; Hrapkiewitz and Medina, 2007). The volume of the cecum is relatively small compared to the volume of the colon. The cecum holds 23% of the dry matter content of the large intestine compared to the rabbit (57%) and guinea pig (44%). The thin-walled, sacculated, and coiled cecum is comparable to that of the pig, horse, and rabbit (Chen-Pan and Fujiwara, 1989).

Physiology

Similar to other rodents, chinchillas do not vomit, and are hindgut fermenters (Jenkins, 1992). Chinchillas produce two types of fecal pellets; a nitrogen-rich pellet for cecotrophy, and a nitrogen-poor pellet as a typical fecal pellet (Donnelly and Brown, 2004) at a 3:1 ratio (Holtenius and Bjornhag, 1985). Ebino (1993) reports that chinchillas, guinea pigs, and rabbits all exhibit “vigorous coprophagy” as compared to mice, rats, hamsters, and voles. Holtenius and Bjornhag (1985) characterized the “colonic separation mechanism” in chinchillas, a concept which is further explored by Sakaguchi (2003) and Wolf et al. (2003). These authors found that chinchillas exhibited a diurnal activity rhythm, in that they eat and deliver all of their fecal pellets at night, and are inactive during the day except for periods of cecotrophy. This “mechanism”, found in both chinchillas and guinea pigs, is characterized by a longitudinal furrow in the proximal part of the colon which facilitates production of caecotrophs by which bacteria are moved towards the cecum via an antiperistaltic movement. This capability permits rapid passage of less-digestible food particles while retaining microorganisms and more digestible food particles in the cecum to allow adequate opportunity for fermentation (Bjornhag and Snipes, 1999). Worthington and Fulghum (1988) explored the cecal and fecal bacterial flora in healthy chinchillas, isolating species of *Bifidobacterium*, *Bacteroides*, *Eubacterium*, and anaerobic *Lactobacillus*.

Nervous and Endocrine Systems

Endocrine System

ANATOMY

The endocrine glands of the chinchilla have not been shown to be significantly different in structure or location from those of other mammals. The adrenal glands are elongated and large (Williams, 1976), dirty white to yellow, and dimorphic in size, shape, weight (Kraft, 1987). The location of the thymus is entirely thoracic (Cartee, 1979; Hrapkiewicz and Medina, 2007). It is located at the base of the heart and extends along the heart's ventral surface approximately half of the distance between the base and the apex (Cartee, 1979). Histologically, the cortical and medullary areas appear similar to other species (Cartee, 1979). Studies have documented age-related changes in the thymus. Chinchillas aged 2–8 weeks were compared with chinchillas aged 4–8 years. In general, there was involution with age. The thymus of older chinchillas was lighter in color and more lobulated. There was decreased parenchymal tissue, a lower concentration of lymphocytes, and increased adipose tissue (Cartee, 1979). The pituitary gland has a ventrocaudally oriented infundibulum (pituitary stalk), and the glandular anterior pituitary is positioned nearly horizontal (Kraft, 1987). The thyroid gland's isthmus is only sometimes present (Kraft, 1987).

Nervous System

GENERAL ANATOMY

In chinchillas, blood to the brain is supplied only through the vertebral arteries, with no internal carotid blood supply (Gielecki et al., 1996; Jablonski and Brudnicki, 1984). The vertebral arteries anastomose to form the ventral basilar artery, which then divides cranially to form the cerebral arterial circle. The cerebral cortex is supplied by three cerebral arteries branching from this cerebral arterial circle: caudal, medial, and rostral (Panesar et al., 2001). The cerebral arterial circle resembles that of other rodents (Panesar et al., 2001), but it is open rostrally, because the rostral cerebral arteries do not anastomose to complete the circle of Willis (Gielecki et al., 1996). The rostral arterial circle is also asymmetric, due to the unusually strongly developed right anterior cerebral artery (Kuchinka et al., 2005). The middle cerebral artery supplies the ventral surface of the cerebral hemisphere via three branches – the rostral, caudal, and central (striated) branches (De Araujo and Campos, 2009).

There is little published describing the chinchilla nervous system in general, although the auditory cortex has been described. The primary auditory cortex is 2–3 mm caudal to the medial cerebral artery (Panesar et al., 2001). The auditory cortex is made of distinct

regions in the temporal cerebral cortex. The structure and number of regions varies with species. In chinchillas, there are regions dorsal and caudal to the primary auditory cortex in which the neurons are less responsive to tone stimuli but more broadly tuned and complex than neurons in the primary auditory cortex (Pienkowski and Harrison, 2005). In chinchillas, three separate auditory areas have been revealed in the temporal cortex by optical imaging of intrinsic signals, a method of indirectly monitoring neural activity in the cortex. These areas correlate with the primary auditory cortex, and two secondary auditory areas. The primary auditory cortex is the most dorsocaudal field, with the secondary areas ventral and rostral to it. Neuron response latencies in the primary auditory cortex are shorter than those in the secondary auditory areas (Harel et al., 2000). The cochlear nucleus is large and well developed, but its organization is generally similar to that described in other mammals (Morest et al., 1990).

The epicardial ganglia have been examined. The highest density of epicardial ganglia is on the ventral surface of the right atrium. There is another, less dense plexus on the left atrium, and a few small ganglia on the ventricles' dorsal surfaces (Kuder et al., 2003).

The trigeminal ganglion has also been described. It is closely connected to the trigeminal nerve where it divides into the ophthalmic and maxillary nerves (Szczerkowski, 2005).

Special Senses (Vision, Olfactory, Somatosensation, Taste, Auditory)

Auditory System

ANATOMY

The auditory system of the chinchilla has been closely examined. Chinchilla ears have features characteristic of species adapted to open, arid areas. These include a large middle-ear space divided into compartments; a large tympanic membrane and ossicular dimensions; and increased mechanical sensitivity to low-frequency acoustic stimuli relative to other animals with a similar hearing range (Rosowski et al., 2006). The tympanic membrane is difficult to see via the external ear canal because the canal runs dorsal–ventral (Browning and Granich, 1978). The tympanic membrane diameter is an average of 8.3–8.5 mm, and the circumference is an average of 26.5 mm (Vrettakos et al., 1988).

Beyond the tympanic membrane is the middle ear, with the auditory bullae and conductive ossicles. The chinchilla is known for its large auditory bullae, which are thin-walled (Hillyer and Quesenberry, 1997), well-developed, and extend upwards towards the top of the skull (Williams, 1976). Because the bone of the bulla is

very thin, its strength relies on a large number of internal septae (Browning and Granich, 1978). The dorsal part of the bulla is subcutaneous, and mostly palpable on the top of the head, except for the anterior and posterior rims which are covered, respectively, by the temporal and platysma muscles (Browning and Granich, 1978). The labyrinthine part is at the bottom of the bulla, and is palpable in the neck. The digastric muscle originates from its surface. The eustachian tube enters into the labyrinthine part, but aerates the entire bulla (Browning and Granich, 1978). The eustachian tube has a vertical orientation (Hoa et al., 2009). The mastoid part of the bulla sits in the middle, but is not palpable because it is covered by the occipital muscles (Browning and Granich, 1978). The total middle ear air volume is large (Rosowski et al., 2006; Vrettakos et al., 1988), and has been measured from 1.5–2.8 cc (Drescher and Eldredge, 1974; Rosowski et al., 2006; Teas and Nielson, 1975; Vrettakos et al., 1988). The middle ear's multiple compartments are joined by narrow passages (Browning and Granich, 1978), so the air space is segmented into multiple subcavities (Browning and Granich, 1978; Vrettakos et al., 1988; Williams, 1976). Some details about the ossicular chain (malleus, incus, stapes) have been published. The structure of the chinchilla's conductive apparatus, similar to the human's, is described as "freely mobile", in which the malleus and incus are attached by suspensory ligaments and are able to move independently. This contrasts with the less highly evolved "micro-type" apparatus of other species such as the mouse, gerbil, and hamster, in which there is a bony fusion between the malleus and the tympanic ring (Fleisher, 1978).

The handle of the malleus and posterior margin of the long process of the incus are almost perpendicular to the rotational axis (Vrettakos et al., 1988). The joint between the malleus and the incus is fused, and these two ossicles form a curved bar which fits snugly into the epitympanic recess (Vrettakos et al., 1988). The long process of the incus articulates with the stapes (Browning and Granich, 1978) at a right angle (Vrettakos et al., 1988). The stapes has been measured at 1.78 mm high (Vrettakos et al., 1988). Its footplate is convex on the labyrinthine (medial) side and concave on the tympanic (lateral) side (Vrettakos et al., 1988). It has a toe oriented posteriorly, and its crura are more central than in mice (Vrettakos et al., 1988) or humans (Browning and Granich, 1978; Vrettakos et al., 1988). The crura provide the surface onto which the stapedius muscle inserts (Vrettakos et al., 1988). There is no stapedal artery (Vrettakos et al., 1988). The tensor tympani and stapedius muscles are well developed (Vrettakos et al., 1988).

The chinchilla's inner ear is easily accessible, via the large middle ear bulla (Panesar et al., 2001). The cochlea makes $3\frac{1}{2}$ turns, and projects into the labyrinthine part of the tympanic bulla (Browning and Granich, 1978).

The organ of Corti averages 18.4 mm in length and has 102 inner and 405 outer hair cells per mm (Browning and Granich, 1978). The oval window's diameter has been measured at 2.19×0.78 – 0.93 mm, with an average area of 1.55 mm^2 , and the round window's diameter has been measured at 1.4×0.95 mm (it is oval in shape) with an average area of 1.06 mm^2 (Vrettakos et al., 1988). The round window membrane is thin, one-sixth of the thickness of that of the human (Chen et al., 1999).

PHYSIOLOGY

Chinchillas are frequently used in hearing research due to the easy access to the inner ear via the large auditory bullae. The chinchilla's auditory sensitivity is similar to that of humans (Henderson and Hamernik, 1973) and thus has been extensively investigated. Chinchillas are more sensitive than humans at lower frequency ranges (<1100 Hz) and higher frequency ranges (>6500 Hz). In the middle range of 1100–6500 Hz, chinchillas are less sensitive than humans (Miller, 1970). Chinchillas also appear to be more sensitive than guinea pigs, except at very high frequencies (Miller, 1970). In general, chinchillas have increased mechanical sensitivity to low-frequency acoustic stimuli relative to other animals with similar hearing ranges (Fay, 1988; Miller 1970).

Chinchillas show presbycusis. McFadden et al. found a small but significant decline of auditory sensitivity and outer hair cell function in 44 chinchillas examined between 3–15 years of age (McFadden et al., 1997). This age-related hearing loss is similar to age-related hearing loss in humans and more similar to humans than that of rodents with shorter life spans. As in humans, the high-frequency losses exceed low-frequency losses, and the rate of loss in chinchillas approximates that of the human male (McFadden et al., 1997).

Vestibular System

ANATOMY

The semicircular canals sense angular acceleration. The semicircular canals' orientation is relatively planar, and all of them have a similar deviation from that plane (approximately 10°) (Hullar and Williams, 2006).

PHYSIOLOGY

Because their semicircular canals are all relatively planar with similar deviations from planarity, chinchillas are relatively equally sensitive to rotations in all directions (Hullar and Williams, 2006).

Olfactory System

ANATOMY

The chinchilla's bilateral vomeronasal organs are about 6 mm long, lie along the base of the nasal septum, and are encircled rostrally by cartilage, and caudally by

bone (Oikawa et al., 1994). It communicates with the nasal cavity via a pore at the rostral end (Oikawa et al., 1994).

PHYSIOLOGY

Histologically, the vomeronasal organ appears functional (Oikawa et al., 1994).

Vision

ANATOMY

The internal anatomy of the eye includes an anterior chamber of moderate depth and a large, spherical lens (Peiffer and Johnson, 1980). The large and spherical lens is characteristic of a nocturnal animal (Donnelly and Brown, 2004). Another nocturnal characteristic is the sensitive retina (Donnelly and Brown, 2004), which is anangiotic, without visible vessels (Peiffer and Johnson, 1980; Williams and Kern, 2008). The optic disc is gray, with a variable shape, being round to oval, in either a horizontal or vertical plane (Peiffer and Johnson, 1980). The vascularization of the optic disc varies (Williams and Kern, 2008). For example, small blood vessels were visible on the optic disc of approximately half of the chinchillas examined by Peiffer and Johnson (1980). The size of the physiological (i. e., optic) cup varies, from a small central depression on the optic disc to almost total involvement of the nerve head (Peiffer and Johnson, 1980). The average intraocular pressure is 18.5 mmHg (Peiffer and Johnson, 1980).

PHYSIOLOGY

There are no reports of the chinchilla's vision being different from that of other rodents.

BEHAVIOR

Chinchillas are described as gentle, docile, quiet, timid (Hillyer and Quesenberry, 1997; Lyon, 2003; Riggs and Mitchell, 2009), lively, and curious (Hillyer and Quesenberry, 1997; Hoefer and Crossley, 2002; Johnson, 2006; Lightfoot, 1999; Lyon, 2003; Merry, 1990). They use their mouths to explore, and may perform trial bites (Johnson, 2006) when exploring an object or person. They also gnaw regularly (Hoefer, 1994; Hoefer and Crossley, 2002), similar to other rodents. Chinchillas are naturally nocturnal, being active at dusk and at night in the wild, but in captivity they can adapt to a diurnal lifestyle (Hoefer 1994; Johnson-Delaney, 1998; Hillyer and Quesenberry, 1997; Lyon, 2003; Riggs and Mitchell, 2009; Webb, 1991). They are active (Riggs and Mitchell, 2009) and agile, and enjoy climbing and jumping (Hillyer and Quesenberry, 1997; Hoefer 1994; Hoefer and Crossley, 2002; Johnson, 2006; Johnson-Delaney, 1998). They are "excellent leapers" (Honeycutt, 2003),

and can jump over 6 feet high, with no apparent fear of heights (Johnson, 2006). They will run on an exercise wheel (Johnson, 2006).

Chinchillas are mainly herbivorous, eating grasses and seeds. However, they will also eat insects (Honeycutt, 2003). Chinchillas show biphasic ingestion behavior. An examination of chinchilla ingestion indicated that their highest level of ingestion (70% of their daily intake) is from 9pm–7am, with peak ingestion from 9pm–11pm. No ingestion was seen from 7am–3pm (Wolf, 2003). Their daily food intake was approximately 4–5% of their body weight (Wolf, 2003). Daily water intake was low, at 20–40 ml/chinchilla (Wolf, 2003). Chinchillas eat by sitting upright (Nowak, 1999) and holding food in their front paws (Honeycutt, 2003; Johnson, 2006; Williams, 1976). They sometimes throw pellets out of their cages (Williams, 1976). They are also coprophagic (Johnson, 2006; Lightfoot, 1999).

Generally, chinchillas will urinate in a specific location (Coulton, 1989; Johnson, 2006), and will use a litter box (Johnson-Delaney, 1998). However, they do not always defecate in the same specific place (Coulton, 1989; Johnson, 2006), and are harder to train to a litter box for defecation (Johnson-Delaney, 1998).

Chinchillas sit upright when grooming and sunbathing (Nowak, 1999). When they sleep, their most common posture is to be upright, but other normal postures include lateral or dorsal recumbency, or even wedged upside down in tight spaces (Johnson, 2006).

Chinchillas are fastidious groomers (Johnson, 2006). Part of their normal grooming behavior is dust-bathing (Donnelly and Quimby, 2002; Johnson-Delaney, 1998; Webb, 1991). They dust-bathe in the wild (Merry, 1990), and in captivity a dust bath must be provided to remove lipids from the fur (Barber and Thompson, 1990) and maintain their coat health (Hrapkiewicz and Medina, 2007). Some chinchillas chew on their own fur, or that of other chinchillas, a behavior known as "fur-chewing" (Kitchen and Kitchen, 1967). Because self-chewers can only chew off the fur they can reach on their lower, caudal body, they can look like a lion, with motley fur (Hrapkiewicz and Medina, 2007). Trichobezoars are found in the stomachs of fur-chewers at necropsy (Hrapkiewicz and Medina, 2007) and are associated with fur-chewing (Donnelly and Quimby, 2002). The definitive cause is unknown (Hrapkiewicz and Medina, 2007). Some causes postulated have been maladaptive displacement behavior (Donnelly and Quimby, 2002), boredom, housing stress, malnutrition (Eidmann, 1992), poor diet (low fiber), or hereditary factors (Merry, 1990; Webb, 1991). Fur-chewing does occur more in certain families (Hrapkiewicz and Medina, 2007). Hormonal imbalances have also been suspected. Thyroid hyperplasia has been correlated with the size of the area of the body with fur removed, and the hyperplasia was interpreted

as a reaction to loss of insulation with respect to body heat (Eidmann, 1992). In fur-chewing chinchillas, there is increased hormone activity of the thyroid and adrenal glands consistent with stress-induced changes. Varonjack and Johnson (1973) compared thyroid activity and corticosterone levels in fur-chewers to those of non-fur-chewers. Both were higher in the fur-chewers. Additionally, changes in the adrenal glands and skin consistent with hyperadrenocorticism have been described in fur-chewing chinchillas, suggesting that stress and genetic factors are involved (Tisljar et al., 2002).

Chinchillas are creatures of habit, do not adjust well to change (Johnson, 2006), and are easily frightened (Webb, 1991). They are sensitive to noise, startle easily, and are disturbed by unfamiliar sounds (Johnson, 2006). When alerted to potential danger, they will stand on their hind limbs (Johnson, 2006). In general, their defense mechanism is flight rather than fight (Hillyer and Quesenberry, 1997; Johnson, 2006), and when they are fearful, they run for cover or cower in corners or small spaces (Johnson, 2006). As a prey species, they also hide illness (Riggs and Mitchell, 2009).

Chinchillas are social, and live in colonies of multiple smaller family groups in the wild (Hoefer, 1994; Honeycutt, 2003). These colonies can be composed of several hundred individual (Donnelly and Brown, 2004; Donnelly and Quimby, 2002; Nowak, 1999). Due to their social nature, they can generally be housed as pairs, single-sex groups, or polygynous (harem) groups in captivity (Hoefer and Crossley, 2002; Johnson-Delaney, 1998), although they have been reported to be monogamous in the wild (Brower, 2006; Honeycutt, 2003).

Intraspecies behaviors include physical contact. Chinchillas participate in allogrooming, and family groups huddle when at rest (Kleiman, 1974). Another interactive behavior is the "frisky-hop", an active performance of vertical leaps, body twists, head tosses, racing, pivoting, and prancing, which involves little physical contact (Kleiman, 1974).

They rarely fight (Hoefer, 1994; Hoefer and Crossley, 2002), but they can be aggressive (Weir, 1967). When fighting, they will sometimes kill each other. They kill by climbing onto the opponent's back and biting the back and neck (Johnson, 2006). Generally, aggression occurs during breeding or introduction (Johnson, 2006). Chinchillas can be territorial and will defend against intruders (Johnson, 2006). Female chinchillas are dominant, with a larger body size and higher levels of aggression than males (Donnelly and Quimby, 2002; Johnson, 2006). Anecdotally, females are more territorial (Johnson, 2006). A female in estrus can be aggressive (Johnson, 2006), especially towards males (Brower, 2006; Williams, 1976), and this must be taken into consideration when breeding chinchillas. Females can be aggressive if approached by a male if she is not ready to copulate. She may jump

vertically, and then kick him or urinate on him (Bignami and Beach, 1968). Near parturition, females can also show increased aggression towards previously compatible males (Strake et al., 1996). After parturition, females with pups may show aggression towards males, even the father (Brower, 2006). Females are also aggressive towards other females' young. If one female's offspring get into the cage of another female, she may kill the offspring (Weir, 1967). However, orphans can be adopted by another lactating chinchilla (Strake et al., 1996; Webb, 1991; Williams, 1976) or a guinea pig (Strake et al., 1996; Webb, 1991). Females which were raised together, or mother and daughter pairs are compatible (Johnson, 2006). However, newborn pups may be aggressive with each other, especially if there are more than two of them (Johnson-Delaney, 1998). Males may also show aggressive behavior, and intact males housed in a group may fight (Johnson, 2006). Chinchillas are known to use an unusual form of defense or protest: spraying urine at the offending party. Chinchillas urinate as a defensive or perhaps aggressive behavior. Chinchillas may project urine 2–3 feet with accurate aim in defense (Weir, 1967) or if annoyed (Donnelly and Brown, 2004; Williams, 1976). Both females and males defend their territory with this method, but females reportedly have better aim in general (Johnson, 2006).

Chinchilla are highly vocal (Honeycutt, 2003), and their vocalizations have been studied to produce guidelines as to their likely meanings. Donnelly and Brown (2004) described many vocalizations. The "click" sound has a similar function to the "chutt/cluck" of guinea pigs. A female will click at her nursing pups if they nip her. A young chinchilla uses a "squawk" to elicit a grooming response by its mother. A chinchilla that is injured or handled awkwardly may "squeal". Other chinchillas react to this sound by leaping around in their cages. They will "tooth chatter" when they are confronted with an unknown chinchilla or are being aggressive for another reason. During fighting, they may make a "rasp-like snarl". Males make a "purr" sound after mating, which is described as sounding like hiccups. Others have categorized some vocalizations. Chinchillas "bark" when they are defensive or irritated, "honk" for attention, (Johnson, 2006); and "chattering teeth" or "growling" sounds are used as threat noises (Nowak, 1999). "Soft cooing" indicates contentment; a "spitting growl" is made when upset; and chinchillas "cry" when injured or frightened (Merry, 1990).

Chinchillas can habituate to humans when handled frequently at a young age (Hillyer and Quesenberry, 1997). They respond best to gentle handling and a light touch (Hrapkiewicz and Medina, 2007), and are generally easy to handle (Donnelly and Brown, 2004; Donnelly and Quimby, 2002). They are not usually aggressive towards people (Hrapkiewicz and Medina, 2007; Johnson, 2006; Weir, 1967; Williams, 1976) and rarely bite

(Hillyer and Quesenberry, 1997; Hoefer 1994; Johnson-Delaney, 1998; Lyon, 2003; Webb, 1991). However, they may bite if agitated (Donnelly and Brown, 2004; Hrapkiewicz and Medina, 2007; Weir, 1967; Williams, 1976), although the bite may be preceded by a warning nip (Donnelly and Brown, 2004).

INTRODUCTION

Chinchillas (*Chinchilla laniger*) have proven to be a practical animal model because of their small size, ease of handling, long life span (12–20 years), and relative freedom from diseases that interfere with research. Maintaining chinchillas in a laboratory setting is easily accomplished because their care and husbandry are similar to that of rabbits and other hystricomorph rodents. Facilities already housing rabbits and other rodents can readily adapt to housing chinchillas with few problems.

HOUSING SYSTEMS

Caging Systems

Chinchillas are housed in either solid-bottom or suspended (metal or plastic) cages. Solid-bottom caging is preferred for pregnant females that are nearing parturition. Standard rabbit cages are typically used for housing chinchillas in the laboratory setting because they are readily available and because cages designed specifically for housing chinchillas in a research setting are not commercially produced. Care should be taken to

FIGURE 40.1 Chinchilla caging. (A) Standard plastic rabbit cages can be modified for housing chinchillas. White arrow indicates potential escape point. (B) Close-up of unmodified rabbit cage. White arrows indicate potential escape points. Note that when dropping pan from the above cage is removed, chinchillas can escape between individual cage units. (C) Close-up of rabbit cage modified for housing chinchillas. Black arrows indicate where additional enclosures have been added at potential escape points. Arrow with asterisk points to stainless steel panel added horizontally between individual cages to prevent escape when dropping pans are removed.

evaluate the spacing of metal bars or perforated flooring when using rabbit cages for housing chinchillas. A minimum of 15×15 mm has been recommended to prevent injuries to limbs (Hoefer, 1994) and to prevent escape of neonates in breeding situations. Animals housed on suspended metal floors should also be provided with a solid resting board or other enrichment devices on which to rest. A further consideration when using suspended plastic cages is to ensure that the chinchillas cannot escape since their bodies fit in any opening through which their skull fits. Many plastic rabbit cage systems currently produced allow the escape of chinchillas unless modifications are made to close potential points of egress (Figure 40.1).

There are no published floor space or height requirements for chinchilla housing but chinchilla fancier and breed organizations recommend approximately 1–2 ft² per animal (Donnelly and Brown, 2004) and 12 inches of cage height. Since most commercially available rabbit cages exceed these dimensions, pair and group housing of chinchillas is easily accomplished. Chinchillas are very active and will climb and jump when provided

with enrichment devices and sufficient space to exhibit these behaviors.

Bedding

Hardwood shavings, heat-treated softwood shavings, or paper-based (cellulose) animal bedding are used in solid-bottom cages for chinchillas. Pine shavings and untreated softwood products should be avoided because these products can contain aromatic hydrocarbons that may alter drug and anesthetic metabolism, and induce respiratory problems. For animals housed in suspended cages, dropping pans are handled like those of rabbits. The pans can be lined with a variety of absorbent materials including plastic-backed paper products, cardboard, pelleted paper, or alfalfa pellets.

Chinchillas need regular access to a dust bath because they produce a significant amount of lipid from their sebaceous glands like other rodents adapted to arid environments (Barber and Thompson, 1990). Without access to a suitable substrate, their fur becomes matted and greasy. Chinchilla dust is generally a mixture of

silver sand and Fuller's earth (a type of clay) but a variety of dusting materials including diatomaceous earth, talc, cement byproducts, and volcanic ash are available (Donnelly and Brown, 2004). It should be noted that talcum has been shown experimentally to induce pulmonary granulomas and epithelial hyperplasia (Trautwein and Helmboldt, 1967). Avoiding dust containing this material may be warranted.

Recommendations for the frequency of offering bathing substrate range from daily to monthly. In our experience, a 3-day-a-week schedule (Monday, Wednesday, and Friday) in the laboratory setting is sufficient. The dust bath should be removed from the primary enclosure daily so that it can be cleaned of urine and feces. Dust can also be an irritant to the eyes and daily removal will prevent overuse. Dust baths should not be shared between cages of animals since chinchillas can be inapparent carriers of ringworm dermatophytes and the dust and bath can serve as a fomite for these agents. Marking the individual baths with the cage identifier allows for storage and reuse. Otherwise, empty the bath and replace with fresh dust in a clean, sanitized bath or disposed of the bath daily. In a research setting, standard mouse shoebox-style cages work well as dust baths.

ENVIRONMENTAL CONDITIONS

Ventilation

The recommended ventilation rate of 10–15 air changes per hour (NRC, 1996) is usually appropriate for rooms housing chinchillas. Actual ventilation rates should take into account the number of animals housed in the room, room dimensions, frequency of cage/dropping pan changing, and the temperature and humidity requirements of the animals (see Temperature and Humidity below). Caging should be situated such that animals are not subject to drafts from the ventilation system.

Illumination

A survey of the literature indicates that chinchillas in research institutions are typically housed in conditions of 12 hours of light and 12 hours of darkness or 14 hours of light and 10 hours of darkness. Some articles describe the use of natural photoperiod similar to what the animals would be exposed to in the wild (Busso et al., 2005, 2007). A 14 light: 10 dark photoperiod approximates the conditions at maximum day length (i.e. summer solstice) in the chinchillas' natural habitat. This photoperiod may be more desirable when breeding is occurring.

One report in the literature indicates that the spectrum of artificial (incandescent) light used to maintain

chinchillas can influence the sex ratio of offspring (Ott, 1964). When housed outdoors under natural light, chinchillas produced an equal distribution of male and female offspring but when moved indoors under daylight incandescent bulbs, litters were predominantly male. When the bulbs were changed to an alternate spectrum, sex ratios returned to normal.

Temperature and Humidity

Chinchillas are very resistant to hypothermia and are known to withstand sub-freezing temperatures in their natural habitat while showing a significant sensitivity to heat. At temperatures above 35°C, chinchillas appear stressed and mean body temperatures rise significantly (Orsetti and McManus, 1971). The thermoneutral zone of chinchillas has been established to be between 20 and 35°C (Arends and McNab, 2001; Gorecki, 1967). A stable temperature of 18–22°C is therefore recommended as optimal for chinchilla housing (Donnelly and Brown, 2004).

Chinchillas are also relatively sensitive to elevated humidity. Their natural habit in northern Chile has an average humidity below 60%. Prolonged elevations in humidity above 60% can result in adverse effects on hair coat quality and contribute to the risk of heatstroke with elevated temperatures (Hoefer, 1994). The recommended humidity range for chinchillas is 40–60%.

Enrichment

Environmental enrichment for chinchillas can be similar to that provided for rabbits. Toys that can be gnawed to assist in wearing down teeth should be provided. Wood blocks (e.g., birch, oak, maple), young tree branches (e.g., elm, grapevines, birch), bark (e.g., apple, pear, peach, ash trees) or porous stones (e.g., pumice) can be given for gnawing (Donnelly and Brown, 2004). Appropriately sized plastic or hard rubber toys (e.g., dumbbells, balls or drums with bells, KONG®, Nylabone®) are readily accepted and chinchillas will orally manipulate stainless steel chains and other items hung on the front of the cage. Because chinchillas are adept and relentless chewers, it is critical that the condition of enrichment items be assessed daily and damaged toys removed. In our experience, gastrointestinal foreign bodies have not been a clinical issue; however daily observation for missing pieces of enrichment devices is advisable. For animals housed in suspended caging, checking the cage pan may reveal bells and other small, missing pieces of concern.

Chinchillas are a shy, prey species and in the wild they conceal themselves in rock crevices (Donnelly and Brown, 2004). This habitat can be mimicked in captivity by providing them with a structure in which to hide (e.g., a plastic igloo, T- or L-shaped sections of

polyvinyl chloride plumbing pipes). When structures with flat tops are provided, the animals will also use these as a perch.

Food treats can be provided in moderation, either in the feeder, on the cage floor or on top of structures. Acceptable treats include hay (loose or cubed), fresh or dried produce (e.g., apples, carrots, figs, pears, raisins, sweet potatoes, and snow peas), nuts and seeds (e.g., hazelnuts, sunflower seeds), and grain or cereal mixes (Hoefler, 1994; Lightfoot, 1999; Quesenberry et al., 2004; Ryerson, 2009). Fresh produce should be well washed to minimize the risk of introducing pathogens. Perishable items should be removed daily to prevent consumption of spoiled produce. Any changes in types of foods provided, including treats, should be done slowly to avoid the development of enteric problems (Hoefler, 1994).

Sanitation

The sanitation schedule for the chinchillas' primary enclosures is dependent on the type of housing system used. Solid-bottom caging is changed as often as necessary to keep the animals clean and dry; and is dependent on the size of the cages, the bedding material and the animal housing density.

Dropping pans from suspended cages are changed at a minimum once a week but more typically 2–3 times a week to remove accumulated urine and feces. Primary enclosures should be cleaned minimally once a month, but more commonly this is necessary every 2 weeks because of accumulation of urine scale in the enclosure. Individual facilities should establish standard operating procedures for cage cleaning based on housing density and experience with particular cage types. However, primary enclosures should be cleaned whenever they become visibly soiled.

The room sanitization schedule should take into account the fur and dander generated by these animals as well as the use of the dust bath. Chinchilla rooms may need to be swept and mopped daily after the use of the dust bath because dust may be thrown from the primary enclosures during use. The walls of the room can also become coated with the dust and should be monitored for such accumulation and wiped down as appropriate. If filters are present on the HVAC exhaust, these should be monitored regularly for accumulation of dust and fur.

NUTRITION

Feed Type

Ideally a palatable pelleted formulation should constitute the bulk of the chinchillas' diet along with daily

high-fiber supplementation (grasses or hays) since most pelleted diets alone have insufficient fiber to maintain the health of the lower intestinal tract. Several commercially produced chinchilla diets that are modeled after guinea pig and rabbit formulations (based on the anatomic similarities of the lower gastrointestinal tract) are available (e.g. Mazuri® and Oxbow Animal Health). Unlike other hystricomorph rodents, chinchillas manipulate food items with their forepaws. The pellets should therefore be long enough to handle. For this reason, guinea pig and rabbit diets should not be substituted when a specific chinchilla formulation is available. Loose, mixed-feed diets should be avoided, since chinchillas tend to select out the most palatable components and leave the less desirable ones. Over-supplementing chinchillas with dietary treats can also alter intestinal microflora and motility. Supplemental grains, fruits, and seeds should be provided, but cautiously rationed either daily or weekly.

Nutritional Requirements

Current chinchilla-specific formulations provide crude protein 16–21.6%, crude fat 2.5–4.0%, and crude fiber 15–23% (Wolf et al., 2003). Chinchillas will consume between 4–5% of their body weight daily when offered a complete pelleted diet or hay (Wolf et al., 2003). If feed is provided *ad libitum*, most chinchillas will self-regulate feed intake. Chinchillas are nocturnal and consume more than 70% of their daily feed ration during the dark phase (Wolf et al., 2003), therefore a single daily feeding in late afternoon is acceptable.

Few studies on chinchilla nutrition have been performed and the early nutritional studies on daily ascorbic acid and thiamine requirements (King and Orcutt, 1952) lacked sufficient numbers of animals or were prematurely terminated due to disease onset (Larrivee and Elvehjem, 1954). These early studies therefore drew only tentative conclusions on nutritional needs of this species. While chinchilla-specific diets are available, their exact dietary needs, reflective of their natural intake, are still unknown.

Hydration

Chinchillas are native to arid habitats at high elevations and are physiologically adapted to low daily water intake. Similar to desert-dwelling rodents, the renal medulla of the chinchilla is significantly larger than the cortex, allowing for significant urine concentration and water retention (McManus, 1972). Water consumption correlates directly with the moisture content of the food provided, but on average is 20–40ml/day (Wolf et al., 2003). Given enough succulent feed, chinchillas can cope without drinking water.

To assure sufficient hydration, clean drinking water should be available each day (Donnelly and Brown, 2004). Most laboratory animal facilities provide water *ad libitum* either from bottles or an automatic watering system.

Nutrition-related Diseases

Fiber is critical to the chinchillas' diet and deficiencies in the amount and type of daily fiber can contribute to health problems. Chinchillas, like guinea pigs, have an open-rooted system for all teeth. Malocclusion is more prevalent in species with full open-rooted dentition (Legendre, 2002). It is most frequently associated with the uneven wear of the molars or "cheek" teeth. However, incisor abnormalities can also occur and if caught early these animals may have absent or limited clinical signs (Crossley, 2001). In moderate cases the animal can present with reduced appetite and hypersalivation due to oral pain. Bone spurs on the buccal or lingual aspect of the molars can cause trauma to the oral mucosa. Severe cases may also present with dental abscessation or fistulation into the palate and nasal cavity. Clinical evaluation of the oral cavity may prove to be very difficult unless animals are chemically immobilized. The oral cavity is long and narrow, making visualization of the molars challenging even with the use of a speculum. Examination of the oral cavity may require anesthesia. Radiograph and CT imaging can be used to assist in the examination and diagnosis. Although malocclusion is considered a polygenic trait, inadequate nutrition also contributes to the development and progression of this condition. Providing long-stranded coarse hays and grasses allows for appropriate mechanical wear on the teeth compared to consumption of fiber through highly processed pelleted diets alone. Proper dental trimming should occur as often as necessary to maintain healthy weights and minimize oral pain in animals with malocclusion.

Fiber deficiencies can also contribute to reduced intestinal motility (constipation). A diet predominated by highly digestible energy and proteins and limited in fiber will significantly reduce gastrointestinal motility. To prevent constipation, provide chinchillas with grass hay or high-fiber leafy greens on a regular basis. If chinchillas become constipated, supplementation with fresh apple, pear, or leafy greens is therapeutic (Quesenberry et al., 2004).

Chinchillas are highly sensitive to mycotoxins and can die from acute aflatoxicosis. Aflatoxins are a group of naturally occurring mycotoxins that can grow on a wide variety of improperly stored feed, particularly when stored under conditions of high humidity and high temperatures. Gonzalez Pereyra et al. (2008) described an outbreak of acute aflatoxicosis that resulted in the death of 200 animals on an Argentine

chinchilla farm. Feed analysis identified the presence of aflatoxins B₁, B₂, G₁, and G₂ in the pelleted oat-based commercial feed. Diagnosis of aflatoxicosis is difficult because clinical signs are non-specific, but may include inappetence, weight loss, diarrhea, and discoloration of the fur and skin. Grossly, livers were friable and were characterized by generalized hepatomegaly with diffusely pale areas throughout the parenchyma. Histologic changes were characterized by moderate to severe intrahepatic vacuolation and lipid deposition. Diagnosis requires feed analysis and corresponding histopathologic lesions.

BREEDING

Reproductive Biology

Chinchillas are sexually dimorphic, with adult females typically larger than males (Table 40.1). Sexing chinchillas through examination of the genitalia can be challenging since the urethral papilla (urethral cone) in females strongly resembles the penis in its location and appearance. It is prominent, cone-shaped, and situated ventral to the vaginal opening (Strak et al., 1996). However, chinchilla sex is best determined by measurement of the anogenital distance and may be performed at a very young age. Like most rodents, this distance is significantly greater in males than in females. Sexing females during estrus can be easier since the vaginal closure membrane is perforated at this time and the perineum intensely deep red in color (Brookhyser and Aulerich, 1980). The testicles are not typically well visualized because they are situated just beneath the skin overlying the inguinal canal or retracted into the abdomen and a true scrotum is not present (Quesenberry et al., 2004). The testicles become more prominent when females are present. Gentle pressure along the prepuce will expose the penis.

Puberty in females occurs between 4–5 months of age; however, they are typically 8–10 months old before the first breeding estrus occurs. Females are seasonally polyestrous, with a 7-month breeding period (November to May) and a 5-month anestrus period in their natural habitat. In captivity, under a constant light-cycle, chinchillas breed year round with a mild breeding depression in the winter months. Chinchillas are spontaneous ovulators with cycling occurring every 30–50 days throughout the breeding season. Females can demonstrate a post-partum estrus; however, breeding during this period is typically not productive. Chinchillas raised in captivity typically only breed until 10 years of age despite their 20-year lifespan.

Chinchillas, similar to other species in the suborder Hystricomorpha, have a relatively long estrus cycle compared with other rodents. Vaginal cytology

TABLE 40.1 Reproductive Physiology

	Females	Males
Adult weight (g)	400–600	400–500
Puberty (months)	4–5	3–4

Implantation (days)	5.25	
Gestation (days)	105–115	
Litter size	1–6	
Weaning (weeks)	6–8	

is a reliable method for determining the sexual cycle in chinchillas (Bekyrek et al., 2001). The cycle is divided into four periods (proestrus, estrus, metestrus, and anestrus) with the start of estrus correlating clinically with evidence of vaginal closure membrane perforation. As with most mammalian species, the cytologic profile of the vaginal epithelium exhibits a continuum of cellular change that correlates with the hormone profile of the estrous cycle. Each cycle period is defined by the predominating cell types. The proestral period is typified by a mixed cellularity that undergoes a shift from moderate numbers of parabasal and small intermediate cells predominating early in the period to large numbers of superficial cells typifying the late period. A high neutrophil density and the presence of goblet cells are also characteristic of proestrus. Non-cornified and cornified superficial squamous epithelial cells predominate estrus and neutrophils, small intermediate cells and parabasal cells re-emerge during metestrus. Neutrophils and large intermediate cell densities are greatest during metestrus. Only during this period may foam cells (non-cornified cells containing vacuoles) and metestrum cells (non-cornified cells containing leukocytes) be present. Anestrus is characterized by the presence of superficial and parabasal epithelial cells with small numbers of intermediate cells and neutrophils.

Large, waxy vaginal plugs are produced to signify the beginning of estrus. Behavioral displays of female receptivity involve lordosis, hindlimb extension, and lateral deviation of the tail allowing for exposure of the perineum. Male mounting behavior involves clasping his forelimbs just cranial to the pelvic region of the female and the initiation of a short series of preliminary thrusts that increase with depth of insertion until ejaculation has occurred. Ejaculation terminates with the deposition of a seminal (copulatory) plug in the vagina that can remain in place up to several hours after mating (Bignami and Beach, 1968).

Females are not consistently receptive to males throughout estrus. Despite receptive posturing, females may not consent to male mounting, insertion, or ejaculation; or mounting may be allowed but insertion may be refused. The likelihood of receptivity is significantly reduced after a female has already engaged in one successful mating (Bignami and Beach, 1968). Following copulation, females may display intense aggression towards males, which can result in severe trauma to the male or even death. For this reason, breeding cages are designed to allow for male escape. The classic cage design involves small exit tunnels for males that preclude neck-collared females from entering.

Common Breeding Systems

Although chinchillas typically breed in monogamous pairs in the wild, most commercial breeding systems utilize a harem scheme with one male for every 4–6 females. With the breeding tunnel cages, one male can visit multiple females during periods of receptivity.

Since female-to-male interactions can be very aggressive, some breeding facilities utilize artificial insemination in addition to natural breeding techniques. Testicular volumes are typically smaller during the summer months compared with the fall and winter breeding season; however, total ejaculate volumes, spermatozoa numbers, and functional activity demonstrate minimal monthly variability (Busso et al., 2005; Leal and Franca, 2009). Puberty, defined by the presence of sperm within the epididymis, occurs by 3 months of age. However, full sexual maturity does not occur until about 17 months. By this time the testicular weight and tubular diameter have stabilized (Leal and Franca, 2008). Unanesthetized electroejaculation using a rectal probe set at 220 V (sinusoidal wave), 50 cycles/s repeated at 5–10-second intervals can produce good ejaculate volumes and high spermatozoa concentrations during early stimulation (Ponce et al., 1998). Alternatively, electroejaculation performed under heavy sedation or anesthesia requires higher voltages and more stimuli to achieve ejaculation (Busso et al., 2005). Chinchilla spermatozoa have been successfully cryopreserved, however viability was significantly lower compared to fresh samples. Freezing and thawing compromises membrane integrity that can lead to a reduction in viable acrosome-intact gametes and functional motility (Ponce et al., 1998).

Care of Young

Dams display minimal nesting behaviors in preparation for parturition and deliver in the early morning similar to other rodents. Kits are precocious, born

fully haired with their ears and eyes open and weighing between 30–50 g. Unlike altricial rodents, at parturition, chinchilla kits have a low tolerance for CO₂ and a high demand for oxygen (Brower, 2006). Once placental detachment occurs, any delay in delivery can quickly lead to compromise of the kits. Chinchillas rarely experience dystocia but are prone to retained feti due to late-term fetal death (Brower, 2006). Dams should always be palpated after parturition to evaluate the uterus for fetal retention and any retained, decomposing feti should be surgically removed. Failure to do so can result in compromise of the dam and litter. Dams may display a prolonged post-partum agalactia (12–72 h) with a gradual increase in milk production (Brower, 2006); during this period kits may require hand feeding. Consumption of solid food typically occurs within a week of birth, with weaning at 6–8 weeks.

COLONY HEALTH

Preventive Medical Strategies

Husbandry is often the most significant factor in medical problems of chinchillas (Lightfoot, 1999). Problems with husbandry are less common in a well-designed research program. A periodic review of procedures and expectations with animal care and research staff can assist in detecting any deviations that might eventually negatively impact animal health. Like other species, a daily observational health check should be performed. The daily check should include assessment of the volume and character of feces and urine, and the amount of food and water consumed (if on water bottle). Healthy animals are active, hold their tail erect, and their fur will be thick and smooth (Lightfoot, 1999). Healthy animals that are comfortable in their surroundings are curious and investigate activities in their housing room. Typically, they come to the front of the cage when a familiar caregiver enters the room, particularly if accustomed to receiving a food treat at this time. If time permits, it is beneficial to gradually accustom each animal to a gentle handling each day. Most chinchillas will soon seek both treats and attention, which will make handling for physical examinations and other procedures less stressful. Some animals may not come all the way to the front of the cage, but should still appear alert and responsive to their surroundings. Animals that appear disengaged or depressed (tail down, or a ruffled, moth-eaten, or barbered appearance to their fur) could be ill or may simply be experiencing excessive dominance from a cage mate. If dominance issues are suspected, standing well back from the cage for a longer observation period can be helpful in determining whether animals should be separated.

Colony Health Monitoring

Health monitoring is generally limited to physical examinations at acquisition and clinical observations made during daily visual examinations. Areas of particular concern are anorexia/weight loss, dental abnormalities, dermatologic conditions (barbering, dermatophytosis, environmental issues such as excessive temperature or lack of dust bath), diarrhea or constipation, or straining to urinate. Physical exams and specific diagnostic tests are typically only performed if clinical abnormalities are noted. However, some conditions that develop gradually are difficult to detect visually. For example, the chinchillas' thick fur can disguise weight loss (Lightfoot, 1999). For animals housed long term, handle periodically (e.g., monthly) to assess for weight loss (by simple palpation or actual weight), dental abnormalities, length of nails and lesions on feet, fur ring on the penis of males, and any conditions commonly seen in the colony. In large breeding colonies, individual health exams of animals that appear healthy at cage side during daily checks may be limited to veterinary assessment immediately prior to shipment.

RECORD KEEPING

Use of Records

Records should function to meet regulatory requirements, aid in providing adequate husbandry and veterinary care, and facilitate research objectives. Each facility should review the activities and needs of their program when determining number and type of records to be used to meet professional standards. To assure accurate communication between all people involved in animal care, the number and complexity of records should be minimized.

Breeding Records

Record systems developed for laboratory mouse colonies can be adapted to chinchillas. These include breeder cards at the cage level and pedigree and production logs to evaluate long-term colony performance (Fox et al., 2007). Various styles of cage cards, production logs, and pedigree charts are also available from chinchilla breeder organizations (e.g., www.chinchillabreeders.org). As with other species, production planning and management of large colonies is best accomplished with a computer database.

Husbandry Records

A single check sheet for recording daily care and environmental parameters is sufficient for documentation of

husbandry activities. However, to adequately record the variety in an extensive enrichment program a separate enrichment log should be used (Figure 40.2). Regardless of style or number of forms, there should be a place to document provision of dust baths and information regarding enrichment.

Health Records

The Animal Welfare Act and Animal Welfare Regulations do not specifically require or provide guidance regarding documentation of medical care for this species. Similarly, the *Guide for the Care and Use of Laboratory Animals* discusses the value of medical records in general and individual medical records specifically for some species (dogs, cats, non-human primates, farm animals, “large long-lived animals”), but does not specifically comment on chinchillas or other larger rodents (NRC, 1996). However, health records

for regulated rodents are included in the USDA Animal Care Policy 3 – Veterinary Care (USDA-APHIS, 2007), which stipulates that at minimum records should include identity, description and resolution of clinical abnormalities, dates and details regarding medically related activities (observations, diagnostics, treatments). In regards to the style of the records, it states, “As long as all required information is readily available, records may be kept in any format convenient to the licensee/registrant (e.g., on cage cards for rodents)” (USDA-APHIS, 2007). A cage card-style record will be sufficient for many colonies. These can either be created for each animal when it is received into the facility (or weaned) or issued only if a health concern is reported (Figure 40.3). A larger, standard medical record (hard copy or electronic system) may be preferred when managing colony-wide outbreaks or if frequent clinical interventions are required to support a particular research model.

INTRODUCTION

Performing basic experimental procedures on chinchillas can be a challenge due to their small size, their unique characteristics, and the limited amount of literature available describing these techniques. However, in general, many of the methods and concepts used in other rodent species may be applicable when performing basic procedures in chinchillas. Procedures such as handling, restraint, collection of samples, or administration of compounds can all be done relatively stress-free with minimal complications if performed

appropriately by skilled personnel. A thorough understanding and knowledge of the experimental procedure should be obtained prior to initiation to ensure the task is carried out properly. Oftentimes, first practicing the procedure on animals that have not yet begun an experimental study may be warranted. This allows the person who is performing the experimental technique to establish a level of comfort with the method to assure optimal execution when performed on experimental animals. The following text and figures highlight basic experimental methods in chinchillas based upon the literature and personal experiences of the authors.

HANDLING AND RESTRAINT

General Precautions

Chinchillas are typically quiet and shy rodents that can be easily handled if done so in a calm, quiet, and gentle manner. However, as a prey species, chinchillas may exhibit a flight response when presented with an uncomfortable situation. They may thus move about in short darting bursts or quick forceful lunges to attempt escape. Chinchillas may vocalize, lunge, box, and even urinate on people when attempts are made to pick them up, and so the handler should be quick and confident as well. Although chinchillas rarely bite, biting or scratching can occur if they become agitated, frightened, or stressed (Donnelly and Brown, 2004; Hrapkiewicz and Medina, 2007). Leather or Kevlar[®] gloves may be worn to add a layer of protection for the handler (Strake et al., 1996); however, gloves may be bulky and limit the handler's ability for delicate feel which could lead to inadvertent application of excessive pressure during manual restraint. Care should be exercised when attempting to handle and restrain chinchillas so as to avoid "fur slip," an escape mechanism in which a patch of hair is abruptly shed if enough tension is applied to the fur while the chinchilla is struggling to escape (Hoefer and Crossley, 2002; Riggs and Mitchell, 2009). Fur slip is not a degloving injury since typically the skin is not damaged but rather remains smooth and intact, though hairless. The fur may take months to regrow, and may grow in thin, sparse, and discolored in comparison to the original fur coat (Strake et al., 1996). Although mostly cosmetic in nature, fur slip may be alarming to the handler or restrainer if it occurs unexpectedly. On the other hand, attempting to catch a moving chinchilla by the tail may result in a degloving injury of the tail and is thus not recommended (Quesenberry et al., 2004). Other complications that may occur if chinchillas are handled improperly or restrained inadequately include bone fractures (e.g. tibia) from falls or trauma, restriction of respiration from excessive compression around the thorax, or loss of fetuses in pregnant chinchillas from rough handling or poor support of the dam's larger body size (Quesenberry et al., 2004; Strake et al., 1996). As is the case with other species, proper acclimation of the chinchilla to the handling or restraint method, whether physical or mechanical, should be done to minimize stress.

Physical Methods

Chinchillas should be handled in a manner that uses the least amount of restraint but is still firm enough so that the handler has good control of the animal. Excessive force or aggressive restraint beyond what is needed may promote additional stress to, and cause

FIGURE 41.1 Handling of a chinchilla with one hand supporting the hind legs and tail, and the other hand supporting the ventral thorax.

further struggling by, the chinchilla. Procedures should be performed quickly since the chinchilla, as a high-stress animal, may not tolerate handling, restraint, or procedures very well (Briscoe and Syring, 2004). Having additional hands available to help restrain the chinchilla may be of use in some circumstances (Donnelly and Brown, 2004), but may be limited by the body surface area available to hold the animal.

Chinchillas should not be scruffed (Donnelly and Brown, 2004; Riggs and Mitchell, 2009), but rather should be picked up by grasping the base of the tail with one hand while supporting the front end with the opposite hand. For additional control, it is often best to incorporate the hind limbs of the chinchilla in the same hand used to grasp the base of the tail. There are a variety of options for supporting the front end of the chinchilla depending on what is being performed. If minimal restraint is needed, such as during transport of a docile chinchilla for a short distance, the animal may be secured by the base of the tail with one hand while the opposite hand is placed gently under the chinchilla's ventral thorax for support (Figure 41.1). Alternatively, the chinchilla may be secured and carried in a "football" hold. This is done by allowing the chinchilla to rest on the handler's forearm with the base of the tail secured and the chinchilla's head and face tucked against the handler's body and arm (Figure 41.2). Nervous chinchillas often prefer to be held close to, and with their heads tucked into, the handler's body (Lightfoot, 1997, 1999).

For procedures that may require more control of the chinchilla or which have the need to orient the animal in a particular position (e.g. venipuncture), the animal may be secured by the base of the tail with one hand

FIGURE 41.2 The "football" hold. The chinchilla is placed on the handler's forearm with the base of the tail secured and the head tucked against the handler's body.

FIGURE 41.4 Restraint of a chinchilla in lateral recumbency.

FIGURE 41.3 Restraint of a chinchilla with one hand grasping the base of the tail and hind legs, and the other hand securing the back of the skull and dorsal neck.

and the head with the opposite hand (Figure 41.3). In this method, the restrainer's thumb is placed on one side of the chinchilla's head below the ear, the index and middle fingers placed over the top of the cranium, and the remaining fingers placed near the base of the skull, opposite the thumb. Depending on the size of the handler's hands or the size of the chinchilla, this hold may be modified by changing the position of the fingers on top of, or on the side of, the chinchilla's cranium to suit

FIGURE 41.5 Restraint of a chinchilla with one hand grasping the base of the tail and hind legs, while the other hand is placed around the dorsal thorax. Photo shows ventral aspect of the chinchilla.

the handler's preference. The chinchilla may then be securely presented in a variety of positions, such as in lateral recumbency (Figure 41.4), to facilitate whatever procedure is being conducted. Alternatively, support of the front end of a chinchilla may be accomplished by placing the hand over the animal's dorsal thorax with the handler's thumb cranial to the chinchilla's forelimb and the index and middle fingers encompassing the animal's opposite forelimb (Figure 41.5). Variations of this restraint technique may be performed by placing the thumb caudal to the animal's forelimb rather than cranial to the forelimb (often referred to as the "three-finger hold" in other species), or by encompassing the animal's forelimb with the thumb and index finger and the opposite forelimb with the middle and ring finger (often referred to as the "four-finger hold"). It should be noted that when performing restraint techniques that require the hand to be placed around the

FIGURE 41.6 Wrapping a chinchilla in a towel (A to D) as a method of restraint.

chinchilla's thorax, care should be exercised so that respiration is not inadvertently limited. Careful attention should always be paid to the respiratory pattern and other physical signs to assess for hypoxia due to excessive pressure around the thorax.

Towels or drapes may be of great use for handling and restraint of chinchillas. A towel should be laid out on a flat surface, the chinchilla placed on top, and then the towel is wrapped snugly around the chinchilla's body with only the head or necessary limb exposed (Figure 41.6). This method may be of use when performing oral exams, syringe feedings, or oral gavage to prevent chinchillas from using their front limbs to knock syringes or otoscopes away, or from using their powerful hind limbs to kick or lunge. Towels or drapes may also be useful for aggressive chinchillas prone to biting or scratching.

MECHANICAL METHODS

There are only a few reports in the literature describing restraint devices for chinchillas. Snyder and Salvi

(1994) describe a novel, custom-made restraint device to support auditory research constructed from inexpensive and readily available hardware supplies such as polyvinyl chloride (PVC) piping. Another custom-made restraint device described by Strout (1976) was designed to assist with restraint and oral dosing of chinchillas. It was also reported that this restraint device is suitable for performing clinical procedures such as taking rectal temperatures, clipping teeth, or obtaining blood samples. Although both of these devices permit restraint without anesthesia, their utility may be limited to procedures in which the required body part is accessible. To the authors' knowledge, no commercially available mechanical restraint device is available for chinchillas.

Chemical Methods

Chemical restraint of chinchillas may be performed by either using injectable or gas anesthetics. Many of the same principles, drugs, and dosages utilized in chinchillas for complete anesthesia may be suitable for restraint and will depend on the procedure being performed and the desired recovery time. Both gas and injectable

FIGURE 41.7 Delivering gas anesthetics to a chinchilla in an induction chamber.

anesthetics may be titrated to provide complete immobilization and restraint, or to calm and sedate an otherwise active chinchilla. Typically, for short-term restraint, gas anesthesia can be used since recovery is often rapid after cessation of anesthetic administration. Injectable anesthetics or sedatives may take longer for the chinchilla to metabolize and recover, however many of these drugs are now available with reversing agents; therefore, when selecting injectable agents, those with corresponding reversing agents are preferred. Specific anesthetic drugs and regimens for chinchillas have been reported in the literature (Heard, 2004; Hoefer and Crossley, 2002; Hrapkiewicz and Medina, 2007; Johnson-Delaney and Harrison, 1996; Riggs and Mitchell, 2009).

Gas anesthetics may first be delivered to the chinchilla via an induction chamber (Figure 41.7) and then, once immobilized, the chinchilla is transferred over to a nose cone on a non-rebreathing circuit (Figure 41.8). Alternatively, the chinchilla may be exposed to gas anesthesia solely via a nose cone; however, the chinchilla's protest to the gas anesthetic odor or the initial anesthetic excitement phase may necessitate additional physical restraint during these periods. Wrapping a chinchilla in a towel or drape as described in the section on physical methods of restraint is a suitable solution for these scenarios. Intubation can be difficult in chinchillas and so maintenance via a nose-cone may be sufficient for quick procedures which only require a short period of immobilization or restraint. However, if intubation is desired, direct visualization of the glottis using a 1.9- or 2.7-mm rigid endoscope to assist with the placement of an endotracheal tube in chinchillas has been described (Riggs and Mitchell, 2009). Both isoflurane and sevoflurane are commonly used gas anesthetics for chinchillas and can easily be titrated to the desired effect and duration of restraint. Sevoflurane may have a less objectionable odor than isoflurane (Riggs and Mitchell, 2009) and in one author's experience, chinchillas recover more rapidly with sevoflurane than with isoflurane. Halothane

FIGURE 41.8 Delivering gas anesthetics to a chinchilla using a nose cone and non-rebreathing circuit.

and methoxyflurane use in chinchillas has also been reported (Hoefer, 1994). Atropine (0.01–0.2mg/kg) given subcutaneously (SQ) or intramuscularly (IM), or glycopyrrolate (0.01–0.02mg/kg) given SQ or IM may be administered 10–20 minutes prior to induction if needed.

Use of injectable drugs and drug combinations for chemical restraint may induce prolonged recovery times when compared to the use of gas anesthetics. Therefore, deciding on which chemical restraint method to use and the amount or dose should be given careful consideration. Protocols used by the authors to provide mild sedation or short-term restraint include: (a) midazolam (0.2mg/kg, IM) to make chinchillas calm and “malleable” without significant sedation to perform short procedures such as radiographs; (b) midazolam (0.2mg/kg) + butorphanol (0.2mg/kg, IM) for short procedures of less than 20 minutes; this is reversible with flumazenil (0.02mg/kg, with half the dose given IM and half the dose given SC) and naloxone (0.02mg/kg, IM); (c) ketamine (5mg/kg, IM) + dexmedetomidine (0.03mg/kg, IM). Note that ketamine and dexmedetomidine can be mixed in the same syringe; and the combination may be used for longer procedures lasting about 45 minutes. This combination is reversible with atipamezole. These protocols may be supplemented with isoflurane and oxygen as needed.

Although some withhold food from chinchillas for periods ranging from 1–6 hours prior to an anesthetic event (Hrapkiewicz and Medina, 2007; Riggs and Mitchell, 2009), fasting may not be necessary in chinchillas since they cannot vomit or regurgitate (Boschert, 2005; Donnelly, 2004; Riggs and Mitchell, 2009; Strake et al., 1996; Zeinert, 1983), making the risk of aspiration low. Since fasting of many rodents may cause ileus and exhaustion of glycogen stores leading to hypoglycemia

(Heard, 2004), the same may be true of chinchillas, and the risks of fasting as opposed to the benefits should be evaluated for each animal.

SAMPLING TECHNIQUES

Blood

Collection of blood from chinchillas can be performed from a variety of anatomic locations. The volume of blood needed, the accessibility of the vessel, the temperament of the chinchilla, and the phlebotomist's skill are all factors to consider when selecting a site for blood collection. Larger vessels are better for obtaining samples in which it is critical that clotting does not occur since a larger and faster flow of blood can be obtained than from vessels of smaller size. Smaller vessels may be suitable for samples requiring less volume or samples in which clotting is acceptable (e.g. serum) since the slow blood flow and prolonged collection time may increase the likelihood of clotting. Regardless of which vessel is selected for blood collection in the chinchilla, clipping the hair and/or applying sufficient amounts of alcohol to wet down the fur may assist with visualization of the vessel. Sedation or anesthesia may be used to reduce the amount of stress a chinchilla may undergo during the procedure, as long as the potential effects of the anesthetics on experimental data obtained from the blood sample are taken into consideration (Briscoe and Syring, 2004). Because blood collection in anesthetized chinchillas may in fact be more challenging due to the drop in blood pressure caused by the anesthetic agent, it is recommended that blood collection first be attempted without chemical restraint.

As with all rodent species, the amount of blood removed from a chinchilla should be closely monitored to avoid any side effects related to iatrogenic blood loss. In general, the total circulating blood volume of most animal species can be estimated as 7% of their body weight and approximately 10% of the total blood volume may be safely removed (Table 41.1) (Diehl et al., 2001; Hrapkiewicz and Medina, 2007; Morton et al., 1993; Quesenberry et al., 2004). Alternatively, the amount of blood in ml equal to 1% of the body weight in grams may be safely removed from a healthy animal (Table 41.1) (Joslin, 2009; McClure, 1999; Pilny, 2008). Based upon recommendations in other rodent species (Diehl et al., 2001; Hoff, 2000), removal of 10% of the circulating blood volume should be limited to once every 2 weeks in healthy animals. Fluid supplementation should be provided for single blood collections of volumes greater than 10% of the circulating blood volume. However, even with fluid administration, blood collection volumes in healthy chinchillas should still

TABLE 41.1 Estimates of Blood Total Circulating and Withdraw Volumes in Adult Chinchillas

Chinchilla Weight (g)	Total Blood Volume (ml) ^a	Withdraw Volume: 10% of Total Blood Volume (ml)	Withdraw Volume: 1% of Body Weight (ml)
400	28	2.8	4.0
500	35	3.5	5.0
600	42	4.2	6.0

^aEstimated based upon 7% of body weight.

TABLE 41.2 Needle Sizes, Average Volumes Collected, and Anesthesia Requirements for Various Blood Collection Methods in Chinchillas

Method	Needle Size (gauge)	Average Volume Collected (ml)	Anesthesia Required
Jugular	22–25	1–3	No
Femoral	25–27 ^a	0.5–1	No
Cephalic	25–27 ^a	0.3–1	No
Lateral saphenous	25–27 ^a	0.3–1	No
Cranial vena cava	22–23	1–3	Yes
Retro-orbital	Not applicable	1–3	Yes
Transverse sinus	25	1–3	Yes
Cardiac	20–23	>5	Yes ^b

^aAn insulin syringe may also be used.

^bTerminal procedure, euthanize while under anesthesia after blood collection.

be limited to 15–20% of the animal's circulating blood volume.

As with other species, removing the needle prior to transfer of the blood sample from the syringe to a tube is recommended in order to limit the amount of hemolysis that may result from attempts to force red blood cells through a narrow needle. For insulin syringes, a hemostat can be used to grasp the base of the needle to detach it from the syringe prior to transferring the sample to the collecting tube.

Table 41.2 summarizes the needle sizes, average volumes collected, and anesthesia requirements for the various blood collection techniques described in the following sections.

Jugular Vein

Collection of blood from the jugular vein of chinchillas is generally well tolerated by the awake, unsedated, or unanesthetized animal. The jugular veins, located in the ventral cervical neck, may be the best option when large samples of blood are required that need to

FIGURE 41.9 Jugular vein blood collection from a chinchilla in dorsal recumbency.

be collected in a timely fashion (e.g., for anticoagulated blood samples). One method to access the jugular vein in chinchillas is with the animal on its back. As with some rabbits, chinchillas may become relaxed when placed on their backs, thus aiding in the procedure. This technique is performed by having an assistant restrain the hind end of the chinchilla with one hand while the other hand supports and extends the neck by grasping the loose skin around the ear and neck (Figure 41.9). After a sufficient amount of alcohol is placed over the area of the jugular vein to help with visualization (clipping the fur may also be used), the phlebotomist uses the thumb or index finger of one hand to apply gentle pressure on the vessel at the level of the thoracic inlet, and the other hand to position the syringe and insert the needle into the jugular vein at an approximately 20° angle. Since chinchillas may attempt to use their forelimbs to bat at the syringe in the phlebotomist's hand, it may be necessary to provide additional restraint of the chinchilla's front legs.

Alternatively, jugular vein blood collection in chinchillas may be performed similar to the method used in cats in which their bodies are in sternal recumbency, their head and neck extended, and their forelimbs extended forward and ventrally (Figure 41.10) (Briscoe and Syring, 2004; Ness, 1999; Pilny, 2008). The hind legs should be securely supported and controlled to prevent the chinchilla from kicking during the blood draw. A 22–25-gauge needle should be used attached to a 1–3-ml syringe. The needle can be bent slightly at a 30–45° angle to facilitate the angle of approach into the vessel if necessary (Joslin, 2009).

Femoral Vein

The femoral vein in chinchillas can be used to collect blood in a way similar to the method used to sample the medial saphenous vein in cats (Joslin, 2009). This vein is located on medial aspect of the hind limb providing easy

FIGURE 41.10 Restraint of a chinchilla in a sternal position for jugular vein blood collection, similar to the method used in cats.

access with a 25–27-gauge needle and a 1-ml syringe (Ness, 1999). The chinchilla should be placed in lateral recumbency with the non-recumbent hind limb held in a flexed position against the chinchilla's body. The medial aspect of the recumbent hind limb is now accessible and slight pressure can be applied proximally on the medial thigh over the vein to assist with venipuncture.

Cephalic Vein

The cephalic vein runs along the cranial aspects of the lower forelimbs and can be sampled using a 25- or 27-gauge needle and a 1-ml syringe (Briscoe and Syring, 2004; Lightfoot, 1997; Riggs and Mitchell, 2009). The chinchilla should be restrained on a table and the hair clipped along the cranial aspect of the forelimb. The forelimb can then be extended by the restrainer while simultaneously holding off the cephalic vein (Figure 41.11). The phlebotomist can then hold and secure the paw with the non-dominant hand and manipulate the syringe and needle with the dominant hand. Paolini et al. (1993) reported that they rarely collected greater than 0.5 ml of blood when using the cephalic vein. Although typically only small amounts of blood may be obtained due to the small size of the cephalic vein, this vessel, along with the jugular and femoral veins, are preferred venipuncture sites in the chinchilla since most phlebotomists are familiar and have experience with these vessels in other species.

Lateral Saphenous Vein

Similar to the cephalic vein, the lateral saphenous vein in the chinchilla may be used to collect small samples of blood. The vein is located on the lateral aspect of the

lower hind legs (Figure 41.12) and can be sampled using a 25- or 27-gauge needle on a 1-ml syringe or using an insulin syringe (Briscoe and Syring, 2004; Riggs and Mitchell, 2009).

Cranial Vena Cava

Although there have been reports describing the use of the cranial vena cava for blood sample collection in the chinchilla (Briscoe and Syring, 2004; Hrapkiewicz and Medina, 2007; Joslin, 2009; Riggs and Mitchell, 2009), this procedure, as in other species, is more invasive and may have a higher incidence of complications (e.g. bleeding into the thoracic cavity) when compared to blood collection from other anatomic sites. However, large volumes of blood can be obtained from the cranial vena cava and Joslin (2009) categorizes this anatomic

location as a recommended site for chinchilla venipuncture in the private practice setting as opposed to a venipuncture site of last resort. To perform this procedure, the anesthetized chinchilla is placed in dorsal recumbency with the forelimbs pulled downwards and caudally. The phlebotomist, standing at the head of the animal, secures the head and inserts a 22–23-gauge needle connected to a 3–5-ml syringe at a 45° angle into the notch between the manubrium and the first rib slightly lateral to midline, directing the needle toward the opposite hind leg (Briscoe and Syring, 2004). The plunger on the needle is then pulled back to create a slight vacuum while the needle is slowly withdrawn until a flash of blood is seen in the hub. If unsuccessful, probing for the vessel is not recommended due to the risk of laceration and damage to surrounding structures. After the sample is collected, direct pressure should be placed on the sampling site, and the chinchilla should be watched closely to ensure adequate recovery.

Orbital Sinus

Collection of blood from the orbital sinus has been described for use in the laboratory setting (Brookhyser et al., 1977; Strake et al., 1996), however it is generally recommended only as a last resort (Joslin, 2009) or not recommended at all for use in pet chinchillas (Hoefer, 1994; Ness, 1999). In the laboratory setting, as is the case with this technique in other rodents, minimal complications may be observed if performed properly by skilled personnel. Complications reported in the chinchilla include hemorrhage, conjunctivitis, and corneal opacities (Brookhyser et al., 1977), although no differences in food consumption or body weights were noted in chinchillas that were bled twice weekly for approximately 2 months vs. those that were not bled (Brookhyser et al., 1977).

FIGURE 41.11 The cephalic vein (arrow) in the forelimb of a chinchilla.

FIGURE 41.12 (A) Restraint of a chinchilla for blood collection from the lateral saphenous vein. (B) The lateral saphenous vein (arrow) in the hind limb of a chinchilla.

The technique is similar to that described for mice and rats and can be used to obtain 1–3 ml of venous blood (Brookhyser et al., 1977). The chinchilla should be anesthetized, the head held firmly with its nose pointing downward, and the eyelids held wide open with the thumb and forefinger. A microhematocrit tube is placed at the medial canthus of the eye between the globe and the eyelid, and directed medially and caudally. The microhematocrit tube should be gently advanced while rotating it along the long axis of the tube until blood is seen. Blood can be collected in the microhematocrit tube itself, or allowed to drip from the end of the microhematocrit tube into a larger collection tube. After removal of the microhematocrit tube, hemostasis should be ensured by using a piece of gauze to hold the eyelids closed and applying gentle pressure over the eye.

Transverse Sinus

The transverse sinus is a venous system that encircles the large auditory bullae in chinchillas and is connected to the zygomatic venous system and the superior sagittal sinus (Figure 41.13A) (Browning and Granich, 1978; Paolini et al., 1993). The transverse venous system may be used to reliably obtain 1–3 ml of blood in an anesthetized chinchilla and may even be used to obtain 10 ml of blood or more (Boettcher et al., 1990; Paolini et al., 1993). The fur over the auditory bullae, located on the dorsal aspect of the head and between the two ears, should be clipped and the skin prepared aseptically. A 25-gauge, 3/8-inch butterfly needle attached to a 1-ml syringe should then be inserted perpendicular to the skull approximately 1 mm medial from the edge of the auditory bulla, just slightly lateral to the midline of the skull (Figure 41.13B). The needle should be gently advanced approximately 1–2 mm with a slight twisting motion to get through the skin and then through the thin layer of bone overlying the sinus. Once through the roof of the sinus, the bony floor of the sinus can be found only 1 mm from the roof and so care should be taken to avoid advancing the needle too far into the auditory bulla or cranium. With the needle seated in the sinus, negative pressure can be applied to the 1-ml syringe to begin blood collection. Once proper placement has been verified, the 1-ml syringe can be changed to a larger 5- or 10-ml syringe. Paolini et al. (1993) suggested starting with a 1-ml syringe to aspirate as opposed to a larger syringe to avoid producing excessive negative pressure and potentially rupturing the tympanic membrane should the auditory bulla be inadvertently accessed. Unintentional entry into the auditory bulla was the most common complication reported, however no adverse sequelae were noted (Paolini et al., 1993). Boettcher et al. (1990) described damage to the central nervous system and partial paralysis in one of 15 chinchillas when the subject was not completely anesthetized and

FIGURE 41.13 (A) Dorsal aspect of the head of a chinchilla with the fur removed and the venous system highlighted (A: transverse venous sinus; B: zygomatic venous system; C: superior sagittal sinus). The needle is inserted approximately 1 mm lateral to the asterisks into the transverse venous sinus. (B) Blood collection from the transverse venous sinus of the chinchilla. Figures published in and obtained, with permissions, from Paolini et al., 1993.

subsequently moved during the procedure. However, they described use of a 25-gauge, 5/8-inch needle, thus use of a shorter needle, such as the 3/8-inch butterfly needle, is recommended.

Cardiac Puncture

Cardiac puncture should only be performed with the animal under complete anesthesia or immediately after euthanasia has been confirmed. Large volumes of blood may be obtained via this method, however it should only be utilized as a terminal procedure (Hrapkiewicz and Medina, 2007). The anesthetized chinchilla may be placed in lateral recumbency and a 20- or 23-gauge, 1-inch needle on a 5- or 10-ml syringe used to access the heart through the ribs. Alternatively, the chinchilla may be placed in dorsal recumbency with the needle entered just below the xiphoid process, directed cranially and at a 30° angle toward the heart.

Other Peripheral Veins

Collection of blood from other peripheral veins such as the auricular, tail, dorsalis penis, and lateral abdominal vein have been described in the chinchilla (McClure, 1999; Ness, 1999; Tappa et al., 1989). Sampling from these sites is typically performed by laceration of the vein and drip collection of the blood into a tube since these vessels will collapse due to their small size if aspiration is attempted with a needle and syringe. However, these sites typically only yield very small amounts of blood, are not easily accessible, and may carry a greater risk of post-venipuncture complications. As a result, these veins are not commonly used and may be considered unsuitable for blood sampling in some applications. For example, the tail vein, lateral abdominal vein, and dorsal vein of the penis are all very difficult to identify and locate and so are generally not practical for routine blood collection (Ness, 1999; Tappa et al., 1989). Boettcher et al. (1990) and Paolini et al. (1993) state that the thick cartilaginous sheath surrounding the tail vessels in the chinchilla makes venipuncture difficult and results in variable yields.

As with pet rabbits, the use of the auricular vein in chinchillas is generally frowned upon and not recommended when treating the pet population due to risk of thrombosis and trauma of the pinna (Hoefer, 1994; Joslin, 2009). In contrast, the auricular vessels are often used in rabbits in the research setting with few complications. Nonetheless, since such small volumes are obtained from the auricular vessel in chinchillas and other more convenient sites are available, the ear may not be the optimal choice for blood collection unless only very small amounts of blood are needed and other collection sites are not practical. The vessel may be pricked with a needle, or a 27-gauge needle may be inserted into the vein, and then the blood collected with

a microhematocrit tube (Ness, 1999). However, repetitive sampling should be avoided to minimize the risk of complications with the ear (Hoefer, 1994; Hrapkiewicz and Medina, 2007).

Urine

Collection of urine from chinchillas may be performed similar to other species. The simplest method of urine collection is to place them in a metabolic cage. Similarly, performing a free catch or collection from a table or floor may be sufficient as chinchillas will often urinate when agitated or annoyed (Hrapkiewicz and Medina, 2007). Manual expression may also be performed by applying gentle pressure to the urinary bladder through the abdominal wall (Hrapkiewicz and Medina, 2007; Ness, 1999). However, if urine is needed for microbiologic culture, these methods may not be suitable due to contamination with environmental bacteria. To obtain a sample for urine culture, cystocentesis may be performed. Sedation or anesthesia may be used, although some chinchillas may tolerate this procedure awake. The chinchilla should be placed in dorsal recumbency and the urinary bladder located through the abdominal wall (Figure 41.14A). While holding the urinary bladder securely with the non-dominant hand, a 25-gauge, 5/8-inch needle with a 1- or 3-ml syringe should be inserted cranial to the external genitalia and at an approximately 30–45° angle to the table (Figure 41.14B). Ultrasound may also be used to assist with cystocentesis if available (Riggs and Mitchell, 2009). Catheterization of the urinary bladder to obtain urine may be difficult due to the chinchilla's small size, however it may be possible when necessary to relieve an obstructed urethra (Ness, 1999). An open-ended, 3½-French, 5½-inch-long tom cat catheter or a 3½-French red rubber catheter is recommended for use in chinchillas.

Cerebrospinal Fluid

Cerebrospinal fluid collection in the chinchilla can be performed in the subarachnoid space beneath the atlantooccipital membrane (Juhn et al., 1974). Although a detailed description of the procedure has not been described for chinchillas, the cisterna cerebellomedullaris, also known as the cisterna magna, is the most common site for obtaining cerebrospinal fluid in other species and is located where the caudal surface of the cerebellum meets the dorsal surface of the medulla oblongata (Fenner, 2000; Fletcher, 1993). To perform the procedure, the chinchilla is placed under anesthesia and the cranial portion of the dorsal neck and occipital area of the skull are then clipped to remove the fur. The chinchilla is then placed in lateral recumbency and with the neck in slight flexion. The clipped area is

FIGURE 41.14 (A) Palpation of the urinary bladder through the abdominal wall. (B) Cystocentesis in a chinchilla using a needle and syringe.

aseptically prepared. Sterile technique should be followed for the procedure. A spinal needle is then inserted on the midline caudal to the occipital protuberance in the space between the base of the skull and the atlas bone. The needle should be inserted approximately perpendicular to the long axis of the spine and parallel to the table surface. A loss of resistance can be felt when the needle enters the subarachnoid space. The stylet is then removed and cerebrospinal fluid is collected. A 25-gauge, 1.6-cm-long hypodermic needle is described for use in cerebrospinal fluid collection in ferrets (Platt et al., 2004) and so needles of similar size may be suitable for cerebrospinal fluid collection in chinchillas.

Semen

Collection of semen and spermatozoa by electroejaculation has been described in the chinchilla (Busso et al., 2005; Ponce et al., 1998). Electroejaculation provides the advantage of being able to collect multiple samples from one individual, as well as avoiding surgery or euthanasia for sample collection. The authors describe using a bronze bipolar electrode with a length of 40 mm and diameter of 4.2 mm. The chinchilla was restrained, the genital area cleaned, the prepuce retracted, and the penis introduced into a 2-ml plastic tube. The electrode was lubricated and inserted in the rectum approximately 20–30 mm and an alternating current (sinusoidal wave, 50 cycles/s) was applied for 5 of every 10 seconds. A rheostat was used to control the electrical potential across the poles of the electrode and measured with a voltmeter. A series of one to six pulses at 6–6.8 volts was used (Ponce et al., 1998), or four series of up to five pulses were applied at 6–6.5, 7.5–8, 9.5–10, and 11.5–12 volts (Busso et al., 2005). Busso et al. (2005) found that ketamine (40 mg/kg, intramuscular) anesthesia significantly reduced the success rate of electroejaculation from 100% to 60% in unanesthetized

vs. anesthetized chinchillas, respectively. Also the volume of semen obtained in anesthetized chinchillas was greatly reduced.

Bone Marrow

Bone marrow collection in chinchillas may be performed as a single procedure, or at the same time as placing an intraosseous catheter to administer fluids or compounds. The proximal femur (via the trochanteric fossa) or the proximal tibia (via the tibial crest) are the most common sites to access the medullary cavity (Briscoe and Syring, 2004; Riggs and Mitchell, 2009), although the ileum or the proximal humerus may be utilized in some small exotic species and may be useful for chinchillas (Pilny, 2008). To perform the procedure, the chinchilla should be put under general anesthesia, the hair over the insertion site clipped, and the site aseptically prepared. All subsequent steps should be performed using sterile technique. Injection of 2% lidocaine in the sampling site should be performed to locally anesthetize the surrounding structures and periosteum. A small stab incision can then be made through the skin using a scalpel or needle. The bone is then firmly grasped with the forefinger placed along the long axis of the bone to assist with orientation and needle placement. A 20-, 22-, or 25-gauge, 1-1/2-inch spinal needle with an internal stylet is then inserted through the stab incision and seated into the medullary canal by rotating the needle on its long axis while concurrently applying gentle pressure to advance the needle. The stylet prevents a core of bone from plugging the tip of the needle; however standard hypodermic needles may be used if spinal needles are unavailable. Once the needle is advanced through the cortex, a sudden loss of resistance will be noted as the medullary space is entered. The stylet is then removed and a syringe attached to apply negative pressure until bone marrow is aspirated into the hub of the needle.

COMPOUND ADMINISTRATION

Administration of compounds or fluids in chinchillas may be done by a variety of routes including oral, intravenous, intramuscular, subcutaneous, intraperitoneal, or intraosseous. Selecting the optimal route of delivery for compound administration is dependent on multiple factors. Absorption of the compound into the bloodstream and subsequently into the target organ will vary depending on the route, thus contributing to the length of the time before the desired effect occurs. In general, intravenously administered compounds have a very rapid effect since the compound is delivered directly into the bloodstream and thus immediately distributed systemically after administration. On the other hand, intramuscularly or subcutaneously delivered compounds must first be absorbed from the muscle or subcutaneous tissues, respectively, into the bloodstream, thus prolonging the time for distribution. Furthermore, selection of a delivery route may be dependent on the compound itself since some compounds may cause tissue irritation or necrosis via one route but not the other. The volume to be administered also plays a role in selecting a route of administration since some locations accommodate larger volumes than others (Table 41.3). Considering these factors, careful thought and consideration should be made prior to selecting a method of delivery.

Oral

Delivering compounds to chinchillas orally may be done by administering the compound in food, in the drinking water, via a syringe, or by gavage. Although putting the compound in the chinchilla's daily food or water source may be the simplest method, it is often difficult to control the amount of compound that is ingested. Also, if the compound is not palatable, it

may decrease the chinchilla's intake of food and water. Therefore, it is recommended that compounds in tablet form be administered by crushing them into a powder and placing them in treats such as raisins (Donnelly and Brown, 2004; Hrapkiewicz and Medina, 2007; Quesenberry et al., 2004). Alternatively, the powder may be mixed with water in a syringe and manually fed into the side of the chinchilla's mouth. Small syringes or eyedroppers may be used to administer small volumes (Strake et al., 1996), while large volumes may be dispensed with a 35-ml catheter tipped syringe. Mixing the compound with fruit-flavored electrolyte solution (Riggs and Mitchell, 2009) or with sweetened water (5ml of sugar or syrup per liter of water) (Hrapkiewicz and Medina, 2007) may increase palatability and success. A feeding tube may also be used to deliver compounds directly into the stomach. It is recommended that a speculum or other device be used to prevent the chinchilla from biting through the tube during the procedure (Strake et al., 1996). However, passing a feeding tube in an awake and excited chinchilla may be difficult and so should only be attempted in animals with a calm, quiet demeanor. Additionally, their long and narrow oral cavity may add to the level of complexity of this procedure (Riggs and Mitchell, 2009).

Intravenous

Generally, the same methods and sites described to access a vessel for blood collection may also be used for intravenous administration. The more common sites for intravenous compound administration include the jugular, cephalic, femoral, and lateral saphenous vein. Other veins which can be used or that have been described include the auricular, lateral abdominal, tail, or dorsalis penis vein. For most of these vessels, a 22–25-gauge needle connected to a 1- or 3-ml syringe, or an insulin syringe is suitable. Alternatively, butterfly needles of the same gauge can be used.

Catheters may be used to facilitate intravenous compound administration as well as blood sampling. Although catheter placement in chinchillas may be a challenge due to their small size and fragile veins (Quesenberry et al., 2004), 24-gauge or smaller catheters may be placed in the cephalic, femoral, or lateral saphenous veins (Briscoe and Syring, 2004; Riggs and Mitchell, 2009). It may be helpful to first puncture the skin with a 22-gauge needle and then place the catheter through the hole in the skin to avoid burring and bending the catheter (Briscoe and Syring, 2004). Alternatively, a jugular cut down may also be performed if the other peripheral vein catheterization attempts are unsuccessful. As with other species, an Elizabethan collar may be necessary to prevent the animal from chewing and removing the catheter (Riggs and Mitchell, 2009).

TABLE 41.3 Single Bolus Injection Volume Limits in Adult Chinchillas

Route of Administration	Volume (ml)
Subcutaneous ^{a,g,h}	25–50
Intraperitoneal ^{a,c,d}	10
Intravenous ^a	1
Intramuscular ^{a,b,c,d,e,f}	0.3–0.5

^hAuthors' experience.

Vascular access ports, or VAPs, are commonly used in laboratory animals to provide long-term intravenous access. Typically, the titanium or plastic ports are surgically implanted under the skin. The ports are connected to catheters that are tunneled through the tissues into the lumen of a blood vessel. The vessel can then be accessed through the silicone septum for either administration of compounds or withdrawal of blood. Drawbacks of using VAPs include the need for surgery to implant the ports, continuous maintenance and flushing of the ports to ensure patency, and risk of infection if a break in aseptic technique occurs during access. However, when properly implanted and cared for, VAPs can be used in a variety of vessels and maintained for long periods.

Intramuscular

Intramuscular injection in the chinchilla may be performed in the epaxial muscles (typically lumbar region) or the muscles of the hind leg (Hrapkiewicz and Medina, 2007; Quesenberry et al., 2004). To locate the lumbar muscles, the chinchilla should be securely restrained in the “football” hold or on a flat surface. The spine should be located at the level of the lumbar vertebrae. A 23- or 25-gauge needle should be used to inject just laterally to the spine where the lumbar muscles can be palpated. Injection into the muscles of the upper hind leg or thigh of the chinchilla is similar to that in other species, and the cranial or caudal portion of the leg may be used. As in other species, avoidance of the sciatic nerve is recommended.

Subcutaneous

Subcutaneous injection is commonly performed on the dorsum of the chinchilla anywhere from the neck/interscapular region down to the lumbar region. Injections can also be performed more laterally over the thorax or in the flank region as well. Care should be taken to avoid fur slip when attempting to administer a subcutaneous injection (Johnson-Delaney and Harrison, 1996; Riggs and Mitchell, 2009). When compared to other administration routes, large volumes may be injected subcutaneously due to the elasticity of the skin and the ability to use multiple injection sites at one time. However, the amount injected per site should still be limited as the stretching of the skin may become painful with high volumes. Although some report a maximum of 8–35 ml per site (Hrapkiewicz and Medina, 2007; Quesenberry et al., 2004), the authors have routinely administered up to 50 ml of sterile saline per site. Of course, the maximum amount will depend on the chinchilla’s size and demeanor, elasticity of the skin,

characteristics of the injected material, and frequency of injection. A 22-gauge needle attached to a syringe may be used, or alternatively butterfly needles and fluid bags may be utilized.

Intraperitoneal

The intraperitoneal cavity is a common route of compound and fluid administration in small animals such as the chinchilla. Absorption is presumed to occur through the serosal surfaces of the abdominal organs and the peritoneal membrane (Riggs and Mitchell, 2009). The procedure is best performed with two people. The restrainer should place the chinchilla in dorsal recumbency with the head tilted slightly down so that the visceral organs will presumably rest cranially due to gravity. Administration into the right lower quadrant of the abdomen is preferred when performing intraperitoneal injections in other rodent species in order to avoid the spleen and cecum (Bihun and Bauck, 2004). The person performing the injection should use one hand to extend the chinchilla’s right hind leg caudally while performing the injection with the other hand. A 22-gauge or smaller needle is then inserted in the posterior right quadrant of the abdomen at an approximately 30° angle in relation to the chinchilla’s ventrum. Negative pressure should be applied to the syringe to see if any material is aspirated. If any fluid or material is seen in the syringe, then the gastrointestinal tract may have been inadvertently entered. In this case, the needle and syringe should be removed and discarded as the compound is now contaminated with gastrointestinal bacteria and should not be injected into the sterile abdominal cavity. A new needle, syringe, and fresh compound should be obtained and the procedure attempted again. If no fluid or material is seen upon aspiration, then the compound may be injected.

Intraosseous

Intraosseous catheters provide access to the medullary canal in which fluids or compounds may be infused and are rapidly absorbed (Briscoe and Syring, 2004). Since vascular access may be challenging in smaller species like chinchillas, intraosseous catheters may be a reliable and useful alternative technique for compound administration. These catheters may remain in place for up to 72–96 hours if necessary (Briscoe and Syring, 2004; Riggs and Mitchell, 2009). Placement of an intraosseous catheter is the same as already described in the section on bone marrow collection in the chinchilla. Once the spinal needle is seated in the medullary canal of the proximal femur or tibia, placement can be verified by moving the limb since the

needle should move in the opposite direction to the limb when the limb is moved. Antimicrobial ointment should be applied to the insertion site and the catheter secured with a thick non-compressing bandage encompassing the hub of the catheter and the limb distally. Alternatively, the catheter may be secured by applying an adhesive tape butterfly around the hub of the needle and suturing the tape to the skin. An extension set or intravenous fluid line can be attached to the end of the intraosseous catheter for compound and fluid administration.

SPECIALIZED RESEARCH TECHNIQUES

Auditory Research

The chinchilla is well known for its utility as an animal model for auditory research and diseases of the ear (Amoils et al., 1992; Bakaletz, 2009; Henderson et al., 1994; McFeely et al., 2000; Tang et al., 2009; Tanaka et al., 2009). Chinchillas have large, thin-walled tympanic bullae that measure approximately 25 mm long craniocaudally, 22 mm high, and 12 mm wide (Brown, 2007; Daniel et al., 1982; Hanamure and Lim, 1987). These large bullae lie subcutaneously and can be palpated on the dorsal skull of the chinchilla between and slightly rostral to the base of the pinnae (Brown, 2007; Daniel et al., 1982; Browning and Granich, 1978), thereby providing easy access to the structures of the middle and inner ear. Brown (2007) describes the surgical approach to access the middle ear of chinchillas when used as a model for otitis media. This approach is used to collect fluid or inflammatory material from the normally air-filled tympanic cavity, or to inoculate bacteria to induce the middle ear infection. Briefly, the chinchilla is anesthetized and placed in sternal recumbency. The area over the tympanic bullae on the dorsal part of the skull is clipped, prepared aseptically and draped. A 14–16-gauge needle is placed perpendicular to the bone and gently advanced while rotating the needle on its long axis into the tympanic cavity through the bone. The needle is then removed and the cut end of tubing from a butterfly infusion set can be placed through the hole left by the needle. A syringe attached to the butterfly tubing can then be used for aspiration or infusion. Alternatively, the needle used to enter the tympanic bulla may be left in place and a polyethylene catheter passed through the needle for sample collection (Antonelli et al., 2006). Antonelli et al. (2006) also describe the use of a second needle (23-gauge) concomitantly inserted into the tympanic bulla to vent the middle ear and prevent rupture of the tympanic membrane. After the procedure, the tube is removed, the skin is

closed with tissue adhesive, and the bone left to heal by second intention (Brown, 2007).

Access of the large tympanic cavity of chinchillas also allows access to the structures of the inner ear. Perilymph, a fluid contained in the inner ear, may be collected with small glass capillary micropipettes by exposing the round window, a membrane separating the middle and inner ear (Juhn et al., 1974; Rybak et al., 1979).

The tympanic membrane, or ear drum, is a thin membrane that separates the outer ear canal from the middle ear. The chinchilla is used as a model to induce and study diseases of the tympanic membrane (Amoils et al., 1992; McFeely et al., 2000). Otoscopy, otomicroscopy, myringotomy/ectomy, and tympanometry are just some examples of specialized research techniques that have been used in chinchillas to evaluate the tympanic membrane (Antonelli et al., 2006; Valtonen et al., 2001).

INTRODUCTION

Almost all publications describing disease prevalence for chinchillas have been related to the pet trade or raised for fur rather than for chinchillas that are housed within a limited number of well-managed

research facilities. For pet chinchillas, most abnormal health conditions are a result of husbandry or diet deficiencies (Donnelly, 2004). Diseases resulting from bacteria in chinchillas usually relate to opportunistic agents by commensal bacterial residents that will cause overt disease, either localized to one organ (e.g., *Streptococcus*,

colibacillosis) or as septicemia. Organisms, such as *Listeria* may lead to disease through contamination of feed. Disease by opportunistic agents or parasites usually occurs in animals that are immunocompromised whether through age, nutritional status (improper diet), or environmental stress. Other conditions in chinchillas that require veterinary care are typically secondary to metabolic, nutritional, traumatic, reproductive disorders, and a limited number of age-related and miscellaneous conditions. Additional comprehensive reviews of diseases observed in chinchillas are found in Donnelly (2004), Donnelly and Quimby (2002), Hayes (2000), and Pridham et al. (1996). A comprehensive review of normative clinical data and supportive therapy for chinchillas is described by Quesenberry et al. (2004).

INFECTIOUS DISEASES

Bacterial Diseases

The indigenous bacterial flora of the lower intestinal tract was evaluated in two chinchillas by Worthington and Fulghum (1988) from the Virginia Polytechnic Institute Anaerobe Laboratory. Using anaerobic techniques, the predominant bacterial flora of the colon, cecum, and fecal pellets were evaluated. Species of *Bacteroides* and *Lactobacillus* were commonly identified, and *Bifidobacterium* was cultured once. The recovered flora did not differ significantly from other species of rodents (Worthington and Fulghum, 1988) and their findings are similar to earlier work by Mathieu et al. (1982). Bacterial infections and inadequate husbandry were the most common causes of death in chinchillas at one veterinary college in Canada (Pridham et al., 1966). To alleviate some bacterial infections, chinchillas on fur farms in Germany are vaccinated to prevent disease from *Pseudomonas*, *Escherichia coli*, and *Yersinia* (Matthes, 1985) and chinchillas in Canada have shown immunity to *Pseudomonas* for 36 weeks following vaccination with two doses of a *P. aeruginosa* bacterin (Lusis and Soltys, 1971a).

Listeriosis

BACKGROUND

Listeriosis in chinchillas is common in fur-ranched chinchillas but is not frequently observed in chinchillas within a research environment (Finley and Long, 1977; MacDonald et al., 1972; Nilsson and Soderlind, 1974; Wilkerson et al., 1997). MacKay et al. (1949) provided the first report of listeriosis in chinchillas. Several authors suggested that chinchillas appear to be the most susceptible animal to infection with *Listeria monocytogenes* (Gray and Killinger, 1966; MacDonald et al., 1972), but the prevalence is probably attributed to case reports of listeriosis in chinchillas located on ranches in

cold climates where the animals are fed silage or substitute roughage in pellets, such as beet pulp (Cavill, 1967; Finley and Long, 1977; Wilkerson et al., 1997). Similarly, listeriosis is reported in group-housed animals such as cattle, sheep, goats, deer, swine, rabbits, rodents, birds, and turtles maintained with similar environmental and dietary circumstances (MacDonald et al., 1972; Nilsson and Soderlind, 1974). Advances in taxonomy, isolation methods, bacterial typing, molecular biology, and cell biology of *L. monocytogenes* have contributed to understanding of the agent and associated disease (Low and Donachie, 1997; Rouquette and Berch, 1996; Schlech, 1996).

ETIOLOGY

Listeria monocytogenes is a pleomorphic, motile, non-spore-forming, β -hemolytic, Gram-positive bacillus that inhabits the soil for long periods of time. The organism is a highly adaptable environmental bacterium that can exist both as an animal pathogen and plant saprophyte with a powerful array of regulated virulence factors.

EPIZOOTIOLOGY

Most animal and human cases of listeriosis arise from the ingestion of contaminated food and water, and the disease is particularly common in animals fed silage (Low and Donachie, 1997). The organism is a resident of normal microbial flora in healthy ruminants and is found in environmental sources such as decaying vegetation. The visceric form of listeriosis is more common in chinchillas, chickens, and monogastric species, while the encephalic form is more common in agricultural ruminant species (Gorham and Farrell, 1955; Gray and Killinger, 1966; MacDonald et al., 1972; Shalkop, 1950; Wilkerson et al., 1997).

CLINICAL MANIFESTATIONS

Listeriosis may cause an acute, sporadic disease associated with visceral and neurological signs or result in a chronic infection that may be subclinical. Although most food-borne pathogens primarily cause gastrointestinal disease, *L. monocytogenes* causes a number of additional invasive syndromes, such as encephalitis, abortion, and septicemia. The disease may present as an isolated case or with multiple animals affected. In chinchillas, clinical signs may include sudden death, anorexia, listlessness, diarrhea, weight loss, and ataxia.

PATHOLOGY

In chinchillas, listeriosis is a cecal disease with blood-borne dissemination to other tissues. Grossly, miliary abscesses (approximately 1-mm white foci) are commonly observed in affected organs, and microabscesses may be observed in the liver (Figure 42.1A,B), spleen, cecum (Figure 42.2), and colon. The main target organ is the liver

FIGURE 42.1 Listeriosis. (A) Classic lesions of multiple random white foci on the capsular surface of a chinchilla liver. (B) Necrotic areas of chinchilla liver containing numerous intrahistiocytic and extracellular Gram-positive bacilli. FIGURE 42.2 Listeriosis. Scattered white foci visible on the serosal surface of the cecum in a chinchilla. Photograph courtesy of Animal Health Laboratory, University of Guelph and Armed Forces Institute of Pathology.

as bacteria multiply inside hepatocytes. Early recruitment of polymorphonuclear cells leads to hepatocyte lysis, bacterial release, septicemia, and in surviving hosts, abscesses may develop within the lung, brain, spleen, lymph node, and liver (Donnelly, 2004; Donnelly and Quimby, 2002). Necrotizing enteritis of the small intestine, particularly within the duodenum, may be observed (Loellinger, 1961). The invasion of peripheral nerve cells and rapid entry into the brain, giving the classic histopathological lesion of monocytic perivascular cuffing, is believed to be a unique characteristic of its virulence.

DIAGNOSIS

Initial diagnosis is made from clinical signs, and diagnosis is confirmed by culture and immunohistochemistry. The organism can be isolated from the liver, intestine, colon, and spleen, but other locations include

the lung, stomach, and heart. Impression smears will demonstrate the pleomorphic Gram-positive characteristics of *Listeria*. Of the 16 known serotypes of *L. monocytogenes*, 30% of human cases are caused by three serotypes (Low and Donachie, 1997; Rouquette and Berche, 1996). Although somatic (O) and flagellar antigens (H) may be used to discriminate among strains of *Listeria* (Low and Donachie, 1997), serotyping is not used commonly in infectious outbreaks of listeriosis in animals.

PREVENTION AND THERAPY

Prevention and control involve general precautions to break the cycle of oral transmission, such as disinfection of cages, water and feed containers, and dust baths. Removal of contaminated feed or hay to preclude the development of new infections is also recommended. Treatment, particularly of moribund animals, is not recommended because of the zoonotic potential of the organism.

Yersiniosis

BACKGROUND

Although 11 species of *Yersinia* are recognized, only *Y. pestis*, *Y. pseudotuberculosis*, and specific serovars of *Y. enterocolitica* are important infectious organisms for humans and warm-blooded animals. Yersiniosis is associated with *Y. pseudotuberculosis* and *Y. enterocolitica*. The disease entity occurs worldwide in areas of moderate and subtropical climate, and outbreaks in chinchillas have been described (Gueraud, 1988; Raevuori et al., 1979; Wuthe and Aleksic, 1992). Environmental contamination from asymptotically infected warm-blooded animals is considered the most important factor for spread of the disease agents.

Molecular biological techniques have contributed extensively to the understanding of *Yersinia* pathogenicity. A 70-kilobase plasmid, which is essential for

virulence expression, is present in *Yersinia* associated with human disease and microbiologists have identified 13 plasmid-encoded polypeptides. Pathogenic factors, such as survival in serum, resistance to phagocytosis, cell adhesion, and cytotoxicity, are mediated through the plasmid-encoded polypeptides (Donnelly and Quimby, 2002; Heesemann, 1990). Although virulence of *Y. enterocolitica* depends on a chromosomal gene, endocytosis in intestinal epithelial cells does not appear to be encoded by a plasmid. For *Y. pseudotuberculosis*, virulence depends on a single chromosomal locus (Cornelis et al., 1987). Serologic diagnosis of yersiniosis using plasmid-encoded proteins in immunoblotting and indirect immunofluorescence techniques has resulted in more reliable diagnostics relative to using whole bacterial antigens (Heesemann, 1990). A "chinchilla-type" strain of *Y. enterocolitica* (biovar 3, antigens, or serovar 1, 2a, 3) that appears to persist enzootically among chinchilla stock worldwide was described by Wuthe and Aleksic (1992). Cases of yersiniosis have been reported in mammals (including chinchillas) and birds in both the United States and Canada (Hubbert, 1972; Langford, 1972), and the incidence of yersiniosis in mammals and birds in Antwerp Zoo was reported by Kageruka (1970).

ETIOLOGY

Yersinia enterocolitica is a Gram-negative, aerobic, and facultative anaerobe of the family Enterobacteriaceae. *Yersinia pseudotuberculosis* is a Gram-negative, non-hemolytic, exotoxin- and enzyme-producing, pleomorphic rod. Enteric infections predominate in the diseases caused by these bacteria. *Y. pseudotuberculosis* causes classical pseudotuberculosis or mesenteric adenitis in guinea pigs and has been isolated from many rodents including rabbits. However, *Y. enterocolitica* is currently the species of *Yersinia* most frequently isolated from human and animal infections. *Yersinia* includes both pathogenic and non-pathogenic strains. Among the human pathogens, those isolated in America are more virulent than those isolated elsewhere, especially in Europe and Japan, and these isolates differ biochemically and serologically (Cornelis et al., 1987).

EPIZOOTIOLOGY

Most animal cases of yersiniosis arise from the ingestion of contaminated food, by inhalation, or through dermal lacerations. Offspring may be infected from mothers. A chinchilla epizootic of *Y. enterocolitica* in France was reported by Guerard (1988) and the pathological effects, distribution of the organism within chinchillas, and microbiological isolation methods were described. Raevuori et al. (1979) investigated the virulence and experimental pathogenicity of *Y. enterocolitica* in chinchillas.

CLINICAL MANIFESTATIONS

Yersiniosis is typically an enteric disease in chinchillas and signs may include diarrhea, weight loss, anorexia, severe abdominal pain, dehydration, and bloody feces. Endometritis and septicemia also have been reported in chinchillas (Furowicz et al., 1996). In acute cases, animals may present with sudden death.

PATHOLOGY

Yersiniosis results in epithelial lesions of the ileum, cecum, and colon, which results in mucosal hemorrhage and ulceration. Lymphoid infiltration of the Peyer's patches and mesenteric lymph nodes results in hypertrophy with necrotizing granulomas. Septicemia results in granulomatous lesions in the lungs, spleen, and liver (Donnelly, 2004; Donnelly and Quimby, 2002; Langford, 1972; Wuthe and Aleksic, 1992).

DIAGNOSIS

Palpation of enlarged mesenteric lymph nodes are suggestive of Yersiniosis. Organisms can be observed and cultured from lesions.

PREVENTION AND THERAPY

Yersiniosis can be controlled by obtaining disease-free animals and then preventing contact with wild rodents and birds. Immunization of chinchillas against *Yersinia pseudotuberculosis* has been reported (Furowicz et al., 1996). Tissues from affected chinchillas should be handled and disposed of properly, and housing areas of infected animals should be adequately sanitized.

Pseudomoniasis

BACKGROUND

Opportunistic *Pseudomonas aeruginosa* systemic infections have been described in chinchillas (Lusis and Soltys, 1971b; Menchaca et al., 1980). Pseudomoniasis may result in a rapidly progressing epizootic characterized by significant mortality (Keagy and Keagy, 1951) or sporadic deaths of individual animals (Gorham and Farrell, 1955). Epizootic outbreaks are usually associated with contamination of the water supply to animals (Keagy and Keagy, 1951).

ETIOLOGY

Pseudomonas aeruginosa is a motile Gram-negative rod.

EPIZOOTIOLOGY

Pseudomonas aeruginosa is not a normal inhabitant of the enteric flora of the chinchilla (Mathieu et al., 1982; Worthington and Fulghum, 1988), but is an opportunist agent that inhabits moist environments. Following inhabitation of a host, the agent may be found in the nasopharynx, oropharynx, and gastrointestinal tract. *Pseudomonas*

FIGURE 42.3 Pseudomoniasis. Inguinal dermal pustules and swollen genital region in a chinchilla with *Pseudomonas aeruginosa* infection. Photograph from Doerning et al. (1993) with permission from Laboratory Animals.

aeruginosa has been cultured in a limited number of clinically healthy chinchillas (Mathieu et al., 1982).

CLINICAL MANIFESTATIONS

Pseudomoniasis may be asymptomatic, unless chinchillas are stressed by experimental procedures or an underlying disease (Graham, 1980). Alternatively, affected chinchillas may present with a variety of rapidly progressing clinical signs prior to death (Doerning et al., 1993), or animals may be found dead without any clinical evidence of disease (Gorham and Farrell, 1955). A variety of clinical signs may be observed prior to death, including conjunctivitis, otitis (Wideman, 2006), anorexia, weight loss, diarrhea, corneal and oral ulcerations, scrotal swelling, and inguinal pustules (Figure 42.3).

PATHOLOGY

Septicemia results in necrosis or abscess formation in the liver and other affected organs. Histological findings may include centrilobular vacuolization of hepatocytes as well as hemorrhage, inflammation, and necrosis of affected tissues, such as skin, muscle, and mesenteric lymph nodes.

DIAGNOSIS

Pseudomoniasis is diagnosed on the basis of history, clinical signs, lesions, and isolation of the organism.

PREVENTION AND THERAPY

Control of *P. aeruginosa* often focuses on water quality and reducing colonization of animals through chlorination (10–13 ppm) or acidification (pH 2.5–3.0). Treatment with an antimicrobial may eliminate the infection in chinchillas but may not be practical for large groups of animals. A vaccine against *P. aeruginosa*

has been developed for immunization and is used in fur-ranched chinchillas, but the vaccine may have limited duration of immunity (Lusis and Soltys, 1971a).

Miscellaneous Diseases

ENTEROTOXICOSIS

Enterotoxemia was described in chinchillas attributed to *Clostridium* spp. (Moore and Greenlee, 1975) and *C. perfringens* (Nowakowska et al., 1991). Similarly, Bartoszcze et al. (1990a) described acute deaths in a chinchilla flock due to *C. perfringens* A enterotoxin. Clinical signs included rectal prolapse, flatulence, and diarrhea. Acute deaths, particularly in young chinchillas of 2–4 months of age, are common. Gross findings include hepatic centrilobular necrosis, congestion and necrosis of intestinal mucosa, and proliferation of splenic white pulp. Enterotoxemia is diagnosed on the basis of history, clinical signs, lesions, and identification of the enterotoxin by immunological assay. Treatment for enterotoxemia is primarily through supportive fluid therapy.

SALMONELLOSIS

Several case reports of *Salmonella* infection in chinchillas were available. *Salmonella arizona* (Mountain, 1989), *S. enteritidis* (Yamagishi et al., 1997), and *S. pullorum* (Jones and Henderson, 1953) have been isolated from individual chinchillas. Outbreaks of salmonellosis in multiple animals have been associated with undefined *Salmonella* sp. (Holm and Graves, 1940), *S. sofia* (Naglić et al., 2003), *S. dublin* (Watson and Watson, 1966) as well as *S. enteritidis* and *S. typhimurium* (Misirlioğlu et al., 2002).

KLEBSIELLOSIS

Klebsiella pneumoniae infection was reported in breeding chinchillas (Bartoszcze et al., 1990b). Affected animals had clinical signs of depression, respiratory distress, inappetence, diarrhea, and death. Gross lesions included congestion and consolidation of the lungs, hydrothorax, cardiomegaly, gastroenteritis, and subcapsular renal petechiation. Histological findings were consistent with gross lesions where lungs demonstrated congestion of alveolar capillaries and suppurative exudate of the alveoli. Treatment of the affected chinchillas with gentamicin resulted in recovery of about 50% of treated animals (Bartoszcze et al., 1990b).

Viral and Chlamydial Infections

Two reports were available of herpes virus infection in chinchillas. Goudas and Giltroy (1970) described a spontaneous herpes-like viral infection in an adult female chinchilla. Following acute death of the chinchilla, mild discoloration of the perineal fur was observed. Gross lesions included a pale, friable liver and 2–5 mm white foci dispersed through the adrenal

glands. Wohlsein et al. (2002) described a spontaneous human herpes virus type 1 in a 1-year-old male chinchilla. The animal exhibited conjunctivitis followed by neurological signs of seizures, disorientation, recumbency, and lethargy. Gross and microscopic lesions of non-suppurative meningitis and polioencephalitis with neuronal necrosis and intranuclear inclusion bodies were observed in the chinchilla on postmortem examination. Other findings included bilateral ulcerative keratitis, uveitis, retinitis, retinal degeneration, optical neuritis, and a purulent rhinitis. No other viral or chlamydial diseases have been described for chinchillas.

Parasitic Diseases

Protozoa

TOXOPLASMOSIS

BACKGROUND Although once commonly found in fur-ranched chinchillas (Keagy, 1949), toxoplasmosis has not been reported for chinchillas maintained in laboratory environments as laboratory chinchillas do not have access to sporulated cysts shed by infected cats.

ETIOLOGY *Toxoplasma gondii* is an obligate intracellular coccidial parasite of the family Eimeridae. Cats are the only definitive host, but numerous warm-blooded animals may serve as intermediate hosts.

EPIZOOTIOLOGY Transmission of the protozoon by the definitive host is through ingestion of tissue cysts.

CLINICAL MANIFESTATIONS Clinical signs depend on the location of the parasite within organ tissues, but may include vulvar bleeding, abortion, stillbirths (Green and Morgan, 1991; Vetterling, 1976) or encephalitis (Markham, 1937).

PATHOLOGY Asexual stages of *T. gondii* may be distributed in most organ tissues as tachyzoites or bradyzoites in brain, heart, and skeletal muscle. Necropsy lesions include hemorrhagic lungs, splenomegaly, and enlarged mesenteric lymph nodes. The wide pathological manifestations of toxoplasmosis, with or without necrosis, and tissue cyst formation as it occurs in sheep, cattle, pigs, horses, dogs, cats, chinchillas, and humans was reviewed by Turner (1978). Chinchillas with focal necrotic meningoencephalitis due to *Toxoplasma gondii* have been reported by Meingassner and Burtcher (1977). Several lobulated *Frenkelia* cysts up to 0.6 mm diameter in the brain of two chinchillas were present independent of and remote from the *Toxoplasma* inflammatory reaction. The cysts resembled both morphologically and in staining *Frenkelia* in various *Microtus* species and *Ondatra zibethica*.

DIAGNOSIS Diagnosis is based on serological methods and histopathology.

PREVENTION AND THERAPY Control and prevention depend on limiting access of chinchillas to feces or to items contaminated with feces from cats. As the oocytes are resistant to deactivation by dessication, temperature extremes, and disinfectants, extensive cleaning of infected environments is required.

GIARDIASIS

Giardia duodenalis (synonymous with *G. lamblia*) is a flagellated protozoan that colonizes and reproduces in the small intestine of animals, including the chinchilla.

Giardia sp. are considered to be normal inhabitants of the chinchilla gastrointestinal tract with 66% of fecal samples from chinchillas showing the presence of *Giardia* sp. (Pantchev et al., 2005). Although an examination of feces from chinchillas found a number of *Giardia* organisms (Figure 42.4), a histological examination of the intestines was not conducted (Eidmann, 1992). Historically, group-housed chinchillas, such as in fur ranches and research colonies, often had a high prevalence of *Giardia* infection (Newberne, 1953; Shelton, 1954a, 1954b). A case report of *Giardia* infection in chinchillas located in Taiwan showed a large number of trophozoites within the intestinal lumen and mucosal crypts of the jejunum and ileum (Chang et al., 1986). Stress and poor husbandry can result in an increased number of *Giardia* organisms and predispose animals to opportunistic gastrointestinal bacterial infections, resulting in severe diarrhea and death. While *Giardia* sp. may be present in healthy animals, an increased number of organisms on a fresh fecal smear along with diarrhea may be suggestive of giardiasis. If giardiasis is suspected, treatment may be

FIGURE 42.4 Giardiasis. *Giardia* trophozoites in a wet mount of a fresh fecal sample. Structural characteristics include the prominent pair of nuclei, longitudinally oriented flagella, and curved median bodies. Photograph from Donnelly (2004) with permission from Saunders.

initiated with fenbendazole, albendazole, or metronidazole (Alves et al., 2008; Donnelly, 2004).

MISCELLANEOUS PROTOZOA DISEASES

EIMERIA The etiology, pathology, and host range of *Eimeria chinchillae* in chinchillas, guinea pigs, hamsters, mice, rats, and rabbits in South Africa have been reported (Vos, 1970; Vos and Dobson, 1970). Infected chinchillas showed clinical signs of depression, anorexia, and diarrhea. Necropsy revealed congestion and edema of the cecum and colon, and a large number of oocysts were present within the large intestine. Sporulated oocysts from infected chinchillas resulted in transmission of *Eimeria* infection to other species.

CRYPTOSPORIDIUM Gastroenteritis associated with a *Cryptosporidium* sp. in a pet chinchilla (Yamini and Raju, 1986) has been described. An 8-month-old chinchilla had severe diarrhea unresponsive to antimicrobials for 8 days prior to death. Grossly, the stomach, small intestine, and colon were bloated and contained yellowish fluid. Histologically, numerous spherical bodies (2–5 µm diameter) characteristic of *Cryptosporidium* were noted on the luminal surface of the epithelial cells of the stomach, small intestine, and colon. Electron microscopy of the small intestine confirmed the presence of *Cryptosporidium*.

SARCOCYSTOSIS Acute hepatic sarcocystosis in a pet female chinchilla has been described (Rakich et al., 1992) in an animal found dead. Hepatic architecture was disrupted by numerous randomly distributed coalescing areas of inflammation and necrosis (Figure 42.5A) and the lung was congested and atelectatic. Various stages of *Sarcocystis* sp. (Figure 42.5B) were dispersed within the areas of hepatic necrosis and inflammation.

Nematodes

Cerebral nematodiasis caused by the raccoon ascarid (*Baylisascaris procyonis*) in chinchillas in western Canada has been described (Sanford, 1989, 1991). Chinchillas from multiple ranches presented with central nervous system signs of ataxia, tumbling, torticollis, paralysis, incoordination, and death. Grossly, no lesions were evident. Histologically, malacic tracts or areas of necrosis, swollen axons, and infiltrates of inflammatory cells in perivascular sites and necrotic areas were noted in the brainstem and cerebellum. The usual source of infection is contamination of feed stored in barns by raccoon feces. Treatment is supportive care.

Although uncommon, other nematodes have been reported in chinchillas. *Ostertagia* sp. females and a *Trichostrongylus colubriformis* male were found in one animal from a group of emaciated chinchillas (Stampa and Hobson, 1966), and chinchillas infected with *Haemonchus contortus* have been reported (Kraft, 1960). In both reports, chinchillas had been fed grass from pasture housing ruminants. Susceptibility for chinchillas to be infected with *H. contortus* was reported by Boisvenue and Hendrix (1968).

Cestodes

Chinchillas may be infected with a variety of cestodes. Gorham and Farrell (1955) reported that the chinchilla could serve as an intermediate host for *Taenia serialis*, *T. pisiformis*, *Echinococcus granulosus*, and *Hymenolepis nana*. Stampa and Hobson (1966) reported infection of chinchillas with *H. nana*; animals in the postweaning period exhibited listlessness and poor body conditioning, while adult and unweaned animals appeared normal. *H. nana* may have both a direct and intermediate life cycle in the chinchillas and can cause

FIGURE 42.5 Sarcocystosis. (A) Necrosis of hepatocytes in liver from a chinchilla infected with *Sarcocystis* sp. Arrow points to schizonts (150x). (B) Higher magnification of the schizonts in (A). Three schizonts (A, B, C) in various stages of division and arranged in presumed order of development in hepatocytes (1050x). Photograph from Rakich et al. (1992) with permission from the Journal of Veterinary Diagnostic Investigation.

heavy intestinal infestations (Olsen, 1950). Several reports describe infections of chinchillas with *Taenia* sp. A *Taenia* coenurus located in the ventral ocular orbit was reported in a single chinchilla (Holmberg et al., 2007), and *Taenia* coenurus was reported in seven chinchillas by Bracken and Olsen (1950). Several hundred cysts of *Taenia crassiceps* were found in the abdominal cavity of a pet chinchilla (Kugi et al., 1999). Staebler et al. (2007) reported the presence of *Echinococcus multilocularis* in a single chinchilla exhibiting painful abdominal distension. Postmortem examination revealed numerous hepatic vesicles and cysts.

Other

Subcutaneous myiasis by *Cuterebra* larvae in Argentina was reported by Led and Brandetti (1974).

Mycoses

Dermatophytosis

BACKGROUND

Ringworm has been reported primarily in chinchillas maintained under poor husbandry practices. These reports of ringworm are in regard to chinchillas raised in the fur industry, but cases for pet or research animals are rare (Hayes, 2000).

ETIOLOGY

Trichophyton mentagrophytes is the dermatophyte most commonly isolated from fur-bearing animals and infected chinchillas. However, *Microsporum canis* and *M. gypseum* also have been incriminated in spontaneously occurring outbreaks in chinchillas (Bohm and Loliger, 1969; Gimesi, 1980; Graham, 1961; Hagen and Gorham, 1972; Horvath and Keri, 1980; Janovitz and Long, 1984; Male and Fritsch, 1966; Morganti and Gomez Portugal, 1970; Torres-Rodriguez et al., 1992).

EPIZOOTIOLOGY

Lesions are seen most often in young or malnourished animals, or animals that are housed in an unclean or stressful environment.

CLINICAL MANIFESTATIONS

Dermatophytosis of chinchillas results in small scaly patches of alopecia on the nose, eyes, behind the ears, anus, or on the forefeet. Lesions may appear on any part of the body, and in advanced cases a large circumscribed area of inflammation with scab formation occurs.

PATHOLOGY

Skin lesions consist of exfoliated debris, exudate, mycelia, and arthrospores associated with hyperemic dermatitis.

DIAGNOSIS

Diagnosis is based on clinical presentation, skin scrape, and fungal culture. Fungal cultures of chinchillas on ranches showed a 5% incidence of *T. mentagrophytes* in animals with normal skin; in contrast, a 30% incidence of *T. mentagrophytes* was observed in animals with fur damage (Hagen and Gorham, 1972; Male and Fritsch, 1966).

PREVENTION AND THERAPY

Prevention is through providing a clean living environment and minimizing stress to animals. Oral or topical antifungals can be used to treat chinchillas with dermatophytosis, and an antifungal powder may be mixed with the dust bath to assist in minimizing transmission to group-housed chinchillas. A live attenuated vaccine, Trichopelen (Bioveta, Inc.), containing *T. mentagrophytes* has been used to prevent dermatophytosis in fur-bearing animals, including chinchillas (Lund and DeBoer, 2008; Sarkisov and Nikiforov, 1981). The vaccination schedule includes two doses by intramuscular injection at an interval of 8–12 days with a 1-year immunity established 1 month after the last dose.

Histoplasmosis

Two reports of spontaneous histoplasmosis due to *Histoplasma capsulatum* have been described in chinchillas. Burtscher and Otte (1962) described histoplasmosis in a chinchilla exported from the United States to Switzerland. Owens et al. (1975) reported histoplasmosis in a female chinchilla originating from a commercial ranch in central Missouri. Clinical signs in the affected chinchilla included anorexia, weight loss, constipation, and tachypnea. Necropsy revealed pulmonary lesions of multiple hemorrhagic foci, consolidation, bronchopneumonia, and epithelioid cells containing the organism. In addition, the spleen and liver contained multifocal pyogranulomatous lesions, and focal glomerular nephritis characterized by accumulation of polymorphonuclear cells in the proximal tubules. Epithelioid cells containing the organism were present in the liver, spleen, and kidneys. Culture of the timothy hay used for food demonstrated the presence of *H. capsulatum*.

GASTROINTESTINAL AND METABOLIC DISEASES

Esophageal Disease

Chinchillas cannot vomit, and esophageal choke can result after the ingestion of large objects. Although choke is not commonly observed, it has been described in chinchillas of all ages (Cousens, 1962). When observed, choke is more common in postparturient

females that eat their placentas or animals that consume their bedding. Affected animals show drooling, retching, dyspnea, and anorexia. Diagnosis is by palpation, endoscopic examination of the oropharynx and esophagus, and radiography. Treatment is through removal of the lodged foreign material from the esophagus.

Megaesophagus has been reported in a female chinchilla that presented with severe, recurrent pneumonia. The recurrent pneumonia was attributed to aspiration of regurgitated content secondary to megaesophagus (Jopp et al., 2004).

Bloat

Gastric tympany or bloat has been reported to be a problem of lactating female chinchillas resulting from overeating of clover, gastroenteritis, or a dietary change such as an addition of fresh green grasses or fruits (Donnelly, 2004). Tympany also may result in chinchillas with gastrointestinal disease. Clinical signs in affected animals are distended and painful abdomens, lateral recumbancy, lethargy, dyspnea, and in severe cases, death. Treatment is through alleviation of gastric distension by decompression with a gastric tube or use of a transabdominal trocar in sedated or anesthetized animals.

Gastric Trichobezoars

Although uncommon, gastric trichobezoars may result from excessive fur chewing. Affected chinchillas typically present with anorexia and lethargy. Diagnosis is by palpation and radiography. Treatment is through administration of fluids and laxatives. Proteolytic enzymes also may be useful to degrade the trichobezoars and animals may be fed a high-fiber diet (Donnelly, 2004).

Constipation

In chinchillas, constipation can be associated with many infectious and non-infectious gastrointestinal disorders and may occur more often than diarrhea (Hartmann, 1993). Constipation is associated with chinchillas fed a diet that is high in calories and protein but contains insufficient roughage or fiber (Cousens, 1962). Other causes of constipation may include obesity, lack of exercise, intestinal obstruction, and intestinal compression due to large fetuses during pregnancy (Hartmann, 1993). Clinical signs of constipation may include straining to defecate, decreased fecal pellets, and any pellets passed are thin, short, hard, and occasionally bloodstained. In chronic cases of constipation, ileus, intestinal torsion, intussusception, and impaction of the cecum or colonic flexure may occur (Bowden, 1959; McGreevy and Carn, 1988). Rectal prolapse may

also occur in severe cases of constipation or diarrhea. From 91 chinchillas necropsied during a 4-year period in a Japanese laboratory, prolapse of the rectum was noted in 6% of the animals (Kuroiwa and Imamichi, 1977). Treatment of constipation is dependent upon the underlying basis, but increasing dietary fiber through gradual provision of hay or fresh vegetables and providing a bulk laxative may be beneficial.

Intestinal Torsion

A single case report of intestinal torsion in a 4-year-old male chinchilla was reported by McGreevy and Carn (1988). Anorexia and listlessness were described for the animal. Necropsy revealed a 360° torsion of the distal small intestine through the mesocolon.

Diabetes Mellitus

Diabetes mellitus in a 5-year-old overweight female chinchilla has been described (Marlow, 1995). This chinchilla had a 3-week history of poor appetite, lethargy, weight loss, and polydipsia/polyuria. Bilateral cataracts were identified in the chinchilla during its evaluation. Blood and urine analysis demonstrated a hyperglycemia greater than 400mg/dl, glucosuria, and ketonuria. Following euthanasia, microscopic examination of pancreatic islets revealed prominent vacuolation consistent with diabetes mellitus. Ewringmann and Göbel (1998) also reported cases of diabetes mellitus in chinchillas.

Hyperthyroidism

Hyperthyroidism was described in a 6-year-old female chinchilla that exhibited progressive weight loss, elevated glucose levels, glucosuria, and elevated T4 levels (Fritsche et al., 2008).

TRAUMATIC LESIONS

Fur Slip

Fur slip in chinchillas is defined by a release of a patch of fur, and it has been attributed to a predator avoidance syndrome, a behavioral disorder, nutritional imbalance, and/or endocrine imbalance. Chinchillas which fight, are handled roughly by humans, or during scruffing may release quantities of fur. The lost fur may take several months to regrow and cover the smooth area of skin (Donnelly, 2004). Prevention of fur slip can be aided through wearing of cotton or latex gloves to prevent hand oils from damaging fur, handling of chinchillas by gently cupping the animal in both hands, and provision of a good-quality diet.

Bite Wounds

Although chinchillas housed in groups rarely fight, frequent bite wounds that abscess occur during breeding. Female chinchillas are larger than males and highly selective in their choice of males for mating. Males not selected for breeding are disenchanted by the female through urination, kicking, and biting (Bignami and Beach, 1968; Weir, 1973). On occasion, a young male housed in the same cage as older females may be killed (Weir, 1970). Culture of the abscesses often yields *Staphylococcus* species (Jenkins, 1992), but collecting samples for culture and sensitivity is recommended. Bite wounds may result in the loss of a portion of the ears and toes. Provision of hiding areas for males in group housing can minimize aggressive behavior by female chinchillas during breeding.

Limb Injuries

Limb injuries usually result from an inadequate housing environment. Wire-bottom caging can result in foot pad injuries to chinchillas, particularly if overweight (Hayes, 2000). Provision of a resting board or other solid surface can prevent foot pad injuries. Traumatic fractures of the tibia are commonly seen and are associated with the animal catching its hind limb in a cage bar (Hoefer, 1994). The tibia is a straight bone longer than the femur and minimal muscle is located over the bone. Tibial fractures are either transverse or short spiral and may be associated with bony fragments. Treatment of tibial fractures commonly requires surgical repair, but malunion may result unless physical activity is restricted during convalescence. Amputation of the hindlimb may be considered if surgical repair is unsuccessful.

MANAGEMENT-RELATED DISORDERS

Fur Chewing

The loss of hair, alopecia, in chinchillas may result from fur chewing in group-housed animals. One theory for fur chewing is based upon a stereotypy transferred from dams to their offspring. Similar to maladapted behavior in other species, a higher incidence of fur chewing is observed in chinchillas maintained in the captivity of commercial herds and not being able to engage in more normal behaviors of free-ranging animals (Donnelly, 2004). Animals also may suffer from malnutrition and chew their fur for dietary requirements (Eidmann, 1992); however, the etiology of the malnutrition has not been defined. Historically, fur chewing in chinchillas has been attributed to

an increased thyroidal and adrenocortical activity (Vanjonack and Johnson, 1973) and a fungus (Shaull, 1988). Thyroid hyperplasia was correlated to the size of chewed fur over the body and was interpreted as a reactive response of the thyroids due to the inability of the body to maintain warmth following fur removal (Eidmann, 1992). An infectious basis of fur chewing was dispelled following review of mycological and bacterial cultures of skin and fur from 39 fur chewers relative to that of 19 healthy chinchillas (Eidmann, 1992).

Matted Fur

Chinchillas are fastidious groomers and dust-bathing is common. Frequent availability of dust baths is recommended for at least 30 minutes per day (Donnelly, 2004). Chinchillas denied dust-bathing may develop matted fur from oily secretions on the back (Hillyer et al., 1997). Schaeffer and Donnelly (1997) reported that dust-bathing can lead to irritative conjunctivitis without clinical signs of upper respiratory infection.

NEOPLASTIC DISEASES

Reports for neoplasia in chinchillas are limited despite a life span up to 20 years of age (Schaeffer and Donnelly, 1997). Postmortem examinations by Brenon (1953, 1955) on 1005 chinchillas (527 males and 478 females) before mid-1949 and another 1000 chinchillas over the subsequent 3 years did not list neoplasia as a cause of death. Although the postmortem examinations were conducted in chinchillas ranging between less than 6 months and 11 years in age, the majority of the animals were less than 3 years of age. Newberne and Robinson (1957) described a malignant lymphoma in a 3-year-old chinchilla that was found dead without any prior untoward clinical signs. A uterine leiomyosarcoma was reported in a 1-year-old female chinchilla as an incidental finding at necropsy (Schaeffer and Donnelly, 1997). Other reported types of neoplasia in chinchillas include malignant lymphoma (Newberne and Seibold, 1953), hepatic carcinoma (Nobel and Neumann, 1963), lumbar osteosarcoma (Simova-Curd et al., 2008), and carcinoma of salivary gland (Smith et al., 2010).

MISCELLANEOUS CONDITIONS

Dental Disease

BACKGROUND

Malocclusion is a common problem in chinchillas, whereby approximately half of all deaths in adult chinchillas in the 1960s were due to digestive tract disorders

and malocclusion accounted for one-quarter of those deaths (Cousens, 1962; Dall, 1963). Abnormalities of cheek tooth overgrowth remain common in chinchillas (Crossley, 1997; Crossley et al., 1997), and chinchilla breeders commonly refer to the condition as “slobbers” based upon the clinical signs of hypersalivation. However, other conditions of the oral cavity may result in hypersalivation, which is not specific to malocclusion (Crossley, 2001).

ETIOLOGY

The dental formula of chinchillas is 1/1 incisors, 0/0 canines, 1/1 premolars, and 3/3 molars. Incisors and cheek teeth of chinchillas grow continuously throughout life at a rate of 2.5–3 inches per year (Hayes, 2000).

EPIZOOTIOLOGY

Genetic predisposition and husbandry practices are considered contributory in malocclusion of chinchillas. Crossley and Miguélez (2001) reported that cheek tooth lengths in captive-bred chinchillas were significantly elongated in comparison to wild-caught animals (Figure 42.6), suggesting that physical form or composition of the diet is a contributing factor in malocclusion and resulting dental disease. During examination of 123 chinchillas, dental disease was found in 32.5% of the animals and chinchillas had a higher incidence of gingival erosions and gingivitis in comparison to rabbits and guinea pigs. In chinchillas, significantly more pathology of teeth and associated soft tissues was noted that corresponded to the fourth premolar (bilateral) and first molar (right side) of the upper arcade relative to other teeth including incisors (Jekl et al., 2008). Similarly, Crossley (2001) reported dental abnormalities, such as tooth elongation, in 35% of apparently healthy chinchillas ($n = 651$) in the United Kingdom.

CLINICAL MANIFESTATIONS

The most common signs of dental disease include hypersalivation and drooling, while other signs may include ventral mandibular swelling, pawing at the mouth, anorexia, dysphagia, weight loss, nasal discharge, and selective choice of finer relative to coarser food particles (Crossley, 2001; Donnelly, 2004). Progressive growth of the cheek teeth (premolars and molars) results in ulceration of the buccal mucosa and tongue. Although uncommon, advanced stages of malocclusion may lead to periodontitis and alveolar abscessation of maxillary and mandibular cheek teeth (Emily, 1991; Griner, 1983). In a pet chinchilla exhibiting anorexia and malocclusion, caries and odontoclastic resorptive lesions were reported by Crossley et al. (1997). During postmortem examination of 104 chinchillas in the United Kingdom, 37% of the animals had caries and resorptive lesions (Crossley, 2001).

PATHOLOGY

Lesions may include root elongation, ulceration of buccal mucosa and tongue with periodontitis, alveolar abscesses, caries and resorptive lesions, and perostitis in advanced stages.

DIAGNOSIS

Clinical signs are pathognomonic for malocclusion in chinchillas. Examination of the narrow oral cavity using an otoscope can assist in visualizing the cheek teeth. Rigid endoscopy provides excellent visualization of the oral cavity to assess dental disease in chinchillas (Jekl and Knotek, 2007). Although manual restraint of chinchillas for the examination of the oral cavity is possible, anesthesia of the animal contributes to a more thorough examination. Radiography of the skull (Crossley, 2001) and computerized tomographic (CT) scanning

FIGURE 42.6 Malocclusion. Malocclusion of the dental arcade in the chinchilla. (A) Lateral view of the chinchilla skull showing outward curvature of the upper molars. (B) Normal mandible of a chinchilla (left) in comparison to a mandible with malocclusion (right). Photograph from Donnelly (2004) with permission from Saunders.

(Crossley et al., 1998) to investigate tooth structure in chinchillas has been shown to be a useful tool in the early diagnosis of malocclusion.

PREVENTION AND THERAPY

Treatment consists of repeated trimming and adjustment of the occlusal surface of overgrown teeth in affected chinchillas. Malocclusion is influenced by husbandry practices and provision of a high-fiber diet may be beneficial. Although hard objects, such as wood blocks and pumice stones, may be provided to chinchillas to minimize malocclusion, wearing is limited to incisors and does not affect cheek teeth. Continued malocclusion of the cheek teeth may result in progressive dental disease. As malocclusion is caused by hereditary elements, affected animals should be eliminated from breeding stock.

Penile Fur Ring

BACKGROUND AND EPIZOOTIOLOGY

Adult male chinchillas commonly develop accumulation of fur surrounding the penis. Fur may come from other males or the same animal as the condition is also seen in group-housed and single-housed males not exposed to females. In some male chinchillas, the penis will extend from the prepuce all the time even when not engorged. In these males, the cause of this condition is not associated with fur ring but is due to overexcitement brought on by separation from their mates or overexhaustion due to too many females in the same cage.

CLINICAL MANIFESTATIONS AND PATHOLOGY

Affected animals may show signs of excessive grooming, frequent production of small quantities of urine, straining to urinate, and repeatedly cleaning of the penis (Schaeffer and Donnelly, 1997). Presumably, the ring of hair accumulates around the penis within the prepuce, which eventually prevents the penis from retracting back into the prepuce leading to paraphimosis. In severe cases, an engorged penis may protrude 4–5 cm from the prepuce. The condition may progress to cause severe pain in the affected animal, and result in urethral constriction and acute urinary retention. Chronic paraphimosis may culminate in infection and severe damage to the penis, which may ultimately impact the breeding ability of the animal. Congestion of penile tissues is associated with fur ring.

DIAGNOSIS

Clinical signs are pathognomonic for penile fur ring in chinchillas.

PREVENTION AND THERAPY

Many male chinchillas have fur accumulation around the penile base without any clinical signs, and

visual examination of penile base in male chinchillas should be routine during any physical examination. Any visible fur ring should be cut or gently rolled off the penis after applying a sterile lubricant. Occasionally, sedation or anesthesia of the male may be required to remove the fur ring.

Ocular Disorders

Eyes of 14 chinchillas ranging from 6 to 17 years of age were examined by Peiffer and Johnson (1980). Mean intraocular pressures in the chinchillas were 18.5 ± 5.75 mm/Hg. Bilateral posterior cortical cataracts and asteroid hyalosis were observed in two animals.

Conjunctivitis from environmental factors may be observed in chinchillas. Precipitating environmental factors range from dirty or poor-quality bedding, inadequate cage ventilation, and excessive dust bathing (Donnelly, 2004; Schaeffer and Donnelly, 1997). Conjunctivitis also may result from infection with *Pseudomonas aeruginosa* (Doerning et al., 1993; Lusi and Soltys, 1971b). Treatment should focus on minimizing exposure to any irritating factor (e.g., limiting duration of access to dust baths, providing fresh bedding) and providing a protective ophthalmic solution or ointment.

Reproductive Disorders

Chinchillas usually give birth early in the morning and only rarely before midnight (Weir, 1966). Cousens (1962) reported that dystocia is usually associated with the presentation of a single, oversized fetus or abnormal presentation of one or more kits, while uterine inertia has been reported as another cause of dystocia (Prior, 1986). Cesarean section is effective to resolve the dystocia (Caspari, 1990; Jones, 1990; Prior, 1986; Sims, 1990; Stephenson, 1990). Coexisting intrauterine and intraperitoneal pregnancy due to superfetation in a chinchilla has been reported (Gitlin and Adler, 1969). A retrospective review of birth-to-weaning mortality in a Japanese laboratory colony of chinchillas was described by Kuroiwa and Imamichi (1977). Among 91 animals that died, the cause of death in 23 (25.3%) was newborn-related. Thirty-seven chinchillas gave birth to 71 kits with an average litter size of 1.9, and 59 kits were successfully weaned (1.6 per litter). Of these kits, 50 (1.3 per litter) attained 240 days of age.

Oxalate Nephrosis

Six spontaneous cases of oxalate nephrosis were described in adult female chinchillas (Goudas and Lusi, 1970). Clinical signs include progressive weakness

followed by death. Histologically, deposition of refractive, translucent, yellowish crystals occurred within renal tubules. Oxalate nephrosis should be considered rare in chinchillas.

Urinary Calculi

Three cases of urinary calculi and urolithiasis in male chinchillas have been reported (Jones et al., 1995; Newberne, 1952; Spence and Skae, 1995) and should be considered uncommon in chinchillas. Animals had a history of hematuria or anuria. Clinical signs may include straining and erythematous preputial and perineal area. Ultrasound and radiography can be confirmatory as the bladder calculi are composed of calcium carbonate (Jones et al., 1995; Spence and Skae, 1995). Diet may have contributed to the cases.

Heat Stroke

Chinchillas are susceptible to stress from temperatures at 80°F or higher, particularly in humid conditions (Jenkins, 1992). Clinical signs include tachypnea, prostrate posture, salivation, hyperthermia, hemoptysis, cyanosis, and death. Treatment includes reducing body temperature through cool water baths and administration of intravenous fluids in severely affected animals.

Schistosomus Reflexus

A case of abnormal embryological development in a chinchilla, resulting in a schistosomus reflexus fetus, was reported by DeNooij (1985).

Diaphragmatic Hernia

A single case report of a diaphragmatic hernia in a female chinchilla was described by Dall (1967). The chinchilla displayed anorexia and depression for 2 days prior to examination. During a procedure, the chinchilla died. Necropsy revealed the rectum was empty, while the stomach, small intestine, and cecum were content-filled. Herniation of the large colon into the pleural cavity through the aortic hiatus was found upon further review, but no strangulation was evident.

Incidental Postmortem Findings

Trophoblastic Emboli

Hemochorial placentation is common to many species, such as humans, mice, guinea pigs, hamsters, porcupines, and chinchillas (Billington and Weir, 1967; Hamir and Rupprecht, 2008; Ilha et al., 2000; King and Tibbitts, 1976; Tvedten and Langham, 1974). As the interhemal membrane of the placental labyrinth is hemomonochorial in chinchillas, it consists of a single layer of syncytial trophoblasts. A trophoblastic pulmonary emboli (Figure 42.7) in a chinchilla was described by Tvedten and Langham (1974). Another report described trophoblastic pulmonary embolism in three chinchillas (Ilha et al. 2000), and one of these chinchillas had trophoblastic infiltration of the myometrium. Trophoblastic emboli in chinchillas are considered incidental findings on histopathological examination.

Fatty Livers

Fatty livers are commonly observed during routine necropsies without clinical signs or other pathological findings (Egri et al., 1994).

INTRODUCTION

Chinchilla is the traditional animal model for most types of research related to the ear (DeMaria, 1989), specifically, hearing loss and otitis media. According to the USDA, 2250 chinchillas were used in research in 2008

in the US, a decline over the last 20 years as chinchilla models are gradually replaced by mice and rats (Salvi and Boettcher, 2008). However, the chinchilla still has important characteristics that make it an ideal model for studying the ear. The chinchilla inner ear anatomy (including the cochlea) and ear physiology are similar

to humans. The chinchilla ear has three turns in the cochlea, a tubotympanum that shares similar anatomy with that of humans (Giebink, 1982; Giebink et al., 1976), a wide tympanic membrane, a cochlea readily accessible for microsurgical procedures, and a middle ear easily accessed through a large and very thin bulla; all attributes that enable researchers to conduct studies on the ear. Owing to the relatively longer lifespan of the chinchilla (15 years) versus a mouse (2 years), the auditory system does not undergo presbycusis (aging) in the chinchilla during the period of study (Giebink, 1982; Giebink et al., 1976), and thus allows a more consistent and less variable animal model (Bakaletz, 2009). The audiogram (range of hearing) of the chinchilla appears to resemble the human audiogram more closely than do other rodent's (Giebink, 1982; Heffner and Heffner, 1991) at 20Hz to 30KHz, making them popular for hearing research. The chinchilla's ear is more sensitive to toxicity because the round window is thinner (10–14 μ m) compared to that of humans (40–70 μ m), thereby enabling more drug penetration into the cochlea, and therefore serving as a sensitive indicator of ototoxic drugs. Low cost, ease of handling, and small size (Giebink et al., 1976) are other attributes that together with those already mentioned, make the chinchilla a reliable and precise model for research (Juhn et al., 1977).

Immunologically and genetically the chinchilla has many advantages for research. Chinchillas have well-defined nasal-associated lymphoid tissue as well as a simple naso- and maxilla-turbinate system that is more like that of other rodents and unlike the branched turbinate's of dogs, cats, and rabbits, which facilitates studies of intranasal delivery of vaccine candidates, adjuvants, and novel therapeutics for studying otitis media (Bakaletz, 2009). The immune response of the chinchilla can be studied with commercially available reagents due to the fact that chinchilla and human cytokines cross-react (Giebink, 1999; Sato et al., 1999). Human cytokines stimulate maturation of chinchilla bone-marrow-derived dendritic cells, and antibodies directed against human immunoglobulins cross-react with chinchilla immunoglobulins (Bakaletz, 2009). However, a lack of molecular and immunological reagents specific to chinchillas (anti-chinchilla antisera) is an obstacle to study at molecular levels that are routine in rats and mice (Bakaletz, 2009; Lim et al., 2005) including immune regulation, lymphocyte traffic, and genetic predisposition (DeMaria, 1989). At the genetic level there are now multiple examples of close homologies between the products of human genes and those of chinchillas including mucin genes, genes that encode effectors of innate immunity, and genes that encode for epithelial cell receptors (Bakaletz, 2009).

Chinchillas are not inbred or commercially available and are typically obtained from local chinchilla

ranchers whose coats are unsuitable for fur production (Green et al., 1994). SPF or transgenic lines are not yet available, so research results may be confounded by genetic and pathologic differences (Lim et al., 2005). However, the fact that preclinical trials conducted in this host are typically performed in mixed sex, outbred animals, chinchilla's likely better mirror the diversity of immunological responsiveness one would encounter in a human clinical trial (Bakaletz, 2009).

Chinchillas are used in multiple areas of research but mainly those involved with the ear. These include hearing loss, otitis media, tinnitus, tympanic membrane perforations, cochlear implants, perilymphatic fistulas, superior canal dehiscence, electrode implantation, cholesteatoma, otic drug testing, and pharmacokinetics of antibiotics for treatment of ear infections. They are also used on occasion to study kidney microanatomy, cardiology anatomy, arterial blood supply to the brain and ear, and ovarian endocrine activity. Other research fields in which chinchillas have been used include studies of Chagas disease, gastrointestinal disease, pneumonia, *Listeriosis*, as well as *Yersinia* and *Pseudomonas* infections. The more common and significant uses of chinchillas as models related to the ear will be covered in this chapter.

MODELS RELATED TO AURAL DISEASE

Models of Otitis Media

Several rodent hosts including the gerbil, rat, mouse, guinea pig, and chinchilla, have been used to develop models of single pathogen-induced otitis media, however the chinchilla is the predominant host and considered the gold standard (Bakaletz, 2009; McGillivray et al., 2007). The use of chinchilla in otitis media research is predated by its use in auditory and acoustic research owing to its anatomical and physiological similarities between the inner ear and that of man (Bakaletz, 2009; Giebink, 1999). Chinchillas make excellent models to study the pathogenesis of aural disease for several reasons. First, chinchillas do not naturally develop otitis media, as do some mice, rats, gerbils, guinea pigs, and rabbits (Bakaletz, 2009; Giebink, 1982), presumably because they are not coprophagic. Second, chinchillas can be colonized and experimentally infected with human pathogens (Harris et al., 2004; Lim et al., 2005; McGillivray et al., 2007) both active bacterial and viral infections in the uppermost airways whereas most rodents only support lower-airway disease. Third, chinchillas have a large and thin cephalid bulla, from which large quantities of middle ear fluids can be withdrawn easily and assessed (Bakaletz, 2009; Harris et al., 2004). This characteristic permits serial recovery of middle ear fluid without compromising the integrity of the

tympanic membrane, which is a distinct advantage to researchers (DeMaria, 1989; Giebink, 1999; Harris et al., 2004). Fourth, chinchilla have a permanently semipatulous Eustachian tube highly similar to the “floppy” Eustachian tube of children, making them a relevant model of pediatric otitis media (Bakaletz, 2009; Harris et al., 2004). Lastly, the juvenile chinchilla model mimics the immunological immaturity of the human child, the age when otitis media mostly occurs (Bakaletz, 2009; Lim et al., 2005).

The single pathogen chinchilla model of otitis media was first developed in 1975 by Dr. Giebink (Bakaletz, 2009), whereby the pathogen is directly instilled in the middle ear. This single-pathogen direct-challenge middle ear model is still used extensively to study therapeutics and surgical intervention strategies (Bakaletz, 2009). Single-pathogen models allow for a simple interpretation of experimental data over that of co-infection models described below (Yang et al., 1998). The drawback however to these models is that they bypass the early steps in the development of pathogenesis, i.e. colonization of the nasopharynx, ascension up the Eustachian tube, and initiation of middle ear infection typically seen in human otitis media cases. Single-pathogen intranasal inoculation models were developed later and became more popular because of their clinical relevance (Bakaletz, 2004).

The first dual-infection otitis media model in the chinchilla was developed later in 1980 (Bakaletz, 2009). These models attempt to replicate the synergistic relationships between upper respiratory tract viruses (influenza A, respiratory syncytial virus, adenovirus, rhinovirus), and one or more bacteria (*Streptococcus pneumoniae*, *Moraxella catarrhalis*, non-typeable *Haemophilus influenzae*) (Bakaletz et al., 1998; McGillivray et al., 2007). Partnering an upper respiratory tract virus with an otitis media bacteria and further timing the interval between inoculations of virus and bacterium, represents a specific interrelationship. Dual-infection models add significantly to the understanding of the mechanism by which upper respiratory infections predispose to bacterial otitis media. Chinchillas were the only viral–bacterial co-infection animal models for otitis media until a recent murine model was developed (Bakaletz, 2004). This chinchilla dual-challenge model has a sequence of events with all the hallmark signs of pediatric otitis media which significantly parallel the course of viral and bacterial disease seen in natural disease in humans (Gitiban et al., 2005). This model has evolved into a key system for use in studies of the molecular mechanisms of the pathogenesis of otitis media, the immune response to infection, and for preclinical evaluation of vaccine candidates for the prevention of otitis media (Bakaletz, 2009). This model also is used to identify and characterize antimicrobial peptides expressed by the epithelium lining the upper

FIGURE 43.1 Schematic illustrating the three compartments of the ear; outer, middle, and inner. The round window is located between the stapes bone of the middle ear, and the fluid-filled cochlea in the inner ear. (Drawing courtesy of Brent de Riszner.)

airways, and help to determine their role in bacterial colonization and help to determine how many viruses might contribute to the pathogenesis of otitis media (Harris et al., 2004) (Figure 43.1). The following chapter describes specific-pathogen otitis media models.

Streptococcus pneumoniae

Streptococcus pneumoniae (SP) is one of three bacterial pathogens most frequently isolated by culture from middle ear effusions of children with both acute and chronic otitis media (others are *Haemophilus influenzae* and *Moraxella catarrhalis*) (Forbes et al., 2008). SP is the primary bacterial pathogen associated with 50% of all cases of otitis media in children (Carlsen et al., 1992; Linder et al., 1994). The first chinchilla model of otitis media was developed in 1975 using SP (Giebink, 1999). Until 1999 when a rat model was later developed (van der Ven et al., 1999), the chinchilla was the only non-bacteremic animal model of SP disease, whereby otitis media could be produced by very small amounts of inoculi and in which the disease remained localized (Giebink, 1999). The SP chinchilla model is still used to demonstrate hearing loss which has important

implications for transient sensorineural hearing loss seen in humans following otitis media (Giebink, 1999). In particular, the SP model is used most extensively to study local and systemic immune responses, pathogenesis, and efficacy of treatments (Alper et al., 1996) including the study of pharmacokinetics of antibiotics and passive and active immunoprophylaxis (vaccines) (Giebink, 1999). Chinchilla models of SP do not mimic human pathological processes on extension or severity (Giebink et al., 1976), but do provide a useful system to study the spectrum of disease induced by multiple clinical SP strains of unique genotype (Forbes et al., 2008).

Two methods to induce SP otitis media models are (1) direct transtympanic inoculation or inoculation of the middle ear via the cephalad bulla, and (2) intranasal inoculation (Giebink et al., 1979). Several intratympanic SP single-pathogen model variations have been developed. Strains used to induce models include serotypes 6A, 6B, 14, 19F, 23F which represent 65% of human clinical cases (Bakaletz et al., 1998; Linder et al., 1994). Other models use wild-type strain 3 (Sato et al., 1996), heat-killed encapsulated SP (Lowell et al., 1980), or non-encapsulated SP (Carlsen et al., 1992). To induce a transtympanic model for example, chinchillas are anesthetized and inoculated with 1.5×10^2 of SP in 0.3ml injected directly either through the transtympanic membrane or the epitympanic bulla, resulting in a greater than 75% success rate (Giebink et al., 1980). However, a model of acute otitis media that instills 10^2 – 10^8 bacteria/ml of type 23 SP, can result in 40% of chinchillas developing meningitis and/or bacteremia; conditions which are not desirable or comparable to the human clinical experience (Giebink et al., 1976).

Intranasal inoculation models are aided by applying mechanical or functional obstruction to the Eustachian tube, and then inoculating the nasal airway with SP (Carlsen et al., 1992). The addition of negative pressure (–25mmHg) to the intranasal otitis media model increases the success rate significantly by greater than 50% (Giebink et al., 1980). In humans, negative pressure is believed to be secondary to Eustachian tube dysfunction and a characteristic of otitis media with effusion (Giebink et al., 1979). When creating a model, negative pressure aids in the migration of bacteria along the eustachian tube from the nasopharynx to the middle ear. Negative pressure is applied on an anesthetized chinchilla by first applying saline to the nares (barotrauma), prepping the skin over the bulla (Green et al., 1994; Giebink et al., 1979), and inserting a needle into the bulla which is attached to a mercury manometer and firm plastic tubing. Negative pressure is applied while visualizing the tympanic membrane with an otoscope. When the membrane retracts the pressure is maintained for 5–20 minutes before the needle is removed. If negative pressure is applied 3 days after

nasal inoculation of SP, 59% of chinchillas will develop otitis media: 35% bilateral otitis media and 24% unilateral otitis media. For example, 0.5ml 10^6 type 7F SP instilled intranasally with negative pressure (–25), results in 98% incidence of otitis media within the first week and a purulent otitis media with middle ear effusion in 62% of chinchillas (Giebink et al., 1979).

Fluid samples (effusions) are typically collected from the middle ear for analysis following the establishment of the otitis media model by using either a capillary glass tube (0.7mm) (Giebink et al., 1980), aspiration with a 25-g needle, or lavage with 0.5ml of sterile saline. Disease progressions are assessed with tympanometry (an instrument that measures the eardrum responses to sound at different pressures) and otoscopy (Bakaletz, 2009). Otitis media is defined and identified as tympanic membrane changes with or without a visible fluid line (DeMaria, 1989), a red and inflamed tympanic membrane, detectable air–fluid levels, a bulging membrane with yellow fluid, or a tympanic membrane that is perforated with drainage to the external canal (Green et al., 1994; Tong et al., 2000).

Streptococcus pneumoniae and Influenza A

Chinchillas are significantly more prone to otitis media when *Streptococcus pneumoniae* (SP) is co-infected with influenza A, than when infected with either agent alone (Giebink et al., 1980). Only 4% of chinchillas develop otitis media with influenza alone and only 21% develop otitis media with SP alone ($17 \times$ increase in otitis media with both compared to influenza A alone, and $3 \times$ increase with both compared to SP alone) (Giebink et al., 1980). Overall, the incidence of otitis media increases to 67% in dually infected animal models (Bakaletz, 2009). In this dual-infection model, the virus compromises the eustachian tube mucosal integrity and results in impaired clearance function (Tong et al., 2002). This leads to development of negative middle ear pressure and viral suppression of polymorphonuclear white blood cell function which promotes a significant increase in nasopharyngeal colonization of Influenza A (Tong et al., 2002). Typically influenza A is inoculated intranasally, followed 3–4 days later by a SP intranasal inoculation (Giebink, 1999). The influenza strain most often used is A/Alaska/6/77 (H3N2) in a 0.2–0.5-ml suspension containing 6×10^6 CFU of virus/ml (Tong et al., 2002). The model is created by dripping viral solution into both nares (Abramson and Hudnor, 1994) followed by 0.5ml of SP type 6A containing 5×10^7 CFU/ml (Tong et al., 2002) or 1×10^5 SP (Abramson and Hudnor, 1994). This model causes a high incidence (67%) of otitis media with purulent effusions in middle ears but chinchillas survive without bacteremia. This model has been used extensively over the years for the preclinical assessment of various candidate antigens and adjuvants (Bakaletz, 2009).

Non-Typeable *Haemophilus influenzae*

Non-typeable *Haemophilus influenzae* (NTHi) is an opportunistic pathogen of the normal flora of the human nasopharynx and it accounts for 25–30% of all otitis media cases in humans (Tong et al., 2000). NTHi has mechanisms which enhance its infectivity, notably the ability to form biofilms which make it resistant to immune-mediated clearance (Jurcisek and Bakaletz, 2007). NTHi also does not require co-infection with virus to cause otitis media (Yang et al., 1998). Strains to induce animal models are selected from clinical isolates from patient specimens (Green et al., 1994). Non-typeable *Haemophilus* strains used as models include 1885, 1128, 1712, 86-028NP (Bakaletz et al., 1998; Hong et al., 2007). Because of virulence, each strain of NTHi must complete a dose-dependant curve prior to initiating an animal study to ensure otitis media will not result in complications (DeMaria, 1989). Possible complications are contralateral ear involvement, bacteremia, meningitis, and mortality (DeMaria, 1989). The NTHi chinchilla model is used to distinguish among multiple NTHi strains with respect to virulence parameters and varying ability to cause both local and systemic disease (Buchinsky et al., 2007), and are used for evaluation of antimicrobial agents and vaccine candidates.

NTHi is injected directly into the chinchilla middle ear to develop a transbullar challenge model (Yang et al., 1998). Chinchillas inoculated with 10^4 CFU of non-typeable NTHi result in 100% mortality from the development of meningitis by day 26 (Giebink, 1982). Likewise direct inoculation of 5×10^2 CFU, results in 40% of ears developing effusion by day 7, with only 25% mortality (Giebink, 1982). Severity of infection is therefore serotype- and dose-dependent (Giebink, 1982). Typically, NTHi transbullar models result in severe otitis media in virtually all ears of all animals within a very short period of time (24–48 hours). Direct middle ear inoculation of only a few bacteria produces a model without mortality and a 100% infection rate (Giebink, 1982). Elimination of negative pressure and co-infection reduces stress imposed on the chinchilla and uses fewer animals (Green et al., 1994; Yang et al., 1998). The transbullar model is useful for investigating the importance of host immunity in prevention of NTHi-related disease and for screening potential vaccines (Yang et al., 1998). This model is not useful to study NTHi adhesins which play a crucial role in the initial step of colonization (Yang et al., 1998). Other disadvantages are that the mechanism of this model is not analogous to the natural disease course of otitis media in children (Yang et al., 1998), which is typically subsequent to or coincident with a viral upper respiratory infection that then compromises host protective functions, predisposing the child to retrograde bacterial ascension up the eustachian tube (Bakaletz, 2009).

Intranasal inoculation of NTHi yields a low incidence of otitis media. NTHi must therefore be combined with adenovirus to produce a model with high incidence of otitis media by this route (Giebink, 1982). NTHi must also be followed by negative pressure to aspirate the bacteria into the middle ear via the eustachian tube which is usually done 18 hours after nasal inoculation (Yang et al., 1998). Typically a streptomycin-resistant strain of NTHi is used to create the animal model (Yang et al., 1998). When collecting middle ear fluid samples, streptomycin is added to the agar on which nasal lavage fluids are plated, to distinguish NTHi from other resident bacteria that colonize the chinchilla nasopharynx (Yang et al., 1998). This model is used as a tool to screen potential otitis media vaccine antigens, test colonization factors, and screen for NTHi adhesins (Yang et al., 1998). Disadvantages are that because chinchillas have lower infection rates, larger numbers of animals are required per experimental group. Moreover, additional manipulation and stress is experienced by the animals when applying negative pressure (Green et al., 1994).

Younger animals (2–3-month-old chinchillas) produce a higher incidence of NTHi otitis media compared to 4–5-month-olds or 1–2-year-olds (Yang et al., 1998), and thus serve as a model for pediatric NTHi otitis media. Age does not influence the degree of nasopharyngeal colonization with NTHi but has a marked effect on subsequent development of middle ear infection (Yang et al., 1998). Chinchillas of any age can be used to study colonization of the nasopharynx, but 2–3-month-olds are crucial to study middle ear infections, particularly with induction of 10 CFU with only a single nasal wash (Yang et al., 1998).

A significant improvement in the otitis media model of NTHi is the bioluminescence model (Novotny et al., 2005). A non-typeable *Haemophilus influenzae* has been developed with a plasmid-containing *luxCDABE* gene cluster of *Photobacterium luminescens* which emits light that penetrates through bony processes surrounding the middle ear space and that can be detected in a quantitative and qualitative manner. When chinchillas are inoculated intranasally or transbullarily with this strain, disease progression and colonization can be followed in the nasopharynx, eustachian tube, and middle ears. The advantage of this model is that it eliminates repeated nasal lavages, therefore significantly improving the ability to model otitis media in a non-invasive manner (Novotny et al., 2005).

Non-Typeable *Haemophilus influenzae* and Adenovirus

Synergistic models contribute to a better understanding of pathogenesis of virus-augmented NTHi disease (Yang et al., 1998). The development of the viral-bacterial super infection model in the chinchilla has been very

successfully used to study otitis media, highly reproducible (Bakaletz et al., 1993, 1995) and very similar to the disease process seen in children with otitis media. NTHi alone inoculated into the chinchilla nasal cavity will simply colonize the nasopharynx, however when a viral-bacterial dual challenge model is developed, NTHi ascends the eustachian tube to induce otitis media (Bakaletz, 2009). This model uses the juvenile chinchilla and challenges them first with an intranasal serotype of pediatric isolate of adenovirus. Once signs of viral upper respiratory tract infections develop, animals are subsequently challenged with an intranasal low-passage clinical isolate of NTHi, timed to coincide with maximal viral compromise of the eustachian tube (Bakaletz, 2009). For example, doses of 6×10^6 of 50% tissue culture of adenovirus are given intranasally with a pipette, followed 7 days later with an intranasal inoculation of 10^9 CFU of NTHi (Bakaletz, 2009; Suzuki and Bakaletz, 1994). NTHi usually reaches the tympanum at 7–10 days, with 77% of all ears showing disease by day 14 (Bakaletz, 2009). NTHi will multiply to high concentrations in the middle ear fluid, however as in children, these fluids are eventually cleared and the host re-establishes homeostatic conditions, however this process takes 5 weeks or more in chinchillas (Bakaletz, 2009).

When using preclinical vaccine efficacy studies, one additional step is added to this model and that is to passively transfer immune serum pools (derived from separate adult chinchillas directed against specific candidate vaccine antigen) to the juvenile chinchilla the day before they are challenged intranasally with NTHi. This protection maintains the immune status of the juvenile chinchilla, which helps support their permissivity to challenge with human wild-type viruses (Bakaletz, 2009). The advantage to this juvenile chinchilla model is that it seems to fit well with epidemiological data regarding the polymicrobial nature and natural disease course of otitis media in humans. The chinchilla passive transfer superinfection model is used to investigate the mechanism of pathogenesis and as well as its prevention, and has been used in several large cohort preclinical vaccine trials since its development in 1994 (Bakaletz, 2009).

Moraxella (Branhamella) catarrhalis

Moraxella catarrhalis (MC) is the third ranking commensal inhabitant of the upper respiratory tract (Chung et al., 1994) capable of inducing otitis media, sinusitis, conjunctivitis, and bronchitis in pediatric populations (Bakaletz et al., 1995; Luke et al., 2007). Traditionally, a MC otitis media animal model whereby viable organisms persist and multiply has been difficult to develop (Bakaletz et al., 1995; Chung et al., 1994). The only animal model that existed prior was the mouse pulmonary clearance model, but the organism was eradicated within 24 hours of inoculation (Luke et al., 2007). The

chinchilla model is therefore unique in that it serves as a self-limiting, less severe experimental nasopharyngeal MC model. Compared to other otitis media pathogens (Chung et al., 1994; Lim et al., 2002), this model only shows local infection with no bacterial multiplication, and eradication even after receiving large inocula (Bakaletz, 1995). MC will stably colonize the chinchilla nasopharynx for up to 2 weeks, and thus the chinchilla host can serve as a useful model of the earliest stage of otitis media development, namely colonization, inflammation, antibody development, and clearance (Bakaletz, 1995; Luke et al., 2007). This model is not used to evaluate effects of immunization or treatments due to the rapid elimination of bacteria from the ear (Chung, 1994).

Moraxella catarrhalis and Adenovirus

A dual model (pathogen synergy model) requires the addition of adenovirus to predispose the chinchilla to host *Moraxella catarrhalis*. To induce this model in the chinchilla, both organisms are introduced through intranasal inoculation. A 50% tissue culture of 6×10^6 pediatric adenovirus type 1 is inoculated in 0.5 ml divided between two nares via passive inhalation. This is followed 7 days later with inoculation of 10^8 CFU of *Moraxella* 1857 suspended in 0.5 ml. This model results in 100% pure culture of *Moraxella* from the nasopharyngeal lavages from days 1–4 post inoculation (Bakaletz et al., 1995). Despite colonization of MC in the chinchilla, no synergistic effect is found between these two organisms, as is with other combinations of bacteria and viruses. It is not possible therefore to use this model to evaluate effects of immunization or treatment modalities due to the rapid elimination of MC; however it does represent a model of colonization and clearance (Bakaletz, 1995; Chung et al., 1994).

Adenovirus

Chinchillas readily support infection, and respond serologically to adenovirus given either by intranasal or middle ear routes (Bakaletz et al., 1993). Adenovirus alone is used to study roles of upper respiratory viruses in the pathogenesis of bacterial otitis media, to assess the time course of disease and recovery, and to assess functional correlates of any induced histopathology. The model is induced with nasal inoculation of 0.6 ml of 6×10^6 TCID₅₀ divided between nares or transbulbarly with 0.3 ml per ear (Bakaletz et al., 1993). Intranasal inoculation results in mild-moderate tympanic membrane inflammation lasting 35 days, while transbulbar inoculation results in significant severe infection within 48 hours, lasting 10 days (Bakaletz et al., 1993). Chinchillas inoculated intranasally develop varying degrees of lethargy, malaise, wheezing, conjunctivitis, and labored breathing. These signs are not seen with

transbullar inoculation (Bakaletz et al., 1993). In comparison to influenza A virus, adenovirus time course is delayed both in disease onset and recovery in identical models (Bakaletz et al., 1993). The chinchilla is a valid model of adenovirus type 1 disease as it results in culture positives, seroconversion, cytopathologic changes, and distinct histopathology that correlate with functional assessments of the eustachian tube (Bakaletz et al., 1993). Adenovirus predisposes to NTHi and MC otitis media but does not predispose to *Streptococcus pneumoniae* otitis media (Bakaletz, 2004).

Influenza A

Influenza A induces acute otitis media (Lim et al., 1989) on its own and is used to develop a model of otitis media in the chinchilla. Eustachian tube and middle ear mucosa of chinchilla, similar to humans have glycoproteins with sialic acid which may have receptors for Influenza A (Lim et al., 1989). Influenza A acts to cause negative pressures in the eustachian tube which allow migration of bacterial pathogens to the middle ear (Lim et al., 1989). Influenza A attaches primarily to the ciliated cells of the tubotympanum, causing massive ciliated cell destruction (Lim et al., 1989) that does not restore for 3 weeks (Chung et al., 1993; Giebink, 1999). Influenza A/Alaska 16/77 (H3N2) virus strains are used to create the model (Chung et al., 1993). The virus is inoculated via bullar puncture with 7×10^6 PFU or 2.8×10^7 PFU (Chung et al., 1993; Lim et al., 1989). Ears show inflammation from 6–28 days (average infection lasts for 10 days), but few develop effusions (Chung et al., 1993; Giebink, 1999). The intranasal route results in a marked metaplasia of eustachian tube epithelium, increased secretions, and obstruction of the tube lumen (Giebink, 1999). Influenza A predisposes *Streptococcus pneumoniae* (Bakaletz, 1995, 2004) to develop otitis media.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a key co-pathogen of otitis media (Bakaletz, 2004). In the past, a lack of relevant animal models prevented the study of mechanisms by which RSV predisposes to otitis media. Several animal models exist of RSV lower respiratory tract infections, but none of upper airway infections (Gitiban et al., 2005). Chinchillas are unique in that they are susceptible to RSV and show signs of illness, viral replication, and inflammation. The chinchilla model is useful to test the role of RSV in bacterial otitis media and efficacy of RSV vaccines, pathogenesis, and host immune function (Gitiban et al., 2005). The RSV model is created by inoculating a viral suspension of 10^6 or 10^7 PFU per animal intranasally via passive inhalation of droplets to juvenile chinchillas of ~3 months. At day 4, signs of ruffled fur, lethargy, and signs of upper respiratory tract infection develop in 33% of animals (Gitiban et al., 2005). Overall RSV shows

milder signs of illness than influenza A or adenovirus and clinical signs are dose-dependent. RSV's role in otitis media is to compromise the eustachian tube function by increasing mucous secretion which predisposes to bacterial superinfection (Gitiban et al., 2005). This chinchilla model is the first experimental system where the predisposition to bacterial otitis media by RSV was studied. This model however is still not practical for proof-of-concept studies and preclinical vaccine candidate trials (Gitiban et al., 2005).

Models of Biofilms

Biofilms are associated with the three primary causative agents of otitis media, non-typeable *Haemophilus influenzae* (NTHi), *Streptococcus pneumoniae*, and *Moraxella catarrhalis* (Bakaletz, 2009). Biofilms are a highly organized multicellular network of bacteria encased in a polymeric matrix and found in close association with a surface (Bakaletz, 2009). They grow into towers several hundreds of bacteria in height (Ehrlich et al., 2002). Biofilms promote bacterial persistence due to the matrix which protects against phagocytosis (Ehrlich et al., 2002) and increases resistance to clearance by host defenses or antibiotic therapy (Hong et al., 2007). The chinchilla biofilm model is developed by using *Haemophilus influenzae* strain 1128 bacteria, derived from a clinical isolate from a child with middle ear otitis media, injected into the bulla bilaterally (Ehrlich et al., 2002). After 72 hours the chinchilla is treated with ampicillin 150 mg/kg BID for 4 days to reduce the complications of systemic infection and to sterilize the middle ear effusion to culture negative (Ehrlich et al., 2002). In animals that develop middle ear effusion, ~50% develop biofilms within 5 days (Ehrlich et al., 2002). Multiple consecutive lavages provide a means to acquire biofilm samples without sacrificing the animal (Leroy et al., 2007). The chinchilla biofilm model of otitis media is consistent with the biofilm theory in many human infections (Ehrlich et al., 2002).

Models of Cholesteatoma

Cholesteatoma is associated with chronic ear disease. Cholesteatoma is defined as an accumulation of exfoliated keratin produced from stratified squamous epithelium which often overlays connective tissue. It develops within the middle ear and is an erosive space-occupying lesion associated with chronic otitis media (Masaki et al., 1989). It is difficult to develop a model with persistent tympanic membrane perforations seen with cholesteatoma, and since this syndrome is relevant to older patients, it requires a long-term animal model. The chinchilla serves as a model to evaluate factors involved in the development of otitis media that could play a role in the pathogenesis of acquired cholesteatoma (Lim

et al., 2002). This model is also used to explain the fate of prenatally acquired keratin and its relevance to post-natal ear disease (Camacho et al., 1997). To create a model of cholesteatoma in the chinchilla, non-viable keratin is introduced to the tympanic bulla. Tissue and hair are harvested from the abdomen of the same chinchilla (autologous) and minced, autoclaved, made into slurry, and instilled into one bulla. Chinchillas receive ampicillin for 3 weeks post inoculation, to sterilize the middle ear. Alternatively, a "viable" model is made by collecting autologous tissue excised from the conchal surface of the pinna of the chinchilla and inserted into the bulla. This viable model simulates the neonatal situation of amniotic fluid reflux into the eustachian tube. This model results in a robust inflammatory foreign body giant cell response from 1–9 months post inoculation (Camacho et al., 1997).

The cholesteatoma chinchilla also serves as a model to demonstrate the "migration theory" of how cholesteatoma develops. The chinchilla model demonstrates slow epithelial migration and true cholesteatoma formation in the middle ear with deliberate perforation of the tympanic membrane. No other animal model exists that can demonstrate the migration theory through a deliberate tympanic membrane perforation. This model is created by placing a chemically modified gelatin membrane from the external auditory canal through a tympanic membrane perforation, which can contact the epithelium of promontory (Hueb et al., 1993). This model simulates the migration of squamous epithelial cells and cholesteatoma, and mimics findings observed in humans. The advantage of the chinchilla model is that it can be easily and predictably repeated in over 50% of chinchillas (Hueb et al., 1993).

Another method to create a cholesteatoma model in the chinchilla involves the instillation of propylene glycol. Many commercially available otic preparations utilize propylene glycol as a solvent and it is thought to be the cause of this condition (Masaki et al., 1989). This model is created by instilling 0.2 ml of a solution of 50% of propylene glycol containing 5 mg/ml of neomycin and 10000 units/ml of polymyxin B into the middle ear by injection through a small hole in the superior aspect of the bulla, without damaging the tympanic membrane (Masaki et al., 1989). The result is hyperplasia of the tympanic membrane epidermis and epidermal invasion and penetration through an intact tympanic membrane (Masaki et al., 1989).

Models of Therapeutic Treatment of Aural Disease

Antibiotic Pharmacokinetics

Pharmacokinetic models are used to study the antibiotic drug distribution into the middle ear and evaluate

its relevance and significance to the clinical treatment of otitis media (Huang et al., 2001). Currently, there is little information on the middle ear distribution of antibiotics after systemic administration in clinical use, since reliable data from experimental animal models of otitis media treatment efficacy are rare. Inability to access and sample middle ear fluid frequently with traditional techniques is a major impediment in assessing pharmacokinetics and pharmacodynamics (Huang et al., 2001). Chinchilla otitis media models provide well-controlled conditions for measuring antibiotic pharmacokinetics. These models can be reliably produced with reasonable homogeneous pathology, enable repetitive sampling of middle ear fluid, and provide baseline pathology and fluid biochemistry that is well described as a means of reference (Canafax et al., 1994; Giebink, 1999).

The first type of model permits analysis of drug concentration on serial samples of very small volumes of ear fluid and blood samples (Canafax et al., 1989). Limitations are that only small volumes of middle ear fluid can be sampled (Jossart et al., 1990). This model is created by first surgically exposing the eustachian tube through the soft palate. Three silastic sponges (1–2 mm) are inserted to obstruct the eustachian tube. *Streptococcus pneumoniae* type 7F is inoculated in the lower portion of each bulla (10–50–400 CFU/ml). Antibiotics are given systemically, and a series of blood samples are collected. Middle ear fluid samples are collected on day 5 (purulent otitis media) or at 2–4 weeks (serous otitis media) using a 16-gauge needle inserted into the tympanic bulla. A catheter is passed through the needle into the bulla (Canafax et al., 1989). Most chinchillas survive 1 week, however by 3 weeks, 20% of chinchillas die due to sepsis, pulmonary edema, labyrinthitis, and/or pneumonia (Canafax et al., 1989). This model allows for the study of antibiotic pharmacokinetics and is used to determine how it relates to the biochemical, microbiological, and histopathological events that occur during treatment of acute otitis media (Canafax et al., 1994).

The Drug Diffusion Model measures the rate constant of antibiotic as it leaves the middle ear fluid (Canafax et al., 1994). This equates to the rate the drug penetrates the middle ear mucosa and is used to determine the concentration achieved in the middle ear (Jossart et al., 1990). This model assumes the exit rate is the same as the entry rate. This model is created 3 days after developing bacterial otitis media with SP type 7F and obstructing the eustachian tube as described above. Purulent material is aspirated out of the middle ear cavity before antibiotic solution is added. This model is created by placing a catheter in the central bulla (passing a 16-g needle then sliding a thin catheter through the needle), and inserting a 23-g needle to act as a pressure vent to prevent rupture of the tympanic membrane during injection of antibiotic. An antibiotic solution is infused

at 1ml/min to the middle ear through the catheter. Samples are aspirated using the same catheter at various time points. One disadvantage to this model is that only small effusion volumes can be obtained (Jossart et al., 1990).

A variation of this model is the drug systemic administration model which measures the constant rate K value calculated from the concentration of middle ear versus time after systemic drug administration. The K values from either a drug systemic administration model or a diffusion model are similar for assessing antibiotic pharmacokinetics (Canafax et al., 1994). After an otitis media model is established with *Streptococcus pneumoniae*, fluid is aspirated from the middle ear (3 days post inoculation). Following systemic antibiotic administration, fluid samples are collected from the middle ear (150µl) at 1, 2, 3, 4, and 6 hour time points. The rate constant K value is calculated from the middle ear concentration versus time. The advantage of this model is that middle ear fluid can be repetitively sampled. Limitations are the small middle ear fluid volumes, difficulty to assess the effects of various factors on antibiotic penetration, and difficulty to quantitate antibiotic appearance and disappearance from the middle ear (Canafax et al., 1994).

Chinchilla Microdialysis Model

The most advanced method to study antibiotic pharmacokinetics is the microdialysis model. This model is used to compare the antibiotic concentration in the middle ear fluid to serum levels (Cheung et al., 2006). It allows continuous measurements of plasma and middle ear fluid levels of an antibiotic in an awake, freely moving animal model which more closely resembles a pediatric human patient (Huang et al., 2001). This model is created by first obstructing the eustachian tubes, followed 24 hours later with instillation sterile PBS into the middle ear (artificial middle ear fluid), followed 24 hours later with the inoculation of 50CFU of *Streptococcus pneumoniae* into the middle ear. Catheters are placed 48 hours later in the jugular or femoral veins and femoral artery to administer antibiotics and collect blood samples. Microdialysis probes are implanted into both middle ears. Elizabethan collars are placed around the neck of the chinchilla to maintain the tether that contains the microdialysis tubing and catheters. Dosing of antibiotic occurs over the next 6–72 hours by IV bolus or infusion. Drug concentration in blood and middle ear fluid is monitored continuously with microdialysis and samples are analyzed by HPLC (Huang et al., 2001). A variation of this model is to use non-infected chinchilla ears prepared as described above but without the instillation of SP to determine unbound concentration of antibiotic drugs. Alternatively antibiotic can be delivered directly into the middle ears, and microdialysis

probe samples are collected over 17 hours to evaluate elimination kinetics from the ear (Cheung et al., 2006). The advantage of this chinchilla microdialysis model is that it allows continuous sampling and long-term monitoring of antibiotic concentration versus time in blood and middle ear fluid (Huang et al., 2001). It omits the potential side effects of anesthetics as a complicating factor. It overcomes the challenge of limited volumes of fluid because it does not remove fluid from the middle ear. Because of minimal restraint, normal physiological conditions are evaluated approximating those of human otitis media patients more closely. This model can be applied to a number of different antibiotics and is a powerful tool in the discovery and development of new anti-infective agents for treatment of otitis media (Cheung et al., 2006; Huang et al., 2001).

MODELS RELATED TO HEARING LOSS

Overview

Hearing loss is a major problem in industrialized societies (Henderson et al., 2006). Animal models play important roles in auditory research to study long-term well-controlled hearing loss over days, weeks, months, or years that is impossible to do in human populations (Salvi and Boettcher, 2008). Models with well-defined types and patterns of hair cell lesions (hearing loss) are aimed at improving cochlear prostheses, understanding central auditory plasticity, and developing strategies for inner ear rescue and repair. Most biological studies of sensorineural hearing loss have been conducted on cat, chinchilla, gerbil, guinea pig, mouse, and rat (Salvi and Boettcher, 2008). Chinchillas are an important animal model because their range of hearing is nearly identical to that of humans (Miller, 1970). They are an ideal animal model because of their ease of handling, excellent response to otoacoustic emissions testing (OAE), their contralateral ear can serve as its own control, and their thin round window membranes allow ototoxic drugs to cross easily (the membrane in the chinchilla is one-sixth as thick as that of a human) (Chen et al., 1999). Chinchillas are used by NIOSH (National Institute for Occupational Safety and Health), PHS (Public Health Service), and CDC (Centers for Disease Control) to determine guidelines for occupational exposure to noise in industry (Dunn et al., 1991). However, with rapid developments in molecular biology and genomics, research has shifted toward the use of rats and mice for hearing research, in particular, inbred strains in which the effects of genetic variability are greatly reduced (Salvi and Boettcher, 2008).

Animal models of hearing loss are developed using chemical agents or loud noise. Noise is thought to

create toxic free radicals and result in increases in reactive oxygen species (ROS). ROS damage is believed to be the common pathway of cell death leading to hearing loss resulting from loud noise and agents like aminoglycoside antibiotics, anticancer drugs, aging, industrial solvents (toluene) (Henderson et al., 2006), and quinolinic acid (Yellon et al., 1994). The administration of aminoglycoside antibiotics and antineoplastic drugs create hair cell lesions in a predictable pattern of damage in the mammalian inner ear.

The ear is divided into three compartments; outer, middle, and inner. Sounds are collected by the pinna and channeled toward the tympanic membrane (eardrum) which is coupled to the ear ossicles (malleus, incus, and stapes). Sound-induced vibrations transmitted through these three bones are transferred through the round window into the fluid-filled cochlea in the inner ear. The spiral tube of bone that forms the cochlea is subdivided along its entire length by three parallel, fluid-filled compartments; scala tympani, scala vestibule, and scala media. The cochlea spirals around the hollow bony core that contains the spiral ganglion neurons whose axons give rise to the auditory nerve. The outer hair cells (OHC) form three rows and the inner hair cells (IHC) form a single row that spirals along the length of the cochlea from base to apex. Outer hair cells help amplify sound vibrations entering the inner ear from the middle ear. When hearing is working normally, the inner hair cells convert these vibrations into electrical signals that travel as nerve impulses to the brain, where the impulses are interpreted as sound. The majority (95%) of auditory nerve fibers make synaptic connections with the IHC; only 5% connect with the OHC. The stereo cilia bundles protrude from the apical pole of the hair cells and are seen using a scanning electron microscope (Salvi and Boettcher, 2008). When typical cochlear damage occurs it is characterized by base to apex, outer hair cell to inner hair cell, and first row to third row gradients of hair cell loss (Figures 43.2–43.4).

To test the degree of hearing loss and assess methods of prevention or treatment, various dependent measures or tests are used. Typically the chinchilla is trained (operant conditioning) to distinguish characteristics of sound (via hearing), as a way for researchers to understand hearing loss and sound perception. This is accomplished by training the chinchilla to press keys through positive and negative reinforcement techniques to receive a food reward. Physiological measures of hearing loss used by researchers include measures of distortion product otoacoustic emissions (DPOAE), compound action potential (CAP), single auditory nerve fibers, and auditory brainstem response (ABR). DPOAE is a selective and sensitive tool for assessing the status of the OHC in noise-induced hearing loss. DPOAE amplitude is greatly reduced or absent with OHC loss. The CAP and single auditory

FIGURE 43.2 Dissection of the tympanic bulla of the chinchilla showing the relative location to the ear pinna. Bulla are extremely large in the chinchilla.

nerve fiber responses reflect the combined output from the OHC, IHC, and supporting cells of the cochlea. The ABR is a reflection of the neural activity that is transmitted from the inner ear to the auditory brainstem and used to measure the threshold of hearing to acoustic stimulation. These tests are all used in chinchilla models to assess hearing and quantify the degree of hearing loss (Salvi and Boettcher, 2008) (Figures 43.5, 43.6).

Models of Chemical-Induced Hearing Loss

Cisplatin

Cisplatin is a pharmaceutical chemotherapy drug that is used widely to treat different cancers including testicular, germ cell, head and neck, bladder, and lung cancer. The most common problems experienced during cisplatin therapy and overdosage are nephrotoxicity, electrolyte disturbances, myelosuppression, neurotoxicity, anaphylactic reactions, and ototoxicity. Hearing loss is thus a serious consequence for humans undergoing chemotherapy. Cisplatin can therefore be used to develop a model of hearing loss in chinchillas. Cisplatin primarily damages the outer hair cells more than the

FIGURE 43.4 (A) Photomicrograph of the chinchilla cochlea showing the stapes plugged into the oval window in the base of the cochlea next to the round window. The cochlea spirals from base to apex around the modiolus, a central bony core containing the spiral ganglion neurons whose fibers give rise to the auditory nerve. The solid line depicts the axis of the modiolus within the cochlea; the dotted triangle depicts a cross-section through the basal turn of the cochlea. (B) Schematic cross-section of one turn of the cochlea showing the three fluid-filled compartment, scala media, scala vestibuli, and scala tympani. Scala media is separated from scala vestibuli by Reissner's membrane; the stria vascularis lies along the lateral wall of the cochlea. The organ of Corti containing the sensory hair cells and supporting cells rest on the basilar membrane. The tectorial membrane, an acellular structure, lies above the outer hair cells (OHC) and inner hair cells (IHC). Approximately 95% of the auditory nerve fibers contact the IHC; the remaining 5% contact the OHC. (Photo courtesy of Richard Salvi.)

FIGURE 43.5 Distortion product otoacoustic emissions (DPOAE) test on an anesthetized chinchilla. Probes/microphone insert is shown, that is placed in the ear. Microphone produces sound and the probe detects sound reflections. DPOAE is performed in a sound-proof chamber. (Photo obtained with assistance of Don Coling.)

FIGURE 43.6 Auditory brainstem response test-pressure field (ABR) shown on an anesthetized chinchilla. Sound is directed into the ear. Electrodes to the head are used to record electrical activity from the auditory nerve which is converted to fiber optics by instrument on the left. Electrode impedance meter is shown on the right. ABR is performed in a sound-proof chamber. (Photo obtained with assistance of Don Coling.)

inner hair cells (Janning et al., 1998). It is applied topically directly to the round window membrane via the bulla with 25 μ l solution of 0.25 mg/ml in saline with a micropipette in an anesthetized chinchilla. One ear is used as the experimental model and the other ear serves as a control. Ototoxicity takes up to 7 days to develop with significant hearing loss as measured by increased ABR thresholds (Janning et al., 1998). Alternatively, cisplatin can be injected systemically at 2.75 mg/kg IP for 3 consecutive days (Ding et al., 2007). Subcutaneous fluids (saline) are administered during cisplatin administration to diurese the kidneys, but despite this precautionary effort, mortality can still be high due to kidney

damage. Direct application of cisplatin to the round window reduces the systemic side effects (nephrotoxicity) of the drug.

Cisplatin and Ethacrynic Acid

Ethacrynic acid diuretic alone causes temporary hearing loss that is reversible. By combining cisplatin with ethacrynic acid, the ototoxic effects are enhanced (Ding et al., 2007). This combination of drugs produces toxic hydroxyl radicals and decreases antioxidant levels; the result of which is 100% outer hair cell loss at the base of cochlea (and 10% at apex). Inner hair cell loss is uniform along the length of cochlea. This model is

created in chinchillas with 0.2 mg/kg IP of cisplatin and 40 mg/kg IV of ethacrynic acid (Ding et al., 2007). The benefit of this drug combination is that the toxic side effects of cisplatin can be reduced or avoided (nephrotoxicity) and a robust model of hearing loss can still be accomplished.

Carboplatin

Carboplatin is a chemotherapy drug used against some forms of cancer (mainly ovarian carcinoma, lung, head and neck cancers); however it can cause secondary auditory neuropathy. Auditory neuropathy is also associated with hereditary disorders such as Charcot-Marie-Tooth disease, Friedreich ataxia, kernicterus, and hypoxia theory due to history of high-risk birth (Harrison, 1998). Humans with auditory neuropathy have absent or severely abnormal ABRs that do not correspond to their audiometric thresholds or to relatively normal OAEs (Harrison, 1998). Carboplatin preferentially damages the inner hair cells, auditory nerve fibers, and type 1 spiral ganglion neurons, but spares the outer hair cells (El-Badry and McFadden, 2007; Wang et al., 2003). In contrast, most ototoxic drugs and trauma (noise) damage the outer hair cells. Carboplatin is therefore used to produce a chinchilla model of auditory neuropathy with a unique advantage to providing fundamental information about the function of the inner hair cells (Harrison, 1998; Wang et al., 2003). This model is developed by injecting 50 mg/kg IP of carboplatin (low dose) (Wang et al., 2003) or 75 mg/kg IP (high dose) (El-Badry and McFadden, 2007), or 400 mg/cm² given IV (Harrison, 1998) and results in death of 50% of the inner hair cells. The spiral ganglion neuron and afferent terminals are damaged a few hours after carboplatin application, and hair cell damage begins 1–2 days later (Wang et al., 2003). High doses of carboplatin in the chinchilla show IHC loss and partial OHC loss, whereby low to moderate doses show only IHC loss which is a unique feature in the chinchilla; the effects of which do not occur in other rodents or humans (McFadden et al., 2002; Wang et al., 2003).

Aminoglycosides

Aminoglycosides are bactericidal antibiotics that are active against aerobic Gram-negative bacilli and staphylococci. Although the ototoxic effects of aminoglycosides are well documented, this class of drugs is still widely used today. Aminoglycosides are cleared more slowly from inner ear fluids than from serum and therefore latency exists to the ototoxic effects resulting in a progression of hearing loss after cessation of treatment. Aminoglycoside toxicity primarily targets the renal and cochleovestibular systems. Kanamycin, amikacin, neomycin, and dihydrostreptomycin are preferentially cochleotoxic. Gentamicin affects both cochlear and

vestibular systems. Streptomycin and tobramycin are primarily vestibulotoxic (Mudd et al., 2008). Cochlear toxicity that results from aminoglycoside hearing loss usually begins in the high-frequency range and is secondary to irreversible destruction of outer hair cells in the organ of Corti, predominantly at the basal turn of the cochlea.

Aminoglycosides are used to induce models of hearing loss in chinchillas for two practical reasons; (1) to selectively destroy OHC (Ryan and Dallos, 1975), and (2) to mirror the clinical practice of chemical vestibular ablation used in the treatment of Ménière's disease (Chen et al., 1999; Hirvonen et al., 2005). The former is valuable to study IHC function, since aminoglycosides selectively destroy only the OHC. Unlike noise-induced hearing loss, which creates mixed hair cell death models, this model is selective and thus has a distinct advantage to allow for the study of IHC function (Ryan and Dallos, 1975).

Gentamicin is specifically used in chinchillas to create a model with damage to the vestibular apparatus of the inner ear (Hirvonen et al., 2005) and severe outer hair cell loss, primarily the inner two rows, while sparing the inner hair cells. The degree of neuroepithelial and vestibular damage is directly related to the dose; with higher dosages, the contralateral ear can have injury. To create this model an incision is made over the superior bulla to make a 3-mm opening to the middle ear cavity and 0.2–0.6 ml of gentamicin (26.7 mg/ml) is administered to fill the middle ear. The head of the chinchilla is turned toward the ceiling (ear up) to allow 30 minutes for the solution to bathe and diffuse across the round window (Lyford-Pike et al., 2007). Chinchillas will develop a static roll head tilt by approximately 2.5–3 weeks (anywhere from 4–22 days post injection) (Chen et al., 1999; Hirvonen et al., 2005). At 3 weeks, outer hair cells are eliminated from all the canals (Lyford-Pike et al., 2007). This animal model displays more cochlear than vestibular damage (McFadden et al., 2002) and will cause damage to the contralateral ear, both characteristics which do not reflect the human experience of hearing loss (Chen et al., 1999). Since this chinchilla model is unable to support vestibular selectivity it may not be an adequate model for Ménière's disease either, however it does replicate the histopathological changes seen in humans (Chen et al., 1999).

Streptomycin was the first clinically applied aminoglycoside antibiotic and was used successfully for treatment of tuberculosis. Streptomycin preferentially affects the vestibular system rather than the auditory system, with more severe damage in the basal turns and more outer hair cell involvement in a dose-dependent fashion (Chen et al., 1999; Hilton et al., 2002). Streptomycin has therefore become a popular form of vestibular treatment for Ménière's disease (Chen et al.,

1999). Streptomycin given in one instillation to the middle ear of chinchillas at full strength (26.7 mg) creates a model of severe OHC loss at basal and mid turns of the cochlea (Chen et al., 1999).

Kanamycin has a propensity to cause profound cochlear hair cell damage, marked high-frequency hearing loss, and complete deafness. The damaging effect is primarily to the cochlea, while the vestibular system is usually spared injury. Kanamycin (150 mg/kg SC) plus bumetanide (20 mg/kg IV) a diuretic, given 2 hours apart will cause primarily a basal inner hair cell loss model in the chinchilla (McFadden et al., 2002). Kanamycin given systemically at 200–300 mg/kg SC daily for 6–35 days results in OHC damage, threshold shifts of 42–52 dB, but maintains intact IHC (Ryan and Dallos, 1975).

Gentamicin and Ethacrynic Acid

Gentamicin can be combined with ethacrynic acid (EA) since ethacrynic acid greatly enhances ototoxicity. The combination decreases problems associated with long-term systemic effects associated with gentamicin. The two drugs can be administered together or given separately by 1–1.5 hours. By preserving normal vestibular end organ morphology while eliminating all cochlear hair cells, this model is useful to study vestibular function and responses of the vestibular system to sound. To create this model, 125 mg/kg of gentamicin is given IM and 40 mg/kg of ethacrynic acid given IV (McFadden et al., 2002). This model destroys all inner hair cells and outer hair cells; however up to 30% mortality can be seen with this regime. Dosages of 10–40 mg/kg of gentamicin and 40 mg/kg ethacrynic acid results in destruction of nearly all outer hair cells, with dose-dependent inner hair cell loss, normal vestibular function, and no mortality. Delaying the second administration of drug by 1 hour results in partial lesions of inner hair cells, and delaying second drug by 1.5 hours preserves most of the inner hair cells, with only less than 50% outer hair cell loss (McFadden et al., 2002). An animal model with normal vestibular end organs but no hair cells is useful to study vestibular function and responses of the vestibular system to sounds. This model does demonstrate a unique feature in that gentamicin on its own is vestibular toxic and shows base to apex IHC loss, but when combined with EA the vestibular system is spared and apical hair cell loss predominates. By inner hair cell lesions not following the base to apex gradient as seen in the carboplatin model, this model represents unique characteristics which are not hallmarks of human ototoxicity (McFadden et al., 2002).

Kainic Acid

Glutamate is an excitatory amino acid and neurotransmitter at the inner hair cell and auditory nerve

fiber synapse, in all mammalian cochlea. Excessive amounts of glutamate are excitotoxic to type 1 ganglion neurons in cochlea and are implicated in diseases such as sudden deafness, noise-induced hearing loss, and presbycusis (age-related hearing loss). Kainic acid is an analog of glutamate and establishes a model of hearing loss to study the recovery of function of the auditory nerve and inferior colliculus (Zheng et al., 1999). Glutamate agonists coupled with acoustic overstimulation causes early damage to type 1 afferent synapses (Wang et al., 2003). This model is created by first making the chinchilla monaural by surgical destruction of the left cochlea. Chronic recording electrodes are implanted in the left inferior colliculus and kainic acid is applied topically (60 mM) to the intact right round window membrane. Chronic electrodes are implanted directly on the trunk of the auditory nerve to record compound action potentials. Another electrode is implanted directly onto the auditory nerve within the internal auditory meatus after exposure of the cerebellum via posterior craniotomy. One end of the electrode is placed against the trunk of the nerve while the other is cemented to the top of the skull subcutaneously for EVP (evoked potentials) and DPOAE (distortion product otoacoustic emissions) measurements. Kainic acid induces cochlear excitotoxicity and immediately (3 hours post application) causes massive swelling of type 1 afferent endings under inner hair cells, but hair cells are spared. Ten days post inoculation the auditory afferent synapses rapidly regenerate and re-establish viable synapses with inner hair cells (fibers respond to sound). The purpose of this model is to understand the plasticity of the central auditory system to reorganize itself during restoration of input from the auditory periphery as might occur with cochlear prosthesis or other clinical interventions for hearing loss (Zheng et al., 1999).

Noise-Induced Hearing Loss Models

Loud noise exposure is a common health hazard in industrial, recreational, and military activities (Hu et al., 2008). Noise-induced hearing loss (NIHL) can be caused by a one-time exposure to an intense “impulse” sound, such as an explosion, or by continuous exposure to loud sounds over an extended period of time. Sound is measured in units called decibels (dB). On the decibel scale, an increase of 10 means that a sound is 10 times more intense. The humming of a refrigerator is 45 decibels, normal conversation is approximately 60 decibels, the noise from heavy city traffic can reach 85 decibels, and rock ‘n’ roll music can reach 120–125 dB SPL (Henderson et al., 2006). Long or repeated exposure to sounds at or above 85 decibels can cause hearing loss. Impulse (impact) sound can result in immediate hearing loss that may be permanent and

may be accompanied by tinnitus (phantom noise or ringing in the ears) (Sun et al., 2009). Continuous exposure to loud noise also can damage the structure of hair cells, resulting in hearing loss and tinnitus, although the process occurs more gradually than for impulse noise.

Noise can cause physical damage to the stereo cilia causing them to fuse, break, or lose structural integrity (Henderson et al., 2006). Dendritic terminals of the auditory nerve afferent fibers can swell and rupture (Henderson et al., 2006). Loud noise levels can decrease blood flow to the cochlea and damage the outer hair cells, particularly those at the basal end of the cochlea. The organ of Corti can be ripped from the basilar membrane from loud noise and hair cells can continue to die 30 days post exposure (Henderson et al., 2006). Early cell death and high levels of noise (>120 dB SPL) is attributed primarily to apoptosis, and later stages or lower levels of noise (<105 dB SPL) are the result of necrosis and to a lesser degree apoptosis (Hu et al., 2008; Yang et al., 2004).

Animal models have played an important role in determining how the intensity, duration, and spectrum of a noise affects the amount of hearing loss and how hearing perception changes when the OHC and IHC are damaged. High-level noise exposures tend to damage OHC before IHC (Salvi and Boettcher, 2008). Noise can be described as (1) impulse noise (impact) which is similar to the collision of masses or related to the release of compressed gases characterized by rapid fire and rapid decay (Dunn et al., 1991), or (2) steady state (continuous) which has no fluctuation (Dunn et al., 1991). Impulse noise is more damaging to hearing than continuous noise (Dunn et al., 1991).

Impulse and Impact Noise

Impact noise, which can be produced electronically, similar to the sound produced when striking a steel plate with a hammer (Henderson et al., 1991), can simulate the noise produced by the U.S. Army M-16A1 rifle with a time amplitude profile as would be seen utilizing a 5.56 caliber round (Henderson et al., 2006). Both impulse and impact noise can cause direct mechanical damage (Zheng et al., 2000). Hearing loss depends on the level, frequency, content, duration of exposure, and rate of repetition (Henderson et al., 1991). Outer hair cell loss is more likely a consequence of impulse/impact noise than inner hair cell loss, which is the contributing factor to hearing loss in humans (Zheng et al., 2000). Death of outer hair cells not only takes place during the noise exposure but continues for at least 30 days post exposure (Yang et al., 2004).

Chinchilla models can be used to study the applicability of equal energy hypothesis to impact noise in industrial settings (Henderson et al., 1991) and to determine a model of cell death and preventative measures of hearing

loss (Hu et al., 2008). Following ABR and DPOAE pre-testing, animals are placed in restraint tubes to ensure ear position remains constant, and then placed in a noise exposure chamber. Animals are awake during the exposure, and placed directly in front of the speaker at a distance 4 inches from the ear midline to speaker (Hight et al., 2003; Zheng et al., 2000). A microphone positioned within the cage at the level of the animal's head, measures the levels of the noise. Noise exposure can be presented at 145–150 dB SPL at 100 impulses delivered in 50 pairs, 50 ms apart with a 1000-ms pause between each pair (Hight et al., 2003; Zheng et al., 2000). Another model uses octave band noise of 4 KHz at a low level (85 dB SPL) for 10 days (6 hours/day) and then high levels (90 dB SPL) for 48 hours (Zheng et al., 2000). To assess noise-induced threshold shift and recovery in the animals, ABR testing is performed at several time points following the noise exposure period: for example 6h, 24h, 3 days, 7 days, and 21 days after the noise exposure (Bielefeld and Henderson, 2007).

Continuous Noise

To create hearing loss models, chinchillas can be exposed to continuous noise at >115 dB SPL (Pourbakht and Yamasoba, 2003), or 110 dB SPL for five consecutive days (Dunn et al., 1991). ABR is typically measured before and after exposure in a sound-proof test chamber. Continuous noise produces far less damage to outer hair cells than impact/impulse noise (Dunn et al., 1991). Levels of 110 dB SPL for 1 hour induce metabolic changes to the cochlea (reactive oxygen species formation, glutamate excitotoxicity), without generating significant mechanical damage (ripping of the OHC from their supporting cells, permanent fused stereocilia) (Bielefeld and Henderson, 2007).

Models of Aural Pathologic Conditions Associated with Hearing Loss

Treatment of Vestibular Symptoms Associated with Ménière's Disease

Vertigo (imbalance, dizziness) is one of the clinical signs of Ménière's disease, a disorder of the inner ear that can affect hearing and balance to a varying degree. Gentamicin is a popular method to treat this condition by chemical destruction of the vestibular labyrinth (Hoffer et al., 1999; Li et al., 2004). Gentamicin controls vertigo with a 90% success rate but causes 25% of patients to lose their hearing. The chinchilla is used as a model to study the treatment for Ménière's disease and is used to understand actions of gentamicin and facilitate safer use of this medicine. To create this model, gentamicin is placed in the middle ear in a sustained release vehicle, i.e. 0.5 ml of liquid fibrin tissue sealant containing 2.5 mg of gentamicin to completely fill the

middle ear. The sealant is allowed time to gel. Ears are then collected for histopathology (Hoffer et al., 1999). The advantage of this model is that cell damage is much faster than with systemic administration of gentamicin or when placed in the bulla in liquid form. This model can determine the most effective route of administration, total dose and frequency, end point of therapy, and correct dose to produce enough vestibular damage to cure vertigo with little or no cochlear damage. This model serves to study the regenerative properties of the inner ear following ablation and to examine medications that cure rather than just treat inner ear disorders (Hoffer et al., 1999).

The chinchilla is also a model for the cold-caloric nystagmus response used to study treatment for Ménière's disease. This model is used to assess the vestibular system, which is typically chemically destroyed for treatment of vertigo. This model is created by irrigating the ear canals with cold water (0.5 ml of 0°C water) and measuring time to return to normal nystagmus. Nystagmus results from the flow of endolymph through the semicircular canals induced by the temperature gradient between the external and inner ear. Since the semi-circular canal is closest to the cold water it experiences the largest temperature gradient and generates the largest response (Li et al., 2004). DPOAE measures the input and output function.

Tinnitus

Tinnitus is defined as the perception of sound without an external acoustic source commonly referred to as "ringing in the ears" (Bauer et al., 2008). Roughly 25 million Americans have experienced tinnitus. It is often triggered by cochlear hair cell damage due to hearing loss, or consuming high doses of salicylate (aspirin) (Sun et al., 2009). Tinnitus is assessed in animal models by using conditioned suppression of an operant behavior. This is performed by training chinchillas to press a lever for a food reward (operant training) and to refrain from lever pressing in the absence of acoustic stimulation (conditioned suppression). Animals are trained to discriminate between "sound on" and "sound off". Training occurs prior to cochlear trauma and tinnitus induction. After cochlear trauma, behavioral testing is repeated and tinnitus assessed. Tones of varying intensities are presented. Animals with tinnitus hear sounds differently and can hear sounds when the speaker is off. ABR thresholds are conducted to assess hearing loss, performed before and after acoustic exposure (Bauer et al., 2008).

Three models have been developed to study tinnitus; (1) acoustic exposure resulting in inner hair cell and outer hair cell loss, (2) round window cisplatin resulting in pronounced outer hair cell loss mixed with some inner hair loss, and (3) round window carboplatin with pronounced inner hair cell loss and no outer

hair cell loss. The acoustic exposure model of tinnitus is created by fitting a stainless steel speculum with an attached speaker driver into the left ear canal. A 4-kHz tone at 85 dB SPL sound pressure level is applied. This produces psychophysical tinnitus in chinchillas. The round window cisplatin model is created by applying 0.66 mg/ml to the round window in the left bulla through a 2-mm opening. The drug is applied to the tympanic membrane and left on contact for 15 minutes, then flushed away. This creates more high-frequency than low-frequency hearing damage. ABR tests will result in a 5–15 dB SPL increase in thresholds. The carboplatin model is produced with the application of 4 mg/ml of drug to the round window using the same techniques as the cisplatin model. This results in a 10–35-dB SPL increase in hearing threshold measured by ABR. All three models produce comparable tinnitus both qualitatively and quantitatively. Cisplatin results in slightly less levels of tinnitus than others but still gives significant results (Bauer et al., 2008).

Perilymphatic Fistulas

A perilymph fistula (PLF) is an abnormal opening in the fluid-filled inner ear or an abnormal connection between the air-filled middle ear and the fluid-filled inner ear. Perilymphatic fistulas may induce hearing loss, tinnitus, aural fullness, vertigo, disequilibrium, or a combination of these symptoms (Roland, 2010). Animal models of PLF that permit controlled experiments are sparse or non-existent, and currently no non-invasive method of detection is available to clinicians; only exploratory surgery. The chinchilla model provides a basis by which the sensitivity and specificity of potential perilymphatic fistula tests can be evaluated and compared. The chinchilla model simulates bony, round window, and oval window fistulas. The model is created with three sites of micropunctures made to recreate these three types of fistulas. Ice water caloric stimulation is used to assess semi-circular canal function before and after micropuncture surgery. Eye movements are recorded using electro-oculographic electrodes placed on the surface of the head. This model creates positive post-operative responses and has high sensitivity (78%) and specificity (100%) (Wall and Casselbrant, 1992).

Superior Canal Dehiscence

Superior canal dehiscence syndrome (SCDS) is a rare medical condition of the inner ear, leading to hearing and balance disorders in those affected. SCD is manifested by a hole in the bony wall between the superior semicircular canal and the brain case (Songer and Rosowski, 2007). The symptoms are caused by a thinning or complete absence of the part of the temporal bone overlying the superior semicircular canal of the

vestibular system. This may result from slow erosion of the bone or physical trauma to the skull and there is evidence that the defect or susceptibility is congenital. The surgical removal of the superior canal wall is used to treat severe cases of cholesteatoma in human patients but results in various degrees of conductive hearing loss (Siedentop et al., 2004) and vestibular symptoms (vertigo and nystagmus) (Songer and Rosowski, 2007). Loud sounds or changes in intracranial or middle ear pressures stimulate vestibular symptoms (Carey et al., 2004; Songer and Rosowski, 2007). Reconstruction of the wall is required to restore anatomic conditions in both these pathological and surgical treatment conditions of SCD (Siedentop et al., 2004). The gap in the temporal bone can be repaired by surgical resurfacing of the affected bone or plugging the superior semicircular canal. The chinchilla model is made by creating a fenestra 0.3 mm in size in the uppermost portion of the superior canal where it protrudes into the mastoid bulla (Hirvonen et al., 2001). This model is used to compare material to repair canal defects, and is used to evaluate effects of graft material on stability, healing processes, and integration into the canal wall (Siedentop et al., 2004). Various materials and combinations are tested in this model for repair including muscle, cyanoacrylate, cartilage, and fibrin tissue adhesives (Siedentop et al., 2004). This model is also used to predict the effect of dehiscence on auditory sensitivity and mechanics (Songer and Rosowski, 2007).

The superior canal dehiscence model is also used to investigate changes in firing rates of vestibular nerve afferents in response to changes in external auditory canal pressure before and after fenestration and after repair (Hirvonen et al., 2001; Siedentop et al., 2004). This model is created by exposing the bulla and internal canal on one side and making a small fenestra 0.25 mm at the top of the superior canal (Songer and Rosowski, 2007). The anesthetized chinchilla is mounted in a stereotactic frame mounted to a gimbaled structure for vestibular stimulation that allows roll and pitch tilts (Carey et al., 2004). Speakers deliver acoustic stimulation. This model is used to predict the effect of dehiscence location and size on auditory sensitivity and mechanics, and provides a framework for generating models on the effect of SCD in human patients. Limitations to this model are that the fenestra are open to the air in chinchillas rather than open to the dura and CSF as in humans (Carey et al., 2004). Differences in acute versus chronic and location and size of fenestra may also play important factors in this model that may not correspond well to human conditions of SCD (Songer and Rosowski, 2007).

Tympanic Membrane Perforation Repair

Tympanic membrane perforations are a common problem in humans secondary to infection, trauma,

or an extruded pressure-equalizing tube. Most membranes heal spontaneously but 10% will become chronic (Downey et al., 2003). The chinchilla is used as a model to test techniques of surgical repair and graft materials used to treat perforations to the tympanic membrane that do not heal. The chinchilla is an ideal model because of similarities between the anatomy of human and chinchilla tympanic membranes. To create this model, the anterior half of both ear tympanic membranes is perforated. A right-angle hook is used to fold the free edges of the drum medially (Spiegel and Kessler, 2005). Analgesics and antibiotics are administered post surgery (Downey et al., 2003). After 6–8 weeks post surgery, only chinchillas with mature perforations lacking signs of epithelial repair regeneration and with no signs of infection are selected as models (Downey et al., 2003). Grafts can then be tested in one ear and the other ear serves as a control. Repairs and grafts are evaluated after 6 weeks (Spiegel and Kessler, 2005). This animal model provides details of graft integration into the host tympanic membrane, of inflammatory responses, and is used to compare graft materials such as autografts, allografts, xenografts, and alloplasts (Downey et al., 2003).

Stem Cell Transplants

The regenerative activity of the inner mammalian ear is limited. Cell transplantation is pursued for cell therapy of degenerative inner ear diseases, of which most are incurable. Currently restoration of hearing with cochlear implants is the only therapy available for deafness and requires survival of a large number of spiral ganglion neurons. Stem cells have the potential to be utilized for regenerating inner ear cells and preventing further cell death. The chinchilla model is used to study if autologous bone marrow stromal cells have the potential to survive, migrate, and differentiate in damaged cochlea. The chinchilla model is based on a gentamicin-damaged inner ear model. This model is created by treating chinchilla with gentamicin (125 mg/kg IM) and ethacrynic acid (40 mg/kg IV). Bone marrow is harvested 2 weeks prior to drug treatment by exposing femur and aspirating 0.1 ml of the medullary cavity. Stem cells (10^5) are injected into the round window with a 30-g needle and into the bony axis of cochlea (where spiral ganglion and cochlear nerves are located). The fate of stem cells is monitored for migration and differentiation (Naito et al., 2004).

Otic Suspension Safety Testing

Chinchillas are used to assess safety of ototopical agents particularly in regards to the risk of ototoxicity, because they are a well-established animal model for hearing loss. Chinchillas are used because they have a wide tympanic membrane, a readily accessible cochlea,

and an audiogram more closely aligned with the human (Daniel and Munguia, 2008). Many ototoxic drugs are tested in the chinchilla including but not limited to aminoglycosides, otic preparations, Cerumenex®, and hydrogen peroxide (Daniel et al., 2008). (Hydrogen peroxide is used to flush ventilation tubes that are inserted to aerate the middle ear of children with recurrent ear infections (Nader et al., 2007).) These models are created by inserting ventilation tubes in both ears, and administering ear drops BID for 7 days. The chinchilla's head is positioned so the ear is facing upwards and four drops are instilled into the ventilation tube, followed by ten compressions. The head is held in place for 5 minutes before re-positioning. In this model, gentamicin serves as a positive control for its known ototoxic effects. The contralateral ear serves as a negative control by receiving 0.45% saline. ABR (auditory brain stem response) is measured at baseline and after tube placement at days 4, 8, 15, 22, and 60 to assess hearing loss (Daniel and Munguia, 2008; Nader et al., 2007). The disadvantages to this model are that ototoxicity varies between species and results may not correlate well to humans. Animals tend to be more sensitive to otic drug effects than humans because their round window is thinner and more permissive to agents, allowing more penetration to the inner ear than in humans. However if products are determined to be safe in chinchillas they are likely safe to use in humans (Daniel and Munguia, 2008).

FUTURE OF CHINCHILLA MODELS

Several new areas of research using chinchillas will be developed. To study pediatric otitis media, infant chinchilla models of pneumococcal otitis media will be developed to study relationships between maternal and infant antibodies. The young age will correlate better to human patients and may reveal determinants to the risk of otitis media at later stages in life (Giebink, 1999). Models of other disease pathogens such as *Neisseria*, *Pseudomonas*, and *Escherichia coli* will continue to be developed (Bakaletz, 2009). Ongoing efforts to obtain the chinchilla genome sequence are in progress (Bakaletz, 2009). Whereas inbred and knockout chinchillas are not likely to be available, knockdown chinchillas have already been achieved and can be expected to be more widely used for avenues of disease and prevention research (Bakaletz, 2009). Already several middle ear cell lines have been established from chinchilla tissues (Lim et al., 2002). Chinchillas will still continue to be important models for ear-related research and play critical roles due to their specific attributes, despite the trend toward mouse models.

INTRODUCTION

The degu, *Octodon degus* (Figure 44.1), a moderate-sized, precocious yet slow-maturing hystricomorph rodent from central Chile has increased in use and popularity as a laboratory animal species. Though most frequently associated with the study of circadian rhythms due to their diurnal activities in the wild, degus have also been established as valuable animal models in the study of a wide range of scientific areas including developmental biology, diabetes mellitus, cataracts, and Alzheimer’s disease. However, with few established laboratory colonies, much remains to be discovered regarding optimal housing, disease control, and veterinary care of the species.

HISTORY AND TAXONOMY

Taxonomy

Octodonts are members of the family Octodontidae, the infraorder Hystricognathi, the suborder Hystricomorpha, and the order Rodentia (Lavocat, 1974; Myers et al., 2006;

Pine et al., 1979; Redford and Eisenberg, 1992; Wilson and Reeder, 2006). Hystricomorph rodents are identified anatomically as being both hystricomorphous (having enlarged infraorbital foramina) and hystricognathous (having a mandibular angle in a latero-external position). The family Octodontidae is indigenous to South America. The term “octodont” is a reference to indentations resembling a figure-of-eight found on the surface of their molars (Woods and Boraker, 1975). The *Octodon* genus is comprised of four species: *O. degus*, *O. pacificus*, *O. bridgesi*, and *O. lunatus*.

Geographical Distribution

The four species of octodonts are distributed through several geographical regions. *O. degus* is found in northern and central Chile, *O. bridgesi* and *O. lunatus* are both found in central Chile and *O. pacificus* is found only on Isla Mocha in central Chile (Contreras et al., 1987; Hutterer 1994; Redford and Eisenberg 1992; Zunino and Vivar, 1986). The species also differ by habitat, with *O. degus* occupying open terrain, *O. bridgesi* occupying forest terrain, *O. lunatus* occupying terrain characterized by dense shrub cover, and *O. pacificus* inhabiting a small coastal island. *O. degus* is one of the most common mammals in central Chile and the cause of numerous agricultural problems (Meserve et al., 1984). *O. degus* is the most widely distributed of the four species and is sympatric with *O. lunatus* and possibly also with *O. bridgesi* in some areas.

Origin and Domestication

Prior to 1970 there were miscellaneous reports on the anatomy and biology of degus and their limited use in biomedical research. Little information on laboratory maintenance was provided in these reports. The first description of an established laboratory colony of degus was by Weir who reported on a colony at the Wellcome

FIGURE 44.1 The adult degu.

Institute of Comparative Physiology at the Zoological Society of London (Weir, 1970). Woods and Boraker also made note of two large colonies maintained at the University of Vermont and at the Instituto de Medicina Experimental del Servicio Nacional de Salud at the Universidad de Chile (Woods and Boraker, 1975).

Genetics

Very little information is available on the genetics of *O. degus*. The diploid chromosome number is 58 and the karyotype has been described (George and Weir, 1972). There are no inbred or unique strains described. Honeycutt et al. (2003) analyzed the phylogenetic relationships among members of the superfamily Octodontoidea using nucleotide sequences from mitochondrial RNA and showed that members of the genus *Octodon* are monophyletic but closely related to *Spalacopus* and *Aconaemys*.

The National Center for Biotechnology Information (NCBI) Nucleotide database (<[http://www.ncbi.nlm.nih.gov/sites/entrez?db=nucleotide&cmd=Search&dopt=DocSum&term=txid10160\[Organism%3AAnoexp\]/>](http://www.ncbi.nlm.nih.gov/sites/entrez?db=nucleotide&cmd=Search&dopt=DocSum&term=txid10160[Organism%3AAnoexp]/>)) includes a number of nucleotide sequences from *O. degus*. A small number of these are partial or complete sequences of known genes while the remaining 40 sequences included sequences with no known coding function, several unknown genes, microsatellite sequences, and retroposons.

Similarly, a small number of proteins from degus were recorded in the NCBI Protein database (<[http://www.ncbi.nlm.nih.gov/sites/entrez?db=protein&cmd=Search&dopt=DocSum&term=txid10160\[Organism%3AAnoexp\]/>](http://www.ncbi.nlm.nih.gov/sites/entrez?db=protein&cmd=Search&dopt=DocSum&term=txid10160[Organism%3AAnoexp]/>)). All but three have been identified.

ANATOMY, PHYSIOLOGY, AND BEHAVIOR

Introduction

Although the degu has been utilized in research for more than 40 years, there has not been a systematic assessment of its anatomy and physiology. Instead, those organ systems and physiological processes that have made the degu a useful animal model in various areas of research have been described in detail while other areas have received little or no attention.

External Features

The body morphology of degus is similar to that of other rodents used in biomedical research. In fact, degus resemble gerbils but are larger. Adult degus measure 250–310 mm in body length and have a tail of

75–130 mm. Weight ranges from 170–300 g. The dorsal fur is yellow-brown, the underbelly is creamy yellow, and the feet are white to gray. The tail is covered in yellow-brown fur and ends in a black brush, leading some to refer to them as “trumpet-tailed rats”. The external pinnae are pigmented and have little fur. The feet have four well-developed digits with a fifth digit that is reduced in size (Nowak, 1999; Woods and Boraker, 1975).

Musculoskeletal System

Very little information has been published on the skeletal anatomy of the degu. Woods and Boraker (1975) provide a brief review. They note that degus have prominent auditory bulla and that the proximal ends of the tibia and fibula are fused. Degus have skeletal characteristics consistent with other members of the infraorder Hystricognathi and the suborder Hystricomorpha. Specifically, in hystricomorphous rodents, the infraorbital foramen is very large and the medial masseter muscle passes through it. In hystricognathous rodents the angular process of the mandible, to which the masseter muscle is attached, is flared laterally (Myers et al., 2006).

Woods (1972) conducted an extensive analysis of the jaw, hyoid, neck, pectoral girdle, and forelimb musculature of 13 genera of hystricognathous rodents for the purpose of determining taxonomic relationships. Degus did not display any unusual muscular anatomy.

Degus and other hystricognath rodents exhibit differences in the anterior nasal skeleton compared to other rodents. Specifically they lack a continuous anterior nasal floor, the nasal septum has a ventral keel below the lamina transversalis anterior, and the lamina transversalis anterior and nasal septum are connected at the same level as the ventral border of the paries nasi (Mess, 1999).

A brief survey of radiographic images of the degu has been published (Capello et al., 2008).

Digestive System

Degus have a total of 20 teeth. The dental formula is incisors: 1/1, canines: 0/0, premolars: 1/1, and molars: 3/3. When viewed from the occlusal surface, the cheek teeth have a figure-of-eight appearance as indicated by the genus name (Edwards, 2009). As with other hystricognathous rodents, the incisors and cheek teeth are continuously erupting (Jekl et al., 2008).

A review of the nutrition of the degu has recently been published (Edwards, 2009). The degu has a simple glandular stomach. There are no descriptions in the literature of the small intestine. The cecum possesses both taenia and diverticulations. Fermentation occurs in the cecum similar to many other rodents. The colon has taenia but lacks diverticulations. On an ad libitum

diet, the gastrointestinal transit time is 5.1 hours for solids and 5.2 hours for fluids. Degus are coprophagic. In a 24-hour period, 38% of feces are reingested, primarily at night (Kenagy et al., 1999b).

Absorption of water occurs in the colon. Three aquaporins (AQP-1, AQP-3, and AQP-8) are expressed in the colon of the degu (Gallardo et al., 2002). By immunohistochemical staining AQP-1 was identified in epithelial cells on the surface and in the crypts of the colon. Blockage of AQP-1 with p-chloromercuribenzenesulfonic acid caused a reduction in fluid absorption rate. AQP-8 was found only in the cytoplasm of surface epithelial cells. AQP-3 was not found in epithelial cells but was identified in the subepithelial area and muscularis of the colon. The roles of AQP-3 and AQP-8 in water regulation are not clear (Gallardo et al., 2002).

Circulatory System

A systematic study of the vasculature of degus has not been conducted. As reviewed by Woods and Boraker (1975), the brain is supplied by the vertebral artery. There are external carotid arteries but the internal carotid arteries are absent. Left and right anterior vena cavae are present.

The arterial supply of the abdomen and pelvic regions of degus has been described (Ventura et al., 1996). The arterial anatomy of the degu is similar to that of the guinea pig as both degus and guinea pigs have a celiacomesenteric trunk arising from the aorta that is the origin of the cranial mesenteric and celiac arteries. The celiacomesenteric trunk has not been described in sciurognathous rodents. In contrast to sciurognathous rodents, these two hystricognathous rodents also have a cranial abdominal artery that supplies the transverse and oblique abdominal muscles. In sciurognaths, these muscles are supplied by the deep circumflex iliac artery, a vessel that is not present in the degu or guinea pig.

The hematology of degus was reported by Murphy et al. (1978). Male degus had a hematocrit of 42.1% and hemoglobin of 12 g/dl. The hematocrit in females measured 40% and the hemoglobin was 11.7 g/dl. Red blood cells numbered $8.7 \times 10^6/\mu\text{l}$ in males and $8.9 \times 10^6/\mu\text{l}$ in females; and leukocytes numbered $8.5 \times 10^3/\mu\text{l}$ in males and $8.2 \times 10^3/\mu\text{l}$ in females. Total protein measured 5.7 g/dl in males and 5.6 g/dl in females. Red blood cell indices in males and females, respectively, were MCV (49.4 and 49.5 fl), MCH (14.1 and 14.4 pg), and MCHC (28.8 and 29.6 g/dl). The male leukogram consisted of 40% neutrophils, 1.2% eosinophils, 0.5% basophils, 38.1% lymphocytes, and 0.6% monocytes. The female leukogram was similar and measured 37% neutrophils, 1.2% eosinophils, 0.5% basophils, 59.1% lymphocytes, and 1.3% monocytes (Murphy et al., 1978).

TABLE 44.1 Hematology Parameters of University of Michigan Colony Degus

Parameter	Mean	Range
WBC	$6.23 \times 10^3/\mu\text{l}$	$1.84\text{--}11.36 \times 10^3/\mu\text{l}$
Neutrophils	$3.37 \times 10^3/\mu\text{l}$ (54.1%)	$1.34\text{--}6.32 \times 10^3/\mu\text{l}$
Lymphocytes	$2.00 \times 10^3/\mu\text{l}$ (32.1%)	$0.27\text{--}5.36 \times 10^3/\mu\text{l}$
Monocytes	$0.77 \times 10^3/\mu\text{l}$ (0.12%)	$0.13\text{--}1.87 \times 10^3/\mu\text{l}$
Eosinophils	$0.06 \times 10^3/\mu\text{l}$ (0.01%)	$0\text{--}0.34 \times 10^3/\mu\text{l}$
Basophils	$0.02 \times 10^3/\mu\text{l}$ (0%)	$0\text{--}0.07 \times 10^3/\mu\text{l}$
RBCs ($\times 10^6/\mu\text{l}$)	8.76	7.07–12.64
Hemoglobin (g/dl)	13.87	11.2–20.4
Hematocrit (%)	39.10	32.2–55.4
MCH (pg)	15.9	14–18.5
MCV (fl)	44.7	41.5–52.2
MCHC (g/dl)	35.5	33–38.8

TABLE 44.2 Clinical Chemistry Parameters of University of Michigan Colony Degus

Parameter	Number of Animals Evaluated	Mean	Range
Total bilirubin (mg/dl)	23	0.49	0.2–1.2
AST (U/l)	24	139.54	21–546
ALT (U/l)	23	21.83	8–103
Alkaline phosphatase (U/l)	18	136.50	57–224
Glucose (mg/dl)	27	192.41	93–305
Urea nitrogen (mg/dl)	28	41.54	16–99
Creatinine (mg/dl)	26	0.39	0.2–0.7
Protein (g/dl)	23	5.94	4.8–8.3
Albumin (g/dl)	23	3.90	2.7–4.9
Sodium (mEq/l)	23	150.70	142–161
Potassium (mEq/l)	24	5.59	3.9–8.1
Chloride (mEq/l)	25	110.92	101–131
Calcium (mg/dl)	16	10.71	9.1–11.6
Phosphorus (mg/dl)	17	6.19	4.5–9.9

We have surveyed the hematology and clinical chemistry of degus in the University of Michigan colony. Values are given in Table 44.1 and Table 44.2 and represent the values obtained from 24 adult males. Results for female degus were not significantly different.

Pulmonary System

There is only one report on the pulmonary system of degus (Wallau et al., 2000). The morphology of the

lungs of a number of rodent species was compared for the purpose of taxonomic classification. Using 23 characteristics of pulmonary morphology such as presence or absence of various lung lobes, number of bronchi, and airway distances and diameters, the authors described ten lung types in rodents. The octodon type was one of the ten. The right lung of degus had four lobes and the left lung had three. Histologic examinations were not performed.

Urinary System

Degus have been the subject of studies in comparative renal physiology because, like many rodents from arid and semi-arid environments, they have well-developed adaptations for conserving water. At the upper elevations in northern and central Chile where degus are found, the climate consists of hot, dry summers and cold, rainy winters. Several studies have examined the urine-concentrating ability of degus. Under laboratory conditions, the urine osmolarity of degus subjected to food and water restriction exceeded 4000 mOsmol/kg (Fonda and Horst, 1976). More recently, Bozinovic et al. (2003) examined water flux rate, urine osmolarity, and the expression of kidney aquaporins in free-ranging degus. They reported that the mean urine osmolarity in the summer was 3137 ± 472 mOsmol/kg and 1123 ± 472 mOsmol/kg in the winter. The higher urine osmolarity in summer is consistent with the scarcity of water.

Recent studies have explored cellular physiology associated with the urine-concentrating ability of the degu. The aquaporin family of proteins is involved in transmembrane water transport in a wide variety of organisms and cell types (Gomes et al., 2009). Field studies conducted with *O. degus* have demonstrated changes in expression of aquaporin-2 (AQP-2) in the kidneys of degus captured in summer and winter months. Using immunohistochemical labeling, the renal medulla of degus captured in the summer had greater AQP-2 staining compared to winter-captured degus. Also in the summer, there was increased labeling of AQP-2 in the apical cell membranes and increased AQP-2 protein production by immunoblotting. No changes were observed for AQP-1 (Bozinovic and Gallardo, 2006; Bozinovic et al., 2003; Gallardo et al., 2005).

Reproductive System

Male Reproductive System

The adult male degu has a perianal circle measuring 25×15 mm made up of thin, pale hair (Contreras and Bustos-Obregon, 1980). The penis, which measures 16 mm in length, is at the anterior border of the perianal

FIGURE 44.2 Genitalia of the male degu. (A and B) Juvenile male demonstrating the absence of cornified spikes; (C and D) adult male with cornified spikes protruding from the intromittent sac.

circle and points posteriorly at rest and anteriorly when erect (Contreras and Bustos-Obregon, 1980; Contreras et al., 1993). The glans penis measures 10×3.5 mm and is covered in multitoothed spines (Contreras and Bustos-Obregon, 1980; Contreras et al., 1993). There are two external openings in the glans. The dorsal opening is the urethral opening and the ventral is the opening to the intromittent sac (Contreras and Bustos-Obregon, 1980; Contreras et al., 1993). The intromittent sac is a structure common to hystricomorph rodents. The sac is an invagination of the glans that everts during sexual activity. In the adult, the surface of each sac is covered in spines and at the base of each sac are two cornified spikes (Figure 44.2) (Contreras et al., 1993). There is an os penis dorsal to the urethra (Contreras et al., 1993). Parallel to the penis and just beneath the perianal circle are two subcutaneous muscular pockets, the cremasteric sacs. The caudal epididymis lies inside the sacs. The testes are intraabdominal (Contreras and Bustos-Obregon, 1980). Accessory sex glands include the prostate, seminal vesicles, and bulbo-urethral glands (Contreras and Bustos-Obregon, 1980).

The spermatozoa of *O. degus* have been described (Berrios et al., 1978). The head is flattened dorso-ventrally and measures $7.7\mu\text{m}$ long by $5.9\mu\text{m}$ wide. The tail measures $41\mu\text{m}$ long. The rim of the acrosome is U-shaped.

Male castration is frequently used to prevent breeding of pair- or group-housed degus as well as for select research models. The method of castration employed must functionally close the degus' wide, open inguinal canal through which the testicles normally move in and external to the abdominal cavity (Powers et al., 2008). Specific techniques for degu castration have been described (Capello, 2005; Fehr et al., 1994).

Female Reproductive System

The anatomy of the reproductive tract of female degus has not been described comprehensively. However, some components have been studied in detail. There is a vaginal membrane covering the opening of the vagina (Figure 44.3) (Reynolds and Wright, 1979). The vaginal membrane is open only during proestrus and estrus (Labyak and Lee, 1995). The uterus is bicornuate (Woods and Boraker, 1975). There are four pairs of mammary glands.

The placentation of the degu has been described and is similar to that of the guinea pig. Degus have a chorioallantoic placenta that is hemomonochorial and labyrinthine (Bosco, 1997; Bosco et al., 2007; Mess, 2007a). Caviomorphs, in general, are useful models of human placentation because they also have a hemochorial placenta similar to humans, a single trophoblast layer, and trophoblast invasion (Mess et al., 2007). Caviomorphs have labyrinthine and highly lobulated placenta that is different from the villous placenta of humans. In contrast to other caviomorphs, the degu has a simpler placenta that is not highly lobulated, a characteristic that makes it more useful as a model of human placentation (Mess, 2007b). Recent studies on the pathogenesis of preeclampsia in humans suggest that this condition is associated with a failure of fetal trophoblasts to invade the maternal tissues in the formation of the placenta (Cudihiy and Lee, 2009). Trophoblast invasion in the degu placenta shows similarities to that seen in the human placenta (Mess et al., 2007a).

Nervous System

Wright and Kern (1992) developed a stereotaxic atlas of the degu brain using adult male degus. Despite differences in body weight, the atlas is applicable to female degus as well since brain size was found to be equal in both sexes. The atlas contains 38 transverse sections and two sagittal sections through the prosencephalon, mesencephalon, and rhombencephalon (Wright and Kern, 1992).

FIGURE 44.3 Adult female degu vaginal area. (A and B) A closed vaginal membrane; (C) perforated vaginal opening; (D) vaginal opening with presence of vaginal secretions. Arrows indicate the vaginal opening.

The brain weight was 2.52g in males and 2.42g in females. The rostral-caudal length of the cerebrum measured 16.6mm in males and 16.3mm in females with a width of 17.0mm in males and 16.7mm in females (Wright and Kern, 1992).

Wright and Kern (1992) compared the forebrain and midbrain of degus, guinea pigs, and rats. Some minor differences (1–2 mm) in the precise location of brain structures (i.e., amygdaloid complex, hypothalamus, and thalamus) relative to the rostral and caudal commissures were seen. In the degu and guinea pig, the hypothalamus appears more compact than in the rat. The degu mesencephalon is more compact than in the guinea pig and rat. This leads some structures (e.g., trochlear nerve, red nucleus) to be situated more rostral than in the guinea pig and rat. The hindbrain of degus and rats are similar although the rat brainstem tends to be wider and flatter. As noted in the midbrain, some structures in the degu brain are either slightly more rostral or caudal than in the rat brain.

The morphology of the degu pineal gland and its role in the synthesis and secretion of melatonin have been described (Lee et al., 2009; Uria et al., 1992). The degu pineal gland is similar to that of other rodents. It is adjacent to the third ventricle and is 0.68–0.95 mm in length, 0.36–0.52 mm in width, and 0.34–0.46 mm in height. No sexual dimorphism is observed. The gland contains three cell types: type I cells are likely pinealocytes, similar to those seen in other rodents; type II cells correspond to astroglial cells, also described in rodents; and type III cells do not resemble pinealocytes and are closely associated with vascular structures. Their significance has not been determined.

Endocrine System

The degus' adrenal glands are relatively large when compared to other rodents of similar size. The predominant glucocorticosteroid produced by the degu is cortisol (Kenagy et al., 1999a). During lactation, female degus produce cortisol titers of 1000 ng/ml, declining to 500 ng/ml just prior to breeding. Similar cortisol levels are noted in males (Kenagy et al., 1999a).

Special Senses

Auditory System

The morphology of the middle ear of degus is very similar to that of the chinchilla and guinea pig (Argyle and Mason, 2008). In all three, the head of the malleus is elongated and the malleus and incus are typically fused. Although in the early literature, the malleus and incus were reported not to be fused (Woods and Boraker, 1975). Other commonalities between the three species include a bony spicule passing through the intercrural foramen of the stapes and the absence of a pars flaccida in the tympanic membrane (Argyle and Mason, 2008). The middle ear cavity is septated in the degu and chinchilla but not in the guinea pig.

The guinea pig and chinchilla have a stapedius muscle but this structure is absent in the degu (Argyle and Mason, 2008).

Visual System

In mammals, the ratio of rods to cones and their distribution throughout the retina varies with habitat and lifestyle. For nocturnal rodents, rods are the predominant photoreceptor; although cones are also present (Chavez et al., 2003). The retina has cones that are sensitive to various wavelengths of light (long (L), middle (M), short (S), and ultraviolet (UV)). Rodents exhibit three main cone patterns, M/S, M/UV, and M only. There are about 3 million cones in the degu retina consisting of M and UV types (Jacobs et al., 2003). The M type predominates with the ratio of M : UV being 13 : 1. There are approximately 6.5 million rods per eye. The ratio of cone types is similar to other mammals and the spectral absorption properties of the cones and rods in the degu are similar to other rodents. Degus can discriminate between some colors (Jacobs et al., 2003). They likely have dichromatic vision based on the presence of green-sensitive M cones and UV-sensitive S cones (Chavez et al., 2003). An age-related increase in optical density was observed in the lens of the degu (Jacobs et al., 2003). Additional adaptations have been noted of the degu's visual system, presumably in response to its diurnal lifestyle (Jacobs et al., 2003). As occurs in other precocial species, neonatal degus have well-developed vision at birth although the visual system continues to mature until adulthood (Delgado et al., 2009).

The histology of the harderian glands has been described (Antolin-Gonzalez et al., 1993). In female degus the secretory cells contain numerous basophilic granules and clusters of lymphocytic and plasmacytic cells. These structures are absent in the harderian glands of male degus.

Behavior

Degus in their natural habitat live in social groups and utilize a variety of sensory modalities in communication. Tactile communication through group huddling and mutual grooming is frequently observed among familiar and related individuals (White et al., 1982; Wilson, 1982; Wilson and Kleiman, 1974). Several visual signals have been identified in association with male–male aggression, mating, and play behaviors (Davis, 1975; Wilson and Kleiman, 1974). A variety of vocalizations are produced, all apparently within the range of human hearing (Long, 2007; Reynolds and Wright 1979). Degus produce specific courtship calls; contact calls between mother and young; loud alarm calls; and a variety of squeaks, whistles, snorts, and whines, which are apparently related to varying levels of arousal but the specificity of which is still unknown

(Braun and Scheich, 1997; Kleiman et al., 1979; Poeggel and Braun, 1996). They also produce tooth-chattering and foot-thumping sounds typical of other rodents during aggressive interactions. Likely, the most highly developed communication method is the olfactory system (Fischer et al., 1986; Fulk 1976). Degus produce highly individual and recognizable (by other degus) odors in the urine and with specialized scent glands (Fischer and Meunier, 1985). Both odor sources are used by both sexes to mark their territory and members of the group (Fischer and Meunier, 1985). Meetings between individuals include extensive olfactory investigation, mutual sand bathing on marked areas, and spraying of one another. Interestingly, in degus, unlike many other species, the female engages in more scent marking, more investigation, and demonstrates greater ability to identify individual odors than does the male (Kleiman, 1975).

A variety of other behaviors, many related to their territorial, semi-fossorial, multi-adult groups, have also been studied (Ebensperger et al., 2004; Quispe et al., 2009). These include their hoarding behavior (Quispe et al., 2009), social foraging behavior for avoidance of predators (Ebensperger and Hurtado, 2005; Ebensperger and Wallem, 2002; Ebensperger et al., 2006a; Quirici et al., 2008), locomotor patterns (Vasquez et al., 2002), maternal-offspring nursing interactions with a group of adults (Ebensperger et al., 2007), exclusivity of the maternal relationship in the shared burrow (Ebensperger et al., 2006b; Jesseau 2004; Jesseau et al., 2008, 2009), and spatial distribution of adults (Hayes et al., 2007; Milstead et al., 2007). A wide variety of studies have examined the impact of environmental conditions (e.g., temperature, humidity, cover, time of day, predator presence, nutrition) on behavior and physiology. Due to their unique physiology and behavioral patterns, degus are frequently used as an animal model to study many aspects of human behavior.

MANAGEMENT, HUSBANDRY, AND COLONY HEALTH

Introduction

A critical component of the management of the degu colony is maintaining sufficient social contact during development for the animals to mature with normal behavioral patterns. Poeggel et al. (2003) reports severe deficits as a function of maternal deprivation. In an early experiment that required young animals be housed alone with a running wheel, the authors discovered that when adults they were terrified of other degus, and were aggressive to humans. Interestingly, single housing of animals that have already reached maturity does not produce the same problems,

particularly if there is environmental enrichment (Poeggel et al., 2003). Without enrichment, some single-housed animals are lethargic and not very attentive.

Housing Systems

Caging

At the University of Michigan, degus are housed with parents and littermates in large polycarbonate solid-bottom cages ($42.5 \times 46 \times 19.5$ cm) until weaning. Degus are weaned between 5 and 6 weeks of age and housed in opaque $42.5 \times 22 \times 19$ cm cages with 2–3 same-sex siblings. When individually housed, we use opaque polycarbonate cages ($42.5 \times 22 \times 19$ cm). We equip cages with Nalgene running wheels (9×34.5 cm). Cages are stored on stainless steel racks in open rooms, or in ventilated, light and temperature controlled housing units that hold 4–8 cages.

Bedding

We found that pine shavings sometimes cause irritation to the skin of the animals, so we use only inert bedding such as ground corn cobs. Degus do not readily build nests, although some will keep new litters in shelters.

Environmental Conditions

The following describes the environmental conditions provided by the authors in support of a long-established breeding colony at the University of Michigan.

Ventilation

Animal rooms are provided with a minimum of 7–10 fresh air exchanges per hour. Animal rooms are maintained under negative pressure with respect to hallways. Exhaust air from the animal rooms is not recirculated, but directly discharged from the building.

Illumination

The entire colony, including breeding groups, is maintained on a 12 : 12 hour light:dark cycle. When housed in an open room, the light intensity within cages may vary significantly (e.g., 50–200 lux). When animals are housed in light-controlled, ventilated isolation chambers the light intensity can be varied from 10–250 lux, as needed. Under some experimental conditions animals are housed in constant darkness (DD), dim red light, or constant light (LL). Circadian rhythms free-run under such conditions and do not become disorganized under LL, as occurs with some nocturnal species. We find that females continue having estrous cycles in all conditions, suggesting that degu reproduction is not strongly photoperiodic.

Temperature and Humidity

Degus have difficulty thermoregulating and may suffer dehydration when at temperatures of greater than 32°C. The breeding room is maintained at 20°C ± 2°C. Cages that contain a litter have a heating pad set on low under one corner of the cage to provide additional warmth for the pups, if they choose. When animals are provided with running wheels, the room is maintained at 17–18°C. When housed at higher temperatures and placed in running wheels, many animals demonstrate masking (i.e., altered circadian pattern without a change in suprachiasmatic nuclei (SCN) function), and their activity is crepuscular or nocturnal (Kas and Edgar, 2001; Kenagy et al., 2002a, 2002b). Room humidity is not tightly controlled and ranges from approximately 30–60%.

Enrichment

We provide all animals not in experiments with alfalfa hay once or twice per week. Breeding pairs and juvenile degus receive alfalfa hay 3–4 times per week as a dietary supplement. We have tried providing individually housed and group-housed degus with large PVC tubes and “nesting boxes”. They never preferred to sleep or nest in either device, typically using them (if at all) as a location for defecation. Nest building was not observed with any of multiple bedding substrates provided. The provision of a dust bath is recommended by some (Johnson, 2002), however colonies maintained over multiple generations without access to dust baths have demonstrated no apparent negative effects (Lee, 2010). Degus are very active animals and will run thousands of revolutions in a running wheel in a day, sometimes even in an hour. When degus must be isolated for experimental reasons, the addition of a running wheel to the cage seems to maintain healthy activity and eating patterns. Whereas degus housed alone for more than a few weeks sometimes become lethargic and relatively unresponsive to the presence of a human. Female degus can readily be introduced as a living partner with any other female, and fighting rarely ensues. Once males have reached maturity, however, we find that they can only be re-housed after isolation with a male sibling, and sometimes that is also not feasible.

Individual housing of young animals has been associated with the development of severe behavioral and neural deficits (Poeggel et al., 2003) and difficulty handling (Lee, 2004). To avoid the developmental disruption induced by social isolation, young animals are housed alone with running wheels for no more than 4 weeks, and then returned to co-housing with a same sex sibling (Hummer et al., 2007). Through the first 6 months of life we maintain social contact between related degus as much as possible. With this protocol,

the behavior of the mature animals is normal, and the behaviors we study were not different between adults that were never tested during development and those that were tested periodically during development (Hummer et al., 2007).

Sanitation

Cages are changed once a week during the light phase, and changed under dim red light every other week when animals are housed in constant conditions for the purpose of studying undisturbed endogenous circadian rhythms. This rate of cage change is acceptable because degus urinate very little, and we house them in cages with considerably more floor space than is required for other comparably sized rodents (Institute of Laboratory Animal Resources (US). Committee on Care and Use of Laboratory Animals, 2011).

Nutrition

Field Studies

The diet of the degu in its natural environment in Chile has been studied in detail. In the wild, the degu consumes a diet of grass, shrub, forb foliage, flowers, and seeds (Meserve 1981; Meserve et al., 1983, 1984; Simonetti and Montenegro 1981). The wet and dry seasons affect the availability of specific plants and hence dietary intake. Simonetti and Montenegro (1981) demonstrated that degus prefer new rather than mature matorral shrubs when given the choice, and do not discriminate between new leaves of different species. In controlled laboratory studies, degus exhibit a strong preference for low-fiber, high-nitrogen plants over high-fiber plants (Bozinovic, 1995; Gutiérrez and Bozinovic, 1998). Other studies confirm that the degu will select high-quality foods when available (Kenagy et al., 1999; Torres-Contreras and Bozinovic, 1997). During the dry season, the degu can compensate for lower-quality food by increasing consumption, whereas in the laboratory the degu can lower its metabolic demands when food quality declines (Bozinovic et al., 1997; Mabry et al., 1988; Veloso and Bozinovic, 1993). Sakaguchi and Ohmura (1992) found that the degu has reduced digestive ability for fiber compared to the guinea pig and that the degu does not appear to readily consume an alfalfa-based diet.

Laboratory Maintenance

The nutritional requirements of degus have not been studied. Several diets are mentioned in the degu literature, ranging from (low-fiber, high-energy) rodent diet (Mabry et al., 1988; Popovic et al., 2009; Wright and Kern 1992); rodent diet supplemented with vegetables and fruit (Poeggel and Braun, 1996); rodent chow with cereal seeds, sunflower seed, and hay (Braun and

TABLE 44.3 Commercial Diets Evaluated for Effect on Reproductive Performance

Designation	Diet Name	Relative Dietary Composition	Manufacturer
Rodent Diet (RD)	LabDiet® 5001	High-protein, medium-metabolizable-energy, low-fiber	PMI International, St Louis, MO
Rodent Breeder Diet (RBD)	Prolab® RMH 2000	Moderate-protein, high-metabolizable-energy, low-fiber	PMI International, St Louis, MO
Guinea Pig Diet (GPD)	LabDiet® 5025	Low-protein, low-metabolizable-energy, high-fiber	PMI International, St Louis, MO
Chinchilla Diet (CD)	Mazuri® Chinchilla Diet 5E05	High-protein, low-metabolizable-energy, high-fiber	PMI International, St Louis, MO

Scheich, 1997); guinea pig pellets (Long and Ebensperger, 2010); and rabbit pellets (Becker et al., 2007; Bozinovic et al., 1997; Veloso and Kenagy, 2005). Edwards (2009) described and provided an analysis of the diet used for a colony of non-reproductive female degus at the Smithsonian National Zoological Park as consisting of a high-fiber herbivore pellet supplemented with greens, roots, and hay. The compositions (fiber, protein, fat, vitamins, and minerals) of several other diets used in degu colonies were reported.

Unlike the closely related guinea pig, the degu does produce the hepatic enzyme L-gulonolactone oxidase and does not have a dietary requirement for ascorbic acid. Therefore, diets supplemented with ascorbic acid are not required for maintenance of this species (Edwards, 2009).

At the University of Michigan (UM), we evaluated reproductive performance, growth, and maintenance of degus maintained on different commercial diets in our colony (Rush, 2010). Specifically, we assessed the fertility of breeding females, litter survival rates, growth patterns of pups, and maintenance of healthy body size in adults. The diets we compared (RD, RBD, GPD, and CD) are summarized in Table 44.3.

RD was selected because it had been used in the UM colony for many years. GPD and CD were selected because of the guinea pig's (a caviomorph rodent) and chinchilla's (a hystricomorph rodent) close taxonomic relationship and similar dietary habits to the degu. Finally, RBD was selected because of its largely wheat-based composition, which was thought to better represent the degu's natural diet. The biggest difference between RD and RBD is the use of corn and soybean in RD while RBD used wheat as the primary ingredient. In addition, RBD was the only diet with no added sugar.

The two high-fiber alfalfa-based diets (GPD and CD) and the high-protein, low-fiber, medium-energy RD were found to be inappropriate for degu reproductive success. CD was insufficient to support gestation (36% of pups were stillborn), caused a high mortality rate

in young degus, produced the smallest animals, and caused the largest weight gain in adult animals. The high-protein, low-fiber, medium-energy RD was also found to be an insufficient diet for the reproductive degu, with a large percentage (33%) of pups being stillborn. Stillbirths in dams fed GPD were not increased but post-weaning mortality in pups fed GPD was significantly higher than for other diets.

Pups were weaned when they reached a weight of 50 g, usually between 4–6 weeks of age. Pups fed RD or RBD reached the weaning weight significantly earlier in development than pups fed CD or GPD. However, only 56.3% of pups fed RD survived to weaning, although the surviving animals appeared to do quite well on RD once past weaning.

Animals raised on RBD had the largest and healthiest pups, with a high survival rate. During the period between weaning (4–6 weeks of age) and 10 weeks of age, mortality rates for pups fed RBD (2% mortality) were significantly lower than for litters on GPD (23% mortality) and CD (14% mortality).

In general, we found that lactating mothers and juvenile degus have different dietary needs than non-breeding adults. We found that RBD produced the best combination of litter size, pup survival, and growth rate. Our results are also supported by findings from Veloso and Bozinovic (2000) who reported that pregnancy and lactation are the most energy-demanding periods for the female degu and that low-quality (high-fiber, low-protein) feed correlates with lower litter mass and size.

Given the literature and our data, we recommend that breeding adult degus and juveniles (up to 10 weeks to 6 months of age) be sustained on RBD. However, without access to exercise wheels, adult degus become overweight on RBD. After 10 weeks of age, a change to RD suffices for juveniles and non-breeding adults, since the animals' response to the RD was not significantly different from that of the RBD after weaning and provided good adult body maintenance and prevented obesity.

Water

Water metabolism has been studied in the degu (Bozinovic and Gallardo, 2006). In their natural environment, degus obtain water primarily through consumption of food. In captivity, water is generally provided ad libitum. In the University of Michigan degu colony, the average 24-hour water intake for an adult degu is 23 ml.

Breeding

Estrous Cycle

Degus are spontaneous ovulators, have regular estrous cycles, and maintain functional corpora lutea. Earlier literature suggested that degus were induced ovulators and required the presence of a male for cycles to occur (Weir 1970, 1974). However, vaginal patency, increased wheel running activity, increased body temperature, and sexual receptivity (estrus) all occur in the same 1–2-day period and occur in a cyclical and regular basis (Labyak and Lee, 1995). The average cycle length in adult females is 21.1 ± 0.56 days and can range from 16–26 days (Labyak and Lee 1995; Mahoney et al., 2005). Cycle length is uniform within an individual and thus one can reliably predict when the next day of estrus will occur using physiological information. Vaginal opening can be detected easily by examining the anogenital region of the female daily or every other day. Degus, like other hystricognathous rodents, have a vaginal membrane that is typically closed throughout the cycle but becomes open, or perforated, at the time of estrus (Figure 44.3) (Addo et al., 2007; Brookhyser and Aulerich, 1980). The opening is present for only 1–3 days each cycle, thus vaginal smears cannot be used to detect changes in the stages of the estrous cycle in this species, as can be done with laboratory rats and mice (Marcondes et al., 2002). At the time of estrus one can also detect associated changes in the perineum and it may appear more swollen and pink in color. Degus may also produce whitish vaginal secretions or plugs around the time of estrus. This is an unreliable indicator of estrous cycle stage as it does not always appear each cycle, and the number of days it is detected varies within and between individuals.

Hormone data and ovarian histology confirm that degus have spontaneous ovulation and corpora lutea formation. On the day of vaginal perforation and the increase in wheel running, (day 1) estradiol concentrations in the blood are also relatively high then drop on days 4, 8, and 16. In contrast progesterone concentrations are elevated on the 8th and 16th day following estrus when compared to the day of estrus. Correlated with these endocrine data, ovaries collected on the day of estrus contain Graafian follicles, secondary follicles, and corpus albicans. Ovaries collected from animals

on day 6 relative to the daily rise in wheel running had well-developed corpora lutea. Primary follicles are also evident at this time but have not progressed to secondary follicles. Sixteen days after the detection of estrus, within a week of the next estrus, ovaries contain both primary and secondary follicles, and corpora lutea are becoming atretic and reduced in number compared to day 6. It should be noted that other laboratory rodents (rats and mice) do not have a spontaneous luteal phase; these species require vaginal stimulation or mating to induce corpora lutea formation (Schwartz, 2000). Thus, degus are a unique and advantageous laboratory model for a variety of research programs, as they are smaller than an adult rat or guinea pig, long-lived, relatively slowly developing (when compared to other rodents), readily adjust to laboratory conditions, and have an estrous cycle which resembles that of primates or sheep.

The pattern of luteinizing hormone (LH) release has not been fully characterized in the degu. Presumably the high concentration of estradiol on the day of estrus triggers a preovulatory surge of luteinizing hormone from the pituitary, as occurs in other mammals. It is also unknown whether the circadian timing system regulates the timing of events such as mating and the LH surge in animals with a long luteal phase (e.g., common laboratory rodents). In rats, mice, and hamsters, the LH surge occurs 6–15 h prior to ovulation and both events occur at precise circadian intervals (Alleva et al., 1971; Christian et al., 2005; Legan and Karsch 1975). The role of the circadian system in species with a true luteal phase has been examined only in sheep and rhesus monkeys. In those species, there is no evidence of a circadian control of luteinizing hormone release (Karsch et al., 1973; Nett et al., 1984). It is unclear at this time whether the lack of a circadian timed release of luteinizing hormone in sheep and rhesus monkey is because they have a spontaneous luteal phase or because of another physiological feature they do not share with most rodents.

Mating and Pregnancy

In our laboratory we house breeding degus in male–female pairs or as groups of one male and two females. Females are reproductively mature at 4 months of age but we do not pair them until they are at least 6 months old to allow the animals to reach adult body weight (170–210 g is typical for females in our laboratory). Breeding animals are housed in 20 in $\times$ 20 in $\times$ 8 in cages (double-width rat boxes). The sire remains with the dams after litters are born so as to have the opportunity for females to mate during postpartum estrus. Males do not direct any aggressive or cannibalistic behavior towards the young; in fact males have been seen huddled over the young. Females of this species are also unusual as they do not exhibit any signs of maternal aggression

when their pups are handled by an investigator. We are able to remove and handle young and return them to their home cage without being attacked by the dam, although she may show some signs of anxiety.

Females exhibit behavioral receptivity (estrus) at the time of vaginal patency and elevated wheel running. Females housed continuously with males throughout their estrous cycle will typically begin mating around the time of their rise in activity. Receptivity does not appear to be strictly regulated by the light:dark cycle. Mating activity continues throughout the day and night with the exception that animals are quiescent for a 3-hour window between 6 and 9 hours after lights off. Mating bouts may be observed periodically for 7–24 hours but copulation does not occur as frequently as seen in lab rats and hamsters. Animals mate only once or twice an hour. Females exhibit a brief lordotic posture when males mount them; males thrust once or twice with no copulatory lock.

Degus have a 90–95-day gestation (Lee, 2004; Weir, 1974). Implantation starts by day 7 and is complete by day 12 (Mess, 2007a). Litter size can range from 1–12 pups (Long and Ebensperger, 2010). The first litter a female produces typically contains 4–6 pups and subsequent litters have 6–10 pups. If dams have more than this number it is difficult for her to provide adequate nutrition to all the young. If it is critical that the pups from a large litter all survive, they can be handfed with commercially available “kitten milk”.

If females breed successfully after delivering young, they may have up to four litters per year (every 3 months). If they do not mate and become pregnant during the postpartum estrus, then females will not mate until after the young are weaned (Lee, 2004). Although degus in the laboratory can live until 5 years of age or more, female reproduction begins to decline after 4 years as we see longer intervals between pregnancies. Thus we stop breeding females by 4 years of age. Breeding animals, their pre-weaned young, and weaned animals up to 6 months of age may be given Prolab RMH 2000 5P06 diet (Lab-Diet®, PMI International, St. Louis, MO) as it improves health and weight gain in lactating females and growing pups although we have recently started providing the RMH diet for only 10 weeks after birth as young were observed to reach mature weights and undergo puberty earlier than desired. We also supply slightly acidified water (2.5 ml of 3.7% HCl solution per gallon of tap water) to prevent diarrheal infections in the pups. Lastly we supply a large handful of fresh or dried alfalfa twice a week to supply additional nutrition for lactating females.

In the wild, degus live in groups, usually with more than one female sharing a burrow system (Ebensperger et al., 2004; Fulk, 1976). Breeding typically occurs once a year but in some populations two litters may be produced in a particularly rainy season (Fulk, 1976;

Meserve et al., 1984). Litters range from 3–10 pups (Weir, 1970). Breeding may be triggered by production of rain and/or green leafy vegetation becoming more abundant (Meserve et al., 1984).

Care of the Young

At birth pups are precocial, fully furred, and their teeth are erupted. Their eyes are typically open within 1 day of birth and their ears are open by postnatal day 3 (Lee, 2004; Reynolds and Wright, 1979). Pups are mobile within the first week of life and begin to nibble on solid food by 2 weeks of age (Lee, 2004). In the wild, young are seen emerging from their burrows at 4 weeks of age (Fulk, 1976). Dams lactate and nurse their young for 4–5 weeks, even though the young are eating solid food (Kleiman et al., 1979; Veloso and Kenagy, 2005). Pups may lay on their backs while nursing from the dam. Males may huddle in a protective way over the young.

Lactation lasts 4–5 weeks (Kleiman et al., 1979; Veloso and Kenagy, 2005). The concentration of solids, lipids, proteins, and ash in degu milk remain constant throughout lactation while carbohydrate concentrations decrease from early to late lactation (Veloso and Kenagy, 2005). Lipids are the main component of degu milk. Total solids average $26.9 \pm 5.8\%$, lipids average $17.3 \pm 5.5\%$, protein average $4.4 \pm 0.4\%$, and ash average $2.7 \pm 0.8\%$. Carbohydrates range from a high of $3.1 \pm 0.3\%$ early in lactation to a low of $1.0 \pm 0.3\%$ late in lactation (Veloso and Kenagy, 2005).

We typically wean pups at 5 or 6 weeks of age, when they weigh 60–70 grams. Weaned pups are housed in same sex social groups; brothers housed together from the time of weaning usually do not show aggression towards one another in adulthood. At the time of weaning, unrelated animals (males or females) can be placed into the same cage without any antagonistic interactions. As mentioned above, weaned young are given acidified water and Prolab RMH 2000 5P06 diet (Lab-Diet®) (Lee 2004) until they are 10 weeks to 6 months of age.

Puberty and Sexual Maturation

In our laboratory, under our feeding program, male and female degus reach sexual maturity around 3 months of age. When animals were fed a less optimal diet, animals did not reach puberty until 4–6 months of age. Males begin to mature at 2 months of age and the majority of males are mature at 6 months of age. Sexual maturity can be assessed by determining the presence and size of the spikes on the glans of the penis, a feature found in the hystricognathous rodents (Contreras et al., 1993). In degus, since the testes are located intra-abdominally, they are less accessible for measurement than the penile spines. Sexual development can be determined by inverting the young animal and gently evert the glans penis to reveal the spikes. Spikes appear at 2.5 months

of age, approximately 60% of males exhibit spikes at 3 months of age and all males exhibit spikes at 3.5 months of age (Hummer et al., 2007). Testes growth also begins at 2 months of age (average 0.2 gram paired testes weight), paired testes weights are about 1.2 grams at 4 months of age. Testes reach their adult size at 6 months of age and on average are about 1.6 grams (Hummer et al., 2007). In parallel with testes growth, spermatogenesis also begins to be detectable in 2-month-old males, then plateaus at 4 months of age.

In female degus sexual maturity can be assessed by determining when vaginal opening occurs. This is done by using a gloved finger to examine the anogenital area for signs of invagination and the color of the perineum. The urethral cone can be gently moved anteriorly to examine this area but care must be taken not to prematurely rupture the vaginal membrane by too much manipulation. The majority of females will exhibit their first vaginal opening between 3 and 3.5 months of age (Hummer et al., 2007). Females may exhibit an opening as early as 1–2 months of age, but this is rare. Intermediate vaginal openings (partial opening, dimpling) may be detected 17–21 days prior to the first full vaginal perforation. Some females will also exhibit an increase in activity or wheel running at the time of these partial signs of vaginal opening. In all animals, after the initial vaginal perforation is detected, it will continue to occur in a cyclical manner. Elevated wheel-running activity typically precedes or coincides with the beginning of full vaginal opening.

Colony Health Monitoring

General recommendations on monitoring animal colonies for the presence of disease have been published (Barthold, 2008; Carty, 2008; International Committee of the Institute for Laboratory Animal Research, 2000). In the case of species other than rats and mice, monitoring for infectious diseases presents a challenge since specific agents may not be known and immunologic reagents may not be available (Weisbroth et al., 1998). In such cases, periodic necropsy assessment combined with the use of mice as sentinel animals may be the best approach. Use of sentinel mice would at least allow detection of agents that can infect mice in other facilities at the institution. This approach has been used with the University of Michigan colony, and no mouse or rat pathogens have been detected.

HANDLING AND RESTRAINT

Physical

Degus should never be picked up by their tail. They will rapidly spin around leaving the sheath of the tail

in the restrainer's hand. The tail bleeds very little after such an event and readily heals, but the animal is left with a stump and other injuries can occur if the animal is dropped. Animals should be picked up by scooping them up with two hands or with a scoop. They are uncomfortable when their feet are not on a stable surface. Carrying them braced against the arm or body, or in a container, will maintain a calm state.

Degus fight aggressively to return to an upright position when they are turned ventral side up. Thus, if it is necessary to turn them over, it is wise to wear a sturdy pair of leather gloves to protect the hands from their nails and teeth. If one does not need access to their ventrum, they can be wrapped in a towel and will be relatively quiet while their ventral or dorsal surfaces are examined.

We have found that giving injections is made much simpler by placing the animal in an empty cage. The animal can be blocked into a corner and will rarely object to the lifting of skin on the back/neck region for subcutaneous injections. To give an intraperitoneal injection the animal's hind legs can be lifted while the front legs remain on the surface of the cage and the needle inserted in the lower, lateral region of the abdomen (Weir, 1970). Degus typically remain calm during this procedure and are not subject to the stress induced by restraining and turning them over to expose the ventral abdomen.

Mechanical

We have successfully used three restraint devices as part of our research program: plexiglass restraining tubes for short-term, full-body restraint; head tethers for select continuous monitoring; and wire-mesh cage dividers for partial isolation of an animal. Plexiglass restraint tubes must be large enough in diameter to accommodate the animal's width, but too small for the animal to turn around. This form of restraint does act as a mild stressor. However, although cortisol rises after animals are placed in the tube, they readily enter the tube repeatedly, suggesting it is not aversive of itself. Animals readily adapt to head tethers that are necessary for collecting EEG data or protecting microdialysis probes. We found that the circadian cortisol patterns return to baseline after 3–5 days of habituating to the tether. Very few animals demonstrate any behavioral signs of stress with the tether attached. When experiments require social, but not physical contact, we use a wire-mesh divider in a 42.5 × 46 × 19.5 cm cage, dividing the cage into two equal sides that are nearly the same size as a single cage. Each animal has independent food and water, and is able to see, hear, and smell another animal through the mesh. This cage adaptor allows us to collect running wheel activity data on both animals, if needed.

Chemical

Chemical restraint can be achieved through use of injectable or inhalant anesthetics. Additional information can be found in the Anesthesia and Analgesia section of this chapter.

SAMPLING TECHNIQUES

Blood Collection

Methods of blood collection in the degu are similar to those used in other rodents and include distal tail transection, surgical exposure and cannulation of the jugular vein, percutaneous cannulation of the anterior vena cava, infraorbital sinus puncture, and cardiac puncture. However, some individuals report poor success in use of tail transection and cannulation of the jugular and anterior vena cava. As with other rodent species, a general recommendation is to withdraw no more than 10% of an animal's total blood volume within a short period of time (e.g., every 2 weeks) without the administration of replacement fluids.

The method of blood collection to be selected is highly influenced by the volume of blood required. Distal tail transection can be repeatedly employed to acquire microliter volumes of blood from a single animal. However, the authors have had great difficulty reliably collecting blood with this technique.

Greater volumes of blood (approximately 1–2 ml) can be obtained from anesthetized animals through puncture of the infra-orbital sinus with a glass pipette or surgical exposure and cannulation of the jugular vein. To access the jugular vein, the ventral neck region is surgically prepared and an approximate 1-cm incision is made over and perpendicular to the jugular furrow of the neck. Tissues are then bluntly dissected, exposing the jugular vein from which blood can be drawn through a needle into a syringe. However, the vein can be fragile and may easily collapse when blood is aspirated. The surgical site is then closed with use of sutures or skin clamps.

Similarly large volumes of blood (approximately 1–2 ml) can be collected from the anterior vena cava of anesthetized individuals. Isoflurane anesthesia may be initiated in an induction chamber and then maintained with use of a face mask. Alternatively, injectable anesthetics can be used although the authors have noted difficulty maintaining an adequate plane of anesthesia followed by successful anesthetic recovery in their colony animals administered injectable anesthetics. The degu is placed in dorsal recumbency with its head extended so as to flatten the ventral surface of the neck, the hair shaved over the left and right thoracic inlets, and the skin disinfected. The front leg on the side of the neck selected for blood collection is extended somewhat

laterally. At this point, it may be possible to visualize the pulsation of the vessel through the skin. A $\frac{3}{4}$ ", 22-g needle attached to a 3-cc syringe is introduced through the skin approximately 1 mm cranial to the clavicle and 1 cm lateral to the midline. The needle is advanced approximately 2 mm along a 45° angle relative to the midline and 10–20° from the horizontal plane of the ventral neck. Gentle suction is applied to the syringe as the needle is slowly withdrawn until blood is visualized in the needle at which time the needle is stabilized and the desired volume of blood collected (Rush et al., 2000). This procedure can be performed repeatedly on a single animal although it does require a significant amount of skill and practice on the part of the technician and can occasionally result in significant complications for the animal (e.g., uncontrolled hemorrhage, unintended lung puncture).

When cardiac puncture is performed, it is recommended that running wheels or other enrichment devices that may promote strenuous exercise be removed or made non-functional for approximately 5–7 days thereby facilitating tissue healing.

Urine Collection

Methods of urine collection are identical to those used with mice and rats (e.g., use of a metabolic cage, bladder expression). However it should be noted that degus infrequently urinate when restrained thereby making restraint an unreliable method for urine collection.

COMPOUND ADMINISTRATION

Recommended sites and maximum volumes for subcutaneous, intramuscular, intravenous, intraperitoneal, and intraosseous injections are listed in Table 44.4.

Oral gavage can also be performed with a maximum recommended gavage volume of 3–5 ml (Johnson-Delaney, 2006b). However care must be taken to avoid the timing of the gavage to occur while a significant volume of stomach contents is present as this may result in gastric rupture (Johnson-Delaney, 2006b).

ANESTHESIA AND ANALGESIA

Recommended dosages of anesthetics and analgesics for use in the degu have been published (Johnson-Delaney, 2006a, 2006b; Visticot, 2002;) although it should be noted that many recommendations are based on anecdotal observations, not pharmacodynamic studies.

Both injectable and inhalation anesthesia are frequently used with the degu. Select, published anesthetic regimens are listed in Table 44.5.

Use of inhalant anesthetics delivered through use of a precision vaporizer is often preferred to use of injectable anesthetics due to the fast induction and recovery periods as well as the ease of anesthetic level manipulation associated with inhalant anesthetics. Also, animals have been noted to develop resistance to some injectable anesthetics (e.g., ketamine and xylazine combination). However, use of select other inhalant anesthetics is contraindicated due to induced adverse effects. For instance, animals administered halothane or methoxyflurane gas anesthesia have been reported to develop

acute centrilobular hepatic necrosis resulting in an approximately 50% mortality rate within 4–7 days of the anesthetic episode (Lee, 2004, 2010). Evidence of liver damage has not been observed in animals administered isoflurane that, in the degu, provides a suitable level of anesthesia for multiple surgical manipulations with quick and smooth anesthetic recoveries (Lee, 2004). Use of an alternate or novel inhalant anesthetic should be considered with caution until its use and potential side effects can be evaluated in this species.

Commonly used analgesics and their recommended dosages are listed in Table 44.6.

In addition to their uncommon physiologic response to halothane and methoxyflurane, the degu has been shown to be unique in its response to morphine administration. The degu has an extremely high tolerance to the pharmacological effects of morphine when compared to that of the Wistar rat and guinea pig (Gaule et al., 1990; Letelier et al., 1985; Villanueva et al., 1980). Its increased ability to metabolize the drug is at least partially due to the high activity level of select hepatic enzymes and possibly due to a unique enzymatic system of drug metabolism (Gaule et al., 1990). The degu's high metabolism of morphine may extend to other drugs utilizing the same or similar hepatic enzyme systems (Letelier et al., 1985). Due to the degu's documented resistance to morphine, it has been proposed as an in vivo model for the study of opiate action and receptors (Paeile et al., 1984). Unlike the closely related guinea pig, the degu does not develop ileal stasis following morphine administration (Pelissier et al., 1989b). In addition, a lower degree of respiratory depression (Paeile et al., 1984), hypotension, bradycardia, and

TABLE 44.4 Recommended Injection Sites and Volumes in the Adult Degu

Injection Route	Injection Site(s)	Recommended Volume
Subcutaneous	Supra/intrascapular	5–10 ml/site
	Dorsal thorax	
	Flank	
Intramuscular	Anterior thigh	0.5 ml
Intraperitoneal	Caudal abdomen	5–8 ml
Intraosseous		1–2 ml bolus
Intravenous and intracardiac	Saphenous vein	1–2 ml bolus
	Cephalic vein	
	Cardiac ventricle (general anesthesia required)	

Table adapted from Johnson-Delaney, 2006b; and Lee, 2010.

TABLE 44.5 Reported Anesthetic Drug Dosages in the Degu

Drug	Dose and Route	Comments	Reference
Ketamine	44 mg/kg IP		(Johnson, 2002)
Ketamine + acepromazine	40 mg/kg + 0.5 mg/kg IP		(Johnson, 2002)
Ketamine + diazepam	40–50 mg/kg + 0.8–1.0 mg/kg IM	Do not give to gravid females as it may cause spontaneous abortion	(Mabry et al., 1988)
Ketamine + medetomidine with supplemental isoflurane administered via face mask	20 mg/kg + 70 µg/kg IM		(Capello, 2005)
Ketamine + xylazine	30 mg/kg + 5 mg/kg IP	May produce inconsistent levels of anesthesia and prolonged recoveries	(Lee, 2004; Rush, 2010)
Isoflurane administered through a precision vaporizer	To effect		(Lee, 2004)
Isoflurane administered in an induction chamber	300 µl isoflurane in a 500 ml volume induction container	For short-term anesthesia (less than 1 minute); isoflurane must not directly contact the animal	Routinely used at the University of Michigan
Pentobarbital	30 mg/kg IV; 35–40 mg/kg IP		(Johnson, 2002)

IP, intraperitoneal; IV, intravenous; SC, subcutaneous.

TABLE 44.6 Recommended Dosages of Select Analgesics, Sedatives, and Tranquilizers

	Drug	Dose, Route, and Frequency
Analgesics	Buprenorphine	0.05 mg/kg SC q 8–12 hours
	Butorphanol	0.4–2.0 mg/kg SC q 8–12h
	Carprofen	1–4 mg/kg SC q 24h
	Meloxicam	0.1–0.2 mg/kg PO or SC q 24h
	Meperidine	10–20 mg/kg SC q 2–3h
	Morphine	2–5 mg/kg SC q 4h
	Naloxone (opioid antagonist)	0.05 mg/kg SC or IP once
	Oxymorphone	0.2–0.5 mg/kg q 6–12h
Sedatives and tranquilizers	Butorphanol	1–5 mg/kg SC q 4h
	Diazepam	1–5 mg/kg IM, IP, IV
	Medetomidine (Atipamazole for reversal)	0.1 mg/kg SC (1 mg/kg SC, IP, IV)

Table adapted from Johnson-Delaney, 2006b.

IP, intraperitoneal; IV, intravenous; SC, subcutaneous.

histamine release occurs in the degu than in the Wistar rat following morphine administration (Pelissier et al., 1989a, 1989b). It has been postulated that many of the differences observed between the degu and Wistar rat are secondary to the activity of the degu's adrenal gland that is proportionally larger (Pelissier et al., 1989a).

EUTHANASIA AND NECROPSY

As in other small mammals, common methods of euthanasia include an overdose of inhaled carbon dioxide or other gas anesthetics and intravenous or intracardiac injection of a high dose of an anesthetic (e.g., pentobarbital). To eliminate associated pain and stress, intracardiac injections and cervical dislocation should be performed only in a fully anesthetized animal.

DISEASES

Non-Infectious Disease

Limited data exist regarding naturally occurring disease in captive-bred populations while more clinical information is available for wild-caught animals either studied in the field or captured and then maintained in a laboratory setting. Given this, it can be difficult to fully understand the level of influence that an animal's

environment and level of nutrition may have on its health status.

However, one association has been clear: the influence of diet on the development of diabetes mellitus and cataract formation in captive-held colonies (Donnelly and Quimby, 2002). Spontaneous development of diabetes mellitus is not uncommon (Fox and Murphy, 1979). However the rate of diabetes mellitus and cataract development can be elevated through provision of diets high in unstructured carbohydrates. The normal blood glucose level of an adult degu is approximately 120 mg/dl or less. Degus will develop cataracts with blood glucose levels of 150 mg/dl, a level lower than that required to induce cataract formation in other species including the rat (Tripathi et al., 1991). Degus may not develop clinical symptoms of diabetes mellitus at this blood glucose level. The most common histopathologic lesions noted in captive diabetic degus include cataracts, fatty metamorphosis of hepatocytes, amyloid deposits in the pancreas, and hyperplasia of islets of Langerhans with an increase in both the number and size of the islets (Murphy et al., 1980). In the University of Michigan degu colony, elimination of fruit and sunflower seed supplements from the diet and use of an exclusive low-fiber, high-energy rodent chow (Prolab® RMH 2000, PMI International, St Louis, MO) reduced the incidence of diabetes and cataracts to near zero (Rush, 2010).

The increased propensity of the degu to form cataracts is due to the presence of high aldose reductase activity in their lens. Aldose reductase converts glucose or galactose to polyol compounds that then accumulate in lens fibers causing them to swell and rupture ultimately resulting in cataract formation (Datiles and Fukui, 1989). The degu has a higher aldose reductase activity in the lens than the gerbil, rat, and human (Datiles and Fukui, 1989). Inhibition of aldose reductase activity delays or prevents cataract development. Histopathic observation of degu cataract development has been described (Worgul and Rothstein, 1975).

In addition to the association with the development of cataracts and diabetes mellitus, the provision of an inadequate or unbalanced diet has been associated with other conditions. Diets high in non-structural carbohydrates (e.g., sugar and starches) may negatively affect reproductive performance (Brown and Donnelly, 2001), however it is unclear what influence associated cataract development may play in this process. In addition, consumption of high-carbohydrate diets may adversely affect the microbial balance of the hind gut and has been associated with the development of obesity (Edwards, 2009).

It has been reported that a change in the color of degu incisors from their normal yellow/orange to white can indicate an underlying nutritional imbalance (Najecki and Tate, 1999; Vanderlip and Earle-Bridges, 2001) although the responsible biologic process is unclear.

Dental disease including malocclusions, caries, elodontomas, and malocclusions are frequently reported in some pet populations (Jekl et al., 2006, 2008).

Kidney disease including nephrosis, pyelonephritis, glomerulonephritis, polycystic kidney disease, and renal failure have been observed (Cadillac et al., 2003) although they are not commonly cited in the literature.

Dystocia and sudden death during pregnancy have been observed infrequently by the authors in captive-bred populations. When they occur, these complications are most frequently noted in primiparous females with a small number of unusually large pups. Histopathologic liver lesions consistent with pregnancy toxemia have been reported in females with sudden death during late gestation (Murphy et al., 1980).

Traumatic lesions have also been reported including one case of a tibial fracture in a 3-month-old degu that was successfully repaired through medullary fixation (Beregi et al., 1994).

Bacterial and Viral Disease

Few bacterial or viral diseases have been reported in laboratory degus and remarkably little is known regarding the pathogenesis of the diseases in their animal hosts. Significant mortality has been associated with *Pseudomonas aeruginosa* septicemia in multiple colonies. Partially as a result, laboratories may choose to acidify drinking water for all or select life stages (Lee, 2004; Mabry et al., 1988). Evidence of a reovirus had been detected in at least one colony and was associated with increased mortality around the period of weaning (Rush, 2010). Similarly, a cytomegalovirus has been found in association with insulinitis and diabetes mellitus in a colony of degu. In this colony, cytomegalovirus inclusion bodies were identified in the pancreas and/or salivary glands of both animals with and without clinical signs of diabetes (Fox and Murphy, 1979). The biological significance of both the reo and cytomegalovirus is presently unclear.

Parasitic Disease

A survey of wild-caught degus from Chile revealed infection with multiple species of helminthes (e.g., *Aprostotandrya octodonensis*, *Graphidioides taglei*, *Longistriata degusi*, *Physaloptera* spp., *Trichuris bradleyi*, *Octodontoxys gigantean*, and *Heteroxynema chilensis*) and one arthropod (*Linguatula serrata*) (Babero and Cattán, 1975). Although these were wild-caught and therefore likely exposed to organisms not normally present in a laboratory setting, it does demonstrate that degus can be parasitized by these species and may be present in animals recently introduced into the lab. Parasites of known or suspected zoonotic importance

have been identified in degus and include *Physaloptera* spp., *Trichuris bradleyi*, *Echinococcus granulosus*, *Echinococcus* sp., *Trypanosoma cruzi*, *Linguatula serrata*, and *Giardia* sp. (Babero and Cattán, 1975; Campos et al., 2007; Najecki and Tate, 1999; Visticot, 2002). In one colony, *Giardia* infections have been diagnosed with a fecal ELISA. Animals from this infected colony with clinical signs of diarrhea were successfully treated with a 100mg/ml solution of fenbendazole at a dose or 25mg/kg PO once a day for 5 consecutive days (Najecki and Tate, 1999).

Neoplasia

The prevalence of neoplasia in degu populations is believed to be low. In one study of 189, 2–60-month-old degus who had died or were euthanized in a colony, seven animals with neoplasias were identified on histopathologic exam. All but one case was found in aged animals and four neoplasias were benign (Murphy et al., 1980). Tumor types reported in the degu include renal transitional cell carcinoma with concurrent choristoma (Lester et al., 2005), primary bronchioloalveolar carcinoma with renal and hepatic metastases (Anderson et al., 1990), parathyroid adenocarcinoma with metastasis and pulmonary adenocarcinoma (Smith et al., 2000), reticulum cell sarcoma of a cervical lymph node, hepatocellular carcinoma with pulmonary and renal metastases, hepatoma, splenic hemangioma, and mesenteric lipoma (Murphy et al., 1980).

THE DEGU AS AN EXPERIMENTAL MODEL

Introduction

When the degu is chosen as an animal model, it is often chosen due to one or more of its following characteristics (Reynolds and Wright, 1979; Weir, 1974):

- individuals are diurnal, tending to be more active in the day and less active at night;
- the young are precocious at birth with open and functioning eyes and ears;
- postnatal development is slow with late weaning and sexual maturity when compared with laboratory mice and rats;
- degu display complex familial and social structure including stable family groups and use of a highly developed vocal repertoire;
- minimal inbreeding has occurred and genetic diversity has been maintained as they have only recently been maintained in laboratory settings;
- individuals are relatively long-lived when compared to many other laboratory rodents.

Circadian Rhythm

As a diurnal species with slow postnatal development and a long lifespan, the degu has been used extensively in the study of human circadian function and rhythm (Hummer et al., 2007; Labyak and Lee, 1995; Lee et al., 2004; Popovic et al., 2009). Degus and humans have similar circadian activity and temperature rhythms, including interindividual and sexually dimorphic variations in rhythmicity. In the degu, sexual dimorphisms develop in the presence of pubertal hormones and the sex differences do not appear until after gonadal puberty is complete (Lee, 2004).

Degu have grown in popularity as a mammalian animal model for the study of behaviors and physiology that may differ in a diurnal niche from nocturnal or crepuscular activity habits (Lee, 2004; Smale et al., 2003). These studies have included examining the sleep patterns of degus (Kas and Edgar, 1998, 1999; Perryman et al., 2006, 2007), impact of social interactions, stress and hormones on recovery from phase shifts of the light:dark cycle, also known as jet-lag (Goel and Lee, 1995, 1996, 1997; Goel et al., 1998; Governale and Lee, 2001; Hagenauer and Lee, 2008; Jechura et al., 2000, 2003, 2006b; Mohawk and Lee, 2005; Mohawk et al., 2005), and the mechanism by which light entrains diurnal patterns (Kas and Edgar, 2000; Labyak and Lee, 1997a; Labyak et al., 1997b; Lee and Labyak, 1997). In addition, they have been useful in demonstrating that adolescent changes in circadian rhythms in humans are not unique, but also occur in other mammals (Hummer et al., 2007; Jechura et al., 2006a; Lee, 2004).

Developmental Biology

Due to many of their reproductive and behavioral characteristics, both those similar and dissimilar to the human, the degu is used as a model for the study of many areas within the field of developmental biology and neurobiology. With a relatively long gestation as compared to mice and rats, the degu has been used in the study of embryonic development (Rojas et al., 1982). They are also frequently used in studies of early behavioral and neurologic development due to their precocial state at birth that facilitates the identification and observation of voluntary behaviors that are not displayed in altricial species of similar ages (Helmeke et al., 2001; Poeggel and Braun, 1996; Reynolds and Wright, 1979). Degus have been used to study the effects of disrupted social interactions early in life on behavior and brain development (Braun et al., 2000, 2009; Ebensperger et al., 2007; Helmeke et al., 2009; Jezierski et al., 2006; Ovtcharoff and Braun, 2001; Poeggel et al., 2003; Seidel et al., 2008). Degus display species-specific and possibly individual-specific vocalizations within the range

of human hearing. This characteristic makes them especially valuable in the study of developmental neurobiology of the auditory system and auditory learning (Braun and Scheich, 1997; Poeggel and Braun, 1996). Degus are also used to study cellular and molecular mechanisms of cognition and can be trained to use a tool (Okanoya et al., 2008).

Reproduction

Placental Development

As in the human, the degu develops a hemochorial placenta with a single layer of syncytial trophoblast separating fetal and maternal blood supply. Unlike in the human, degus have labyrinthine placentation with separate circulatory units supplying each lobe of the placenta (Mess, 2007a). However, due to their simply arranged placental architecture, the degu is useful in the study of placental extension and growth processes and has the potential to serve as a model of placental development in human pregnancy (Mess, 2007a, 2007b) and human placental pathologies (Bosco and Buffet, 2008).

Male Reproduction

The degu has been used as a model of male aging and testicular function (Bustos-Obregon and Ramirez, 1997) including the influence of temperature on spermatogenesis (Bedford et al., 1982). Like the human and sheep, the male germinal line develops to the spermatogonium stage while the degu is still a fetus (Mabry et al., 1988). The degu is preferred by some in place of many more traditional laboratory rodents due to its genetic diversity (Bustos-Obregon and Ramirez, 1997). Degus have also been used as a model when evaluating potential male contraceptives (Moyad, 1987).

Thymic Research

Degus possess select anatomic and physiologic characteristics that make them convenient or unique models for a wide range of research areas. For instance, the presence of two anatomically separate thymus glands (cervical and mediastinal) facilitates their use in thymic research (Science News, 1974). The cervical thymus can easily be removed without complication or negative long-term effects (Science News, 1974). While the mediastinal thymus regresses as the animal ages as is common in many other species, the cervical thymus retains its size and structure throughout the animal's life (Phillips and Boraker, 1975; Woods and Boraker, 1975).

Diabetes

The degu is used as a model for diet-induced diabetes (Spear et al., 1984) partially due to the fact that the

degu, as well as multiple other hystricomorphs (e.g., the guinea pig), possess a unique insulin structure when compared to that of other mammals (Nishi and Steiner, 1990; Opazo et al., 2004). Like humans, they may develop islet amyloidosis (Nishi and Steiner, 1990). The oral glucose tolerance test had been applied to use in the degu (Opazo et al., 2004).

Cataract Development and Prevention

Cataracts develop more consistently and more quickly in the degu than in the rat with most degus developing nuclear opacity within 10–12 days and mature cataracts within 4 weeks following diabetes induction with streptozotocin administration (Datiles and Fukui, 1989; Varma et al., 1977). Cataract development can be noted in 1-day-old offspring of adults with cataracts (Tripathi et al., 1991).

Administration of a potent aldose reductase inhibitor following diabetic induction prevented all ophthalmologic and histopathologic signs of cataract formation while administration of a less potent aldose reductase inhibitor, quercitrin, delayed but did not prevent cataract formation (Datiles and Fukui, 1989; Varma et al., 1977). Due to the role of aldose reductase on the cataract development, degus may serve as a model for evaluating aldose reductase inhibitors for use in human diabetic patients (Varma et al., 1977).

Alzheimer's Disease

The neuropathologic markers associated with Alzheimer's disease have not been identified in wild-type mice or rats. Therefore most previous in vivo models of Alzheimer's disease have necessitated either the creation of transgenic animals or intracerebral injections of amyloid aggregates into the animal host. Degus are being explored as a wild-type rodent model for the neurodegenerative processes associated with Alzheimer's disease as aged (but not young) animals have been shown to develop neuropathological signs of Alzheimer's disease including the presence of amyloid aggregates in multiple regions of the brain and acetylcholinesterase-rich neurons in the cerebral cortex (Inestrosa et al., 2005). The onset of disease is influenced by the source of the animals with the disease onset occurring later in laboratory-maintained than wild-caught animals (van Groen et al., 2009).

Production of Antisera

Degu have been used as a species for preparation of antisera as they have been shown to exhibit a stronger immunologic response to select viruses than is seen in guinea pigs (Phillips and Boraker, 1975).

Atherosclerosis

The degu has been reported as a potential model for atherosclerosis research, as animals fed a high-cholesterol diet developed extensive atherosclerosis with lesions occurring throughout the aorta (Homan et al., 2010).

Naked mole rats are mouse-sized rodents that in recent years have become an important animal model in biomedical research in addition to their unique mammalian role in behavioral and ecophysiological research of life underground.

HISTORY

Naked mole rats (*Heterocephalus glaber*) were first described by Ruppell in 1842 and for many years his taxonomic description was refuted and they were

considered to be either neonates of a much larger species or mammals that had lost their fur as a consequence of disease. Subsequent collections and descriptions were reported in the 1890s through 1957 and are summarized by Brett (1986). Most of those studies focused upon the unusual anatomy of this species and morphological adaptations to life underground. Jennifer Jarvis began studying these animals in the late 1960s and was the first person to bring these hairless rodents into the laboratory. She observed that these animals were highly social and appeared to work together to excavate tunnels and find food. She also noted that she seldom found pregnant animals in the wild and even in captivity had little success with the formation and maintenance of breeding colonies. Subsequently, a group of biologists primarily working with Jarvis (Brett, Buffenstein, Clarke, Faulkes) began studying and reporting on their unique biology. In the mid 1970s, Alexander, an evolutionary biologist whose research focused on the evolution of eusociality (a colonial lifestyle with a strict division of labor culminating in the presence of a single breeding female), described the ideal hypothetical eusocial mammal. At that time no eusocial mammals had yet been identified and only the wasps, ants, and bees were known to be eusocial. He described his hypothetical eusocial mammal as strictly subterranean, living in hard soils and cooperatively foraging on large underground tubers. A colleague and friend of Jarvis, TL Vaughan, told Alexander that he had aptly described the naked mole rat, rodents that Vaughan had seen in the office of Jarvis. Alexander, his doctoral student Sherman, and Jarvis thereafter began an extensive collaborative study on eusociality and behavior in the naked mole rat.

Biologists Bennett, Clarke, Faulkes, O'Riain, and Sherman have contributed greatly to the understanding of naked mole rat behavior. Buffenstein studied with Jarvis and accompanied her on her trip to Kenya in 1980 to assess if naked mole rats in the wild also live in colonies with only one breeding female. Jarvis published this seminal finding in *Science* in 1981 (Jarvis, 1981). Her team published extensively on ecophysiological responses which allow naked mole rats to survive and thrive in their dark, dank environment in the arid and semiarid regions of northeast Africa. These responses include mineral metabolism in the absence of sunlight (Buffenstein et al., 1994), kidney function (Urison and Buffenstein, 1994), thermoregulation (Buffenstein and Yahav, 1991; Withers and Jarvis, 1980), gastrointestinal function (Yahav and Buffenstein, 1991), microecological aspects of the naked mole rat (Bennett and Jarvis, 1995), and finally the biological characteristics that contribute to the exceptional longevity of this, the longest-lived rodent known. Naked mole rats have been documented to live longer than 30 years in the lab (Buffenstein et al., 2008). More recently, neurophysiologists (Catania, Comer, Crish,

Goldman, and Park) have analyzed the nervous system of these animals and have identified many unique neurological features that allow these animals to thrive in their environment. One of the interesting aspects of the naked mole rat nervous system is their lack of ability to sense chemical pain (capsaicin and acid) and inflammatory pain (Park et al., 2008), although they respond normally to acute pinch and heat (Kanue and Hole, 1990; Kanui et al., 1993; Park et al., 2008; Towett et al., 1993).

TAXONOMY

Naked mole rats belong to the order Rodentia in that they have two incisor teeth on the upper and lower arcade that continuously grow. They are in the family Bathyergidae which includes six extant genera (Kock et al., 2006), and includes solitary (Bathyergus; Georchus; Heliophobius), and social taxa (Cryptomys, Fukomys and Heterocephalus). The Suborder is difficult to classify since the criteria for classification are the origination of the masseter muscle and the degree to which the muscle passes through the infraorbital foramen. The Bathyergidae have a small infraorbital foramen and the masseter muscle does not enter into it. Nonetheless, the lateral angle of the jaw relative to the plane of the incisor teeth appears more hystricomorph-like than Myomorph or Sciurormorph. In addition, the Bathyergidae share several Hystricognath features which include similar fetal membranes and sacculus rethralis, a fused malleus and incus, an anterior opening in the pterygoid foss, multiseriate incisor enamel, the loss of the internal carotid artery, and albumin immunology (Honeycutt et al., 1991). Taxonomists thus classify the Bathyergidae in the suborder Hystricognathi. This suborder consists of three super families (the Phiomorpha (e.g. mole rats, rock rats, and cane rats), Caviomorpha (e.g., guinea pigs), and Hystricidae (e.g. porcupines). Interestingly, most hystricognath rodents are found in the western hemisphere, and there are no close relationships between members of the Bathyergidae family and other hystricomorph families.

Molecular genetic data suggest that the naked mole rat is a sister lineage to the group comprising all other genera in the family. *Heterocephalus* forms a monotypic genus with no morphological variation nor variation in chromosome number ($n = 60$). Earliest fossil records of this species were found in East Africa and date back to the early Miocene ~26 million years ago.

GENERAL DESCRIPTION

Good descriptions are available in the literature (Jarvis et al., 1991; Lacey and Sherman, 1991). Naked mole rats are cylindrical-shaped with short limbs and a dorsally

FIGURE 45.1 Photograph of typical naked mole rats. Their elongate tubular shape allows them to move through tunnels. Teeth are exterior to the mouth, and the ears and the eyes are tiny with thickened eyelids and minute eyelashes. The auditory meatus is raised slightly and pinnae are absent. The masseter muscles are prominent.

arched back over lumbar and sacral regions (Hamilton, 1928) (Figure 45.1). The head is cone-shaped and blunted anteriorly in the area of a horseshoe-shaped region that surrounds the nares. Procumbent incisor teeth extend well outside the mouth and are characteristic of the Bathyergidae. Naked mole rats have either two or three molar teeth. The eyes are tiny with thickened eyelids and minute eyelashes. The auditory meatus is raised slightly and pinnae are absent. The masseter muscles are prominent.

The skin is loose, wrinkled, and brownish pink in color. The body is for the most part absent of hairs with the exception of tactile hairs that are regularly arranged throughout the body and which are particularly prominent around the face and to a lesser extent on the tail. The outer edges of the hind feet are fringed with stiff hairs that increase the surface area of the foot. There are five toes on each foot. The tail is about half the length of the body.

Naked mole rats are sexually monomorphic; the external genitalia of males and females appear very similar. Males have internal testes and most females have unperforated vaginas. Males and females have similar-looking external genitalia, ano-genital distance, perineal muscles, perineal motoneurons, brain, and spinal cord (Holmes et al., 2007; Lacey and Sherman, 1991; Peroulakis et al., 2002; Seney et al., 2009) as well as femoral bone morphology and microarchitecture and strength (Pinto et al., 2009). However, these traits differ among breeders and subordinates. There is no sex difference in adult body weight.

Animals raised in captivity have body weights that vary with age, food availability, colony composition, and social and reproductive status (Jarvis, 1985; Jarvis et al., 1991; Lacey and Sherman, 1991; O'Riain and Jarvis, 1998; O'Riain et al., 2000). Most mature animals range from 25–50 grams in captivity but can get as large as 110 grams. This large range in adult body mass is uncommon among small mammals (Jarvis, 1991).

Naked mole rats are one of the slowest-growing mammals and reach stable body mass by the end of the first year of age. Individuals born in the first few litters of a newly established breeding female grow more rapidly than those of later litters (O'Riain and Jarvis, 1998). By 2 years of age all non-breeding animals have stopped growing. Should a dominant animal die or be removed from the colony many individuals will have a growth surge, and this is most pronounced if the breeding female dies.

Any animal within the colony is capable of becoming a breeder and individuals as young as 6 months or as old as 24 years have changed their social status. Should a female change her social status in the colony and become a breeder; she is capable of significant vertebral growth regardless of her age. Indeed a female that became a breeder for the first time at 24 years of age still underwent a prolonged period of lumbar vertebral growth.

NATURAL HABITAT

The members of the Bathyergidae family are all African rodents and are found in distinct geographic locations from the southern-most tip of the continent to about 10°N of the equator. Bathyergids are found in several distinct climatic zones, at different altitudes and in a wide variety of soil types. Naked mole rats are found in the arid and semi-arid regions of eastern equatorial Africa, commonly found in Kenya, Ethiopia, and Somalia. Their habitat gets irregular rain, but it is generally hot and dry with little seasonal or daily variation in climatic conditions, followed by intense short periods of high rainfall. The soil in which they burrow varies from sandy to hard clay soils. The only evidence of the presence of naked mole rats below the surface is small volcano-like mounds of soil excavated by the mole rats during burrow extensions.

Naked mole rats live in an extensive maze of underground tunnels and chambers. Depending upon the size of the colony these may extend more than 1 mile (1.6 km) in length and may reach depths of up to 2 meters. There are multiple layers of interconnected tunnels and chambers. Some tunnels are more permanent (highways) while others near the periphery and surface are opened and closed depending on the needs of the colony. The more superficial tunnels are used for gathering food from tuberous plants, and may be used during behavioral thermoregulation by animals basking in warmer regions of the burrow system. These near-surface tunnels also serve as a path to eliminate soil from new burrows. The deepest tunnels generally open into football-sized nest chambers in which most of the mole rats will huddle together, often resting with many animals piled up on top of each other. The nest area is lined with tufts of grass roots, skins of tubers and bulbs, and other soft detritus encountered in

the burrow system. Often near the nests are deep, blind-ending tunnels that are presumed to be bolt holes and which may possibly serve as drainage systems during periods of heavy rainfall. Interconnecting tunnels that run at a slant are thought to play an important role in ventilation of the colony. Adjacent to the nest chambers in the deeper confines of the burrow system is a blind-ending toilet chamber in which naked mole rats generally urinate and defecate. When these become full, the chamber is plugged with soil and a new toilet chamber excavated. Similarly food hoards or pantry-like chambers are located near the nest; here small bulbs, corms, and roots that have been located during foraging are carried back to the nest and stored or shared among the colony.

Mole rats maintain their burrows all year round, but predominantly extend their burrow system shortly after rains occur when the dry sun-baked soils are moistened and no longer hard and impenetrable.

A sealed subterranean burrow complex protects the inhabitants from predation and also protects against climatic extremes. While surface temperatures above ground may become unbearably hot, the thermal conductivity properties of soil result in attenuated fluctuations in burrow temperatures such that burrow temperatures in the warm confines of equatorial Africa vary by less than 1°C seasonally (Bennett et al., 1988). While superficial burrows may heat up during the day and remain considerably warmer than deeper burrows, burrows at depths greater than 10 cm are thermally stable.

The gaseous atmosphere in the burrow system, and in particular in the deep nests, is extremely challenging (Bennett and Faulkes, 2000). The burrows are usually sealed and gas exchange through soil is limited. This coupled with so many organisms respirating (naked mole rats, commensals such as insects and lizards and microfauna) result in an hypoxic (10–15% oxygen) and hypercapnic (~5% CO₂) atmosphere almost saturated with water, even when soils are dry. Air movement through the burrow is extremely limited and primarily facilitated by animals in tight burrows acting like pistons pushing air in front of them as they move through tunnels. Respiration in such atmospheres, especially in animals that are metabolically active or resting in large communal groups may be especially problematic. Furthermore the impact of high levels of ammonia or methane in nests and latrines could exacerbate respiration and acid-base balance.

BEHAVIOR

Naked mole rats are eusocial, strictly subterranean mammals in the wild. The term eusocial describes species that live in colonies of overlapping litters in which

one or a few individuals produce all the offspring and the rest serve as functionally sterile helpers in colony maintenance, rearing juveniles and protecting the colony (Michener, 1969). The only other mammal that meets these criteria of eusociality is the naked mole rat's close cousin the Damaraland mole rat (*Fukomys damarensis*). A typical naked mole rat colony has only one breeding female (queen) and a few (1–4) breeding males. The remainder of the colony is loosely categorized by body size. The larger animals tend to be the first captured in field studies and are thought to be the defenders of the colony. The smaller animals function as food gatherers and burrow diggers. With the exception of the “dispersomorphs,” animals that occasionally leave their natal colony, presumably to outbreed and form new colonies, naked mole rats only come onto the surface if flooded out of a burrow system or if their burrow system has been breached.

Despite their evolution in a formidable dark, dank environment, naked mole rats thrive in a laboratory setting and display many of the social behaviors that make them unique and of considerable interest for biological and biomedical research. In the wild, colonies of naked mole rats may vary from a few animals to an average of 70 animals to as many as 295 or more animals (Brett, 1991). In an institutional setting, colonies may be formed from breeding pairs and despite being housed in much smaller burrow systems may reach comparable sizes to wild colonies. Average colony size in captivity is ~50, with maximum colony size exceeding 120 individuals. Naked mole rats are extremely xenophobic and readily attack and kill conspecifics from foreign colonies. Members of a colony may roll in the excreta within the toilet to confer a colony scent. This enables colony members to identify each other as members of the group or strangers.

Naked mole rats are strictly herbivorous, feeding on roots, bulbs, corms, and tubers which they locate by excavating tunnels until they stumble across a large tuber or a patch of small bulbs. This is an energetically costly and blind process. NMRs dig/forage in working groups. Typically a lead member digs and passes the soil back to other members who move the soil to other areas of the tunnel system or to the surface. This effort has been described as a chain of diggers. Occasionally members will move the soil to the surface and deposit it in volcano-like structures. This is the only time tunnels are open to predation.

Mole rats generally carry back to the nest small foods (roots, bulbs) they encounter and bites of the large tubers they find. The large tubers may weigh as much as 50 kg and tend to be “farmed” in that animals will gnaw at parts of the tuber, carefully removing the often poisonous outer layers and then plug the regions they have consumed with soil, thereby enabling the tuber

to regenerate. Such large tubers may sustain the colony during the dry season when burrow excavations are energetically prohibitive (Lovegrove and Wissel, 1988). Given the high cost associated with random foraging in regions where food is patchily distributed, a single animal may easily starve to death before foods are found. By working in foraging groups; animals are able to search for food in multiple areas at once and the colony increases its chances of finding a patch of food or a tuber that is large enough to sustain the entire colony. New food sources are communicated to the group through an odor trail (Judd and Sherman, 1996) and cheep-like vocalizations.

Naked mole rats have an extensive vocal communicate repertoire. Pepper et al. (1991) described 18 different vocalizations that include alarm calls, food recruitment calls, mating calls, toilet-assembly calls, and vocalizations specific to pups. These vocalizations range from 65 Hz to 12.8 kHz at 60 dB (Hefner and Hefner, 1993), but the majority of noises are low frequency (1–9 kHz) (Judd and Sherman, 1996). Lower-frequency noises propagate better underground and NMRS take advantage of this. The soft chirp is characteristic of individual members of the group and may be important in identifying individual members (Yosida et al., 2007). There are also several distinct alarm calls employed during cooperative predator avoidance and the defense of the colony.

Colony defense is an important behavior in the colony. If a major predator or member of a foreign colony is encountered in the tunnels, naked mole rats produce a pronounced alarm call and an obnoxious odor, and defenders are recruited in mass to attack the offender. Indeed even snakes may be killed by the wall of teeth they encounter, should they not capture the first mole rat they come upon.

Young pups in the colony employ many different kinds of begging behavior and emit various vocalizations to induce an appropriate response from the breeders and older siblings. One of the most common types of these behaviors is the begging for feces from adults. Adults respond by voiding feces which are directly consumed from the anus.

REPRODUCTIVE BEHAVIOR

Captive colonies of naked mole rats normally contain one breeder female, and she can retain this position for many years (Jarvis, 1991). The breeding females may produce more than 1100 offspring during their breeding reign and litter size tends to increase sometime after the breeders become established. On rare occasions there may be an additional female breeding within the colony. The level of dominant female aggression appears to influence whether this occurs and in most cases the

offspring of the second breeder in the colony seldom survive.

Reproductive suppression occurs by the queen's dominance-related behavioral aggressiveness and requires direct contact between the queen and subordinates (Faulkes and Abbott, 1991, 1997; Margulis et al., 1995). The direct contact takes the form of pushing and shoving. Once dominance is established subordinates readily display subordinate behaviors, they allow the breeders to eat first and they generally tend to be walked over when they encounter a breeder in the tunnel. Aggression in a colony occurs mainly between the queen and other challenging females. Often challengers attack and kill the breeding female when she is at her most gravid or during parturition. If the dominant female dies, succession appears to be rapid, but it may take months to years for colonies to stabilize. Succession appears to come from animals that tend to be larger. This is usually the only time when fighting within a colony occurs. Typically, when the queen identifies a colony member to attack the subordinate animal submits and may even be killed.

Captive colonies of naked mole rats have several breeding males. In contrast to females, there is no evidence of breeding competition in males (Clarke and Faulkes, 1999). Both dominant breeding males and females have higher levels of sex steroid hormones than the non-reproductive colony members.

Lordosis and mounting behavior are commonly observed in the queen and breeding male respectively during the periovulatory period as is seen in other rodent species (Goldman et al., 2006). The female is restless during estrus and initiates courtship behavior by thrusting her rear end into the face of the male and lordosing. Mating occurs several times between a 2–24-hour period and often occurs in the tunnels. Anogenital nuzzling in breeders is also observed and occurs at all phases of the estrus cycle. In this behavior the queen and a breeding male lie side-by-side in the naso-anal position. This latter behavior is not dependent on androgen status in the male, and is most commonly observed in the nest. Naso-genital stimulation of the breeding males is thought to play an important role in elevating and maintaining active hypothalamic/pituitary/gonadal axes compared to non-breeders. The latter have low levels of testosterone and extremely low levels of luteinizing hormone and furthermore are unresponsive to administration of exogenous gonadotropin releasing hormone (Faulkes et al., 1991).

Spermatogenesis occurs in both breeding and non-breeding males. Non-breeding males tend to be sterile, producing fewer and predominantly non-motile sperm (Endo et al., 2002; Faulkes et al., 1994). Similarly subordinate females for all intensive purposes appear to be sterile. Endocrine and anatomical studies reveal that these females show no signs of ovarian cyclicity or

ovulation and that their ovaries are in a functionally quiescent state. This state may change should the subordinate female be isolated from the breeding female of her colony.

Since usually only one female breeds in a naked mole rat colony, the majority of animals (males and females) spend their entire lives in a suspended sterile "prepubescent" reproductive state. These subordinates spend their entire lives maintaining the colony and its burrow systems and generally helping raise the young.

A breeding female breeds continuously throughout the year and may have as many as four litters per year. The average litter size is 12, but may be as small as one pup and as large as 29. In captivity, the gestation period ranges from 64–74 days and there is a 6–11-day post partum estrus, such that the inter-birth interval is approximately 80 days. The first sign of pregnancy is a marked increase in body temperature of the breeding female (Urison and Buffenstein, 1994) and during this time the breeding female spends considerable time basking under heat lamps or in the warmer confines of the burrow. The female becomes obviously pregnant at about 40 days gestation, when her weight begins to increase significantly. Similarly in the last trimester of pregnancy the very gravid queen spends more time in the nest or basking under heat lamps, and other females and males in the colony show signs of nipple enlargement and some females even show perforate vaginas. By the end of pregnancy a female may more than double her non-pregnant body mass. Both pregnancy and lactation are energetically costly processes, increasing metabolic rate 1.5–3-fold (Urison and Buffenstein, 1995). The young weigh about 1.0–2.5 g. The queen nurses the pups for 6 weeks, although they start eating solids and begging for and eating feces from older siblings at 14 days. Fecal consumption provides the appropriate microfaunal inoculum necessary to digest fiber.

Naked mole rats have the highest inbreeding coefficient known for wild mammals (Faulkes et al., 1997; Honeycutt et al., 1991) with a mean coefficient of relatedness among colony members estimated at 0.81 (Reeve et al., 1990) and there is considerable evidence that most new colonies form by fission. There is, however, strong evidence that there is an outbreeding dispersomorph caste with a morphologically, physiologically, and behaviorally distinct phenotype (O'Riain et al., 1996). This disperser caste may occasionally promote outbreeding in naked mole rats, especially in those colonies that are not successfully reproducing. These dispersers are unwilling to engage in colony maintenance, are laden with fat, especially in the neck and pelvic regions, exhibit elevated levels of luteinizing hormone, and solicit mating behaviors with non-colony members and as such are readily accepted by foreign colonies. In captivity, these animals are often seen standing on their hind limbs, trying to

escape from the colony and it seems that if there is a colony escapee it is usually a member of this caste.

GENERAL PHYSIOLOGY

Naked mole rats have low metabolic rates, approximately 70% of that of similar-sized rodents (Buffenstein and Yahav, 1991). Outside the confines of their warm, humid equatorial burrows, naked mole rats cannot regulate their body temperature over a broad range of environmental temperatures (12–37°C) and are thus considered poikilotherms (Buffenstein and Yahav, 1991; Hislop and Buffenstein, 1994). Indeed both their metabolic and body temperature profiles at temperatures below 28°C, closely track that expected for a similar-sized lizard. At temperatures above 29°C, they display a typical mammalian endothermic pattern with the highest metabolic rate at the lowest temperature and a decline in metabolic rate, with the lowest rate at temperatures between 31–34°C; temperatures considered the apparent thermoneutral zone (McNab, 1966). The relative increase in metabolic rate from 29–32°C is similar to that observed in mice housed within their thermoneutral zone and in a refrigerator at 4°C. Hence, given their lack of insulatory pelage, naked mole rats have a much narrower window in which they can thermoregulate relative to other mammals. Indeed it is only at subzero temperatures that mice show the similar hypothermic "reptilian" response of a decline in metabolism and body temperature as conditions become colder. At temperatures above 29°C, naked mole rats employ non-shivering thermogenesis (Hislop and Buffenstein, 1994) initiated by catecholaminergic innervation of interscapular brown fat (Daly et al., 1997). Brown fat is also found in the neck, inguinal, axillary, and perirenal areas. This can generate heat and may maintain a constant body temperature if the animals are housed in large groups in a humid environment that prevents evaporative cooling. Naked mole rats naturally have low thyroid hormone levels, in keeping with the warm temperatures they encounter in burrows or under institutional housing conditions. However, they show increased thyroid activity if housed in the cold for prolonged periods, thus conforming to general mammalian cold acclimation trends (Buffenstein et al., 2001).

Although naked mole rats do not enter a daily or seasonal torpor, like many small mammals do, metabolic rate decreases following prolonged food restriction and may be a mechanism to cope with sporadic and restricted food supplies (Goldman et al., 1999).

Circadian locomotor activity was not observed in general for animals monitored while they were in a colony setting (Riccio and Goldman, 2000a). However, nocturnal rhythms were noted in four males in the colony that were thought to be dispersomorphs. For

individually housed naked mole rats, 65% showed robust circadian rhythms in locomotor activity, and three of four naked mole rats showed circadian rhythms of body temperature and metabolic rate (Riccio and Goldman, 2000b).

ANATOMY AND PHYSIOLOGY OF ORGAN SYSTEMS

Although good descriptions (Hill et al., 1955) of naked mole rat anatomy have been published, very little is known about the basic physiology of naked mole rats. The following are some salient features known about the systems biology of the naked mole rat relative to above ground dwellers.

Digestive System

A unique identifying feature of naked mole rats is the large incisor teeth that are external to the mouth. Having the teeth external enables the animals to dig without the earth coming inside the mouth. Naked mole rats have either two or three molar teeth. The mandibles connect at their anterior extent by a flexible mandibular symphysis, allowing the lower incisor teeth to move independently and provide a greater range of movements and dexterity than is typical of most mammals (Catania and Remple, 2002). The incisor teeth appear to be greatly involved in somatosensory perception (Henry et al., 2006). The parotid, submandibular, and sublingual salivary glands are all well developed (Hill et al., 1955). The esophagus of the naked mole rat has keratinized stratified squamous epithelium and smooth muscle surrounding it. The stomach is monogastric. The length of the small intestine is relatively short, and leads into a very large cecum (Rechkemmer et al., 1988). The intestinal mucosa does not have distinct subdivisions based on duodenal, jejunal, or ileal villar length. The cecum accounts for 8% of the body weight (Buffenstein and Yahav, 1991). Despite the fact that members of the Bathyergidae are strictly herbivorous and eat a diet high in fiber, they nevertheless exhibit the highest digestive efficiency of all mammals (Bennett and Jarvis, 1995). This is primarily due to comparatively long retention times in the gut and highly efficient microbial fermentation processes in the cecum (Buffenstein and Yahav, 1991; Porter, 1957) coupled with coprophagy.

The cecum has a mixed microbial population of ciliate and holotrich protozoa, biflagellates, and fungi as well as an assortment of rod- and cone-shaped bacteria (Buffenstein et al., 1994; Porter, 1957) (Figure 45.2). These abundant microorganisms within the hindgut, provide naked mole rats with high-energy compounds in the form of volatile fatty acids (such as acetic and butyric

FIGURE 45.2 Cecal contents (H&E): The hindgut fermentation of the naked mole rat in health is associated with protozoa and bacteria. This high-power photomicrograph demonstrates several large protozoal ciliates, likely *Balantidium* spp., as well as several smaller flagellates. Also noted are large fusiform organisms.

acid) that are rapidly absorbed into the bloodstream and provide the host with more than 60% of their basal energy requirements (Parra, 1978). To further maximize energy extracted from the diet, NMRs practice coprophagy which provides a good source of proteins in the form of digested microbes.

Fermentation processes in the gut of the naked mole rat function most efficiently at their low body temperature of 32°C. Surprisingly, because fermentation processes are generally considered to be endothermic, cecal temperature in the mole rat is cooler than core temperature (Yahav and Buffenstein, 1992). The scientific reason for this phenomenon has not yet been explained.

The liver has four principal lobes and a number of minor ones, the main lobes being separated by deep fissures extending in most cases completely throughout the hepatic substance, and a gall bladder is absent (Hill et al., 1955).

Respiratory System

The anatomy and physiology of the respiratory system in subterranean animals is of great interest because their environment can have high levels of carbon dioxide (7–8%) and low levels of oxygen (6%) (Arieli, 1979; Contreras and McNab, 1990; Kennerly, 1964; Nevo, 1999). Naked mole rats have three turbinates (maxillo, ethmo, and sphenoidal), three lung lobes on the right and left sides, and a caudate lobe on the right side (Hill et al., 1955). Histologically, they have a preponderant double pulmonary capillary arrangement, incomplete differentiation of alveolar pneumocytes, and extension of the cuboidal epithelium to the immediate vicinity

FIGURE 45.3 Lung (H&E) section of diaphragmatic portion of the naked mole rat lung. In contrast to rat and mouse lungs, the terminal bronchiole is ectatic; and alveolar ducts are short or non-existent, allowing alveolar sacs to branch almost directly from the terminal bronchioles. Terminal bronchioles are lined by cuboidal epithelium, the alveoli by flattened type I pneumocytes. Thus the most distal alveolar spaces abut the pleura and connect with the terminal bronchioles. The lungs thus have an “emphysematous” appearance at low magnification. The relation of this design to the low oxygen needs of the naked mole rat is not understood.

of the alveoli (Maina et al., 1992, 2001) (Figure 45.3). Observations between field animals and animals maintained in the lab were similar, suggesting the naked mole rat is intrinsically intractable to environmental shifts in its habitat. Consistent with their overall reduced metabolism, the respiratory rate of naked mole rats is about half the respiratory rate of mice (Blass et al., 2009).

Circulatory System

Subterranean rodents have increased capillary densities in skeletal, cardiac, and pulmonary tissues, as well as increased fractional volumes of mitochondria in tissue (Arieli and Ar, 1981; Widmer et al., 1997). Also, elevated myoglobin levels have been reported in other subterranean species (Ar et al., 1977). In addition, lower resting heart rate and greater heart mass have been reported in ground squirrels and chipmunks (Burlington et al., 1970; Jones and Wang, 1976). In the naked mole rat, the left precaval vein is retained and is larger than the right precaval vein (Hill et al., 1955). However, little else is known about the cardiovascular system of this species. The left ventricular free wall and interventricular septum are thicker in relation to the right ventricular free wall than seen in rats and mice.

Hematopoietic System

Naked mole rats have the typical variety of leukocytes (Johansen et al., 1976) as seen under light

microscopy, but there are no studies that define cells by markers or immunological function. Erythrocytes are similar to those of other mammals. The spleen is in the typical rodent location and is more slender than typical rodent spleens. Extramedullary hematopoiesis is noted in the spleen of young and pregnant animals.

The hemoglobin molecule has higher affinity for oxygen compared to most other mammalian species, and this is viewed as an adaptation for living under chronic low-oxygen conditions in subterranean burrows (Boggs et al., 1984). Naked mole rats exhibit levels similar to those in other mammals for 2,3-diphosphoglycerate in red blood cells (Johansen et al., 1976).

Integumentary System

The skin of the naked mole rat has many features which are well-suited to its warm, subterranean niche. These include the lack of an insulating layer, and a loosely folded morphological arrangement, both contributing to poikilothermic responses to changing temperatures (Daly and Buffenstein, 1998). The presence of pigment-containing cells in the dermis, rather than the epidermis, which is typical of most mammals, also reflects an environment devoid of sunlight. The lack of fur is compensated by a thicker epidermal layer and a marked reduction in sweat glands. In contrast to having fur composed of numerous short hairs, the naked mole rat has an array of sparsely distributed long vibrissa-like hairs (Crish et al., 2003; Daly and Buffenstein, 1998). The follicles of these body hairs are exceptionally large and well-innervated, similar to guard hair of furred species (Park et al., 2003) (Figure 45.4). The role of these sensory hairs is discussed below under somatosensory perception. The arrectores pilorum muscles are lacking, and the sebaceous glands are degenerate (Hill et al., 1955).

Urinary System

Water balance of naked mole rats is dependent on utilizing the water from food sources only, since pools of water are not normally available in a subterranean environment and even in captivity naked mole rats meet all their water requirements through the consumption of foods. The kidneys of the naked mole rat are unipapillate and unlike other arid-dwelling organisms are capable of only a moderate concentrating of urine (1500 mOsm) (Urison and Buffenstein, 1994). Given the high humidity in their burrows in the wild, this may be adequate for both pulmonary and cutaneous evaporative water loss. However, if high humidity is not maintained under captive conditions, evaporative water loss reaches the highest levels recorded for homeotherms (Buffenstein and Yahav, 1991). Not surprisingly, when water stressed under captive conditions, given their low

FIGURE 45.4 Photomicrograph of sensory hair (tactile, sinus hair, vibrissa-like hair) (H&E): The most important structure to the naked mole rat sensorium, the tactile hair is found distributed throughout the body surface, with concentration at the face, tail, and feet. These coarse long hairs have follicles that contain prominent vascular sinusoids and nerve endings. Striated muscle can be seen at the upper quadrant.

metabolic rates, metabolic water production is too low to counteract high rates of insensible evaporative water loss and the animals cannot maintain plasma osmolality or body mass.

Reproductive System

Both males and females are able to breed at 6 months of age, should the opportunity arise. The external genitalia show no dramatic difference between the sexes. The males have abdominal testes and there may be a slightly greater ano-genital distance in non-breeding males and females. The only accessory sex gland is the vestibular gland. Non-breeding females have a vaginal closure membrane that is slightly dark in color. Breeding males are generally larger, thinner, and the penis is slightly more raised. Breeding females (queens) are large, elongate (Jarvis, 1991; O’Riain et al., 2000), with a swollen and raised genital area, patent vagina, and large mammary (Sherman, 1999). The uterus is bicornuate, there are no fornices, and the ovarian bursa is absent. The ovary is covered by a greatly expanded infundibulum of the uterine tube that has no fimbriae (Hill et al., 1955). The non-breeding males have hyperplastic testicular interstitial cells, reduced numbers of seminiferous tubules, and a simple epididymus without a tail for capacitation of sperm.

Reproductive suppression of non-breeding female naked mole rats is profound in that the majority of females remain in a pre-pubertal state for their entire lives. Concentrations of urinary and plasma progesterone are consistently low in subordinate naked mole rat females (Faulkes et al., 1990a) yet the pituitaries of

subordinate females are responsive to GnRH (Faulkes et al., 1990b). This suggests that the primary site of reproductive hormone inhibition is at the level of the brain (Holmes et al., 2009). Non-breeding males generally have lower levels of urinary testosterone compared to breeding males, but the difference is not as large as in the females. The rapid rise in urinary progesterone in subordinate females following removal from the colony is probably not an indication of reproductive capacity in that breeding rarely occurs in less than 5–6 months (Holmes et al., 2009).

Other anatomical features associated with reproduction that are sexually monomorphic in naked mole rats include Onuf’s nucleus of the spinal cord, perineal muscles, and brain regions (Holmes et al., 2009).

The induction of ovulation has not been determined in naked mole rats, but the Damaraland mole rats are capable of spontaneous ovulation and the act of coitus may advance the onset of ovulation (Snyman et al., 2006).

Average number of mammary glands in males and females averages 11.6 ± 1.6 (Sherman et al., 1999). Neither total numbers of mammae, nor fluctuation asymmetries in mammary numbers differ significantly between males and females, or between breeders and non-breeders. Also, there is no relationship between litter sizes and numbers of mammae.

Endocrine System

Naked mole rats have an unusual endocrine profile relative to above-ground rodents, although several subterranean-dwelling rodents show similar profiles. As mentioned above, naked mole rats have low levels of sex steroids; however they also have low levels of other steroid hormones.

Living in the dark, it is not surprising that naked mole rats are naturally deficient in the “sunshine hormone”, vitamin D. Levels of 25-hydroxyvitamin D are undetectable and the principal active metabolite is low (Buffenstein et al., 1994). Surprisingly, even when exposed to sunlight for prolonged periods, hormone levels remain low and the enzyme responsible for synthesis of the active metabolite (1-alpha hydroxylase) is rapidly down-regulated. Despite these low levels, naked mole rats are able to tightly regulate serum calcium levels and adequately maintain mineral homeostasis, using passive gastrointestinal absorption and vitamin-D-independent mechanisms to retain calcium, magnesium, and phosphorus within the body (Skinner et al., 1991).

Thyroid hormones and thyroid-stimulating hormones are also maintained at low levels for mammals and may contribute to the low basal metabolic rate of this species (Buffenstein et al., 2001). Thyroid morphology is similar to that of most mammals and the thyroid responds positively to cold stress such that thyroid

follicular cell height and free thyroxine levels were significantly greater in cold-acclimated individuals.

Insulin levels in naked mole rats cannot be detected using standard rodent antibody-based assays, suggesting that naked mole rats either have extremely low levels of insulin or have an insulin molecule with a different protein composition to that of other rodents. Although we have not as yet attempted to sequence naked mole rat insulin, there is considerable evidence that the insulin structure in the hystricognaths (e.g. guinea pigs) is substantially different to that of laboratory mice. Unlike laboratory mice, and in a similar morpholoth, insulin-producing cells are distributed in a mantle around the periphery of the islet, rather than in the more usual location of the central core. Similarly, glucagon-producing cells are not located in the mantle, as previously reported in most vertebrates. Indeed, only horses show a similar pancreatic arrangement. Like most mammals, a greater number of insulin-producing cells than glucagon-producing cells are present, and somatostatin-producing and pancreatic polypeptide-producing cells are considerably more scarce and randomly scattered within the islet (Kramer and Buffenstein, 2004) (Figure 45.5).

Naked mole rats have low fasting blood glucose levels, and show an impaired glucose tolerance test, maintaining elevated glucose levels for more than 2 hours. When given a physiologically determined dose of human insulin, blood glucose rapidly drops to extremely low levels (20mg/dl) and remains there for several hours. The exquisite sensitivity to human insulin coupled with the abnormal glucose tolerance test and undetectable levels of insulin suggest that naked mole

rats naturally only produce small quantities of this hormone and that this is usually sufficient for their needs, given their predominant reliance on volatile fatty acids produced during fermentation for their energy requirements. As such, they are unable to regulate blood glucose when given a supraphysiological dose of sugar.

Little is known about the hormones of the adrenal gland. The right adrenal is medial to the right kidney and the left adrenal is ventro-medial to the left kidney. There are no published data on the adrenal cortical axis in naked mole rats. Mole rats have very low levels of corticosterone compared to mice and rats, but predominantly secrete cortisol. It is not known if these two hormones have identical functions or have differences in their regulatory mechanisms.

Apart from the hormones described above, little if anything is known about other hormone secretions and functions and considerable research is needed to glean a better understanding of the endocrine function of this species.

Nervous System

The naked mole rat brain has the normal anatomy of a typical rodent brain (Xiao et al., 2006). What makes the naked mole rat different is the relative amount of cortex devoted to the different sensory inputs. The somatosensory system occupies one-third of the sensory cortex and appears to be a more important sensory input (Henry et al., 2006).

Unlike the majority of vertebrate species, subordinate and breeding naked mole rats lacked vasopressin innervation of the lateral septum and vasopressin-immunoreactive cells in the nucleus of stria terminalis (Rosen et al., 2007). Instead, the dorsomedial septum contained dense vasopressin-immunoreactive innervation, which did not vary with sex or breeding status. Immunoreactive oxytocin fibers were found in the periaqueductal gray, locus coeruleus, parabrachial nucleus, nucleus of the solitary tract, and nucleus ambiguus (Rosen et al., 2008). The high levels in the nucleus accumbens and preoptic area are associated with maternal behavior in other animals (Francis et al., 2000). Breeders, regardless of sex, had more cells than subordinates in the ventromedial nucleus of the hypothalamus and a larger volume of the bed nucleus of the stria terminalis, paraventricular nucleus, and medial amygdala (Holmes et al., 2007). Non-breeding males and females did not differ on any measure.

Special Senses

Somatosensation

The sensation of touch is an important sense in the naked mole rat. The area of the sensory cortex devoted to the sensation of touch is much larger in comparison

FIGURE 45.5 Photomicrograph of pancreatic islet cells (H&E); The islet distribution of beta and alpha cells which produce insulin and glucagon respectively have a distinct zonal arrangement with the mantle cells of beta cells framing a centrally located mass of glucagon producing cells. Human islets are not organized in this manner, but cells of all types are rather randomly distributed within the islet.

to other mammals (Catania and Remple, 2002; Henry et al., 2006). The queen suppresses reproductive activity via touch by pushing and shoving (Faulkes and Abbott, 1997). Like most mammals, naked mole rats have well-developed facial vibrissae (whiskers). However, they also have a system of vibrissa-like hairs that are regularly spaced in rows over the body, and naked mole rats have a robust and accurate orientating response when these hairs are stimulated (Crish et al., 2003). A large number of vibrissa-like hairs are also present on the tail, consistent with the naked mole rat moving as quickly in reverse as in the forward direction.

Naked mole rats also naturally lack neuropeptides and behaviors associated with signaling of chemical irritants on the skin and nasal cavity (LaVinka et al., 2009; Park et al., 2008) which will be discussed in the Models section.

Olfaction and Gustation

Naked mole rats demonstrate prominent scent-marking behaviors and members of the colony are frequently seen rolling in the toilet areas of housing systems. Yet, reproductive suppression does not appear to be influenced by hormones or pheromones present in the urine from the breeding animals (Smith et al., 1997).

In most vertebrates, chemical (pheromonal) communication involves the vomeronasal organ, a structure within the nasal cavity. For rodents in general, the vomeronasal organ is proportionally large (relative to body size) compared to other mammals (Smith et al., 2005). Yet, the vomeronasal organ in naked mole rats is remarkably small, about ten-fold smaller than vomeronasal organs in social rodents such as the meadow vole and mouse. Also, the naked mole rat is the only known mammal to show no post-natal growth of the vomeronasal organ (Smith et al., 2007). This supports the notion that pheromones and chemical sense do not play a major role in sexual suppression in naked mole rats. With regards to traditional odor sensation involving the olfactory system (apart from the vomeronasal system), naked mole rats perform as well as mice in distinguishing odors in a behavioral laboratory test (LaVinka et al., 2009).

Auditory

Naked mole rats do not have pinnae (important for sound localization), and have narrow external ear canals. The majority of subterranean rodents have ear canals filled with cerumen (Burda et al., 1990). Definitive anatomical descriptions of the auditory system are not available for the naked mole rat with one exception (Hefner and Hefner, 1993). They described the brainstem auditory nuclei as being relatively small but present. Generally though, middle ears are vestigial and the inner ear resembles the guinea pig anatomically more than murid rodents in subterranean rodents (Begal et al., 2007).

In contrast to other rodents, the naked mole rat has hearing and communication calls that are primarily in the low-frequency range (Pepper et al., 1991). This is probably because low-frequency sound propagates well through soil. However, naked mole rats perform poorly in tasks based on sound localization ability (Hefner and Hefner, 1993). This may reflect that these tests are not appropriately designed to match the unusual (tubular) environment and behavior of this species.

Vision

Subterranean rodents live in a light-free environment and as a consequence have very small eyes and reduced or absent visual capacities. The naked mole rat is not an exception. They have a rod-dominated retina and have cones that are S-opsin dominated which is similar to other Bathyergidae and unlike any other mammalian species (Peichl et al., 2004). The eye contains 11-cis retinal, the chromophore of visual pigment. The optic nerve cross-sectional area is 10% of the gerbil and had an ERG response typical of other mammals but extremely attenuated and with much slower kinetics (Hetling et al., 2005). They display a variable degree of retinal detachment which may be associated with the less than gelatinous nature of the vitreous humor (Hetling et al., 2005; Nikitina et al., 2004). The superior colliculus and lateral geniculate nucleus are very small in the naked mole rat (Crish et al., 2006). Collectively these findings show that the retinogeniculocortical system in the naked mole rat is considerably smaller than that of rodents that rely heavily on their visual system, but is nevertheless less regressed than that of the extensively studied blind mole rat; this may facilitate limited responses to visual stimuli (Xiao et al., 2006). Indeed all these findings suggest the naked mole rat eye functions for amorphous light detection that may serve for circadian function and/or for the simple assessment of whether or not the burrow has been breached and requires repair.

Magnetoreception

Magnetoreception is magnetic compass orientation. It has been reported in the African Ansell's mole rat (Burda et al., 1990; Marhold et al., 1997), the blind mole rat *Spalax ehrenbergi* (Middle Eastern mole rat unrelated to the Bathyergidae; Burda et al., 1991), the Siberian hamster (Deutschlander et al., 2003), and the laboratory mouse (Muheim et al., 2006). There are no reports in the naked mole rat.

AGING

Aging, the progressive decline in functional morphology that over time leads to increased mortality risk is markedly abrogated in the naked mole rat. Naked

mole rats are the longest-lived rodents known, living approximately 30 years in captivity; 5.3 times longer than predicted on the basis of body size and nine times longer than similar-sized laboratory mice. In captivity both breeders and non-breeders have similar maximum lifespan, whereas in the wild the more protected breeders live considerably longer (17 years; S. Braude, personal communication) than working, predation-vulnerable subordinates (4 years). Not only do naked mole rats have an extraordinarily long lifespan but they show sustained good health for at least 85% of their maximum longevity and show no age-associated acceleration in mortality risk. From the age of 2 to 20 years naked mole rats maintain lean muscle mass (O'Connor et al., 2002), bone health (Pinto et al., 2009), mitochondrial mass, and enzyme activities (Ungvari et al., 2008). Furthermore they sustain their metabolic rate (O'Connor et al., 2002), level of gastrointestinal absorption (Yang and Buffenstein, 2002), and cardiovascular youthfulness (Csiszar et al., 2007) in addition to their level of activity and reproductive potential well into their third decade (Buffenstein, 2008).

Naked mole rats support the evolutionary theory of aging which posits that species that have evolved in areas of low extrinsic mortality such as thermally buffered, sealed burrows that are protected from predation will evolve mechanisms better-suited for extended tissue maintenance and concomitant longevity; whereas those species living in a dangerous environment fraught with challenging climatic conditions and/or high predation risk will evolve life history traits that facilitate early reproduction and shorter lifespans. Naked mole rats also support the environmentally selected lifespan theory which posits that animals that live where resource availability is unpredictable will exhibit extended longevity. The life history of naked mole rats provides some support for this theory: location of food is a random, blind, and energetically costly process and food resources are patchily distributed. The low metabolic rate of NMRs may help them survive periods of limited resources. Extended longevity, like lower extrinsic mortality, is correlated with group-living, such that cave-roosting bats, social insects, and humans all have long lifespans. The cellular, molecular, and biochemical mechanisms facilitating this extended longevity, good health, and delayed aging are however poorly understood.

Naked mole rats do not support the telomere theory of aging. Telomere length and maintenance will govern the number of times a cell may divide and thereby replace damaged cells. Naked mole rats, like humans, have relatively short telomeres compared with mice and lack telomerase and as such cannot maintain telomeres indefinitely. These will shorten with each replication passage and eventually become too short for further replication events.

Similarly, the naked mole rat only provides equivocal support for the most widely accepted theory of aging, the oxidative stress theory of aging that posits that the characteristic traits of aging are due to accrued damage by unchecked reactive oxygen species (ROS), generated during aerobic metabolism. Naked mole rats produce similar amounts of ROS to those produced by shorter-lived rats and mice (Lambert et al., 2007), do not have a stellar antioxidant defense (Andziak et al., 2006), and accrue more oxidative damage even at a young age than do shorter-lived species (Andziak et al., 2006). However, accrued damage appears to be maintained at steady-state levels throughout their long lives (Andziak and Buffenstein, 2006), suggesting that these animals have a higher tolerance threshold for damage prior to inducing mechanisms to remove and repair accrued oxidation products.

Currently, the mechanisms facilitating prolonged good health and lifespan remain elusive and new studies are focusing on mechanisms that may facilitate protein and genomic stability even in the face of cellular endogenous and environmental insults.

HUSBANDRY

Naked mole rats are popular zoological attractions (Petry, 2003) and are also studied at numerous research institutions (Artwohl et al., 2002). They are typically housed at 28–30°C, and humidity levels at 50–60% relative humidity. If housing temperatures are below 25°C, mole rats will stop breeding (Woodley, 2002). The only way to obtain this environment is to curtail the ventilation into the room significantly. The benefit of turning on the light–dark cycle has not been proven since colony-housed animals have not demonstrated a circadian rhythm. As in most facilities that house breeding rodents, noise should be minimized. Wall-mounted shelves can be used or racks that do not rock and have locking wheels can be used. Some facilities put the rack wheels in sand to reduce vibrations in the floor extending into the rack.

Various bedding material can be provided. All current types of mouse bedding have been used with naked mole rats. Each of these kinds of bedding has different pros and cons. For example, wood shavings from pine and ash may have chemicals or odors that may be irritating, causing scratching of the skin. Unless it is of a fine high quality it can also cause splinters in the feet. The advantage of wood shavings is that the shavings are less dusty and tend not to stick to skin. Vermiculite and corn cob bedding are particularly harsh. Some types of paper bedding produce fine particles of dust that may block noses and irritate eyes of naked mole rats. A highly absorbent material should be

placed in the toilet chamber and paper towel, tissues, and corn husks should be given in addition for nesting. Naked mole rats like to move the bedding material and typically gather materials into the nesting chamber. Occasionally naked mole rats will make a ramp with bedding material that can be used to escape from their enclosure.

No water is generally provided when housing naked mole rats in captivity. Fresh food should thus always be available. Food items such as sweet potato can be soaked in water prior to offering the food. The high humidity in the room will diminish insentient water loss. The staple diet for naked mole rats is sweet potato. Some institutions soak the tuber in 10% bleach or weak acid (lemon/vinegar) for a period of time since fecal organisms can regularly be cultured from them. Sweet potatoes are difficult to disinfect because of their porous nature. Additional fresh foods include apple, grapes, bananas, oranges, melons, squash, cucumbers, lettuce, and peppers. These can be supplemented with frozen beans and corn. Mole rats are particularly fond of melons, however, these water-rich foods lead to frequent urination and the need to clean cages more frequently. A vitamin supplement such as Pronutro (Wadeville, South Africa) is frequently offered.

In a laboratory setting, caging is typically made from caging materials that are readily sanitized in a cage washer. Housing systems consist of single and multiple cages that can be connected via 2-inch-diameter pipe. Sanitizing complex caging that utilizes connecting pipes is more labor-intensive since pipes should be periodically scrubbed. Enrichment for naked mole rats includes offering nesting materials for making a nest, increased cage complexity (Figure 45.6) that would include multiple pipe connections or soils in which to burrow. One strategy is to provide un-husked corn. The animals eat the corn and make a nest out of the husk material. Naked mole rats are relentless chewers and constantly gnaw at the corners of chambers. Blocking tubes with whole corn or yams will stimulate burrowing behavior in the tubes and may possibly reduce repairs to the housing structure. That said, care must also be taken to check for holes and loose tubes or lids to prevent escapes from occurring.

Cages can be spot cleaned daily by removing soiled food and spoiled substrates, particularly in the toilet chamber. The entire system can be cleaned every 2–4 weeks with scent-free mild soaps.

Adult naked mole rats can be easily marked using felt-tipped pens which may last up to 10 days. They do not seem to lick the markings off themselves. Toe clipping and transponders can also be used (Braude and Ciszek, 1998). Subcutaneous implanted transponders however can migrate to different areas of the body and often fall out. Tattoos have also worked in naked mole rats.

FIGURE 45.6 Example of a complex caging system used to house colonies of naked mole rats. Cages are connected by 2-inch vinyl tubes which allow the naked mole rats' functional separations of toilet and nesting areas.

COLONY HEALTH

Neonatal and weanling mortality is common in naked mole rats. Facilities should severely limit traffic and curtail noises in rooms with neonates. Naked mole rats respond to noises and vibrations and can bury or carry neonates as part of their care-taking behavior. Sometimes new litters die simply because the mother does not take notice of the neonates.

Problems associated with the birthing process include dystocia and endometritis. Naked mole rats can have very large litters and uterine fatigue can occur. Oxytocin given at mouse dosages helps this condition. Queens with endometritis typically die a few days after birth. Opportunistic bacteria can be isolated from the uterus.

The queen's aggression is part of the eusocial life of naked mole rats. Aggression is heightened when other females are trying to usurp the queen's control. Fight wounds can be observed when this occurs and are one of the most commonly observed clinical problems. These often result in staphylococcal infections. Wounds should be treated with organic iodines.

Naked mole rats have various non-infectious conditions that occur on occasion. Bloating is not an uncommon sign. It is often associated with weaning and can

be associated with ingestion of less-complex carbohydrate food sources. Usually this sign will abate with time, but occasionally the bloat is debilitating, leading to dehydration and can cause death. Clinical evaluation and treatment are necessary in these cases.

A metastatic calcification condition has been observed (Margulis, personal communication (Figures 45.7 and 45.8). The cause for the condition was probably dietary-related since a higher level of rodent chow was used and naked mole rats typically eat diets low in calcium. Some calcium deposits may be dystrophic since they can be seen in areas of inflammation such as around fight wounds and foot lesions. The foot lesions would be considered painful. The calcium deposits are made of a pasty white material that appears like an abscess, but are often sterile and radio-opaque. Similarly London Zoo reported nephrocalcinosis and mineral deposition in soft tissues in animals fed a calcium-rich diet supplemented with vitamin D.

FIGURE 45.7 Metastatic calcification deposit being expressed. This condition should be considered for any mass in a naked mole rat that appears like an abscess.

FIGURE 45.8 Photomicrograph (Von Kossa). A focus of cutaneous mineralization which is stained dark.

Few pathogens have been reported in naked mole rats, which is noteworthy considering the preponderance of naked mole rat colonies in zoos and conventional institutional rodent facilities. Zoos are environments that have less control over the spread of pathogens. Naked mole rats seem to be extremely resilient to pathogens and other toxic insults. Perhaps naked mole rats are less susceptible to murine pathogens because of their lower resting body temperature (33°C), or perhaps because naked mole rats are typically housed at higher room temperatures than other rodents, necrosis sets in rapidly when they die such that pathogens and cause of death cannot be easily identified. As such, incidences of pathogenic outbreaks may not be reported. Surveys of zoo pathologists however support the premise that naked mole rats are extremely resilient and resistant to infectious agents.

Ross-Gillespie et al. (2007) described an acute coronavirus epizootic that caused acute diarrhea, dehydration, and severe enteric hemorrhaging that killed 161 of the 365 animals (44.1%). Age (younger animals more susceptible), sex (males were more susceptible), and the degree of inbreeding (inbreeding increased susceptibility) influenced mortality. The source of the coronavirus was not identified.

An acute death syndrome has been noted at multiple institutions and zoos. It is characterized by multiple deaths, sometimes in multiple species (naked mole rats and Damaraland mole rats) in animals that are in good body condition. Sometimes diarrhea is noted. Available tests for clostridial enterotoxin and mycotoxins were negative. Edematous ileum, cecum, and colon were noted histologically. Since naked mole rats have a complex microflora in this region of the intestine, consideration of dysbiosis as described in rabbits or a pathogen that requires special culture conditions should be made for the cause. Naked mole rats occasionally get localized abscesses where opportunistic pathogens such as *Pasteurella*, *Pseudomonas*, or *Staphylococcus* sp. are isolated. *Helicobacter* sp. have not been identified in NMRs.

Small colonies are particularly vulnerable to dehydration and cracked skin in response to low humidity. Give small colonies mini-chambers to increase humidity. If skin is dry add moist cloths and/or supplement nesting with fresh corn husks, lettuce, or fresh (washed) grass. In the past we have rubbed Vaseline intensive care or hypoallergic moisturizer creams onto skin with considerable success. Recently however, a small proportion (up to 10% of a colony) of animals has gone into shock and although we were able to resuscitate them, we have replaced this moisturizing spa treatment with a rub of olive oil. Ring tail has also been observed in naked mole rats (Figure 45.9).

The immune function of naked mole rats has not been described. Consideration for susceptibilities to experimental infections should be considered. Artwohl

FIGURE 45.9 Ringtail in a naked mole rat.

et al. (2009) reported 100% mortality in naked mole rats given a recombinant herpes simplex virus type 1 that was avirulent to mice. The virus was administered via scarification of the foot.

Neoplasia has not been reported in naked mole rats (Buffenstein, 2008).

It is possible but not substantiated adequately by pathology that old naked mole rats may suffer from cardiovascular insults such as aneurysms and possible strokes.

A couple of considerations when treating naked mole rats are that they take a long time to recover from anesthesia, and the reintroduction of animals back into the colony can cause a xenophobic response. Gaseous anesthesia is preferred and dosages of analgesics are much lower than dog dosages. In addition, the greater amount of time the naked mole rat is removed from the colony, the greater the chance of queen aggression on the animal. Gloves should be cleaned before removing the animal, minimal disinfectants should be used that would impart a foreign scent, and post-procedural monitoring should be performed to be sure the animal is not killed after reintroduction. One tactic is to roll the animal in the toilet area before placing it back in the colony. Animals that are mobbed by colony members after reintroduction should be removed again. Some shoving by the queen is acceptable and usually does not last long.

USE IN RESEARCH

Model of Social Cooperation

Because naked mole rats are social and have cooperative behaviors, the study of their behavior has more applicability to people. Functional castes within a

colony have been identified (Bennett and Faulkes, 2000; Sherman et al., 1992), and some means of communication. No wonder they are popular attractions at zoos and in the biology class.

Model of Reproductive Suppression

Naked mole rats are one of only two species of mammals identified as being eusocial. The advantage of studying this species in comparison to the Damaraland mole rats (the other eusocial mammal) is that they are much smaller and colonies reach much higher numbers of animals. The basic mechanisms involved in reproductive suppression have not been elucidated, but there appears to be some psychological aspect to it (Faulkes and Abbott, 1997).

Model of Somatosensory Processing

The sensation of touch is an important sense in the naked mole rat since they inhabit an environment that is devoid of light. The area of the sensory cortex devoted to the sensation of touch is larger in comparison to other mammals (Catania and Remple, 2002; Henry et al., 2006). Like most mammals, naked mole rats have well-developed facial vibrissae (whiskers). However they also have a system of vibrissa-like hairs that are regularly spaced in rows over the body, and naked mole rats display a robust and accurate orientating response when these hairs are stimulated (Crish et al., 2003). The highly organized pattern of the body hairs and the decisive orienting responses to their touch suggest that the hairs convey somatosensory-based spatial information.

Since naked mole rats have no fur, the vibrissa-like body hairs are easily accessed for precise stimulation by investigators. The superior colliculus, a midbrain center involved in directing orientation movements to somatosensory, auditory, and visual stimuli, provides an excellent area for studying the neural basis of orientation to somatosensory stimuli in the absence of vision (which is dominant in the superior colliculi of more visually guided animals) (Crish et al., 2006). Taken together, the tractable number of body hairs (~50), their ease of access for stimulation, and the lack of visual inputs to the superior colliculus make the somatosensory system of the naked mole rat an excellent system for studying somatosensory processing as it relates to orientating behavior.

Model of Pain Insensitivity

Naked mole rats show a unique and remarkable lack of cutaneous pain-related behaviors to two potent chemical irritants, capsaicin (from chili peppers) and acid (Park et al., 2008), and a lack of trigeminal pain-related

behaviors to capsaicin and ammonia (LaVinka et al., 2009). Furthermore, when exposed to inflammatory insults or known mediators (e.g. Freund's adjuvant), naked mole rats do not display sensitization to heat on the inflamed area (thermal hyperalgesia) as do other mammals. In contrast, naked mole rats do display normal (mouse-like) pain behaviors to mechanical stimuli (pinch) and heat.

Naked mole rats display several physiological and anatomical features that explain their insensitivity to noxious chemical and inflammatory stimuli. Most notably, nerve fibers in the skin that normally respond to acid in other animals are completely insensitive to acid in naked mole rats (Park et al., 2008). Also, while nerves in the skin do respond to capsaicin, those nerves lack the neurotransmitters that would usually be released onto spinal cord cells to signal pain (Park et al., 2003). The neurotransmitters that are missing are substance P (SP) and calcitonin gene related peptide (CGRP).

Why do naked mole rats lack pain from chemical irritants? As mentioned earlier, naked mole rats have a very unusual combination of ecological and social characteristics. They are fully subterranean, extremely social, and they live in colonies with many individuals. In other words, naked mole rats live in large numbers in very tight quarters and in very poorly ventilated spaces where metabolic activity increases carbon dioxide (CO₂) and ammonia to extremely high levels. In other mammals, exposure to chronically high levels of CO₂ and ammonia induces pain, especially in the eyes and nose. It appears that the insensitivity to chemical irritants in naked mole rats is an adaptation to living in an otherwise painful environment.

Model of Cutaneous Substance P (SP) and Calcitonin Gene Related Peptide (CGRP) Knockout

In addition to functioning in certain aspects of pain processing, SP and CGRP also play an important role in regulating blood flow, for example in thermoregulation and digestion. The absence of these neuropeptides in naked mole rats may be related to the finding that naked mole rats are the only known mammalian poikilotherms, and they may not require cutaneous vasodilation to regulate body temperature. Cutaneous vasodilation in other mammals is mediated by nerve cells that release SP and CGRP onto small arteries in the skin to increase regional blood flow and heat transfer. Of interest, naked mole rats have SP/CGRP innervation to mesenteric arteries, which presumably subserves regulation of blood flow related to digestion (Park et al., 2003).

SP and CGRP have been implicated in a direct effector role in tissue maintenance. Absence of this peptidergic innervation raises questions about the capacity

of the skin of naked mole rats to respond to insult and could explain the extreme susceptibility to herpes simplex I administered cutaneously (Artwohl et al., 2009).

Model of Delayed Puberty and Prolonged Hypogonadism

Hypogonadism, be it induced by delayed puberty, exercise-induced amenorrhea, or testicular malfunction, impacts upon bone quality, resulting in impaired bone strength with reduced bone mass and area as well as changes in trabecular architecture (Chevalley et al., 2009). Suboptimal skeletal development during puberty affects long-term bone strength, leading to an increase in fracture risk later in life (Yingling et al., 2008). Current animal models to study delayed puberty and hypogonadism have several drawbacks. Ovariectomy models often manifest with high GnRH, since it is inhibition by sex steroids and inhibition is reduced, whereas GnRH antagonists affect not only the entire hypothalamic-pituitary-gonadal axis, but also have a tendency to increase body weight, serum IGF-1 levels, and complete suppression of the onset of puberty is dose-dependent (Roth et al., 2000; Yingling and Taylor, 2008). While these studies have yielded considerable information in this regard, the short-term nature of these studies as well as the extended duration of bone remodeling and turnover, limits these studies in what they can tell us about "catch-up" growth or chronic hypogonadism and begs the question of whether or not there is a natural animal model for long-term hypogonadic effects on bone.

One such novel animal model may be the naked mole rat. They are naturally suppressed from entering puberty and do not show differences in other hypothalamic pituitary hormones or serum IGF-1 levels, a clear advantage to other models. Further, "puberty" can be initiated within 7 days once isolated from the dominant female and levels of the sex steroid hormones in these recently isolated NMRS reach concentrations comparable to those of their long-term breeding counterparts (Clarke and Faulkes, 1997, 1998). This activation of gonadal activity and fertility is extremely rapid, especially when considering that non-breeders may have been reproductively suppressed for many years, and even 24-year-old females are capable of exhibiting rapid changes from reproductive suppression to ovarian cycling. Further studies in which hormone status may be experimentally manipulated in young individuals both prior to and after attainment of adult mass may shed more light as to whether or not bone morphology and mechanical properties are sustained by sex steroid hormone-independent mechanisms. Elucidating the mechanisms facilitating sustained bone structure and strength in hypogonadic subordinates may yield

pivotal insights into potential mechanisms and therapies for sustaining bone in delayed puberty and exercise-induced hypogonadism.

Model of Bone Elongation

Naked mole rat queens have significantly longer lumbar vertebrae for their body size compared with all other colony members (Jarvis et al., 1991; O'Riain et al., 2000). This finding parallels eusocial insects in that the dominant breeder is physically different. The length of the spine is proportional to the number of pregnancies experienced and suggests that hormones related to pregnancy may have a role in bone growth (Henry et al., 2007). Queens no longer experienced net gain in lumbar spine length after eight pregnancies, but did have some transient elongation during pregnancy after the eighth pregnancy (Dengler-Crish and Catania, 2009).

Model of Aging

Few animal models used in aging studies show slow rates of aging with affiliated prolonged good health-span and lifespan. Rather, traditional aging models are chosen primarily because such animals have poor defenses against aging and are short-lived. For example the most common mammal used in aging is the C57Bl/6 mouse that only lives 50% as long as predicted by body size. Use of short-lived species enables rapid evaluation of whether experimental manipulation of environmental (e.g., caloric restriction (CR)) and/or genetic factors alter lifespan (Miller and Nadon, 2000). Although we recognize the many advances in understanding aging processes in these short-lived models, we do not know if their lifespan extension mechanisms are pertinent to long-lived mammals, such as humans, that naturally age slowly. Long-lived species may possess certain traits germane to retarding aging that enable them to attain their impressive longevity (Austad, 2009). Thus, a complementary approach for studying mechanisms of aging, that we as humans would like to use in translational research, would be to exploit the untapped resource of natural variation in longevity and focus on long-lived successfully aging species such as the naked mole rat.

Similarly, since naked mole rats do not show any signs of spontaneous neoplasia during aging and also exhibit negligible declines in cardiovascular function, bone quality, and cognitive function; this unusually long-lived and healthy species may also prove to be useful models in many age-associated diseases. As such this species may reveal novel, potentially causal, mechanisms naturally involved in abrogated aging and age-associated diseases. Such knowledge will enable therapies aimed at activating mechanisms to delay human aging, prevent degenerative disease, and extend quality of life in old age.

INTRODUCTION

Peromyscus are myomorph rodents belonging to the family Cricetidae, subfamily Neotominae. Neotominae is comprised of 16 genera of New World cricetid rodents including deer mice, woodrats, and their relatives (Musser and Carleton, 2005). The genus *Peromyscus* contains at least 60 species, with *P. maniculatus*, the deer mouse (Figure 46.1), and *P. leucopus*, the white-footed mouse (Figure 46.2), being the most commonly used

in research (Donnelly and Quimby, 2002). While other *Peromyscus* species, such as *P. californicus*, are used in various areas of research, the former two species will be the primary focus of this chapter. This genus has undergone extensive taxonomic revision and requires further study to resolve the nomenclatural proposals. Some systems use the subgenus designations *Haplomylomys*, containing the *californicus* and *eremicus* species groups, and *Peromyscus* containing all other species groups. Others emphasize species group assemblages rather

FIGURE 46.1 *Peromyscus maniculatus gracilis*, woodland deer mouse, Chippewa Co., MI. (Photograph courtesy of Phil Myers, Museum of Zoology, University of Michigan).

than subgenera (Musser and Carleton, 2005). Despite their common names, deer mice and white-footed mice are not closely related to common laboratory mice of the genus *Mus*, or to laboratory rats (*Rattus*) for that matter.

Physical Description

P. maniculatus has a round, slim body typically 119–222 mm in total length. Tail length varies among different populations and ranges from 45–105 mm (Baker, 1983). Body weight also varies among populations and subspecies and ranges from 12–30 g (Jones and Birney, 1988). Characteristic features of this species include a pointed nose with large black eyes, large lightly furred ears, long, prominent vibrissae, and forelimbs which are shorter than the hindlimbs. Like most cricetids, the dental formula of *Peromyscus* is 1/1 0/0 0/0 3/3 and its molars are low-crowned and cuspidate. *P. maniculatus* is grayish to reddish-brown in color with

FIGURE 46.2 *Peromyscus leucopus noveboracensis*, white-footed mouse, Otsego Co., MI. (Photograph courtesy of Phil Myers, Museum of Zoology, University of Michigan).

a white ventrum. The finely haired tail is distinctly bi-colored, dark above and white below, a feature that distinguishes it from other species of *Peromyscus* (e.g., *P. leucopus*) in which the separation of dorsal and ventral tail color is less distinct. The subspecies of *P. maniculatus* segregate into two broad categories, long-tailed, large-eared woodland inhabitants (e.g., *P. maniculatus gracilis*) and small-eared open-country forms (e.g., *P. maniculatus bairdii*) (Baker, 1983; Wilson and Ruff, 1999). In addition to larger ears, the woodland form has a longer tail, skull and hind feet than the open-country form. Despite having sympatric ranges these subspecies do not interbreed, which may be due to lack of contact related to differences in habitat preference (Baker, 1983).

Peromyscus leucopus is similar in size and appearance to *P. maniculatus*, ranging in weight from 17–30 g, with a total body length of 150–205 mm and a tail spanning 65–95 mm in length (Jones and Birney, 1988). Like *P. maniculatus*, the size and coat color of *P. leucopus* vary among geographic populations. *P. maniculatus* is generally more reddish-brown in color in contrast to the grayish-brown coloration of *P. leucopus*, and, as

mentioned above, has a longer, more sharply demarcated bi-colored tail. However, in some geographic regions it may be extremely difficult to differentiate the two species based on external morphology (LTER, 1995). Furthermore, *P. leucopus* has larger hind feet (>22mm), a rounded braincase compared to the flattened and parallel-sided braincase of *P. maniculatus*, and a third upper molar that is approximately equal in width to the first two. This contrasts with the same tooth in *P. maniculatus* which is narrower than the first two upper molars (Jones and Birney, 1988). It should be noted that tail and rear foot length more reliably differentiate *P. leucopus* from the open-country subspecies of *P. maniculatus* as compared to the woodland forms which have hind feet equal in length and longer tails. The ear length of *P. leucopus* (16–18mm) is intermediate between that of *P. maniculatus bairdii* (12–16mm) and *P. maniculatus gracilis* (18–21mm) and can also be used as a means of differentiation (Baker, 1983).

Geographic Range and Habitat

Peromyscus maniculatus has one of the broadest distributions of any small, terrestrial mammal in the New World (Jones and Birney, 1988). It ranges from Alaska and Canada south to central Mexico, although it is absent from the Southeastern United States and some coastal areas of Mexico within this range. *P. maniculatus* occupies a variety of ecological zones within its geographic range. While it most commonly inhabits prairies, bushy areas, and woodlands, it can also be found in alpine habitats, northern boreal forest, desert, grassland, brushland, agricultural fields, southern montane woodland, and arid upper tropical habitats as well as on boreal, temperate, and tropical islands (Baker, 1968, 1983).

Peromyscus leucopus is found throughout the eastern United States. The easternmost part of its range extends north to Nova Scotia and south to Virginia. They range as far west as Saskatchewan and throughout the plains states, extending south through eastern Mexico into southern Mexico and the Yucatan peninsula (Wilson and Ruff, 1999). Like *P. maniculatus*, *P. leucopus* occupies a wide variety of habitats although they most commonly inhabit warm, dry forests and brushlands at intermediate elevations. They are the most abundant small rodent in mixed forests and brushy areas bordering agricultural lands in the eastern United States, nesting in warm dry places such as hollow trees or vacated bird nests (Wilson and Ruff, 1999).

Use in Research

Both *P. maniculatus* and *P. leucopus* readily adapt to the laboratory environment and have been used extensively in the areas of toxicology, epidemiology, ecology,

genetics, physiology, aging, behavior, and ophthalmology (cataracts). Their susceptibility to a variety of zoonotic agents, including hantaviruses, *Borrelia burgdorferi* (Lyme disease), vesicular stomatitis virus, granulocytic and monocytic *Ehrlichia*, *Babesia*, trypanosomes, and *Francisella tularensis* (tularemia), has generated renewed interest in these species (Donnelly and Quimby, 2002; Joyner et al., 1998). *P. californicus* has received attention from research biologists due to their monogamous mating behavior and paternal participation in nurturing young (Joyner et al., 1998). Comparative studies between *Peromyscus polionotus subgriseus* and *P. maniculatus bairdii*, which differ in sexual dimorphism, behavior, and habitat, have demonstrated differences in glucose regulation, particularly among males. *P. polionotus subgriseus* exhibit better regulatory ability compared to *P. maniculatus bairdii*, and studies utilizing interspecies hybrids suggest variations in the Y chromosome as a genetic cause for these differences (Oriel et al., 2008). Crosses between *P. polionotus subgriseus* and *P. maniculatus bairdii* have also been used to study parent-of-origin effects on growth and development which appear to be caused by variation in imprinted loci and control of genomic imprinting (Duselis and Vrana, 2007).

While they adapt well and are easy to maintain under laboratory conditions, less than 25% of the research performed in *Peromyscus* is “biomedical” research, in which *Mus* and *Rattus* are still preferred. A survey of the literature in 1998 for the period 1993–1997 revealed the use of *Peromyscus* in the following areas: community ecology, species interaction, and natural history (23.9%); parasitology and infectious disease (23.2%); physiology and metabolism (13%); systematic, population genetics, and evolution (12.3%); behavior and social organization (9.5%); applied ecology, toxicology, and environmental monitoring (7.1%); molecular biology and cell/organism genetics (6.0%); and reproduction, growth, development, and aging (4.9%) (Joyner et al., 1998). An informal review of the literature from 1998–2009 revealed minor differences in these areas of study, with a few noteworthy changes in the relative proportions of each. Since 1998, infectious disease research accounted for the greatest proportion of publications based on work with *Peromyscus*, followed by community ecology, species interaction, and natural history. Hantavirus studies accounted for the vast majority of articles on infectious disease during this period, followed by *Borrelia burgdorferi*. Physiology and metabolism remained the third most prevalent area of study, while reproduction, growth, development, and aging moved up to fourth on this list.

Two distinct disadvantages of *Peromyscus* as a laboratory species are the limited availability of highly inbred, genetically homogeneous strains and the difficulty in handling due to their quickness and jumping ability.

Both problems might be addressed through various breeding programs. Although a number of inbred lines of *P. leucopus* and *P. maniculatus* have been developed, reduced fertility and viability of inbred animals has limited the success of inbreeding. Selective breeding of some lines of deer mice has resulted in greater docility (Joyner et al., 1998).

Sources

Deer mice were first bred in captivity around 1916 by Francis Summer at the Scripps Institute, and between 1925 and 1975 a particularly large colony was maintained at the University of Michigan. Several contemporary lines can be traced to the Michigan colony. In 1962 the *Peromyscus* colony that would later form the core of the *Peromyscus* Genetic Stock Center (PGSC) was established at the University of South Carolina. The PGSC, formally established in 1985, contains dozens of "wild-type" and mutant genetic stocks and is supported in part by the National Science Foundation as a biological resource (Joyner et al., 1998). While smaller colonies may be maintained at other institutions, the PGSC is the primary source of *Peromyscus* available to the biomedical research community, with several established and thoroughly characterized lines of *P. leucopus* and *P. maniculatus* as well as other *Peromyscus* species.

BIOLOGY

Lifespan

Peromyscus are generally long-lived compared to traditional laboratory rodents (e.g. *Mus*, *Rattus*, and *Mesocricetus*), with a life span of up to 8 years reported for captive specimens. However, in the wild they rarely live longer than 1 year, with some populations undergoing complete turnover annually (Lackey et al., 1985). Their relative longevity in captivity has generated some interest in aging research. Somewhat surprisingly, mortality in *P. leucopus* in the Northeast US is relatively low in the winter and high in spring and early summer. This may be due to increased predation pressure at that time (Wilson and Ruff, 1999). A variety of mammals, birds, and reptiles including foxes, weasels, owls, and snakes prey on *Peromyscus* (Kaufman and Kaufman, 1989).

Genetics

Peromyscus has a constant diploid chromosome number of 48, although karyotypic variation has been reported among species, subspecies, and geographic

populations (Lackey et al., 1985; Rasmussen, 1968). Examination of individual mice representing three subspecies of *P. maniculatus* revealed variability in chromosomal size and centromere position (Rasmussen, 1968). Two distinct karyotypic races of *P. leucopus* have been reported, one in the northeastern and north-central US and the other in the southwestern US. These two populations differ by three euchromatic pericentric inversions. These differences are greater between the two karyotypic races of *P. leucopus* than between closely related species of *Peromyscus* (e.g. *P. leucopus* and *P. gossypinus*). Intermediate karyotypes exist, suggesting extensive hybridization of the two races in some areas (Lackey et al., 1985).

Anatomy and Physiology

Anatomy and physiology of *Peromyscus* is generally similar to that of other cricetid and murid rodents. A detailed account of *Peromyscus* anatomy has been published (Klingener, 1968). For the purposes of this chapter we will focus on a few distinguishing features of this genus. Documented anatomic characteristics include a less distinct line of demarcation between the glandular and non-glandular stomach when compared to Old World rodents (Donnelly and Quimby, 2002). In comparison to most other rodents, the glans penis in *Peromyscus* is structurally very simple. The external surface of at least the proximal portion is covered with spines. Members of the genus *Peromyscus* contain a complete or nearly complete set of accessory sex glands, with documented variation in the preputial glands (Klingener, 1968). These glands are microscopic or absent in the subgenus *Peromyscus*. Notably, *P. leucopus* contains microscopic preputial glands while *P. maniculatus* lacks them altogether. In contrast, the preputial glands are well developed in members of the subgenus *Haplomylomys* (Lackey et al., 1985). Adrenal gland mass, both relative and absolute, has been shown to be larger in *P. leucopus* compared to *P. maniculatus bairdii*. It has been suggested that this difference in adrenal weights reflects fundamental differences in metabolism and behavior (Lackey et al., 1985).

Evaporative water loss from the lungs and skin, a major avenue of water loss among rodents, is moderate to high in *Peromyscus* (MacMillen and Garland Jr., 1989). With regards to their water regulatory efficiency, *Peromyscus* species are considered relatively inefficient compared to many rodent species and of intermediate efficiency when species that subsist on more succulent diets are considered. Water conservation occurs primarily through urine volume reduction (Lackey et al., 1985). The lack of efficient physiologic water regulatory mechanisms is offset by an omnivorous diet which provides adequate intake of both energy and water. Basal

metabolic rates of *Peromyscus* are also considered intermediate among rodents. This general intermediacy is consistent with an omnivorous diet that provides substantial flexibility in meeting both energy and water needs, even in the face of demanding climatic conditions and competitive interactions. This flexibility helps explain the fact that this genus is found over such a far-reaching geographic range and inhabits virtually every terrestrial situation regardless of degree of environmental rigor, often co-existing with rodents that are much more physiologically specialized to handle demanding environmental conditions (e.g. *Dipodomys*). In addition to its omnivorous diet, the employment of torpor as an adaptive strategy allows *Peromyscus* to escape periods of environmental stress (MacMillen and Garland Jr., 1989). Torpor is a physiologic mechanism employed by many small mammalian and avian species to get temporary relief from demanding circumstances related to energy or water regulation. Torpor varies among endothermic species both with regard to temporal patterns and degree of hypothermia. In *Peromyscus* it appears to be very non-specialized in nature, limited to successive diurnal periods and involving only moderate hypothermia (MacMillen and Garland Jr., 1989). Torpor in *P. leucopus* is commonly reported in the colder parts of its range and is associated with drops in body temperature from 35°C to 17°C, and in respiratory rate from 700 breaths per minute in active mice to as few as 60 breaths per minute in torpid mice (Wilson and Ruff, 1999).

Activity and Behavior

Peromyscus are active throughout the year and generally nocturnal. *P. leucopus* is primarily nocturnal, but is occasionally diurnal during the winter (Donnelly and Quimby, 2002; Wilson and Ruff, 1999). *P. maniculatus* is crepuscular and nocturnal, rarely leaving its nest during daylight hours. *P. leucopus* utilizes a significant vertical component within its home range, and is considered semi-arboreal (Lackey et al., 1985; Wilson and Ruff, 1999). Anatomic adaptations to this semi-arboreal lifestyle include a long tail that is used as a prop and balancing organ during climbing. *P. leucopus* is also an adept swimmer which may play a role in population dispersal, especially in island populations. Individuals have been reported to pass between islands up to 233 m apart (Sheppe, 1965a).

Woodland forms of *P. maniculatus* are at home on the ground, but also climb tree trunks easily and adeptly move among limbs and vines. They are likewise skillful in their utilization of rafters, shelves, etc. for traversing areas within human domiciles (Wilson and Ruff, 1999). Like *P. leucopus*, the woodland forms of *P. maniculatus* are equally adapted to terrestrial and arboreal habitats,

often climbing trees as a primary means of escape following release from live traps (Baker, 1983). Food hoarding is documented in both the deer mouse and the white-footed mouse, although *P. leucopus* seems to demonstrate greater geographic and seasonal variation in this behavior.

Peromyscus tend to center their activity around nesting sites and food caches, which may occur in the same location. They also maintain several different home sites and refuges within their home range, varying their primary activity between the sites at different times (Baker, 1968). *P. maniculatus* has a home range of 242–300 square meters. The home range of males tends to be larger than that of females and shows greater overlap with conspecifics. Males use their home ranges for access to feeding and nesting as well as seeking out reproductive females. The home range of males overlaps with those of several females to provide multiple breeding opportunities. Females use their home ranges for feeding, nesting, and rearing young. While males exclude other males from their home ranges, reproductive females tend to be more aggressive in territory defense than males, suggesting a greater investment in the territory (Wolff, 1989). The home range of *P. leucopus* shows significant variation depending on many factors such as population density, age, season, and habitat characteristics. Like *P. maniculatus*, *P. leucopus* is territorial, with females demonstrating a greater degree of aggression toward conspecifics (Lackey et al., 1985; Wilson and Ruff, 1999).

Female promiscuity may be an adaptive mechanism to prevent infanticide by males. Male *Peromyscus* will commit infanticide of unattended young that they did not father. Male *P. leucopus* that have copulated are inhibited from killing any pups within their home range, whereas dispersing males and resident males that have not copulated will kill pups. Therefore, promiscuous mating by females with neighboring and resident males may confuse paternity and prevent infanticide (Wolff and Cicirello, 1991; Wolff, 1989). Male aggression also seems to play a role in dispersal of the previous year's young in the springtime (Baker, 1983; Wolff, 1989).

Peromyscus communicate vocally and visually with associates and intruding conspecifics utilizing buzzing sounds and sharp squeaks, as well as urine odor, fecal deposits, and scented exudates from anal, clitoral, and preputial glands (Baker, 1983).

Nests of both species tend to be located near or slightly below ground level and may be located under logs, in stumps, rocky ledges, hollow trees, dense branches or vines, remodeled bird nests, burrows of other small mammals, under boards and other debris, or in mattresses, cupboards, and drawers of human shelters (Baker, 1983).

Diet and Nutrition

As mentioned above, *Peromyscus* species consume an omnivorous diet in the wild. The diet of both *P. leucopus* and *P. maniculatus* consists primarily of insects and other invertebrates, seeds, nuts, green vegetation, and fruit. The relative proportions of these items vary geographically and seasonally (Lackey et al., 1985; Wilson and Ruff, 1999).

Reproduction

While both *P. maniculatus* and *P. leucopus* breed year-round in the laboratory and in the southern portions of their range, they are seasonal breeders in the northern aspects of their range. A great deal of variation in seasonal breeding is observed among *Peromyscus* and in some cases is restricted to just a few weeks each year. Seasonal breeding occurs in response to a complex combination of environmental cues including photoperiod, temperature, and food availability (Millar, 1989). Sexual maturation in wild populations is dependent on several factors. Reproductive stimulation has been documented in *P. maniculatus*. The presence of females stimulates male reproductive development, as does the presence of female urine. The presence of urine from adult males stimulates vaginal opening and development of the female reproductive tract. Reproductive suppression has been documented in both species. Suppression of female reproductive maturation may be due to such factors as high population density, sibling pairs, and presence of mother or unrelated females. Sexual development in young males may be inhibited by the presence of adult or same-aged males. Data collected from laboratory colonies indicate that all species of *Peromyscus* are capable of maturing at less than 3 months of age (Millar, 1989). *Peromyscus* females are polyestrous and undergo a postpartum estrus, maximizing their reproductive output, especially in populations in which breeding seasons are short. In the wild, most females survive only long enough to produce two or three litters during a breeding season, regardless of the length of the season. However, the frequency of breeding increases with decreasing season length (Millar, 1989). In contrast, females housed under constant environmental conditions in the laboratory environment may produce up to 14 litters per year (Donnelly and Quimby, 2002). In wild populations litter size varies with age, parity, geography, and environmental temperatures during early pregnancy, and gestation has been shown to be longer in lactating females (Millar, 1989).

While males of most *Peromyscus* species are polygynous, *P. californicus* is naturally monogamous. *P. leucopus* and *P. maniculatus* have been reported to be monogamous under certain conditions (Joyner et al.,

1998; Wolff, 1989; Wolff and Cicirello, 1991). Despite the predominance of polygyny, paternal care of young is documented in several species including *P. maniculatus* and *P. leucopus*, although in one study this behavior was reported to be more pronounced in *P. maniculatus* (Millar, 1989; Wolff and Cicirello, 1991).

Studies have been performed to compare reproductive performance between wild-caught and captive colonies. Notable observations were that the semidomesticated colonies (maintained in captivity for at least 25 generations) of *P. maniculatus* bred more readily and had a greater rate of litter production than wild mice, but also had higher rates of cannibalism and desertion of litters (Millar, 1989; Millar and Threadgill, 1986).

HUSBANDRY

Unlike laboratory mice of the genus *Mus* and rats of the genus *Rattus*, *Peromyscus* species are regulated under the Animal Welfare Act. Therefore the care and research use of the species must comply with the regulations and standards described in the [Code of Regulations, Title 9, Subchapter A \(rev. 2002\)](#). USDA space requirements for unconventional rodents mandate only that the enclosure affords each animal the ability to make normal postural and social adjustments with adequate freedom of movement.

Colonies of *Peromyscus* can easily be maintained in rodent cages composed of polypropylene, polycarbonate or polysulfone. Standard cage dimensions allowing 70–75 square inches of floor space are sufficient to house up to six adults. Aspen shavings, processed corncob, and cellulose are all acceptable as contact bedding materials. The addition of pulped cotton fibers (Nestlet™, Ancare Corporation, Bellmore, NY) provides environmental enrichment by permitting species-specific behaviors, including the alteration of environment in captivity. The creation of cotton nests using this material also increases privacy during breeding and neonatal care by dams. Clean cages and bedding should be provided weekly.

Ambient temperatures are not recommended to exceed 33°C; optimal macroenvironmental temperatures range from 22–25°C (Joyner et al., 1998). Relative humidity should be maintained between 30–70%. A 12 : 12h light : dark cycle is adequate to maintain non-breeding colonies of *Peromyscus*. Food and water should be provided ad libitum. Stainless steel wire cage tops with food hoppers and water bottle inserts are suitable delivery methods. A commercially prepared, nutritionally complete laboratory rodent diet is routinely used. *Peromyscus* adapt well to drinking from a water bottle.

Restraint of *Peromyscus* for purposes of examination or experimental manipulation can be achieved by

carefully covering the mouse with the palm of one's hand. With the thumb and forefinger grasp the tail base and lift the animal onto a wire cage top. With the thumb and forefinger of the alternate hand, a *Peromyscus* can now be immobilized by grasping it around the head and shoulders, pulling the skin taut. *Peromyscus* are quick and quite agile. Caution should be exercised during handling as captive-bred mice are reportedly capable of jumping to a vertical height of approximately 30 cm (Botten et al., 2001). To reduce the risk of escaped mice, the bottom half of a plastic sanitizable 55-gallon drum or a changing table with high walls can be used during transfer of mice from soiled to clean caging.

CAPTIVE BREEDING

Several laboratories have demonstrated success in establishing breeding colonies of *Peromyscus* from wild-caught founder stock (Botten et al., 2001; Joyner et al., 1998; Millar and Threadgill, 1987). Mice reach sexual maturity approximately 7–8 weeks after birth but exposure to a light cycle of <12 hours has been shown to delay gonadal development for as many as 7 months (Joyner et al., 1998; Nelson et al., 1997). In addition, shortening of the photoperiod results in ovarian and testicular atrophy in *P. maniculatus* and *P. leucopus* (Dewey and Dawson, 2001). In the laboratory where light and temperature conditions can be controlled mice can be expected to breed throughout the year (Drickamer and Vestal, 1973). Breeding occurs most successfully when *Peromyscus* are maintained under a light : dark cycle of 16 : 8 hours. Reduction of the light cycle to provide a 12-hour photoperiod with incremental advances to 16 hours of light may be beneficial in correcting problems with breeding (Botten et al., 2001). Efficient breeding is best achieved by maintaining monogamous pairs. If a litter has not been produced after 3 months, breeding candidates should be introduced to a new mate. *Peromyscus* have an estrous cycle of 5 days and an average gestational period of 22 days except in lactating females where birth may be delayed 4–5 days (Clark, 1936; Joyner et al., 1998). A postpartum estrus often occurs within 24 hours following parturition. Litter size in *P. maniculatus* and *P. leucopus* ranges from 1–11, averaging approximately five pups per litter (Drickamer and Vestal, 1973; Martin et al., 2007; Price, 1967). Males assist in the care and rearing of neonates (Wolff and Cicirello, 1991). Although nursing ceases at 20 days of age it is recommended not to wean young mice until they reach an age of 25 days (Joyner et al., 1998). Normative data pertaining to reproduction and development are summarized in Table 46.1. As with *Mus* and other rodents, anogenital distance can reliably be used in sexing young deer mice (Donnelly and Quimby, 2002). Newly weaned

TABLE 46.1 Normative data for reproduction and development in *Peromyscus*

Parameters	<i>P. leucopus</i>	<i>P. maniculatus</i>
Puberty (days)		
Male	42–48	35–37
Female	42–48	35–37
Estrous cycle (days)	4–5	4–5
Gestation (days)	22–24	23
Litter size (no. of pups)	1–11 (avg. = 5)	1–11 (avg. = 5)
Birth weight (grams)	1.5–2.4	1.3–2.2
Eyes open (days)	12–15	12–16
Weaned (days)	21–28	21–28

Adapted from Donnelly and Quimby (2002).

Peromyscus can be identified by ear tags or ear punching. [Table 46.1 near here]

DISEASES

Non-Infectious Diseases

Periodontal Disease

Periodontal disease has been described in *Peromyscus* species captured from western North America (Sheppe, 1965b; Wiebe et al., 2001). Originally, the disease was thought to be confined to a small area in British Columbia and Washington, affecting a single species (*P. keeni oreas*), as the disease was not noted in other *Peromyscus* species analyzed (Sheppe, 1965b). However, more recent investigation indicates that the condition may be more prevalent than previously believed. Wiebe et al. (2001) described periodontal disease occurring in three subspecies of *P. keeni* and one subspecies of *P. maniculatus* originating from the west coast of North America. The authors described a scoring system, classifying the disease from I–III based on furcation exposure and degree of bone loss. Incidence of periodontal disease of any class was 3.6% in *P. keeni* and 4.4% in *P. maniculatus*. Animals that were captured on small islands had a much higher incidence of disease compared with those captured on large islands and the mainland (Wiebe et al., 2001). Both reports suggest a genetic component to this disease, and further analysis may prove these mice to be a suitable model for periodontal disease in humans.

Spherocytosis

A recessive mutation causing hereditary spherocytosis has been described in a colony of *Peromyscus maniculatus* descended from mice trapped in Oregon

and California (Huestis and Anderson, 1954; Huestis et al., 1956). The syndrome is characterized by varying degrees of jaundice occurring within a few hours after birth, persisting for 1–2 days, and followed by several days of pallor. Other related findings include splenomegaly, mild hepatomegaly, bone marrow erythroid hyperplasia, and an increased incidence of gallstones. Red blood cell analysis in affected mice revealed an increased proportion of reticulocytes, shortened red blood cell life span, and increased osmotic fragility (Anderson et al., 1960; Fitzpatrick et al., 1963; Huestis and Anderson, 1954; Huestis et al., 1956). Except for the mode of inheritance, the disease was described as identical to hereditary spherocytosis in man, and was thus proposed as a promising model; however, this condition has not been described in recent literature, most likely due to a lack of available mice and replacement with genetically altered inbred *Mus* (Anderson et al., 1960; Rosenblum, 1976).

Neoplasia

Although spontaneous neoplasia occurs at a low frequency in random-bred *Peromyscus* (Parnell et al., 2005), a variety of tumors have been reported in *Peromyscus* species. A report comparing aging and longevity in *P. leucopus* with *Mus musculus* described the occurrence of neoplasias in an established colony of *P. leucopus*. Characteristic tumors included hepatocellular carcinoma, mammary ductal carcinoma, and lymphoreticular and bone tumors. Primary mammary tumors were locally invasive with metastasis to the lymph nodes, in contrast to those of *Mus*, which metastasize primarily to the lung. Other, less frequently observed tumors in this colony included histiocytic lymphoma, papillary adenocarcinoma of the ovary, endometrial adenocarcinoma, choriocarcinoma, and a single subpleural pulmonary tumor of alveolar origin (Sacher and Hart, 1978). A high incidence of highly malignant harderian gland adenocarcinoma was reported in two of three inbred lines of *P. leucopus*; a single case was also seen in a random-bred male. Other neoplasias found in the three described inbred strains included a fibrosarcoma and tumors of giant cell, salivary, and mammary origin (Parnell et al., 2005). Odontomas have been described in a colony of *P. leucopus*. The growths were seen at the root of incisor teeth and were histologically classified as complex-type odontomas. Mice aged 4–5 years were most commonly affected (Finkel et al., 1979). In a colony of hairless *P. maniculatus gambeli*, a low percentage of animals developed spontaneous epidermal papillomas; histological findings were characteristic of benign papillomas. In addition, some mice developed cystic hair follicles, primarily on the dorsum and abdomen (Packchianian and Rigdon, 1970). A single case of granulocytic leukemia and uterine adenocarcinoma has been described

in a wild-caught adult female *P. leucopus* (Davis and Morton, 1993). Thymic lymphoma was also briefly described in one of 12 *P. leucopus* 7 months after undergoing whole-body irradiation (Cosgrove et al., 1974).

Metabolic Disease

Type II diabetes mellitus has been described in a colony of *P. leucopus* that were maintained on a diet containing 25.8% kcal from fat. When these animals were switched to a low-fat diet, serum glucose, triglyceride, and cholesterol levels returned to normal within 6 months, although some animals remained hyperinsulinemic. The mice were initially evaluated for tail and extremity lesions, although the authors concluded that the lesions were traumatic in origin and not related to the presence of a diabetic state (Krugner-Higby et al., 2000).

Miscellaneous

Diarrhea may occur in weanling *Peromyscus*, particularly when stressed. The condition is generally self-limiting, and treatment may be administered in the form of tetracycline following separation from cagemates (Joyner et al., 1998). At the authors' institution, multiple cases of cystic endometrial hyperplasia, mucometra, and mineralization of the ovaries and cervix were noted in a breeding colony of female *P. leucopus*. A review of husbandry practices revealed that the colony had been maintained on a 12 : 12h light:dark cycle. No additional cases were found after corrections to lengthen the light phase of the photoperiod were made. As no controlled studies were performed, a direct cause-and-effect relationship could not definitively be made.

Infectious Diseases

Peromyscus species act as natural hosts or reservoirs of a large number of infectious agents, many of which are zoonotic (Donnelly and Quimby, 2002; Vandegrift and Hudson, 2009). Susceptibility to infection by these organisms is one of the advantages for using this genus in biomedical research. Precautions must be taken when importing these animals into the laboratory, particularly when working with non-captive-bred animals, to decrease the risk of exposure to both handlers and other animals in the colony (Joyner et al., 1998; Mills et al., 1995). This section focuses on those diseases that are known to cause pathology in *Peromyscus* and/or are capable of infecting humans or other laboratory rodents.

Parasitic Diseases

TOXOPLASMA GONDII

As with humans and most mammalian species, *Peromyscus* can act as intermediate or reservoir hosts

for *T. gondii* (Dabritz et al., 2007; Dubey, 1983; Wallach and Boever, 1983). Following infection via oral ingestion of sporulated *T. gondii* oocysts, sporozoites excyst, transform into motile tachyzoites within small intestinal enterocytes, and disseminate to many organs including lymph nodes, heart, lung, spleen, and brain (Dubey, 1997). The organisms then form bradyzoites which subsequently continue to divide, forming tissue cysts; in rodents, these cysts are most numerous in the brain (Baker, 2007; Dabritz et al., 2007). The life cycle is completed by ingestion of these cysts by a felid, the definitive host of *T. gondii*. Disease and clinical signs in infected *Peromyscus* may be silent or include encephalitis, granulomas, pyrexia, lymphadenitis, and/or myocarditis, depending upon location and/or size of tissue cysts (Dabritz et al., 2007; Wallach and Boever, 1983). Of potential importance is the finding that vertical transmission has been demonstrated in *Mus* and *Rattus* species; whether this phenomenon occurs in *Peromyscus* remains to be determined (Dabritz et al., 2007).

GIARDIA

A protozoan that affects both humans and animals worldwide, *Giardia* has a direct life cycle. Trophozoites attach to enterocytes in the host, reproduce via binary fission, undergo encystation, and exit the host in the feces (Baker, 2007). *Giardia* has been isolated from both natural and wild-caught captive populations of *Peromyscus* (Appelbee et al., 2005; Grant and Woo, 1978; Rothenbacher et al., 1970; Wallis et al., 1984; Ziegler et al., 2009). As in many species, infection is generally asymptomatic; however, one report described diarrhea, emaciation, and high mortality resulting from giardiasis in a wild-caught captive colony. Stress and poor-quality diet were suspected as contributing factors to the onset of disease (Rothenbacher et al., 1970; Wallach and Boever, 1983).

SCHISTOSOMATIUM

Peromyscus maniculatus are the natural hosts for *Schistosomatum douthitti* (Malek, 1977; Schwanz, 2006). *Schistosomatum* is a trematode that infects a variety of rodents throughout North America (Malek, 1977). In the natural host, adult schistosomes reside in the mesenteric and hepatic portal veins, producing eggs that pass into the intestines and exit via the feces. Asexual reproduction occurs in a snail intermediate host, which shed cercariae that subsequently burrow through the skin of the definitive host (Price, 1931; Schwanz, 2006). Experimental infection of *P. maniculatus* with *S. douthitti* resulted in diarrhea and bloody feces; enlarged and darkened spleen and liver; increased intestinal mass; and decreased serum alkaline phosphatase and albumin (Schwanz, 2006).

OTHER INTERNAL PARASITES

Peromyscus are host to a large number of other endoparasites that may cause pathology, including *Cryptosporidium* (Appelbee et al., 2005; Perz and Le Blancq, 2001; Ziegler et al., 2007), *Babesia* (Etkind et al., 1980; Hofmeister et al., 1998; Mather et al., 1996; Spielman et al., 1981; Telford and Spielman, 1993), *Hymenolepis* (Munger et al., 1989; Zenchak and Hall, 1971), *Echinococcus* (Carney and Leiby, 1968; Leiby, 1965; Leiby and Kritsky, 1974), *Trichinella spiralis* (Holliman and Meade, 1980; Martin et al., 1968; Meagher and Dudek, 2002), *Pterygodermatites peromysci* (Luong et al., 2009; Vandegrift and Hudson, 2009; Zenchak and Hall, 1971), and *Baylisascaris procyonis* (Kazacos and Boyce, 1989; Page et al., 2001; Sheppard and Kazacos, 1997; Tiner, 1953).

ECTOPARASITES

Peromyscus are natural hosts to a wide variety of ectoparasites, including numerous species of fleas, ticks, and mites (Durden et al., 2004; Glicken and Schwab, 1980; Ritzi and Whitaker, 2003; Storm and Ritzi, 2008). While an extensive list of ectoparasites is beyond the scope of this chapter, it is worth noting that some parasite species that infect *Peromyscus* are important vectors of pathogens that affect humans and other animals. One example is the American dog tick (*Dermacentor variabilis*), which is commonly found on wild-caught *Peromyscus* and is a vector for *Rickettsia rickettsii*, *Francisella tularensis*, and *Coxiella burnetii* (Durden et al., 2004; Norment and Burgdorfer, 1985; Ritzi and Whitaker, 2003; Storm and Ritzi, 2008). Another example is the tropical rat mite (*Ornithonyssus bacoti*), which has been shown to harbor *Rickettsia* spp., *Yersinia pestis*, *Francisella tularensis*, and *Coxiella burnetii* (Baker, 2007; Durden et al., 2004). Additionally, *O. bacoti* itself can inflict a painful bite and cause dermatitis in humans (Baker, 2007; Morishita and Schaul, 2007). Some ectoparasite species that infect *Peromyscus* are well known to infect laboratory mice and rats, including *Myocoptes*, *Radfordia*, *Ornithonyssus*, and *Myobia* (Durden et al., 2004; Ritzi and Whitaker, 2003; Storm and Ritzi, 2008). Depending on the parasite species and burden, clinical signs may or may not be present and can include pruritis, alopecia, anemia, and anorexia (Wallach and Boever, 1983).

Bacterial Diseases

BORRELIA

Peromyscus leucopus is a primary natural reservoir for the spirochete *Borrelia burgdorferi*, which is the causative agent of Lyme disease (Bosler et al., 1983; Burgess et al., 1990; Levine et al., 1985; Steere et al., 1983). Transmission of this microorganism occurs through

the bite of nymph and larval stages of the tick vector, *Ixodes scapularis*, of which *Peromyscus leucopus* is a preferred host (Bosler et al., 1983; Levine et al., 1985; Steere et al., 1983). In *Peromyscus*, the organism has been demonstrated in skin, kidney, spleen, blood, and urine (Levine et al., 1985; Steere et al., 1983). *B. burgdorferi* generally does not cause clinical disease in *Peromyscus*, although systemic disease with neurological signs has been reported in a colony of captive wild-caught *P. leucopus* (Burgess et al., 1990). Contact transmission of *Borrelia* without a vector host has been demonstrated in *Peromyscus* (Burgess et al., 1986).

HELICOBACTER

Peromyscus leucopus has been shown to harbor *Helicobacter* species. A report of wild *Peromyscus leucopus* caught in traps within animal facilities at a large institution demonstrated by PCR analysis the presence of *H. rodentium* and *H. hepaticus* in the cecum, colon, and occasionally the stomach. No lesions were seen on gross examination (Dyson et al., 2009).

OTHER BACTERIA

Potentially zoonotic bacteria and rickettsial organisms that may be present in wild-caught *Peromyscus* but generally do not cause disease include *Francisella tularensis* (Burroughs et al., 1945; Wallach and Boever, 1983; Wobeser et al., 2007), *Yersinia pestis* (Barnes et al., 1974; Gage et al., 1995; Marchette et al., 1962), *Anaplasma phagocytophilum* (Ravyn et al., 2001; Stafford et al., 1999; Walls et al., 1997), *Coxiella burnetii* (Riemann et al., 1979; Wallach and Boever, 1983), and *Rickettsia rickettsii* (Magnarelli et al., 1981, 1984; Wallach and Boever, 1983).

Viral Diseases

HANTAVIRUS

Peromyscus are natural hosts for two hantaviruses found in North America. Sin Nombre virus is a hantavirus endemic in the *Peromyscus maniculatus* population in western North America (Childs et al., 1994; Hjelle et al., 1995). In humans, Sin Nombre causes hantavirus cardiopulmonary syndrome (HCPS), resulting in severe acute pulmonary edema and cardiac depression (Clement, 2003; Lednicky, 2003; Nichol et al., 1993; Schönrich et al., 2008). Zoonotic transmission of hantavirus occurs primarily through inhalation of aerosolized excreta (Hjelle and Glass, 2000; Tsai, 1987). In *P. maniculatus*, the virus localizes to the lung, heart, and brown fat; the animals mount an immune response and become chronically infected (Botten et al., 2000; Camaioni et al., 2001; Green et al., 1998). However, as with most natural hosts of hantaviruses, the animals do not develop clinical disease. Viral replication appears to be low in this species and the infection is not readily transmitted between animals (Green et al.,

1998). Epidemiological studies thus far indicate that the virus is not transmitted vertically (Borucki et al., 2000; Camaioni et al., 2001). New York virus is a more recently described hantavirus and has *P. leucopus* as its natural host. The virus is characteristically similar to Sin Nombre virus and also causes HCPS in humans (Lyubsky et al., 1996). A detailed histological study of *P. leucopus* naturally infected with New York virus demonstrated some pathologic changes consistent with HCPS in humans, including lymphohistiocytic infiltrates in hepatic portal zones and edematous alveolar septae in the lungs (Lyubsky et al., 1996).

Importantly, zoonotic transmission of hantavirus within an indoor laboratory animal facility has been described, and seroconversion in *Peromyscus* during quarantine has been documented (Camaioni et al., 2001; Tsai, 1987). The agents of HCPS are classified as biosafety level 3 (BSL-3) in tissue culture and animal biosafety level 4 (ABSL-4) in rodent hosts permissive to chronic infection (CDC-NIH, 2007). Therefore the Centers for Disease Control and Prevention recommends a quarantine for wild rodents. Published guidelines recommend a 5-week period of seronegativity prior to release from quarantine into the colony (Mills et al., 1995).

OTHER VIRUSES

In an experiment to investigate mouse hepatitis virus infection in *Peromyscus maniculatus*, animals were inoculated intranasally. While seroconversion did occur, clinical disease did not develop and the virus was not transmitted to susceptible laboratory mice (Silverman et al., 1982). Other viral diseases reported in *Peromyscus* include lymphocytic choriomeningitis virus, Western and Venezuelan equine encephalitis viruses, and St. Louis encephalitis virus (Chamberlain et al., 1964; Day et al., 1996; Donnelly and Quimby, 2002).

ANESTHESIA/ANALGESIA

Several inhalant and injectable anesthetic regimens have been used successfully in *Peromyscus*. For brief procedures requiring a greater degree of immobilization than can be afforded with manual restraint, the open-drop method of delivery using isoflurane is effective. Because of its higher vapor pressure along with blood and tissue solubility, concentrated isoflurane should be diluted to a 20% solution in propylene glycol when using the anesthetic in this manner (Itah et al., 2004). The use of precision vaporizers to administer either sevoflurane or isoflurane provides safe and effective anesthesia for surgical procedures or those necessitating a longer duration of immobilization of mice. Induction chambers provide a delivery method

that minimizes animal distress. Once the righting reflex is lost animals can be maintained by nose cone delivery of inhalant vapors of 1–2%. To reduce the risk of waste gas exposure to personnel proper scavenging methods should be utilized at all times.

Injectable agents can also be used to provide effective chemical restraint or anesthesia. Sedation without effective analgesia can be achieved with a ketamine dose of 44–50 mg/kg given intraperitoneally or intramuscularly (Scoles et al., 2001; Silverman and Ingram, 1986). Induction of anesthesia was reported to occur within 1 minute when a combination of ketamine (50 mg/kg) and medetomidine (1 mg/kg) was administered intraperitoneally to laboratory-bred deer mice (Hahn et al., 2005). An intraperitoneal dose of atipamezole (5 mg/kg) provides rapid recovery. Ketamine/medetomidine at these doses does not completely eliminate the response to noxious stimuli. Chloral hydrate was reported to provide effective long-term anesthesia in *Peromyscus* with an intraperitoneal dose of 630 mg/kg (Baumgardner and Dewsbury, 1979). Given its nature as a gastrointestinal irritant and propensity to induce adynamic ileus in several species, the use of chloral hydrate should be limited to non-survival procedures where other available anesthetic regimens are not suitable. At the authors' institution a combination of ketamine (50 mg/kg), xylazine (3 mg/kg), and acepromazine (1 mg/kg) administered intraperitoneally provides sedation suitable for non-invasive procedures. Anesthesia can be achieved with higher doses of intraperitoneal ketamine (150 mg/kg), xylazine (5 mg/kg), and acepromazine (2 mg/kg) allowing for surgeries of 35–55 minutes' duration (Veres, 2010).

The synthetic opioid, nalbuphine, has been used to safely provide analgesia in *Peromyscus* species. Doses similar to published recommendations for *Mus* (5.0 mg/kg) can be administered subcutaneously every 4 hours (Crossland, 2010).

INTRODUCTION

Human monkeypox (MPXV) infections were first diagnosed in the United States (US) in 2003 ([Centers for Disease Control, 2003](#)). Consequently, research efforts were directed to develop a rodent model that could be used to study the MPXV, as it was believed that the virus could be a bioterroristic agent and human MPXV infections appear clinically similar to variola (smallpox) virus infections ([Schultz et al., 2009](#)). [Schultz et al. \(2009\)](#) validated that *Graphiurus kelleni*, a species of African dormouse that is commonly known as Kellen's African dormouse ([Holden, 2005](#)), is highly susceptible to lethal infections with MPXV and a valuable animal model for the evaluation of prophylactics and therapeutics against MPXV infections. *G. kelleni* has risen from relative obscurity in the pet population to a validated research animal model. A few institutions currently house and maintain *G. kelleni* colonies to support MPXV research.

TAXONOMY AND HISTORY (TABLE 47.1)

Dormice are the only members of the Gliridae family that are located solely in sub-Saharan Africa. The family Gliridae contains 28 species in nine genera. It can be divided into three subfamilies: Graphiurinae (*Graphiurus*); Leithiinae (*Chaetocauda*, *Dryomys*, *Eliomys*, *Muscardinus*, *Myomimus*, and *Selevinia*); and Glirinae (*Glirulus* and *Glis*) ([Holden, 2005](#); [University of Michigan Museum of Zoology, 2009](#)).

To the author's knowledge, only three institutions currently house dormice for breeding and research applications: Saint Louis University, Arizona State University, and the Intramural Research Program at the National Institute of Allergy and Infectious Disease (NIAID) of the National Institutes of Health. Vendor-maintained dormice are not currently available.

Following initial human MPXV infections in 2003, traceback investigations implicated a shipment of animals from Ghana that was imported to Texas as the

TABLE 47.1 Taxonomic classification of Gliridae

Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Rodentia
Suborder: Sciuromorpha
Family: Gliridae

probable source of introduction of MPXV. The shipment contained approximately 800 small mammals of nine different species, including six genera of African rodents. These rodents included rope squirrels (*Funisciurus* sp.), tree squirrels (*Heliosciurus* sp.), Gambian giant rats (*Cricetomys* sp.), brush-tailed porcupines (*Atherurus* sp.), dormice (*Graphiurus* sp.), and striped mice (*Hybomys* sp.) (Centers for Disease Control, 2003).

In an attempt to contain the emerging MPXV outbreak, the Department of Health and Human Services (HHS) announced an immediate ban on importation of all African rodents. The ban also included the distribution, sale, transportation, and release of prairie dogs, which are believed to have carried MPXV to humans as well as the six other rodent genera mentioned above (Centers for Disease Control, 2003).

ANATOMIC CHARACTERISTICS

G. kelleni are relatively small rodents, with an average body length ranging from 7–10 cm, and with body weight ranging between 18 and 23 g. They are generally mouse-like in appearance, but resemble squirrels or chipmunks, as they possess furred tails. Their bodies are covered with thick, soft, golden brown fur (Figure 47.1). Dormice are mainly, but not exclusively, arboreal animals, and are agile and well-adapted to climbing as they possess well-developed footpads. *G. kelleni* are nocturnal and have an excellent sense of hearing, and can signal each other with a range of vocalizations. They are omnivorous, typically feeding on fruits, berries, flowers, nuts, and insects. *G. kelleni* and other dormice are unique among rodents in that they lack a cecum (Baudoin, 1984; Nowak, 1999). *G. kelleni* has a dental formula, I1/1, C0/0, PM0-1/0-1, M3/3 = 16 or 20, that is similar to that of squirrels, although they often lack premolars. The incisors are sharply pointed; premolars and molars are brachydont, and their occlusal surfaces are made up of a series of cusps and basins or parallel enamel ridges. The skull of the dormouse has an enlarged infraorbital foramen through which passes a slip of the medial

FIGURE 47.1 Juvenile Kellen's African dormice (*Graphiurus kelleni*).

masseter, as in other myomorphs. Nerves and blood vessels pass through this foramen as well as muscle. Dormice lack the separate infraorbital foramen, for the passage of nerves and blood vessels, that is found in dipodids. The zygomatic plate is not as strongly developed as in most other members of the group (Wahlert, 1978; Wahlert et al., 1993). Limbs are relatively short; feet are broad; and the toes are tipped with short, curved claws. The forefeet have four functional digits and hindfeet have five (University of Michigan Museum of Zoology, 2009).

HUSBANDRY

The distribution of the genus *Graphiurus* is primarily Eurasian, while *G. kelleni* (Kellen's dormouse) is unique by its African distribution. Consequently, native habitats and environmental conditions vary widely. Most species are considered hibernators (Bentz and Montgelard, 1999). *G. kelleni* seems to be the single exception as there are no observable signs of torporous behavior reported in captive research colonies. Knowledge of native food and conditions is limited for this family and few nutritional studies have been done (Nowakowski et al., 2006). The primary source of information available on husbandry, breeding, and health status is from the few known research colonies of *G. kelleni*.

NUTRITION

Non-captive diets are variable, but are reported to include seeds, fruits (Bentz and Montgelard, 1999) insects, small birds, and eggs (Konjevic et al., 2007). Captive *G. kelleni* obtained from domestic pet suppliers have been successfully maintained and propagated on standard laboratory rodent diets (e.g. PMI Rodent Diet 5001 and Teklad Global 18% Protein Rodent Diet 2018) with no additional supplementation. Water is offered ad libitum in bottles with sipper tubes. At least one research facility (NIAID) supplements the diet of dormice with meal worms and soy nuts as additional sources of protein and environmental enrichment (Kastenmayer et al., 2010).

HOUSING

In the wild, dormice live in small family groups with home ranges that vary widely between species depending upon the availability of food (Baudoin, 1984).

Bedding material used for *G. kelleni* ranges from packing paper (Mrosovsky et al., 1980) to other commercially available products, (e.g. Tekfresh and Diamond Soft (Harlan Teklad, Madison, WI)). Cage sizes range from standard (27 × 17 × 13 cm) to larger caging (37 × 22 × 19 cm) (Mrosovsky et al., 1980). *G. kelleni* anecdotally seems to benefit from enrichment with red plastic, miniature toy igloos (Bio-Serv, Inc., Frenchtown, NJ). Red igloos accommodate the nocturnal nature of dormice and allow them to control their level of light exposure in the home cage. It has been noted that *G. kelleni* hides by burrowing in the litter on the cage floor but will choose to remain in the igloo when available and bring the litter inside the igloo to build nests. Males are generally not aggressive and non-littermates may be successfully co-housed. The life span of dormice is up to 5 years.

ENVIRONMENTAL CONDITIONS

While *Gliridae* are considered to be hibernators under natural conditions, that is not the case under laboratory housing conditions. When *Glis glis*, the edible or fat dormouse, was kept under warm conditions it displayed cycles of torpor and weight loss lasting only a few weeks (Mrosovsky et al., 1980), as opposed to torpor lasting the entire winter in the wild. Laboratory-housed *Graphiurus* (*G. kelleni*) have not been noted to demonstrate torporous behavior (authors' observation; Schultz et al., 2009).

Environmental temperatures in the native habitats of the Eurasian and African species vary widely. Information available regarding temperature requirements of the

African genus is anecdotal from pet breeders. However, it is known (authors' observation; Kastenmayer et al., 2010) that *G. kelleni* will breed and thrive in temperatures between 21 and 27°C. Humidity levels can be maintained between 30 and 70% as for other rodent species.

Currently, there have not been any studies done to evaluate the effect of light cycles and intensity on this species. Dormice are reported to be nocturnal and light levels at facilities successfully maintaining dormice colonies have varied between 250 and 325 lux with the light:dark cycles varying between 12:12 and 14:10 (University of Michigan Museum of Zoology, 2009).

HANDLING

Dormice should not be handled by the tail because they are susceptible to degloving injury. *G. kelleni* is very quick when aroused and can climb slick surfaces easily and hide in small crevices. Manual restraint can be done by grasping the loose skin over the neck and back, and requires quick reflexes from the handler.

Captive dormice maintain prey characteristics in that they demonstrate a high level of fearful behavior when aroused or startled. This trait makes standard husbandry activities more challenging than for most rodent species. Development of techniques which accommodate the reticent nature decreases stress for both the animals and handlers. For example, during the daylight hours the animals will cluster in miniature plastic igloos provided for enrichment. The igloo and its occupants can then be picked up by the use of an enclosed scoop and moved, thus avoiding the fearful stimulus of handling. Igloos are also useful as nests for breeding pairs by allowing movement of the litter without disturbance.

BREEDING

In the wild, *Gliridae* typically breed once to twice a year with a gestation period of 21–32 days and have an average litter size of four pups, though litters can range in number of pups from 1 to 6. The number of pups per litter decreases as the female ages. Young are born altricial and the eyes open around 18 days of age. Dormice typically become sexually mature after the end of their first hibernation, with sexual maturity for the females occurring between 6 and 8 weeks of age as evidenced by the production of offspring (author's observation).

The gestation period of captive *G. kelleni* is similar to that of *Mus*. Breeding pairs consistently produce litters every 5–6 weeks and can maintain that level of fecundity for at least 2 years (author's observation). To date, no prospective studies have been done to determine longevity of

the reproductive state. Dystocia has not been noted in this species, but cannibalization of first litters is not uncommon. Birth defects have not been noted or reported.

Pups can be weaned at 21 days of age (Table 47.1). However, distinguishing the sexes is difficult prior to 6 weeks of age due to the visual similarity of the genitalia and lack of difference in anogenital distance. Manual palpation of the penis is the only reliable method in animals under 6 weeks of age. After 6 weeks the scrotal development provides visual evidence of sexual differentiation.

DISEASES AND ZONOSSES

The isolation of MPXV, a member of the Orthopox genus, from the outbreak in the United States brought the genus *Graphiurus* to world attention as these rodents were initially considered a possible source of infection (Hutson et al., 2007). There was some evidence that the imported animals had long-term exposure to MPXV, which would indicate that the pathogen could be endemic in *Graphiurus*. Other reports of diseases and zoonoses carried by the Gliridae family have been primarily determined from field studies on European species and are summarized here.

Encephalomyocarditis virus was isolated from dormice (*Glis glis*) in Italy in 1995. Although the rat is considered the main natural reservoir, domestic swine have experienced several epizootic outbreaks. In that instance, it was suspected that there was transmission between swine and dormice or other rodents in the area (Amaddeo et al., 1995).

Both edible dormice (*Glis glis*) and garden dormice (*Eliomys quercinus*) have been shown to be reservoir hosts for *Borrelia burgdorferi*, the spirochete responsible for Lyme disease, in central Europe (Matuschka et al., 1999). While there are at least four species of *Borrelia* capable of causing human disease, a novel strain of pathogenic spirochete designated as a “dormouse-associated genospecies” and named *Borrelia spielmani* was identified from the garden dormouse (Richter et al., 2004).

In Switzerland, a human case report of tularemia characterized by systemic illness and isolation of *Francisella tularensis*, sub sp. *holarctica* subsequent to a dormouse bite demonstrated the capacity of dormice to act as reservoir hosts for the causative agent of tularemia (Friedl et al., 2005).

The coccidian parasite *Eimeria* has been found and at least two species identified from the garden dormouse in Europe (Bertolino and Canestri-Trotti, 2005). The nematode parasite *Paraheligmomina gracilis* and cestode parasite *Hymenolepis sulcata* have been identified from *Glis glis* in Britain and several European countries. A weight comparison of infected animals versus non-infected animals showed no difference, implying an asymptomatic

infection. Despite the fact that this dormouse is considered a game animal and is sometimes used as a food source, neither of these parasites has been found in humans (Konjevic et al., 2007).

COLONY HEALTH MONITORING

Sentinel monitoring with the CD-1 strain of mouse using dirty bedding exposure transfer has been used by the authors to evaluate colony health of dormice. Serologic monitoring should include screening for Hantaan viruses along with testing for common pathogens of laboratory rodents. Examination of fecal material and cecal contents for endoparasites, and pelts for ectoparasites is recommended. Microbiological testing should include bacterial culturing of cecal, tracheal, and oropharyngeal surfaces and contents.

Laboratory-reared *G. kelleni* have very few health issues. The authors have not noted dermatitis, malocclusion, or neoplasia even in those dormice surviving for over 3 years. Occasionally the young will have stump tails that are presumed to be the result of trauma earlier in life. The remaining stump may be short or hairless and it does not appear to affect the animal in adulthood.

EXPERIMENTAL APPLICATIONS

As noted previously, the sole research interest in this species as an animal disease model in the result of the 2003 outbreak of human MPXV in the US which was the first report of human MPXV infection outside of Africa (Hutson et al., 2007). Although MPXV transmission between humans is not as efficient as smallpox, the zoonotic potential and the absence of widespread smallpox vaccination of human populations was recognized as a concern for spread of the disease (Parker et al., 2007). Because *G. kelleni* was associated with the initial zoonotic disease in the United States, it was chosen as a model. It does not appear that *G. kelleni* is currently used as a model for other diseases.

MPXV infection in *G. kelleni* appears to be disseminated systemically, with no single tissue noted as best for viral DNA testing. The brain, eyelid, gonad, lymph node, spleen, skin, liver, heart, lung, and tongue all gave DNA recovery rates above 80% (Hutson et al., 2007; Schultz et al., 2009). Histopathological changes associated with MPXV infection are shown in Figure 47.2.

Although a number of genera were found to be capable of carrying the MPXV (Hutson et al., 2007), *G. kelleni* has characteristics which make it one of the most practical for modeling the disease. For example, they can be housed in conventional rodent caging; they reproduce well under laboratory conditions; and they

FIGURE 47.2 Histopathologic changes in selected tissues of *G. kelleni* following a lethal intranasal infection with MPXV-ZAI-79. (A–D) Nasal mucosa, bar = 20 μ m. Submucosal inflammation, mucosal necrosis (arrow) and erosion/ulceration were observed with increasing severity over time; (E–H) submandibular lymph node, bar = 100 μ m. Necrosis (arrow) increased in severity and distribution over time; (I–L) Spleen, bar = 20 μ m. Increased death of lymphocytes were followed by the development of patchy areas of necrosis (arrow) over time; (M–P) Liver, bar = 100 μ m. Large necrotic foci (arrows) of hepatic parenchyma were observed at 8 days p.i., which corresponded to maximal viral load in this tissue. With permission from Schultz et al. (2009).

can be maintained free of common laboratory murine pathogens.

For personnel safety, anesthesia of the animals is recommended prior to experimental manipulation with this species. The same anesthetics as those used for laboratory mice can generally be used for *G. kelleni* (Schultz et al., 2009).

Footpad injection has historically been utilized as an infection route in pox virus studies, but its use sometimes results in lesions which are outside acceptable humane limits. In response, intranasal and intradermal infection techniques have been developed and validated (Parker et al., 2007).

BIOMETHODOLOGY

Collection of blood from the submandibular vein using the same technique as that used for laboratory

mice has been used in dormice, but with variable success. Injections sites are the same as for laboratory mice with the exception of intravenous injections since the tail is not an available site in *G. kelleni*. Non-survival blood collection can be performed by cardiac puncture. Euthanasia methods used for laboratory mice may be used in this species successfully.

INTRODUCTION

Taxonomy

The kangaroo rat is a member of the order Rodentia and family Heteromyidae. Heteromyidae contains nine genera and 60 extant species (Carrasco, 2000). The genus *Dipodomys* consists of 21 species, all of which inhabit North America (Donnelly and Quimby, 2002). *D. ordii*, or the Ord's kangaroo rat (Figure 48.1), is the most widely distributed species in the United States (Sjoberg et al., 1984). The Merriam's kangaroo rat (*D.*

merriami) and the bannertail kangaroo rat (*D. spectabilis*) are the most commonly studied species (Donnelly and Quimby, 2002). The diploid number for *Dipodomys* spp. ranges from 52–74 (Patton and Rogers, 1993).

Description

The common name “kangaroo rat” likely originated from descriptions of this animal's hind limb structure and characteristic hopping patterns. The kangaroo rat's hind legs and feet are long and powerful, especially

FIGURE 48.1 *Dipodomys ordii*, the Ord's kangaroo rat, is widely distributed throughout the United States. (Photograph courtesy of Mammal Image Library of the American Society of Mammalogists)

compared to their short weaker forelimbs (Sjoberg et al., 1984). Kangaroo rats have a predominantly bipedal, hopping style of locomotion involving the hind limbs (Alberta Ord's Kangaroo Rat Recovery Team, 2005). The feet of the kangaroo rat can be four-toed (Merriam's and Bannertail) or five-toed (Ord's) (Williams et al., 1993). The forelimbs are used mainly to grasp and manipulate small items (Sjoberg et al., 1984).

The coloring of the kangaroo rat varies with species, ranging from pale yellow to dark brown, frequently with a white belly (Sjoberg et al., 1984). The tail is usually dark in color, sometimes with lateral white lines that are a continuation of white hair from the thighs (Donnelly and Quimby, 2002; Sjoberg et al., 1984). The tail most often ends in a terminal tuft of longer hairs (Sjoberg et al., 1984). The tail of the kangaroo rat can be longer than the length of the head and body combined and is used for balancing during locomotion and as a prop while standing. Tail removal has been shown to result in little to no change in locomotion suggesting that the unusually long tail may have additional functions, such as fat storage (Donnelly and Quimby, 2002; Hafner, 1993; Sjoberg et al., 1984).

The size of the full-grown kangaroo rat varies greatly depending on species, ranging from 35.5–186.3g (Sjoberg et al., 1984). The largest species is the giant kangaroo rat (*D. ingens*), weighing between 133g and 186.3g. In contrast, the average adult Merriam's kangaroo rat weighs between 35.5g and 51.8g, while the Ord's kangaroo rat weighs between 44.3g and 74.0g. The length of the kangaroo rat ranges from 100–260mm. The adult Ord's rat is usually between 230–260mm in length (Alberta Ord's Kangaroo Rat Recovery Team, 2005). The head of the kangaroo rat can be as much as half of the overall length of the animal (Sjoberg et al., 1984).

Kangaroo rats have relatively poor eyesight, despite having unusually large eyes that are located high on

the skull (Sjoberg et al., 1984). Unlike other members of the family Heteromyidae, the cheek teeth of *Dipodomys* grow continuously throughout life (Donnelly and Quimby, 2002). Additionally, *Dipodomys* have external fur-lined cheek pouches, as well as dermal sebaceous glands that are located in the intrascapular region of the back (Donnelly and Quimby, 2002; Williams et al., 1993). See the section *Unique Anatomic and Physiologic Characteristics* for additional information on internal and external morphology of the kangaroo rat.

Distribution

Kangaroo rats are desert rodents. In North America, *Dipodomys* are found from southern portions of western Canada to central Mexico. In the United States, kangaroo rats range from California to central Kansas and Oklahoma (Sjoberg et al., 1984). *D. ordii* are located throughout the Canadian provinces of Alberta and Saskatchewan as well as throughout the western United States. *D. spectabilis* is found in Arizona, New Mexico, and western Texas, while *D. merriami* is located in the southwestern portion of the United States and northern Mexico (Donnelly and Quimby, 2002).

Habitat

The typical habitat of the kangaroo rat is one with high summer temperatures, low rainfall, and high evaporation rates (Sjoberg et al., 1984). Kangaroo rats are nocturnal animals and spend their daytime hours residing in burrows they construct from sandy or gravelly soil (Sjoberg et al., 1984). Peaks of activity occur shortly after sunset and just prior to dawn (Hills and Butler, 1978). Canadian kangaroo rats hibernate during the winter whereas kangaroo rats in the United States and Mexico do not (Alberta Ord's Kangaroo Rat Recovery Team, 2005).

Kangaroo rat burrows are refuges, sites of seed storage, and aid in thermoregulation. These animals compensate for their weak front limbs by burrowing in loose, easily workable soil, and certain species, such as *D. spectabilis*, construct elaborate labyrinths of tunnels (Donnelly and Quimby, 2002; Sjoberg et al., 1984). Burrows are often constructed in sparsely vegetated areas to allow for unobstructed views of the area, which assists animals in identifying predators and aids in defense of their burrows from other kangaroo rats. Adult animals often reside alone with male burrows interspersed among female burrows. Burrow sharing is noted during mating and when young animals are being reared (Sjoberg et al., 1984). An adult male kangaroo rat can have an average home range of one-half acre (21780sq. feet) (Sjoberg et al., 1984).

Behavior

Kangaroo rats are predominantly solitary in nature and spend up to 80% of their time in their burrows (Sjoberg et al., 1984). Animals can hop at speeds of up to 12 mph with individual hop lengths of 24–28 inches (61–71.1 cm) (Muths and Reichman, 1996; Sjoberg et al., 1984). The locomotion of the kangaroo rat helps prevent predation from a number of natural predators, which include great horned owls, barn owls, red-tailed hawks, rattlesnakes, gopher snakes, gray foxes, kit foxes, bobcats, coyotes, and occasionally skunks (Sjoberg et al., 1984). When predators are in close range, kangaroo rats defend themselves by puncturing predators with the nails of their hind feet. Kangaroo rats can be very aggressive both in nature and in the laboratory setting. These animals have been reported to bite handlers, although over time they can become much tamer (Sjoberg et al., 1984).

Foot drumming is another possible anti-predator action for some species of kangaroo rats. The behavior consists of repeated strikes of the hind feet on the ground. The bannertail kangaroo rat is thought to foot drum to alarm and frighten predators, especially snakes (Sjoberg, 1984). In contrast, the Great Basin kangaroo rat (*D. microps*) foot drums before and after mating, similar to what has been noted in gerbils during mating (Randall and Stevens, 1987).

BIOLOGY

Unique Anatomic and Physiologic Characteristics

External Morphology

The head of the kangaroo rat is broad, flat, and triangular with large protruding eyes. The neck is short and the cervical vertebrae are partly fused (Williams et al., 1993). The pinnae are of normal size, and the lining of the external auditory meatus contains ceruminous glands that are sebaceous in nature rather than modified tubular glands, likely an adaptation for water conservation (Webster, 1966). A hypertrophied mastoid region results in a middle ear volume that is greater than the volume of the brain and is the main cause for the triangular appearance of the kangaroo rat's head. The mastoid's large size is thought to narrow the supraoccipital bone in the midline, push the parietal forward, reduce the squamosal in the posterior orbit wall to a small bone, and render the interparietal almost non-existent (Webster and Webster, 1972). The tympanic membrane of a 40-g *D. merriami* was reported by Webster and colleagues (1966) to be approximately 5.5 mm by 1.0 mm with a surface area of 25.9 mm². The manubrium of the

malleus and process of the incus are long in length and this feature, paired with the large middle ear cavity that decreases the damping of the tympanic membrane, allows kangaroo rats to be sensitive to sounds at both low and high frequencies (100–30 000 Hz) (Hafner, 1993). In a field study conducted by Webster and Webster (1966, 1971), the middle ear volume of kangaroo rats was experimentally reduced and the response to predation by owls and rattlesnakes was tested. Sonographic analysis of the sounds produced by snakes and owls during the time of predation fell within the 1000–3000-Hz range. Normal kangaroo rats were more successful in avoiding predation than those with reduced middle ear volume, especially during the dark phase of the moon when lighting was poor.

Kangaroo rats have a highly developed sense of smell that allows them to find hidden food caches and identify reproductively active sexual partners during mating periods (Sjoberg et al., 1984). Fur-lined cheek pouches, similar to those of gophers, allow kangaroo rats to carry seeds to their burrows and arrange them below ground. Transporting seeds in such a manner promotes the growth of a diverse population of fungi and mold in the cheek pouches of the wild kangaroo rat (Wicklow and Rebar, 1988).

Internal Morphology

Midgley (1938) reported on the results of an investigation of the visceral anatomy of *D. microps levipes*, and the reader is directed to his work for detailed pictures and descriptions. Several points of interest will be discussed here.

The gastrointestinal tract of the kangaroo rat includes several unique features that differentiate it from that of other rodents. The small intestine is short, only about twice the length of the large intestine, suggesting that the cells and mucous lining of the small intestine are specialized. The cecum is large and the large intestine is long and highly coiled. Heteromyids, in general, tend to have a distinct colon morphology that includes thick epithelial cells on the mesenteric side that are likely specialized for absorption. Additionally, a limited number of secretory goblet cells have been noted in the colon of the kangaroo rat, along with prominent venous and lymphatic drainages (French, 1993). These characteristics likely allow water to be resorbed from feces, assisting in overall water conservation (French, 1993). Irradiation experiments indicate that the normal intestinal flora of the kangaroo rat is similar to the rabbit and includes *Lactobacillus acidophilus*, other lactobacilli, *Nocardia* spp., *Streptomyces* spp., apocyanogenic pseudomonads, and streptococci (Haley et al., 1960).

The liver has four lobes: the median or cystic lobe, the right lateral lobe, the left lateral lobe, and the caudate or Spigelian lobe. The cystic and right lateral lobes

¹Haley (1964).²Eisenberg and Isaac (1993).

are each further divided into two halves. Kangaroo rats do not have gall bladders (Midgley, 1938).

The parotid and submaxillary glands of the kangaroo rat are large, and additionally, molar glands (close to molars, between skin and external surface of the mandible) are present (Midgley, 1938). The presence and size of such glands correlates with the dry diet and environment of the kangaroo rat and the need for added moisture during mastication (Midgley, 1938). Large Harderian glands are present in the orbit of the kangaroo rat, encircling about half of each eye and running down towards the optic nerves (Midgley, 1938).

The right kidney is slightly larger in size than the left; approximately 181840 glomeruli per kidney with a total glomerular volume per kidney of 8.9mm³ has been reported for the kangaroo rat (Haley, 1964). A long tapering papilla and lobulate glomerulus have also been noted. The glomerular filtration rate of *D. merriami* is 0.77 ± 0.004 ml/min/100g and the collecting ducts are long with cuboidal to flattened to cylindrical-shaped shifting epithelial cell lining (Haley, 1964). Adrenal glands are slightly smaller in males than in females (Midgley, 1938).

The right lung has four lobes: superior, middle, inferior, and medial or postcaval. The left lung has only one lobe. The great blood vessels are similar to most rodents,

with a few slight variations. The aortic arch gives off three branches: left common carotid, left subclavian and innominate branch, which further branches into the right subclavian and the right common carotid artery. The left and right superior venae cavae, the inferior vena cava and the azygous vein enter the right auricle directly (Midgley, 1938). The heart rate of a kangaroo rat is about 420bpm and the respiratory rate about 140bpm (Hills and Butler, 1978). Additionally, the thymus is bilobed (Midgley, 1938).

Development

Developmental characteristics for multiple species of kangaroo rats have been observed in the laboratory setting. Table 48.1 presents information for several *Dipodomys* species.

In Ord's kangaroo rats, both true hermaphrodites and pseudohermaphrodites have been found (Bawdon, 1965; Pfaffenberger et al., 1986). Out of a population of 124 live-trapped Ord's kangaroo rats in New Mexico, 16.1%, or 34% of the non-female animals, were male pseudohermaphrodites. It was noted that the weight of the male pseudohermaphrodite was slightly greater than normal male kangaroo rats of similar age (Pfaffenberger et al., 1986).

TABLE 48.2 Hematology Values for *D. merriami*

Cell type	Blood value (± SE)
Erythrocytes	$8.55 \pm 0.22 (\times 10^6 \text{ mm}^3)$
Platelets	$621 \pm 0.33 \text{ mm}^3$
Hematocrit	$47.3 \pm 0.7\%$
Hemoglobin	$13.2 \pm 0.22 \text{ g}$
Total leukocytes	$7.77 \pm 0.62 (\times 10^3 \text{ mm}^3)$
Lymphocytes	$81.4 \pm 1.49\%$
Monocytes	$3.2 \pm 0.40\%$
Neutrophils	$12.6 \pm 1.23\%$
Basophils	$2.6 \pm 0.36\%$

Table modified from Haley (1964).

Hematological Characteristics

Haley and colleagues (1960) studied the hematological characteristics of *D. merriami* (Table 48.2) and the response of this species to whole-body ionizing irradiation, which was found to be similar to the albino rat. A few findings of note were that lymphocytes constituted about 80% of the leukocyte population, and that despite the various water conservation specializations of the kangaroo rat, hematocrit values for *D. merriami* ranged between 46–48%.

Nutrition

Seeds make-up approximately 78.4% of the diet of the kangaroo rat, while 15.5% consists of insects, and the remaining 1.1–6.1% consists of green vegetation (Reichman, 1975). Seedlings, which are high in the vitamin A precursor carotene, are often the vegetation of choice, and the amount consumed depends largely on the availability of seeds (Reichman, 1975; Sjöberg et al., 1984). Sjöberg et al. (1984) listed the favored vegetation and grasses of the kangaroo rats in California as brome grasses (*Bromus* spp.), filaree (*Erodium* spp.), and fescues (*Festuca* spp.), whereas in the southwest, kangaroo rats preferred grama grasses (*Bouteloua* spp.), needlegrass (*Stipa* spp.), pigweed (*Amaranthus* spp.), fescues (*Festuca* spp.), and plantain (*Plantago* spp.). Forb seeds were the primary seed type consumed by *D. merriami* and other Sonoran Desert rodents (Reichman, 1975).

Kangaroo rats commonly gather seeds and other food items and place them in caches, or temporary storage sites in the soil close to their burrows. Seeds are usually transferred from the cheek pouch of the kangaroo rat to the cache (Sjöberg et al., 1984). Caches are typically located somewhat close to the surface facilitating seed retrieval via smell. A soil depth of 0.25 inches was reported for caches of Merriam's kangaroo rats in Arizona

(Sjöberg et al., 1984). Caching not only provides a safe place for food stuffs, but burying seeds enhances their water content, as the soil promotes water absorption.

Some kangaroo rats regularly practice coprophagy. *D. microps* is a herbivorous kangaroo rat species that ingests close to one-quarter of the feces it produces daily (Kenagy and Hoyt, 1980). In contrast, the granivorous *D. merriami* species rarely ingests feces, suggesting that the extent to which different species of kangaroo rats practice coprophagy depends on their specific diet (Kenagy and Hoyt, 1980). For those species that do ingest their feces, a pattern of coprophagy is observed: all the feces produced during the non-foraging period are ingested, while no feces are ingested during periods of foraging.

Reproduction

The gestation length of the kangaroo rat is 29–33 days, with *D. microps* reported as 31 days, *D. merriami* as 33 days, and *D. ordii* as 29–30 days (Day et al., 1956). Typical litter size is 1–4 offspring, often with fewer than ten offspring born to one dam within 1 year (Wilson et al., 1985). Newborn kangaroo rats are similar in appearance to newborn mice, with notable differences being that the toes of the kangaroo rat are separated at birth and cheek pouches are present as small grooves on either side of the mouth (Eisenberg, 1993). Weaning has been observed in wild *D. spectabilis* at 1 month of age (Jones, 1984). It was speculated that small litter size in these desert animals may conserve body fluids by lessening the lactation demand, though it should be noted that the long hind feet of fetuses may necessitate smaller litters during intrauterine development (Eisenberg and Issac, 1963).

In nature, kangaroo rats practice natal philopatry, or the retention of offspring in natal home ranges past the age of independence from their parents. Both male and female offspring tend to stay with their mothers in their natal mounds for the first 3–4 months of life. This is despite the fact that lactation ends at 1 month of age and that offspring are capable of foraging for themselves at this point in time. Some juveniles have been noted to stay in the natal mound until sexual maturity. These animals may then go on to settle into a secondary mound within the maternal home range or acquire their mother's primary mound when she vacates it or dies. Possible reasons for such behavior include the lack of resources available during the spring when young are born, or that space to build mounds is sparse and requires a great deal of energy expenditure (Jones, 1984).

Sexual maturity is reached at 1 year of age and banner-tail kangaroo rats in nature live through a maximum of three reproductive seasons as adults (Jones, 1984). The estrous cycle for *D. microps* and *D. merriami* is 12

or 13 days long, respectively, with a luteal phase of 1 week. Females are more active during estrous and those in nature are noted to travel more during this period. Vulvar swelling and vaginal opening are signs of estrus. The receptive phase of the estrous cycle is confined to a single day. Slight vaginal bleeding may precede estrus by 2 or 3 days. Vaginal casts consisting of crusty, flaking material have been seen immediately after estrus. Vaginal cytology has been reported to be of little help in determining cycle stages (Jones, 1984). Spontaneous ovulation and corpus luteum function is noted in kangaroo rats, and fertile matings have been noted to occur at first estrus cycling (Daly et al., 1984).

The kangaroo rat placenta is chorioallantoic with trophoblast cells constituting up to two-thirds of the total mass of the placenta (Fuller and Tibbitts, 1973). Young are born without membranes and the umbilical cord is broken by movements of the offspring and the mother. The mother will ingest the placental tissues (Eisenberg and Issac, 1963).

Kooyman (1963) analyzed the milk of a lactating *D. merriami* and found that the milk was relatively low in water content (50.42%). Kangaroo rats spend the hottest portion of the day in their burrows to minimize water evaporation, and it was speculated that offspring may have a lower requirement for water compared to other rodents.

DISEASES

Infectious Diseases

Viral

Five viruses have been reported in wild kangaroo rats, all of which are arboviruses (Whitaker et al., 1993). Powassan virus, Modoc virus, and St. Louis encephalitis (all *Flaviviridae* viruses) have been reported in *D. heermanni*. Bottonwillow virus (*Bunyaviridae*) and Western equine encephalitis (*Togaviridae*) have been reported in *D. nitratoides*. Arthropod vectors are associated with all of these viruses, and clinical disease is uncommon (Whitaker et al., 1993).

Rickettsial

Rickettsia rickettsii infection has been identified in *D. californicus*, *D. microps*, and *D. ordii*. *Coxiella burnetii* infection has been identified in *D. microps* and *D. ordii*. *Coxiella* spp. cause Q fever in humans and are normally carried by the tick *Dermacentor andersoni*. *D. microps* remains infected with *C. burnetii* for up to several months and may therefore represent a reservoir (Whitaker et al., 1993). *R. rickettsii* leads to Rocky Mountain spotted fever and is carried by a number of ticks.

Bacterial

Yersina pestis-positive kangaroo rats were noted in the wild in New Mexico (Whitaker et al., 1993). *Y. pestis* is the causative agent of plague and the true susceptibility of kangaroo rats to *Y. pestis* is unknown. Experimental inoculations of *D. spectabilis* and *D. ordii* showed that these species of kangaroo rat were less susceptible to infection following inoculation than mice (Whitaker et al., 1993).

Francisella tularensis, the causative agent of tularemia or plague-like disease of rodents, has been isolated in *D. ordii* and *D. microps* in Utah (Whitaker et al., 1993).

Parasitic

Various species of protozoa, cestodes, flies, mites, ticks, and fleas have been reported in wild-caught kangaroo rats. Table 48.3 is a partial list of these parasitic infections; the reader is directed to Whitaker et al. (1993) for a more comprehensive list of parasitic agents. There do not appear to be reported cases of parasitism in laboratory-reared kangaroo rats (Donnelly and Quimby, 2002).

Fungal

Mold and fungi were discussed briefly in the *Unique Anatomic and Physiologic Characteristics* section, and the reader is directed to Whitaker et al. (1993) and Wicklow and Rebar (1988) for more information on fungal and mold species noted in the kangaroo rat.

Metabolic/Nutritional Diseases

Suckow et al. (1996) reported an obstructive gastric trichobezoar in a male wild-caught bannertail kangaroo rat. The animal presented clinically as emaciated, listless, and hypothermic. At necropsy, a $1.9 \times 1.2 \times 0.9$ cm dark, hard, brown mass was noted in the gastric lumen. Microscopically, the mass was composed of shafts of hair and proteinaceous material. Excessive oral grooming was listed as a possible cause.

Iatrogenic Diseases

McGinn and Faddis (1997) reported that, like the Mongolian gerbil (*Meriones unguiculatus*), kangaroo rats develop spongiform degeneration of the central auditory system in response to prolonged exposure to low-frequency noise. Wild-caught *D. deserti* and *D. merriami* developed excitotoxic neuronal damage presumably secondary to sustained release of an amino acid neurotransmitter, such as glutamate.

Neoplastic Diseases

Mammary gland adenocarcinoma in a female kangaroo rat housed at a zoo has been reported (Griner, 1983).

USE IN RESEARCH

Water Conservation

The water conservation specializations of the kangaroo rat make it an interesting model for the study of renal physiology and related topics. Turnover times

for exchangeable body water of the kangaroo rat are long: 13.9–22.1 days for the *D. deserti* on a pearl barley diet (Haley, 1964). The mean exchangeable body water content for *D. deserti* is $62.37 \pm 2.16\%$ (Haley, 1964). Kangaroo rat urine is as much as five times more concentrated than human urine. The kidney structure of the kangaroo rat plays a large part in water conservation in this animal and is described further in the section *Unique Anatomic and Physiologic Characteristics* of this chapter. Antidiuretic hormone also impacts the water-conservation properties and urine-concentrating abilities of the kangaroo rat. The kangaroo rat excretes up to 50 milliunits/ml of antidiuretic hormone in the urine, and levels of 0.9 milliunits/ μg were noted in the posterior pituitary gland (Haley, 1964).

In the lungs, ventilation is decreased to reduce water loss (Sjoberg et al., 1984). Kangaroo rats have few to no sweat glands, thus water excretion is handled by other organs such as the lungs and kidneys, which are adapted for water conservation.

Disuse Osteoporosis

The bipedal nature of the kangaroo rat, paired with the animal's ability to hop great distances, puts large accelerative forces on the hind limb musculature and bones, affecting bone remodeling. Muths and Reichman (1996) reported that routine handling and locomotion of kangaroo rats during short periods of laboratory captivity (7–10 days) resulted in hind limb fractures. Additionally, experimental confinement may weaken the bones of the hind limb and decrease mineral content, making the kangaroo rat a valid model for studying disuse osteoporosis. The fact that kangaroo rats eat predominantly seed diets and can thrive in an environment with little to no free water, may also make them valuable models for space research that focuses on the study of disuse osteoporosis secondary to microgravity (Muths and Reichman, 1996).

Marginal Decompression Sickness

Kangaroo rats have been suggested as an alternative to goats as an animal model to study type I decompression sickness (diver's disease). Hills and Butler (1978) found that kangaroo rats reliably bit their tails during decompression procedures in hyperbaric chambers; and tail biting ceased with reversal of the decompression. Microbubbles were noted between the fibers of tendon bundles in the bitten areas of the tail. Similar gas bubbles are noted in humans at the nerve endings of connective tissue and it is thought to be the cause of "limb bends" in deep sea divers (Hills and Butler, 1978).

LABORATORY CARE

Housing

In the laboratory, kangaroo rats have been housed on sand and soil substrates (1–2 in or 2.5–5.1 cm thick), provided with cotton as nesting material, and given cardboard tubing or dark glass bottles to act as an artificial burrow (Haley, 1964). Polycarbonate rat cages (10.5 × 9.5 × 8 in or 26.7 × 24.1 × 20.3 cm) are adequate for laboratory housing (Suckow et al., 1996). Room conditions of 12:12 light:dark cycles, 71.5°F (21.9°C) and 27% relative humidity have been reported in the literature (Muths and Reichman, 1996). Suckow et al. (1996) reported room conditions of 62–65°F (16.7–18.3°C) and room ventilation of 10–15 room changes per hour of fresh outside air. Severe fighting has been reported among newly combined captured kangaroo rats, including breeding pairs, and gradual, supervised introduction is recommended (Booth, 1943). Life spans of 2–5 years have been reported in kangaroo rats (Hooper, 1956; Sjöberg et al., 1984).

Dust bathing is practiced by kangaroo rats in the wild and dust bath sand, such as the type used with chinchillas, or a similar substrate should be made available to laboratory-maintained kangaroo rats. If not able to dust bathe, body sores and hair mats can develop on the body from a build-up of oily secretions (Nowak, 1999).

Nutrition

Many foods have been offered to kangaroo rats in the laboratory setting. A diet of sunflower seeds, wheat, rolled oats, spinach, or lettuce and fresh water offered ad libitum has been used successfully (Butterworth, 1961; Daly et al., 1984). Others have fed an even more varied diet consisting of rolled oats, rolled barley, meat meal, powdered milk, whole wheat kernels, cod liver oil, sunflower seeds, mixed bird seed, iodized salt, powdered calcium carbonate, lettuce, millet, and dried dog food (Haley, 1964). Eisenberg and Isaac (1963) warn against offering water ad libitum to captive kangaroo rats that are used to periods of seasonal drought. The continual availability can lead to water addiction by these animals, and they can develop a diabetes insipidus-like syndrome (Donnelly and Quimby, 2002). Carrots and lettuce have been recommended as sources of water (Booth, 1943).

Breeding

A variety of kangaroo rat species have been bred in the laboratory setting. The reader is directed to Butterworth's (1964) observations on breeding *D. deserti* and *D. merriami* in captivity.

Daly and colleagues (1984) successfully bred *D. merriami* and *D. microps* in the laboratory under the following conditions. Kangaroo rats were housed in Plexiglas® cages (33 × 17 × 28 cm or 13 × 6.7 × 11 in) at 22°C (71.6°F) with a 13-hour light cycle (lights on at 10:00 pm and off at 11:00 am). *D. microps* were housed separately and males and females only introduced briefly during estrus, due to the high prevalence of fighting noted in this species of kangaroo rat. Introduction was performed in a neutral cage and under close supervision. For the less-aggressive *D. merriami* species, one male and one female could be housed in linked cages joined by a tunnel. At the end of the tunnel was a guillotine door that could join or block the two cages depending on its position. In this set-up, after several gradual introductions of the pair, animals could be combined peacefully for a 24-hour period during estrus.

When combined with a female in estrus, a male kangaroo rat will initially rush, chase, and spare the female, followed by nosing and grooming. He will finally lick the female's perineal region and mount her. Mounting often lasts 1–7 min, and although it can occur several times, only the final mount will result in copulation (Haley, 1964). Observation of a copulatory plug after intromission is indicative of successful copulation. Pregnant females can be supplemented with powdered skim milk added to the diet (Daly et al., 1984).

Daly (1984) weaned pups of both *D. merriami* and *D. microps* at 25 days of age. Kangaroo rats do not appear to have a postpartum estrus and females can conceive up to 4 days later. Cyclic cessation and prolonged anestrus can occur if males and females are kept in continuous proximity (Haley, 1964).

Anesthesia and Euthanasia

Kangaroo rats are more sensitive to combinations of ketamine and xylazine than gerbils or mice. An initial dose of 40 mg/kg ketamine and 10 mg/kg xylazine, followed by supplemental doses of 10/2.5 mg/kg ketamine/xylazine has been used for successful kangaroo rat anesthesia (McGinn and Faddis, 1997). Inhalant agents, such as isoflurane, are another anesthetic option, and may be preferable over ketamine/xylazine. Indirect supplemental heat should be provided to maintain the core body temperature. Optimally, a rectal temperature of 38 ± 0.5°C should be maintained throughout surgery (McGinn and Faddis, 1997).

Euthanasia via cardiac puncture and exsanguinations under inhalant anesthesia, or pentobarbital anesthesia (120 mg/kg administered intraperitoneally) has been reported (McGinn and Faddis, 1997; Suckow et al., 1996).

INTRODUCTION

Description

The cotton rat, *Sigmodon hispidus*, is a New World rodent with a stocky, robust stature (Figure 49.1). While the cotton rat has been classified in the family Muridae by one source (Niewesk and Prince, 2002), most sources assign it to the family Cricetidae (Faith et al., 1997; University of Michigan, 2010; Wilson and Reeder, 2005). Average adult weight is between 100–250 grams. The name *Sigmodon* derives from the sigmoid enamel loops on the grinding surface of the molar (Faith et al., 1997). Sexual dimorphism is not prominent, but males and females can be distinguished based on the size of the genital papilla and distance from the anus (Faith et al., 1997). The term *hispidus* refers to pelage with coarse guard hairs (Davis and Schmidly, 1997). The cotton rat is distinguished from the Norway rat by its smaller size, shorter tail, and longer grizzled fur (Hawthorne, 1994). Depending on the source there are up to 14 *Sigmodon* species (Musser and Carleton, 2005). There is

little phenotypic difference between species, but there is striking karyotypic diversity, ranging from 22 chromosomes for *S. arizonae* to 52 for *S. hispidus* (Prince, 1994). The lifespan of the hispid cotton rat is less than 6 months in the wild (Cameron and McClure, 1988). In captivity animals have a survival span up to 23 months of age (Faith et al., 1997).

Distribution and Habitat

Cotton rats range over most of the southern United States, Mexico, Central America, and into Columbia and Venezuela (Hawthorne, 2005; Prince, 1994). For the most part, cotton rats reside in dense, grassy cover such as fencerows and marshy fields. They nest in burrows approximately 3–5 cm in diameter and no longer than 8 meters in length, or in above-ground mounds of grass, weeds, or brush (Davis and Schmidly, 1997). Cotton rats can be nocturnal, diurnal, or crepuscular in the wild, but can change from nocturnal to diurnal under laboratory conditions (Faith et al., 1997; Niewiesk and Prince,

FIGURE 49.1 *Sigmodon hispidus* adult.

2002). In the wild, the cotton rat diet centers around primarily seeds and plants. However cotton rats are known to eat small birds, eggs, and insects (Hawthorne, 2005). In the wild, lifespan is short- between 4–6 months (Faith et al., 1997).

Sources

Cotton rats are available from commercial sources in both Europe and the United States. These colonies were derived originally from inbred stock held at the National Institutes of Health but are currently maintained as outbred lines (Harlan Laboratories, 2010; Niewiesk and Prince, 2002).

BIOLOGY

Anatomy and Physiology

Physical features, general biology, clinical pathology, and physiologic features of the cotton rat have been summarized by Faith et al. (1997), and Sharp and La Regina, 1998. Selected hematologic parameters and organ weights are summarized in Tables 49.1 and 49.2. It has been reported that cotton rats convert 7-alpha-hydroxycholesterol to 7-alpha-hydroxy-4-cholesten-3-one similar to the laboratory rat, but which differs from the predominant pathway in hamsters (Maeda et al., 2006).

Phenotypic hair coat mutants have been described by Niewiesk and Prince (2002). These include a white pelage with black eyes, a partially white hair coat, and a white-footed variety. Some of these variations appear

TABLE 49.1 Hematology Data for Cotton Rats

Total protein (g/dl)	6.7–7.2
WBC ($\times 10^3/\mu\text{L}$)	3.9–11.9
Lymphocytes ($\times 10^3/\mu\text{L}$)	3.2–7.4
Neutrophils ($\times 10^3/\mu\text{L}$)	2.2–9.2
Eosinophils ($\times 10^3/\mu\text{L}$)	0.1–0.8
Splenocytes ($\times 10^6$)	135 (18)

TABLE 49.2 Selected Organ Weights of Cotton Rats

Parameter	7-Week Data (Standard Deviation)	13-Week Data (Standard Deviation)
Relative Organ Weight (% body Weight)	n = 11 (Liver, n = 10)	n = 12
Liver (g/g)	3.6 (0.4)	2.9 (0.3)
Kidneys (mg/g)	655.0 (27.8)	563.4 (23.4)
Adrenals (mg/g)	30.9 (4.8)	22.5 (1.6)
Thymus (mg/g)	28.9 (6.5)	43.3 (8.9)
Spleen (mg/g)	97.7 (9.1)	103.5 (7.3)
Popliteal lymph nodes (mg/g)	3.4 (0.7)	2.5 (0.3)
Absolute organ weight	n = 6	n = 6
Testes (g)	2.23 (0.13)	1.56 (0.32)
Seminal vesicles (g)	1.53 (0.23)	0.89 (0.31)
Epididymes (mg)	550.6 (36.8)	376.7 (89.7)
Coagulating gland (mg)	288.7 (53.0)	57.1 (18.9)
Ovaries (mg)	36.6 (7.3)	35.9 (3.3)
Uterus (mg)	264.3 (92.1)	159.7 (36.0)

Combined data from male and female control animals on 7- and 13-week toxicology study (McMurry et al., 1995).

to be recessive lethal mutations. Cotton rats have been described to have two left and three right lung lobes and 4–13 Peyer's patches in the intestine (Niewiesk and Prince, 2002). However, Faith et al. (1997) list one left and four right lung lobes. It is likely that this discrepancy is related to anatomical terminology, as necropsy performed on animals from the authors' institution revealed one left and three right lung lobes, and one accessory lobe. Like many small rodents, the cotton rat has a squamous and glandular region of the stomach, a large cecum, and is coprophagous. The dental formula is I(1/1) C(0/0) P(0/0) M(3/3). Normal rectal temperature is 36.5°C. The tail is an important organ for thermoregulation.

Data for hematological parameters and normal adult organ weights are presented in Tables 49.1 and 49.2, respectively.

Reproduction and Growth

Cotton rats are generally solitary in the wild (except for mothers with nursing litters) with males and females only coming together to mate. In the wild, males are dominant to females, and adults are dominant over juveniles (Faith et al., 1997). However, in the laboratory environment, they can be maintained as breeding pairs and aggression is seen by females directed toward males. To minimize this problem, some sources indicate breeding pairs should be established at 3 weeks of age (Harlan Laboratories, 2010; Prince, 1994). Animals are not sexually mature at this age, and the first litter is not seen until approximately 6–7 weeks after mating. However, others recommend separating animals by gender at weaning, and not mating until 5 weeks (Ward, 2001) or 7–8 weeks of age (Faith et al., 1997). Both systems seem to be effective, as reproductive parameters are reported to be similar by all sources. When mating, it is recommended that the female be introduced to the male's cage to minimize the risk of fighting (Niewiesk and Prince, 2002; Ward, 2001). Harem mating with one male and two females can be performed, but this increases the risk of fighting (Niewiesk and Prince, 2002). It is not recommended to separate the male and female at the birth of the litter, or to re-pair animals if one of the pair dies, as aggression is seen in these situations (Faith et al., 1997).

Cotton rats are reported to be spontaneous ovulators and breeding is not seasonal in the laboratory environment (Faith et al., 1997). The estrous cycle duration is 7–9 days, gestation is 27–28 days and cotton rats produce on average of five pups per litter, with a range of 1–12. A post-partum estrus occurs within 12 hours of parturition (Faith et al., 1997; Harlan Laboratories, 2010; Niewiesk and Prince, 2002; Sharp and La Regina, 1998; Ward, 2001). Some sources discourage handling the

FIGURE 49.2 A 1-day-old cotton rat (*Sigmodon hispidus*) demonstrating semi-precocial features.

pups immediately after parturition, as this can be associated with maternal cannibalism (Faith et al., 1997). Weaning is typically performed at 2–3 weeks of age. The interval between litters is approximately 1 month for continuously mated pairs (Mitchell, 2009; Niewiesk and Prince, 2002).

Birthing has been described by Ward (2001). Animals normally birth during the night, but can become acclimated enough to staff for birthing to be observed during the day. Experienced females build nests prior to parturition. The animal becomes restless and muscular fasciculation can be observed along the animal's side. Grooming of the perineum occurs right before delivery. The female may assist with pulling out and opening the fetal sac. The young are born semi-precocious with a full hair coat (Figure 49.2). Eyelids are closed at birth and are generally considered to open at 3 days (Faith et al., 1997; Niewiesk and Prince, 2002; Watkins, 2010). However, Sharp and La Regina (1998) list that eyes open at 1 day. Incisors erupt at 5 days. Niewiesk and Prince (2002) and Faith et al. (1997) indicate that young can survive by this age.

First estrus in females and testicular descent in males is reported at 20–30 days, with puberty at 30–40 days (Faith et al., 1997). Niewiesk and Prince (2002) report sexual maturity at 6 weeks (42 days), while Sharp and La Regina (1998) list a range of 30–50 days.

Diet, social environment, and photoperiod can affect sexual maturation. In one study, onset of estrus was not seen until 95 ± 5.88 days on a 4% protein diet, while estrus was seen at 63.9 ± 6.62 days on an 11% protein diet. In this study, animals on the 4% protein diet did not become pregnant. It was noted that estrus occurred at a similar body mass regardless of the diet fed (64.6–66.3 g body weight) (Cameron and Eshelman, 1996).

Social environment has an effect on the age of sexual maturation. Co-housing juvenile females with males affected the age of vaginal perforation and first estrus with younger males inducing sexual maturity at a younger age than older males. The presence of a second juvenile female during maturation was significantly associated with early vaginal opening (39.6 ± 1.7 days) but not with early first estrus (Evans and McClure, 1986).

Exposure to a shortened photoperiod (10 hours light versus 14 hours) delayed maturation of the testes and seminal vesicles, and vaginal opening in juvenile cotton rats, but not spermatogenesis or ovulation. Shortened photoperiod did not affect sexually mature males (Johnston and Zucker, 1979).

Cotton rats have been reported to grow at a rate of between 0.59 and 1.35g/day up to 12 days of age on an 11% protein diet (Cameron and Eshelman, 1996). They have been reported to weigh 20–25g at 3 weeks of age, 60–70g at 6 weeks of age, and 140–160g as adults (McIntire et al., 1944). However, more recent references give adult weight ranges of between 70 and 310g (Faith et al., 1997; Harlan Laboratories, 2010; Niewiesk and Prince, 2002; Sharp and La Regina, 1998). Body length is reported to range between 125 and 200mm, with an additional 75–166mm tail length (Faith et al., 1997; Niewiesk and Prince, 2002). The lifespan of cotton rats in the laboratory is reported as between 2 and 3 years (Faith et al., 1997).

Immunology

The immunology of the cotton rat has been well-defined through its use as a model for infectious disease research. Lymphocytes respond to stimulation by concanavalin A, pokeweed mitogen phytohemagglutinin, and lipopolysaccharide (Faith et al., 1997). Immune response may be affected by age, as control values for splenocyte proliferation indices to concanavalin A and pokeweed mitogen have been reported to be slightly lower after 13 weeks of study compared to 7 weeks of study (McMurry et al., 1995). Cotton rats also develop classic delayed-type hypersensitivity and humoral immune responses, but are considered highly resistant to bacterial endotoxin (Faith et al., 1997). An inversion of the lymphocyte to neutrophil ratio is seen between juvenile and adult animals (Faith et al., 1997; Niewiesk and Prince, 2002). The number of lymphocytes found in the spleen ($5\text{--}10 \times 10^7$) is more similar between cotton rats and mice than rats. The lymph nodes are smaller than those in rats and a lack of sacral lymph nodes has been reported (Niewiesk and Prince, 2002).

HUSBANDRY

Husbandry for cotton rats is generally adapted from that used for other laboratory rodents. Shoe-box-style

FIGURE 49.3 Cotton rat (*Sigmodon hispidus*) housing using contact bedding, nesting material and a nest tube.

rat cages with contact bedding are commonly used (Hill, 2009; Mitchell, 2009; Watkins, 2010;) (Figure 49.3). To prevent boredom and fighting, numerous enrichment objects have been used for cotton rats. Items that have been tried include hazelwood sticks, petite Nylabones, nest boxes, and PVC or cardboard tubing (Hill, 2009; Mitchell, 2009; Niewiesk and Prince, 2002; Ward, 2001; Watkins, 2010). Apples may also provide enrichment as well as a water source (Ward, 2001). Cage space guidelines have not been established, but one commercial source has had good reproductive success providing approximately 120in² for a breeding pair and litter, 12in² per animal from weaning to approximately 4 weeks of age, and 24in² per animal for young adults in same-sex groups (Mitchell, 2009; Watkins, 2010).

Intraspecific aggression is not uncommonly seen with cotton rats. Cotton rats demonstrate organized social behavior and an increased level of agonism was seen for the first 24 hours after introduction to unfamiliar animals (Wolfe and Summerlin, 1968). At one facility, best success with same-sex housing was achieved by co-housing only littermates after weaning, limiting cage groups to no more than two males or four females, providing nesting enrichment, and changing gloves between cages. For males, providing a separate nesting tube for each animal was determined to be critical (Hill, 2009).

While cotton rats have been established as a laboratory strain, they are not docile. Protective gloves are recommended for general handling, and use of nesting tubes provides a convenient method for moving animals without the need for direct handling (Figure 49.4). Cage changing may be performed inside a deep tub or barrel to prevent escape, as cotton rats will readily jump out of an open cage (Mitchell, 2009; Watkins, 2010). If direct handling is required, scruffing the skin over the neck is recommended, as tail restraint may result in injury to the animal or the handler (Niewiesk et al., 1997; Ward, 2001).

FIGURE 49.4 An adult cotton rat (*Sigmodon hispidus*) being restrained manually using protective gloves.

Nutritional requirements for cotton rats were studied by McIntire and colleagues (1944). In general, nutritional requirements were found to be similar to the laboratory rat. However, a requirement for nicotinic acid and inositol was found that was not noted at the time to be a requirement in rats. One commercial source feeds an extruded-type 19% protein, 9% fat balanced diet in breeding colonies (Harlan Laboratories, 2010). Cameron and Eshelman (1996) showed that growth and reproduction were improved in animals fed 11% protein compared to 4% protein in the diet, but differences were not seen between the use of sucrose or dextrin as a carbohydrate source at 3.85 kcal/g diet. Animals on this diet consumed approximately 0.3 g/g body weight/day.

Cotton rats can be maintained on acidified and chlorinated drinking water without reports of taste aversion (Mitchell, 2009; Ward, 2001; Watkins, 2010). One author suggests that water consumption of cotton rats is higher than for laboratory rats (Niewiesk and Prince, 2002). McMurry et al. (1995) report average daily water consumption of approximately 24 ml for adult animals measured over a 7 or 13 week period, beginning at a body weight of approximately 170 g. Taste preference in cotton rats for salt was determined to be 0.005 M and for sugar 0.1 M (Nevitt and Harriman, 1977). While this was determined for use as an incentive in behavioral research, these data may have practical applications for medication administration.

DISEASES

A review of health monitoring data by the authors from commercial colonies (Harlan Laboratories, 2010) showed relatively few incidents of clinical disease.

Proteus mirabilis and *Klebsiella oxytoca* are occasionally reported as normal cecal microflora, while *Staphylococcus aureus*, *Proteus mirabilis*, and swarming *Proteus* spp. may be found in the nasopharyngeal cavity in the absence of clinical signs. Isolation of *Proteus* from the nasopharynx may be associated with transient increase in fecal exposure, such as may occur during transportation (Franklin, 2010). Peribronchiolar lymphoid hyperplasia is seen with some frequency in histologic sections of lungs from healthy animals. There was one report of multiple pulmonary arterial thrombi, and another case of foreign body pneumonia (inhaled bedding), neither with associated clinical signs.

The authors are aware of no reports of naturally occurring infections with common murine pathogens. However, cross-reactivity of anti-mouse and rat antibody conjugates from a commercial multiplex fluorescent immunoassay with cotton rat IgG is low, which could result in under-reporting of infections (Steffen, 2009). One study suggested that the gastrointestinal flora of the cotton rat is very different than the gastrointestinal flora of other rodents in that anaerobic bacteria are the dominant flora in the stomach and intestines of the cotton rat, in contrast to guinea pigs, hamsters, rats, and mice where lactobacilli are the predominate bacteria (Itoh et al., 1989).

Wild cotton rats have been reported to be susceptible to naturally occurring infections from a number of organisms. Reports of bacterial infections include *Bartonella* spp. (Abbot et al., 2007), and *Borrelia burgdorferi* (Burgdorfer and Gage, 1987; Oliver et al., 2003). Viral infections include West Nile virus (Dietrich et al., 2005), Hantavirus (Mantooth et al., 2001), and vesicular stomatitis virus (Jiménez et al., 1996). Nematode infections include *Hepatozoon* spp. (Breshears et al., 2009; Johnson et al., 2007, 2008), *Hypocristata tertercera* (Durette-Desset and Guerrero, 2006), *Strongyloides* sp. (Elangbam, 1990), and *Trichinella spiralis* (Holliman and Meade, 1980). Protozoan infections include *Trypanosoma cruzi* (de Lima et al., 2006), a low incidence of *Toxoplasma gondii* (Smith and Frenkel, 1995), and *Cryptosporidium* sp. (Elangbam et al., 1993). Arthropod infestations that have been reported include *Polygenis gwyni* fleas (Abbot et al., 2007), *Dermacentor variabilis* ticks (Cooney et al., 2005; Gage et al., 1990), sucking lice, chiggers, and mites (Durden et al., 2000).

There are limited reports of non-infectious diseases in laboratory-reared cotton rats. Spontaneous enterochromaffin-like (ECL) cell carcinomas have been reported in an inbred laboratory colony of cotton rats (Martinsen et al., 2003). Spontaneous gastric adenocarcinoma has been reported (Kawase and Ishikura, 1995). Intravascular thrombosis associated with cardiomyopathy and exophthalmos was reported in a small inbred colony (Sorden and Watts, 1996). Adenocarcinomas and a high incidence

of chronic nephropathy and degenerative cardiomyopathy that was associated with exophthalmos have also been reported by others (Faith et al., 1997; Niewiesk and Prince, 2002). Cholesterol cholelithiasis was reported as an incidental finding in wild cotton rats (Pence et al., 1978). Other lesions reported by Faith et al. (1997) include steatitis in the mesenteric and perirenal fat, seminiferous tubule atrophy and aspermatogenesis, a 22–45% incidence of salivary gland mineralization and associated chronic inflammation, and occasional inflammatory or degenerative changes in the lung, liver, gastrointestinal tract, and reproductive organs. Fatty vacuolization of centrilobular hepatocytes has been described in control animals on a toxicological study (McMurry et al., 1995).

Physical injuries can be seen secondary to escape behavior. Posterior paralysis, presumably secondary to spinal fracture, has been observed in animals that were jumping up against the top of their cage (Mitchell, 2009).

EXPERIMENTAL METHODS

Blood sampling is best performed retro-orbitally (Niewiesk, 2009; Prince, 1994; Ward, 2001) since the cotton rat does not have easily accessible tail or other peripheral vasculature. Cardiac collection is also used in some instances. Dosing may be performed by methods commonly used for other rodents (Ward, 2001). Inhalant anesthesia can be performed using isoflurane (Niewiesk, 2009; Niewiesk and Prince, 2002). The use of methoxyflurane has also been reported (Prince, 2004). Injectable anesthetics include ketamine HCl (25mg/kg) and acepromazine maleate (2.5mg/kg) (Prince, 1994) or a mixture of xylazine (7.5mg/kg), ketamine (25mg/kg), and acepromazine (2.5mg/kg) (Ward, 2001). Euthanasia may be performed by an overdose of carbon dioxide gas.

A variety of immunologic reagents and methods have been developed for cotton rats. Macrophage isolation from the peritoneal cavity 2–3 days after injection of bacteria or bacterial lysates, and induction of granulocyte-macrophage progenitor cells from bone marrow have been reported (Niewiesk and Prince, 2002). Chromium uptake of fibroblasts and macrophages in T-cell cytotoxicity systems is lower than that seen in mice, and spontaneous release or leakiness is high. The mouse lymphoma YAC-1 line has been used for NK activity assays (Niewiesk and Prince, 2002). These authors also report that cotton rat T-cells derived from the spleen or lymph nodes adhere to nylon wool columns at over 90%, which should be taken into account when purifying T-cells from these samples. In addition, they note that cotton rat sera should be incubated at 4°C for enzymatic B-cell response assays to prevent non-specific findings, and that B-cells do not proliferate well after in vitro stimulation with LPS unless

membrane-bound immunoglobulins are cross-linked with antiserum.

Cell lines that are available include the CCRT osteogenic sarcoma line that expresses MHC I but not MHC II antigens, and CR-T1 and CR-T2 lymphoid cell lines that express cotton rat T-cell markers (Niewiesk and Prince, 2002). Monoclonal antibodies against cotton rat IgA, IgM, IgG, CD4 cells, and cotton rat macrophages have been developed. In addition, antibodies to human β -2 microglobulin have been shown to cross-react with cotton rat MHC I, while a mouse MHC II antibody cross-reacts with cotton rat MHC II (Niewiesk and Prince, 2002). Cytokine assays for IL-1, IL-2, IL-3, IL-4, TNF, and IFN- γ have also been developed. Reagents and gene sequences for a wide variety of cytokines and cellular markers are available commercially.

USE IN RESEARCH

The cotton rat (*Sigmodon*) species has long been recognized as a significant animal model for diseases caused by a variety of human and rodent pathogens. One of the first uses was by the NIH in 1937 for polio research in wild-caught animals. It was also used as a model in Britain to develop a typhus vaccine for British troops in Southeast Asia during World War II (Prince, 1994) and for early experiments on dental caries (Howell et al., 1948; Wakeman et al., 1948). *Sigmodon hispidus* has been the primary species of interest with *S. fulviventer* less frequently used as a research model (Faith et al., 1997).

The primary research use for cotton rats is for studies into infectious disease and immunology. The immune response of the cotton rat was characterized by Pfau et al. (2001) and Wilson et al. (2003) and is reviewed by Niewiesk and Prince (2002). In addition to polio and typhus research, a wide variety of human and animal pathogens have been studied in the cotton rat, including the measles virus (Wyde, 2000); and development of a measles vaccine was conducted using the cotton rat (Haga et al., 2009; Pasetti et al., 2009). It is also a valuable model for the study of human respiratory pathogens and diseases such as severe acute respiratory syndrome (SARS) (Watts et al., 2008), Everglades virus (Coffey et al., 2004), Metapneumovirus (Williams et al., 2005), human influenza (Jones et al., 2009; Ottolini et al., 2005; Trias et al., 2009), respiratory syncytial virus (Boukhvalova et al., 2009; Niewiesk and Prince, 2002; Nokes et al., 2008), herpes virus (Niewiesk and Prince, 2002), and genital herpes infections (Yim et al., 2005). Other uses have included infectious disease studies of human immunodeficiency virus (Blanco et al., 2009; DeNoon, 1998), *Helicobacter pylori* (Mahter et al., 2005), *Hepatozoon americanum* (Johnson et al., 2007), and nasal colonization of *Staphylococcus aureus* (Kokai-Kun, 2008;

Kokai-Kun et al., 2003). Cotton rats have been evaluated as a model for latent and active tuberculosis infection (Elwood et al., 2009) and Venezuelan equine encephalitis virus infection (Carrara et al., 2007). The cotton rat is the only known rodent model of human adenovirus type 5 (Jackson, 1997). Further, they have also been used for studies of adenovirus-based gene therapy (Niewiesk and Prince, 2002) and as a model for adenovirus-induced ocular disease (Tsai et al., 1992). Cotton rats implanted with syngeneic tumors have been used for the study of oncolytic adenovirus infection (Steel et al., 2007).

The cotton rat has been used for the study of environmental pollution (Paranjpe et al., 1994; Reddy et al., 2000; Tannenbaum, 2009), studies of wildlife population dynamics (Bowne et al., 1999; Mabry et al., 2003; Reed and Slade, 2008), and in nutritional research (Webb et al., 2005; Wilson et al., 2009).

Acknowledgments

The authors thank Lisa Mitchell and David Watkins of Harlan Laboratories and Dr. Lorraine Hill, Baylor College of Medicine for contributions on the biology and husbandry of the cotton rat.

INTRODUCTION

North American pocket gophers have received limited use as a laboratory model due to the challenges of accommodating a fossorial animal in captivity. However, the evolved physiological and behavioral characteristics required for life underground render the pocket gopher valuable for a variety of investigations. For example, restrictions imposed by the subterranean ecotop make pocket gophers ideal subjects to examine the impact of reduced sensory modalities

upon communication and energy costs associated with burrowing. Further, the solitary lifestyle of the pocket gopher allows for a model system to investigate parasite–host relationships where transmission rates are relatively low. Recent advances in the husbandry of pocket gophers now make large-scale laboratory studies feasible. Within the following chapter, the current and potential uses of pocket gophers as laboratory animals are discussed. Information concerning the biology of pocket gophers and diseases to which they are susceptible is provided as well.

Taxonomy and Natural History

Pocket gophers (commonly known as “gophers”) comprise the family Geomyidae within the order Rodentia. Their distribution extends from Central America to Canada, including the western, central, and southeastern United States. Patchy distribution patterns and limited dispersal of the pocket gopher facilitate rapid speciation, resulting in a fluctuating number of confirmed species. However, the physical characteristics common to all species of pocket gopher include: a cylindrical body with a thick-set anterior; broad head; short neck; external fur-lined cheek pouches (from which the name “pocket gopher” is derived); large incisors; small, round ears; tiny eyes; short, heavily clawed forelimbs for digging; lesser clawed, relatively small hindlimbs; and a short, nearly naked tail (Figure 50.1). Pelage above is soft and varies from shades of brown to slate gray and pales ventrally. Patches of white pelage along the bodyline are common and occasional melanistic animals are reported.

The pocket gopher is an aggressive, solitary rodent that lives within individual burrow systems constructed a few centimeters beneath the ground surface (Andersen, 1987). Each tunnel system is actively defended against conspecifics (Hansen and Miller, 1959) and has discrete areas designated for nesting, waste deposition, and food caching (Reichman et al., 1982). As the pocket gopher extends its tunnel system to feed on roots and tubers, mounds of excavated soil are pushed to the ground surface. Considering the pocket gopher is rarely seen above-ground, the presence of these mounds can aid the researcher in locating individuals for capture.

Use in Research

Numerous aspects of the ecology, taxonomy, and social structure of the pocket gopher have been studied extensively in the wild (reviewed in Patton, 1990).

FIGURE 50.1 Baird's pocket gopher, *Geomys breviceps*.

In comparison, laboratory studies of the pocket gopher are limited, but diverse. Captive pocket gophers have served as models to investigate the energetic costs associated with burrowing (Gettinger, 1975; McNab, 1966; Vleck, 1979); factors influencing activity patterns (Hickman, 1984; Werner et al., 2005); swimming ability (Best and Hart, 1976); breeding behavior (Andersen, 1978; Schramm, 1961); estrous cycles (Desy and Druecker, 1979); gestation (Andersen, 1978; Schramm, 1961); neonate growth and development (Andersen, 1978; Barrington, 1942); aggression (Baker, 1974; Gregory et al., 1987); and methods of communication (DeVries, 2007; DeVries and Sikes, 2008; Heffner and Heffner, 1990). Details of such studies are discussed in subsequent sections.

Sources

Pocket gophers must be captured from the wild. Live traps for pocket gophers are not currently available for purchase, but can be readily constructed from numerous design descriptions (Baker and Williams, 1972; Connior and Risch, 2009a; Hart, 1973). State permits and approved institutional protocols (e.g., Institutional Animal Care and Use Committees) for the capture and care of wild animals should be acquired and followed.

Upon capture, pocket gophers should be examined for anatomical or behavioral abnormalities and transported to the laboratory in individual plastic cages lined with 6–10 cm of soil from their respective burrow system. Stress during transport is greatly reduced by covering cages with dark cloth. A 2-week quarantine period for new captures is recommended when bringing pocket gophers into captivity (DeVries and Sikes, 2009). Within quarantine, individuals should be introduced to caging systems designed for pocket gophers (see below), topically treated with insecticidal powder, and administered weight-appropriate dosages of ivermectin to terminate any existing intestinal parasite infections (DeVries and Sikes, 2009). Individuals showing symptoms of advanced parasitic infection (e.g., distended abdomen) require euthanization. Weight at capture should be recorded and monitored throughout the quarantine period. Subcutaneous pit-tags can be used for permanent identification. Pocket gophers are difficult to age, but it is possible to distinguish juveniles from adults (criteria described below). The sex of juveniles can be determined by palpating genitalia for the presence of a baculum. As adults, males are usually larger than females.

Pocket gophers are not commercially available. However, *Thomomys bottae* (Schramm, 1961) and *Thomomys talpoides* (Andersen, 1978) have bred successfully in captivity, suggesting that a breeding colony of pocket gophers could be established within the laboratory.

Laboratory Management and Husbandry

Housing

To encourage caching and nesting behaviors performed as in the wild, pocket gophers should be housed separately in simulated subterranean tunnel systems (DeVries and Sikes, 2009). Each system is constructed of three or more polycarbonate cages (46 by 23 by 20 cm) interconnected with polyvinylchloride (PVC) tubing (Figure 50.2). Stainless steel hose clamps attached to the ends of the PVC tunnels provide stability. Bottoms of cages should be flat as slatted floors can damage claws. Diameter and length of PVC tubing used is dependent upon the size of the pocket gopher species housed. No food dishes or water bottles are provided.

Pocket gophers are accustomed to living in almost total darkness, which can be accommodated in captivity by covering one chamber of the simulated tunnel system with an inverted plastic container. Rims of containers are trimmed to allow a close fit over PVC tunnels. This practice allows individuals to select a microenvironment of darkness without altering the photoperiod of the laboratory.

If provided only soil as a substrate, pocket gophers can die of exhaustion from continuous digging (Hanley, 1944). Therefore, it is recommended that in addition to soil, wood chips and hay should be supplied within each simulated tunnel system. Ideally, these different substrates should be provided in separate containers upon cage changing. This procedure permits the animal choice of container, cover, and substrate in which to construct a nest and provides behavioral enrichment by allowing each individual to mix and move substrates at will. With these additional substrates, pocket gophers quickly construct nests in the laboratory (Figure 50.3) similar to those seen in the wild (Figure 50.4). Individuals typically drag hay and wood chips through the tunnel system to construct nests within darkened chambers. Nests serve as sleep locations and food caches. Providing a small amount of

soil (6 cm) supports moderate digging behavior. Pocket gophers will also spread soil along the bottoms of cages and tunnels (Figure 50.5) to reduce contact of their claws on plastic surfaces. Soil can be obtained from the

FIGURE 50.3 Pocket gopher nest in captivity.

FIGURE 50.4 Pocket gopher nest in the wild.

FIGURE 50.2 A simulated subterranean tunnel system for housing pocket gophers.

FIGURE 50.5 Soil packed within a PVC tunnel.

field and autoclaved or purchased sterile in bagged form. Caging systems should be cleaned weekly.

A diet of fresh vegetation should be provided as pocket gophers do not drink free water (Hanley, 1944). Placing food items in chambers not containing a nest encourages foraging behavior and allows for assessment of general appearance. Individuals drag or store food items in cheek pouches to cache within nests. Pocket gophers are coprophagous and fecal pellets are also cached (DeVries and Sikes, 2009; Wilks, 1962). To prevent overgrown incisors, fruit bark should be provided for gnawing. Claws can be trimmed with pet nail clippers as needed.

In the wild, ambient temperature and humidity of the pocket gopher's tunnel system remain relatively stable (Kennerly, 1964) and efforts should be made to achieve similar results in captivity. An ambient temperature of $22 \pm 2^\circ\text{C}$ is recommended for the laboratory. Humidity should be maintained between 50–70%. Photoperiod can be maintained to correspond with season.

Identification

Temporary forms of identification are not readily used on pocket gophers. However, fur dyes could probably be applied on individuals not undergoing molt. Fur clipping would be less effective due to pelage length and texture.

Passive integrated transponder (PIT) tags are the most efficient means of permanently identifying pocket gophers. PIT tags are injected subcutaneously with a large-bore hypodermic syringe and do not require anesthesia. Once injected, PIT tags should be gently pushed under the pelage away from the point of insertion (Gannon et al., 2007). Syringes should be sterilized between animals.

Radiotransmitters can also be used to permanently identify pocket gophers (Cameron et al., 1988; Connior and Risch, 2009b; Zinnel and Tester, 1991). All radiotransmitters must be surgically implanted and weigh less than 5% of the mass of the pocket gopher. Subcutaneous insertion of radiotransmitters is quicker and less invasive than implantation within the peritoneal cavity (Connior and Risch, 2009b). After lightly anesthetizing animals with isoflurane, the hair is shaved, the skin disinfected, and a small incision made between the scapulae. Radiotransmitters are then inserted between the skin and muscle. The incision is closed with surgical adhesive and antibiotic ointment is applied topically (Cameron et al., 1988). Surgical instruments should be disinfected between surgeries.

Toe clipping of the forelimbs severely hampers mobility and should be avoided (Gannon et al., 2007). Ear tags and ear notches are also unsuitable, given the reduced size of the pocket gopher's pinnae.

FIGURE 50.6 Restraint technique for pocket gophers, with face and claws of the animal facing forward.

Handling and Restraint

Pocket gophers can bite with substantial force. Cowhide leather palm gloves prevent bite wounds without sacrificing hand dexterity. Animals can be grasped and held within a gloved hand, leaving the opposite hand free for minor manipulations (e.g., external examination, palpations, etc.). With the gloved hand, individuals should be pinned to the ground ventral side down. The thumb and middle finger are wrapped around the body under the forelimbs and the index finger is placed behind the head to prevent neck movement (Figure 50.6). Stress of the handling process can often be lessened by providing individuals with a substrate to chew on, such as fruit bark. Complex procedures (e.g., subcutaneous injections, vaginal smears, nail clipping, etc.) require the assistance of a second researcher. Following handling, pocket gophers frequently exhibit displacement behavior in the form of excessive grooming or teeth chattering.

Anesthesia

Surgical procedures on pocket gophers require chemical restraint and inhalation anesthesia is delivered easily. Isoflurane is recommended for short surgeries and is administered by placing an individual within a plexiglass chamber containing a cotton ball that has absorbed 40–80 μl (1–2 drops) of the anesthesia (Connior and Risch, 2009b). Respirations should be monitored closely and once abdominal breathing is observed (usually 1–2 min after initial exposure), the individual is ready for surgery. If necessary, additional doses of

anesthesia can be delivered through placing the cotton ball within a rostral cone. Following short surgeries (<25 min), animals fully recover from anesthesia within 1 hour of the procedure (Cameron et al., 1988; Connior and Risch, 2009b). These methods have proven effective for both juvenile and adult pocket gophers (Connior and Risch, 2009b).

Physical Examination

When assessing the health of pocket gophers in captivity, many observations should first be made without handling. Discharges from the eyes and ears, labored movements, nail length, and excessive weight fluctuations can be detected with no disturbance to the animal. Incisor length can be assessed by observing animals chew on fruit bark. Behaviors performed within simulated tunnel systems should be monitored closely (e.g., food caching, nest construction, etc.). Loss of appetite, reduced mobility, and a reluctance to build nests usually indicate a serious underlying condition.

Closer examination should be made following reproductive attempts or aggressive encounters. Handling is required to examine individuals for bite wounds, skin irritations, and to perform palpations.

Clinical Techniques

TOPICAL MEDICATIONS

Medicated powder can be applied to dorsal and ventral surfaces. Provided that care is taken to avoid the eyes, individuals can be lightly dusted from above without handling. To medicate the ventral surface, individuals should be grasped with a gloved hand and dusted with the other. Powder should be thoroughly rubbed within pelage in areas prone to skin irritation, such as the pelvic or axillary regions. For additional application, powder can also be mixed within hay or wood chips.

INJECTIONS

Two individuals are needed to deliver subcutaneous injections to pocket gophers. One person should restrain the animal while the other lifts the skin and delivers the injection.

VAGINAL CYTOLOGY

Vaginal smears are an effective technique to monitor the estrous cycle of female pocket gophers. Smears can be obtained through either vaginal lavage or swabbing. Performing this procedure also requires two individuals: one to restrain the animal and another to obtain the smear.

MEASUREMENT OF BODY TEMPERATURE

Body temperatures of pocket gophers have been obtained with rectal thermometers (Darden, 1972; McNab, 1966) and temperature radiotelemeters (Vleck,

1979). Accuracy of rectal temperature is questionable due to excessive struggling of the animal during the procedure (Vleck, 1979). Body temperatures obtained through radiotelemeters are lower than reported rectal temperatures (Vleck, 1979), but require surgical implantation, which can result in additional stress for the animal.

BIOLOGY

Unique Anatomic and Physiological Characteristics

Metabolism

Many aspects of the annual metabolic cycle of the pocket gopher have yet to be investigated. However, it has been established that pocket gophers are characterized by low basal metabolic rates and low thermal conductance (McNab, 1966; Vleck, 1979). In the wild, tunnel systems must be continuously lengthened as pocket gophers forage. Digging is an energetically expensive form of locomotion that can require 360–3400 times the energy needed to travel aboveground (Vleck, 1979). Thus, it has been proposed that a low resting metabolism is an adaptation of fossorial rodents to reduce overall energetic costs (McNab, 1966; Vleck, 1979). For example, mean rates of oxygen consumption of *Thomomys bottae* during burrowing ($2.8\text{--}7.1\text{ cm}^3\text{O}_2/(\text{g}\cdot\text{h})$) are much greater than the average resting metabolic rate at the same temperature ($0.84 \pm 0.16\text{ cm}^3\text{O}_2/(\text{g}\cdot\text{h})$; Vleck, 1979). Activity patterns alternate between short bursts of activity and periods of rest. Yet, circadian rhythms of oxygen consumption and activity do not appear to exist within the laboratory (Vleck, 1979).

Due to the relative stability of the subterranean ecotop, pocket gophers have a narrow range of thermoneutrality and cannot tolerate excessive heat. Pocket gophers effectively maintain a body temperature of approximately 36°C when exposed to ambient temperatures ranging from $5\text{--}25^\circ\text{C}$, (McNab, 1966; Vleck, 1979). Body temperatures elevate at ambient temperatures greater than 25°C . Ambient temperatures above 33°C can be fatal (McNab, 1966; Vleck, 1979). Signs of heat stress are easily identifiable. When exposed to excessive heat over a prolonged period, pocket gophers will modify their resting position. A stressed individual will rest either on its side or back. An unstressed animal usually rests on its feet, with its head and tail curled under its body.

Hydration

Pocket gophers do not consume free water and depend upon a diet of fresh vegetation for hydration. Further, they excrete very concentrated urine, similar

to that described for desert rodents (e.g., *Dipodomys ordii*; Howell and Gersh, 1935). Like desert rodents, it is probable that the production of such concentrated urine is an adaptation for life in an environment void of standing water (i.e., underground). Although the physiological processes responsible for water conservation in the pocket gopher are unknown, increased resorption within the urinary bladder or various ducts of the kidney are plausible. Similar mechanisms of water conservation have been described for numerous rodents inhabiting xeric environments (reviewed in Lawler and Geluso, 1986).

Pocket gopher urine is pale yellow in color with a thick, milky appearance. Animals will urinate frequently within the same location and the amount of urine produced can be modified by altering the amount of fresh vegetation provided. Dried urine can be difficult to remove from cage bottoms, requiring some additional effort on the part of the technician when cleaning tunnel systems.

Unique Natural Microenvironment

The microenvironmental conditions of the pocket gopher burrow differ from atmospheric conditions aboveground. Relative humidity of a tunnel system is frequently greater than 80% and oxygen content may be slightly lower than the atmospheric level (Kennerly, 1964). Further, carbon dioxide levels are exceedingly high and can range from 10–60 times atmospheric concentration (Kennerly, 1964). Captive pocket gophers experience no difficulty acclimating to standard laboratory conditions (0.04% CO₂; 21% O₂; humidity > 50%). However, if performing carbon dioxide euthanasia, pocket gophers require longer exposure to the gas than most laboratory rodents.

Behavior

Within captivity, patterns of activity and food consumption of the pocket gopher do not appear to change seasonally. Weight loss ranging from 1–18% of total body mass is common in newly captured animals. After a few weeks in captivity, weights at capture are usually surpassed and only slight weight fluctuations (2–5 g) are subsequently observed (DeVries and Sikes, 2009). Sick animals appear lethargic and will not perform routine behaviors (e.g., nest building, food caching, etc.).

Regardless of handling frequency, pocket gophers are aggressive rodents that do not become docile in captivity. Aggressive behavior does not appear to fluctuate seasonally or differ between the sexes. However, due to their greater size, males can be more difficult to handle than females. Individuals must be housed separately and interactions between pocket gophers should only occur under supervised conditions.

Normal Values

Longevity

From the author's experience, pocket gophers can be successfully maintained in captivity for 2–3 years with a maximum life expectancy of 3.5–4 years (unpublished data, 2009). In the wild, maximum longevity is 4 years and it has been suggested that females live longer than males (Howard and Childs, 1959).

Genetics

The confirmed number of pocket gopher species is in constant fluctuation (Steinberg and Patton, 2000). Many species are characterized by a diploid (2n) number ranging from 38–76 and a fundamental number varying from 68–102. Diploid and fundamental numbers differ among species and within species complexes (i.e., subspecies). In addition, hybrids between species occur frequently.

Hematology and Clinical Chemistry

Blood cell parameters and serum chemistry results have not yet been reported for pocket gophers.

Nutrition

Exact nutritional requirements have not yet been determined for pocket gophers. However, a diet of fresh vegetation effectively sustains animals in captivity (DeVries and Sikes, 2009). Dietary components include: sweet potatoes, Russet potatoes, carrots, apples, and bean sprouts. Considering pocket gophers depend upon the supplied diet for hydration, fresh vegetation must be provided daily. Alfalfa hay and rodent chow (Purina 5012) are also readily consumed and provide important trace minerals and vitamins. This recommended diet promotes seasonal molts, adequate fat deposition, and normal muscle development in juvenile and adult pocket gophers (DeVries and Sikes, 2009).

Reproduction

Overview and Breeding Season

Many species of pocket gopher have extended periods of reproduction (5⁺ months). Exact lengths of breeding seasons differ among taxa and can vary geographically within species. Males of some species (e.g., *Geomys bursarius*, *Geomys breviceps*; Pitts et al., 2005) are capable of reproducing year-round, but female receptivity appears to be restricted to December–October (Howard and Childs, 1959; Pitts et al., 2005). Pregnancy rates peak during February–April. Gestation periods vary from 18–50 days, depending upon species. Litter sizes range from 1–13 young (3–5 average) and most females give birth to only one litter per year. However, it has been suggested that older females in southern populations produce a

second litter at the end of the summer (Sealander and Heidt, 1990).

Male and female pocket gophers do not reach sexual maturity until approximately 8 months of age (Vaughn, 1962). Sex determination of individuals prior to sexual maturation (juveniles and subadults) is difficult. Palpating genitalia for the presence or absence of a baculum is the most effective method of quantifying the sex of immature individuals. Once sexually mature, the sexes are more readily distinguishable. Sexually mature males have a scrotal region and are larger in size than females. During the breeding season, testicular descent from the abdomen into the scrotum is common (Vaughn, 1962). Mature females have an open pubic symphysis and well-developed mammary glands. Sexual receptivity is indicated by the presence of a swollen vulva, open vagina, and cornified epithelial cells in vaginal smears (Andersen, 1978).

Male Reproduction

In the wild, most male pocket gophers are in breeding condition 2–3 months before females (Vaughn, 1962). Enlargement of the seminal vesicles, epididymides, and testes occurs in December–February. The scrotal region enlarges to accommodate testicular descent and/or the swollen epididymides. Unlike most mammals, the position of the testes might not be an accurate indicator of breeding condition in pocket gophers. Even though scrotal development occurs, many males have abdominal testes during the peak of the breeding season (Vaughn, 1962). Rather, testes size is a more reliable measure of reproductive potential. Within geomyids, testes range in length from 3–21 mm and the size at which spermatozoa are produced varies among species. For example, in *Geomys breviceps*, testes larger than 11 mm contain spermatozoa while in *Geomys bursarius*, testes must be 12.5 mm for sperm production (Pitts et al., 2005; Vaughn, 1962). Spermatozoa are produced until testicular regression, which usually occurs during the late summer and early fall. However, the onset of male breeding condition can be asynchronous within populations, resulting in the potential for year-round reproduction.

If maintaining a seasonal light cycle within the laboratory, most males will come into breeding condition during the late winter and early spring, similar to those in the wild. Reproductive organs enlarge and scrotal development occurs. Individuals with these physical characteristics might be viable candidates for reproductive attempts.

Female Reproduction

Vaginal swelling occurs and ovaries and uteri enlarge as females approach breeding condition (Howard and Childs, 1959; Vaughn, 1962). A swollen vulva and perforated vagina usually indicates a reproductively

receptive individual. Reduced genital swelling and a closed vagina indicate anestrus.

Stages of the estrus cycle can be quantified with vaginal smears. Smears taken during proestrus contain many nucleated epithelial cells and few leukocytes. Estrus smears are dominated by cornified epithelial cells. During metestrus, some cornified cells are present and leukocytes greatly increase in number. Diestrus smears are characterized by moderate leukocyte numbers and an increase in nucleated epithelial cells (Desy and Druecker, 1979). Smears can be obtained by removing cells from the walls of the vagina with a moist tapered swab or by flushing the vagina with distilled water. Vaginal solutions should be transferred to a slide and stained for microscopic observation.

Mating is a lengthy process for pocket gophers. If pairs are tolerant of one another, copulatory behavior is exhibited almost immediately (within 5 minutes) upon introduction. During intromission, males mount females and perform rapid pelvic thrusts. Soft vocalizations, such as purrs and/or squeaks, are frequently emitted (DeVries and Sikes, 2008). Intromission attempts have been reported to range from 5–29 within an hour period with each attempt lasting 15–30 seconds (Andersen, 1978; Schramm, 1961). Repeated copulation might be necessary to induce ovulation in pocket gophers as has been suggested for other solitary subterranean rodents (Bennett et al., 2000). Copulatory plugs have been reported in some species (Howard and Childs, 1959).

During copulation, males will exhibit forceful, but non-aggressive behavior, such as grasping females with their teeth and/or forelimbs. However, intolerant pairs will attempt to fight and should be separated immediately. Aggressive behavior may also be displayed at the conclusion of a copulatory period, requiring separation of the pair. Consequently, supervision is necessary during reproductive attempts and all individuals should be thoroughly examined following such encounters.

Laboratory Breeding and Female Fertility

Large breeding colonies of pocket gophers have yet to be established. However, several litters of *Thomomys bottae* (Schramm, 1961) and *Thomomys talpoides* (Andersen, 1978) have been produced in captivity, suggesting that the establishment of breeding colonies is possible.

HOUSING AND PAIR SELECTION

Breeding in captivity has been achieved by pairing scrotal males with receptive females (see above) in neutral locations (e.g., cage, terrarium, etc.). Some pairs are intolerant of one another and exhibit aggressive behavior (Schramm, 1961). Pairs that are tolerant usually copulate. Copulatory behavior can be performed by novel individuals (Schramm, 1961), but, it has been suggested that repeated introductions of potential pair

members could increase breeding success (Andersen, 1978). Considering that olfactory cues could be important in coordinating reproduction in pocket gophers (DeVries, 2007), copulatory behavior might be stimulated by placing feces and urine of receptive females within the simulated tunnel systems of males. After reproductive attempts, pair members should be separated and returned to their individual tunnel systems.

PREGNANCY AND PARTURITION

Once females have copulated, they should be provided sufficient nesting material and subjected to minimal handling. Late-stage pregnancy can be detected by palpation and the presence of enlarged mammary glands. Gestation periods are highly variable among taxa, but of the species that have bred successfully in captivity, parturition occurs 18 days after mating (Andersen, 1978; Schramm, 1961). Females remain within nests for the 1–2-hour process of parturition (Barrington, 1942; Schramm, 1961).

NEONATE GROWTH AND DEVELOPMENT

Pocket gophers give birth to 1–13 altricial young per litter. Newborn pocket gophers are hairless with pinnae follicles present on the head. Eyes, ears, and cheek pouches are closed and forelimbs are not clawed. Newborn weights range from 2.7–6.5 grams, depending on species (Andersen, 1978; Schramm, 1961). Birth weight is negatively impacted by increased litter size (Andersen, 1978).

Neonatal growth is rapid. Offspring of *Thomomys talpoides* acquire juvenile pelage and foreclaws within the first 2 weeks of development and can eat solid food at 17 days old (Andersen, 1978). Eyes, ears, and cheek pouches are open at approximately 3 weeks of age. Litter mates require separation at 2 months and individuals are approximately adult size and begin acquiring adult pelage by month 3 (Andersen, 1978).

NEONATAL MORTALITY

Pocket gophers born in captivity often die due to exposure as females appear hesitant to retrieve young that leave the nest (Andersen, 1978). Many of these litters were housed in open cages with little nesting material (Andersen, 1978; Barrington, 1942). Housing litters within simulated tunnel systems might better protect offspring from exposure and encourage more natural behavior from the mother. Further, adequate nesting material should be supplied and handling of newborn individuals kept to a minimum.

NUTRITION

Fresh vegetation appears to meet the nutritional needs of pregnant and nursing females and developing offspring. No dietary alterations have been described.

DISEASES

Colony Health

Being a solitary mammal, pocket gophers do not readily transmit disease. Minor health issues common to newly captured animals, such as ectoparasite infestations or skin irritations, are eliminated during quarantine. Existing endoparasite infections are also terminated before introducing individuals into the colony. Injuries can occur during reproductive attempts, but most are not severe if individuals are not allowed to exhibit excessive aggression. Dental problems, such as incisor breakage or malocclusions, can occur. Malocclusions are rare, but can cause serious threat to an individual's health. If properly clipped, nail injuries are minimal.

Once established, maintaining the health of a pocket gopher colony is not difficult. For example, a large colony of *Geomys breviceps* (26 animals; 11 males, 15 females) was maintained by the author for nearly 3 years using many of the aforementioned husbandry techniques. Upon termination of the colony, all individuals were determined to be free of internal parasites, with no indication of infectious, degenerative, or neoplastic disease processes at necropsy.

Infectious Diseases

Due to their solitary nature, pocket gophers are not readily susceptible to bacterial or viral disease. However, parasitic infections are common in newly captured individuals.

Parasitic Disease

Wild pocket gophers harbor numerous external and internal parasites (Hafner et al., 2000). Common parasites include fleas, mites, chewing lice, roundworms, and tapeworms. Existing infestations are terminated before new individuals are introduced into the colony. Ectoparasites are eliminated through the application of insecticidal powder. Weight-appropriate dosages of ivermectin appear to exterminate internal parasites. Housing animals within individual caging systems helps prevent subsequent infections. Parasites to which colony-born individuals are susceptible are unknown.

PROTOZOA

Coccidia, such as *Eimeria thomomysis* and *Eimeria fitzgeraldi*, have been found in the fecal pellets of multiple geomyids (Gardner, 1983; Todd et al., 1971).

NEMATODES

Both *Ransomus rodentorum* and *Trichuris fossor* have been found in the cecum of wild pocket gophers (Gardner, 1985; Todd et al., 1971). *Trichuris fossor* has also

been identified within the large intestine (Gardner, 1985; Todd et al., 1971). *Longistriata vexillata* (Todd et al., 1971) and *Heligmosomoides thomomyos* (Gardner, 1985) are harbored within the small intestine and *Protospirura ascaroidea* within the stomach (Todd et al., 1971). *Capillaria hepatica* is occasionally found in the liver (Todd et al., 1971).

CESTODES

Several tapeworm species have been identified in pocket gophers. Taxa residing in the small intestine include: *Catenotaenia linsdalei*, *Paranoplocephala variabilis*, and *Paranoplocephala infrequens* (Todd et al., 1971), as well as *Hymenolepsis horrida* and *Hymenolepis tualatinensis* (Gardner, 1985).

EXTERNAL PARASITES

Pocket gophers are host to many species of ectoparasites and new parasitic taxa are continuously discovered. Those reported include: chewing lice (Trichodectidae: *Geomydoecus*, *Thomomydoecus*), fleas (Ceratophyllidae: *Dactylopsylla*, *Foxella*; Pulicidae: *Pulex*), mites (Haemogomastinae: *Ischyropoda*; Pygmephoridae: *Pygmephorus*; Listrophoridae: *Geomylichus*), and ticks (Ixodidae: *Amblyomma*, *Haemaphysalis*, *Ixodes*). Many external parasites of pocket gophers are host-specific, providing the potential for host-parasite coevolution (Hafner et al., 2000). Consequently, the relationships of pocket gophers and their ectoparasites receive much investigative attention.

Traumatic Disorders

Bite wounds frequently occur during reproductive attempts. Most are not severe and can be treated with topical disinfectants. In addition to bite wounds, incisors can be broken and foreclaws can rupture eyes, resulting in blindness. Consequently, all measures should be taken to reduce aggressive interactions.

Dental Problems

Broken incisors and malocclusions occasionally occur. Such problems can result in difficulty eating and thus, poor condition. Unfortunately, malocclusions are difficult to diagnose and are often not detected until necropsy.

INTRODUCTION

Mystromys albicaudatus is a rodent species rarely used in contemporary research. This species is also declining in the wild. While the status of *Mystromys* has not been evaluated and is not included in the Convention on International Trade in Endangered Species (CITES) appendices, it is listed as an endangered by the International Union for Conservation of Nature (IUCN) due to declining populations and loss of habitat (IUCN, 2006). This chapter is included to provide historical information as well as update any new findings published for this species. Recognizing that *Mystromys* can be maintained in captivity and given the declining wild populations, the information provided in this chapter may also be useful to maintain captive-bred populations for conservation purposes in addition to biomedical research purposes.

TAXONOMY, HISTORY, AND GENETICS

Mystromys albicaudatus is commonly referred to as the white-tailed rat or less frequently the white-tailed mouse. This species is the only living species in the

genus *Mystromys* and the subfamily Mystromyinae. Recent phylogenetic studies place this species in the family Nesomyidae and show that this species does not belong in the hamster family Cricetinae (Steppan et al., 2004). The common name, South African hamster, is now considered a misnomer for this species. Wild populations of *Mystromys* are found in the savanna grasslands of South Africa where it lives in burrows in the ground or shelters in cracks in the soil.

The first research colony was established in 1941 by Davis at the South African Institute of Medical Research (Hall et al., 1967). Animals from this colony were subsequently transferred to the Armed Forces Institute of Pathology (AFIP) in 1962 and 1969 (Howell and Hall, 1977). Additional colonies were established from dissemination of the AFIP colony to several other institutions in the United States. However, the last research publication in the US utilizing this species occurred in 1987 and several research colonies established in the 1960s and 1970s in the US are no longer in existence. Research colonies may still exist in Africa, although most current publications are based on wild-caught animals.

Mystromys albicaudatus has 32 chromosomes consisting of 30 autosomes and the two sex chromosomes X and Y (Srivastava et al., 1974). The X chromosome

FIGURE 51.1 *Mystromys albicaudatus*.

is the longest and the Y chromosome is the smallest of the 32 chromosomes. G banding patterns have been established (Srivastava et al., 1974). While earlier studies focused on trying to establish genetic relationship of *Mystromys* to other hamster species through G-banding analysis, newer sequencing studies of five independent genes have resulted in the placement of *Mystromys* in the family Nesomyidae (Gamperl et al., 1978; Jansa et al., 1999; Steppan et al., 2004).

ANATOMY, PHYSIOLOGY, AND
BEHAVIOR

In the wild, *Mystromys* is a burrowing rodent that is nocturnal and solitary (Nowak, 1999); however, it adapts well to captivity and is described as quick, active and occasionally acrobatic (Hall et al., 1967). It is a medium-sized rodent with gray soft luxurious textured fur with shades of brown over the back and shoulder and a creamy-white-to-gray undercoat on the tail, feet, and belly (Figure 51.1). *Mystromys* has large rounded erect ears, lacks cheek pouches, and has eyes that are dark and prominent. Body weight for adult females averages 95 g (75–125 g range); and males average 145 g (105–185 g range) (Hall et al., 1967). The tail is short and is about 30% of the body length. Life span is relatively long compared to other rodents with an average lifespan of 2.4 years with an upper limit of 6.2 years.

The most unique anatomical features of *Mystromys* include the lack of a gall bladder and the anatomy of the stomach. The stomach is divided into two distinct compartments by an annular muscular band (Hall et al., 1967; Mahida and Perrin, 1993; Vorontsov, 2003). The forestomach is covered with tall keratin papillae having the gross appearance of a rumen, and the stomach was thought for several decades to have a fermentation function. Mahida and Perrin (1994) determined that fermentation occurs in the cecum, classifying *Mystromys* as a hind-gut fermenter (Mahida and Perrin, 1994). The papillae arise from the horny layer of the stratum

FIGURE 51.2 Stomach of *Mystromys albicaudatus*. Arrowhead denotes smooth glandular region and arrow denotes non-glandular region containing tall keratin papillae.

TABLE 51.1 Organ Weights for Female and Male *Mystromys Albicaudatus*

Organ	Female ^a	Male ^a
Body weight	82.90 (16.10)	110.00 (23.80)
Heart	0.39 (0.08)	0.45 (0.08)
Liver	4.37 (.98)	5.10 (1.46)
Spleen	0.13 (0.04)	0.14 (0.03)
Kidney	0.37 (0.06)	0.43 (0.08)
Ovary/testes	0.05 (0.02)	1.77 (.250)
Brain	1.33 (0.08)	1.36 (0.08)
Lung	0.69 (0.18)	0.79 (0.19)
Pancreas	0.32 (0.09)	0.38 (0.08)

^aMean organ weight in grams with standard deviation in parentheses.

corneum and consist of stratified squamous epithelium and the periphery of the papillae are heavily laden with bacteria. It is thought that this adaptation might be more important to fat digestion and may compensate for the absence of a gall bladder in this species (Mahida and Perrin, 1993). The glandular portion of the stomach is similar to that found in other rodents (Figure 51.2).

Mystromys has two pairs of inguinal mammae that the young attach to soon after birth and to which they remain attached until the third week of life (neonatal tenacious nipple attachment). A large subcutaneous sebaceous gland is posterior to the mammae and extends to the vulva. Females have a rudimentary prostate and males have an os penis (Hall et al., 1967). Typical organs weights are found in Table 51.1; and

Volume (ml/h/g body wt)	1.9×10^{-3} (1.0×10^{-4})

Tables 51.2–51.4 contain normal hematology, serum chemistry and urinalysis values (Becker and Middleton, 1979; Becker et al., 1979; Cantrell and Padovan, 1987).

MANAGEMENT, HUSBANDRY, AND COLONY HEALTH

Mystromys can be housed in standard caging sufficient for rats. Animals are generally housed in monogamous lifetime breeder pairs, as mixing of adults results in fighting. Pairs are monogamous and fighting may occur when new mates are introduced if a partner is removed or dies. Offspring can be weaned at 25 days of age and typically weigh 25g. Weaned animals from different litters can be co-housed. New animals should not be introduced to cages after 2 months of age, as fighting occurs with new introductions after this age. Recommended housing space is 70 sq inches per breeding pair and 200 sq inches per four weaned offspring (Hall et al., 1967). Overcrowding results in increased fighting.

Environmental conditions are typical of those for other rodents. A light cycle of 12 hours light and 12 hours dark has been utilized for breeding colonies. In the wild, the diet consists mainly of seeds with also vegetable material and insects. In captivity, *Mystromys* can be fed standard rodent chow and water ad libitum (Hall et al., 1967). Parents will eat offspring that die.

Mystromys become sexually mature between 4–7 months of age and the estrous cycle occurs at 4–9-day intervals. *Mystromys* are considered to be non-seasonal breeders and new litters can be born year-round. Gestation averages 38 days with a range of 36–39 days. *Mystromys* offspring are born hairless and the eyes open around days 16–20. Soon after birth the young attach to mammae and remain attached for approximately 3 weeks. During this time the female drags the young around (Figure 51.3). After this 3-week period they continue to nurse intermittently for another 2–3 weeks. If allowed to remain with the parents, the female will naturally wean the young at 5–6 weeks old, and offspring will weigh around 40g at the time of natural weaning. They can be weaned as early as 25 days of age or at 25g (Hall et al., 1967). This early weaning facilitates regrouping animals from multiple litters. Average litter size is three pups with a range of 1–5 offspring. Typical survival rate at weaning is 80%.

BASIC EXPERIMENTAL METHODS

Mystromys has been used infrequently in research. The majority of studies currently utilizing *Mystromys* are behavioral and biology-related studies not requiring experimental manipulation. Animals should not

FIGURE 51.3 *Mystromys albicaudatus* female with attached offspring. Offspring remain firmly attached to nipples even when female is picked up and the offspring weight is only supported by nipple attachment.

be handled by the tail as the tail is short and the skin is thin and easily damaged, which can result in tail necrosis and/or tail slip. Animals should be grasped from above, around the thorax or abdomen. While animals are not prone to biting, heavy gloves are recommended for handling because they may resist handling. Blood collection techniques listed for *Mystromys* include cardiac collection and tail vein collection utilizing a vacuum apparatus (Hall et al., 1967; Packer et al., 1970). Pentobarbital anesthesia induced by an intraperitoneal route has been described (Padovan, 1985).

DISEASES AND VETERINARY CARE

Very little information has been reported for infectious diseases occurring naturally in *Mystromys*. Hall

et al. (1967) reported a single case each of septicemia, granulomatous retinitis, granulomatous pneumonitis, and suppurative pneumonitis, but no etiologic agent was identified in these four affected animals. Cilia-associated respiratory (CAR) bacillus has been noted in *Mystromys* with chronic pulmonary lesions. However, it is unknown if this CAR bacillus species is the same species infecting laboratory mice and rats, or if it is a separate species (Institute for Laboratory Research, 1991). *Mystromys* has been experimentally infected with *Clostridium piliforme*, indicating that *Mystromys* is susceptible to infection (Waggie et al., 1986). Experimentally infected animals had lesions characterized by focal necrosis and inflammation in the intestine, liver, heart, and brain.

Neoplasia is an infrequent finding in *Mystromys*, and was generally found in animals 3 years of age or older. Tumors found in one colony studied over a number of years included perianal squamous cell carcinoma, adnexal tumor of the skin, osteosarcoma, leiomyosarcoma, hepatic adenocarcinoma, hepatomas, and pituitary gland adenoma (Rantanen and Highman, 1970). *Mystromys* appear to be relatively resistant to chemically induced neoplasia as compared to rats, mice, hamsters, and *Mastomys* (Roebuck and Longnecker, 1979; Yamamoto et al., 1972).

Several other non-infectious and non-neoplastic diseases have been reported in *Mystromys*. Ringtail has been described in pre-weanling aged animals, and is associated with low environmental humidity (Stuhlman and Wagner, 1971). A fatal enteric syndrome associated with topical triple antibiotic ointment containing polymyxin B sulfate, bacitracin, and neomycin sulfate has been documented in *Mystromys* (LaRegina et al., 1978). Affected animals had ruffled fur, anorexia, and increased respiration. Necropsy findings consisted of congestion and inflammation of the cecum, dilation, and petechia in the ileum and colon.

Genetically related disorders reported in *Mystromys* include partial oculocutaneous albinism and diabetes mellitus. Partial oculocutaneous albinism is characterized by a decrease in melanin pigment in the structures of the eye and skin of the head (Priour et al., 1979; Rodrigues et al., 1971). Diabetes mellitus has been noted to occur in colonies at varying incidences ranging from less than 3% to 22% (Hallett and Politzer, 1972; Packer et al., 1970). Affected animals are polydipsic and polyuric, and show abnormally wet cages. Diabetes is not related to obesity and onset occurs by 4 months of age, suggestive of type I diabetes. Diabetes has been linked to other secondary diseases in *Mystromys*, including cataracts and renal glomerular lesions, making this a suitable model for type I diabetes mellitus research (Stuhlman, 1979).

EXPERIMENTAL MODELS

Mystromys was first used in research primarily to determine susceptibility of the species to a number of viral, bacterial, and parasitic pathogens. Viremia does not occur with Wesselsbron, Spondweni, Pongola, West Nile, or Crimean-Congo hemorrhagic fever viruses but occurs and lasts 5 days or less with Bunyamera, Chikungunya, Rift Valley Fever, Middleburg, and Simbu viruses without clinical illness (Jupp et al., 1981; McIntosh, 1961; Shepherd et al., 1989). *Mystromys* is resistant to infection with *Mycobacterium leprae* and *Mycobacterium microti*, but susceptible to *Yersinia pestis* and *Clostridium piliforme* (Davis, 1963; Grasset et al., 1946; Waggle et al., 1986). *Mystromys* is also susceptible to infection with some species of *Leishmania* and is a suitable model for cutaneous leishmaniasis caused by *Leishmania braziliensis* (Beacham et al., 1982; Franke et al., 1985; McKinney and Hendricks, 1980; Sayles et al., 1981). *Leishmania donovani* can be propagated in *Mystromys* (Mikhail and Mansour, 1973). *Mystromys* has also been used in *Schistosoma mansoni* and *Schistosoma haematobium* studies (Pitchford and Visser, 1960, 1962).

Mystromys has been used in dental caries research in which it was found that a combination of a high-sucrose diet with a caries-associated strain of *Streptococcus* was necessary to produce dental lesions (Larson and Fitzgerald, 1968). However Larson indicated that *Mystromys* was more difficult to handle, had smaller litter sizes, and less flexible breeding habits when compared to rats and did not offer any compelling reason for use when compared to rats and hamsters for dental caries studies. *Mystromys* has also been proposed for studies utilizing mitogen-induced T-lymphocyte cultures due to the robust response to mitogen stimulants (Howell and Hall, 1977).

Diabetes mellitus has been extensively characterized in *Mystromys* and at one time *Mystromys* was utilized as a model for human diabetes mellitus type I research (Packer et al., 1970; Stuhlman, 1979; Stuhlman et al., 1974). In *Mystromys*, diabetes is unrelated to obesity or diet, and is characterized by polydipsia, polyuria, hyperglycemia, and glycosuria (Packer et al., 1970). Pancreatic lesions in affected animals include vacuolization and glycogen deposits in beta cells. In more severe cases of hyperglycemia, pancreatic beta cells exhibit degeneration, nuclear pyknosis, and beta cell death (Goeken et al., 1972; Stuhlman et al., 1975). Glomerular changes include capillary basement membrane thickening and mesangial proliferation (Riley et al., 1975). Other changes include skeletal muscle capillary microangiopathy and cataract development (Stuhlman, 1979; Yesus et al., 1976). Thus diabetes mellitus in *Mystromys* has a number of features similar to diabetes mellitus

type I in humans. While this animal model may be useful for the study of human diabetes, the colony at the University of Missouri in which the diabetes was characterized is no longer in existence. Diabetes incidence in other *Mystromys* colonies has been reported to be less than 3%, and this model may be difficult to re-establish.

There are no biomedical research publications for *Mystromys* since the late 1980s and current publications focus more on the comparative biology of *Mystromys*. Swimming behavior studies, thermal biology characterization, and micromammal remains of *Mystromys* as a model of evolution related to environmental conditions have been described for *Mystromys* in more recent publications (Avery, 2001; Downs and Perrin, 1995; Hickman and Machine, 1986).

INTRODUCTION

The introduction and development of the Mongolian gerbil, *Meriones unguiculatus*, as a laboratory animal is recent, compared to other rodents. The gerbil is usually non-aggressive and is one of the easiest rodents to maintain and handle. Its disposition, curious nature, relative freedom from naturally occurring infectious diseases, and adaptability to its environment have contributed to its popularity as a laboratory animal (Wagner and Farrar, 1987). It has several interesting anatomical and physiological characteristics that make it a useful model in biomedical research. Several other species of gerbils (e.g. *Meriones libycus*, *Meriones crassus*) have been used as experimental animals (Belhocine et al., 2010; Khokhlova et al., 2009). However, the Mongolian gerbil (*Meriones unguiculatus*), on which this chapter will focus, is the most common species of gerbil used in biomedical research (Schwentker, 1963).

TAXONOMY AND HISTORY

Taxonomy

It should be noted that mammalian taxonomy is a rapidly changing field. The following description outlines a classification of the Mongolian gerbil based on morphology as well as more recent molecular techniques. Gerbils are in the class Mammalia and order Rodentia. Rodents are divided into five major suborders (Musser and Carleton, 2005). Gerbils are part of the suborder Myomorpha, originally so named because the deep and lateral masseter muscles attach to the front of the muzzle, giving it a forward thrust. Myomorphs also lack premolar teeth (Hurst, 1999). Gerbils belong to the superfamily Muroidea, family Muridae, and subfamily Gerbillinae based on morphology and on evaluation of nuclear protein coding sequences of the Lecithin Cholesterol Acyl Transferase gene and the von Willebrand factor gene (Michaux et al., 2001; Robinson, 1975). The genus *Meriones* was first described by Illiger in 1811, and *Meriones unguiculatus* was first identified in

1867 by Milne-Edwards (Robinson, 1975; Thiessen and Yahr, 1977). Chaworth-Musters and Ellerman (1947) provided a comprehensive description of the genus *Meriones* which was updated by Ellerman and Morrison-Scott (1951), Corbet (1978), and Pavlinov et al. (1990). The genus name, *Meriones*, was derived from a Greek warrior who wore a battle helmet decorated with boar tusks (Robinson, 1975). The species name, *unguiculatus*, is Latin for clawed or fingernail leading to one of the common names, clawed jird. The name gerbil is from the Arabic word, yarbu, which refers to saltatorial, desert-inhabiting rodents. Yarbu was translated into Latin as gerbo and into English as gerbil (Robinson, 1975).

Origin, Domestication, and Geographical Distribution

Approximately 15 genera and 81 species of gerbils are known (Agren, 1986). Gerbils are found in deserts and semi-arid geographical regions of the world (Field and Sibold, 1999; Thiessen and Yahr, 1977). They are native to northern Africa, India, Mongolia, southwestern and central Asia, northeastern China, and regions of Eastern Europe (Robinson, 1976). Because wild gerbils live in arid habitats they dig burrows that extend between 50cm and 1.5m below the surface so the temperature is relatively constant throughout the day and night. The burrows may be small and simple with one entrance or complex with eight to 14 entrances (Agren, 1986; Brain, 1999). The domestication of the Mongolian gerbil is a relatively recent occurrence. They were found by a French missionary, Father Armand David, who traveled extensively in Mongolia and China in the 1860s. Some wild-caught stock were sent to Japan, where they were bred freely (Alderton, 1986). The Mongolian gerbils that are available today originated from 20 pairs of captured animals that were maintained in 1935 by Dr. C. Kasuga in a closed, random-bred colony at the Kitasato Institute in Japan. In 1949 a sub-colony of gerbils was established at the Central Laboratories for Experimental Animals in Tokyo by M. Nomura. In 1954 Dr. V. Schwentker imported 11 pairs from Japan. Five females and four males from this group were

successfully bred and formed a foundation colony which produced gerbils for distribution throughout the United States (Robinson, 1979). This foundation colony was established at Tumblebrook Farm at Brant Lake, NY, founded by Dr. Schwentker. After his retirement in 1971, the Brant Lake facilities were phased out, and the Tumblebrook Farm gerbil production colony was relocated to new facilities in West Brookfield, MA under the ownership of D.G. Robinson. The name "Tumblebrook Farm" was retained (Robinson, 1974). A sub-colony established from seven pairs of animals by Dr. J.H. Marston at the Worcester Foundation for Experimental Biology in Shrewsbury, MA during 1961–62 was the origin of the sub-colony established at the University of Birmingham, England in 1964. This breeding stock produced the animals used in laboratories throughout the United Kingdom and Europe. Charles River Laboratories purchased Tumblebrook Farm in 1996 giving rise to the Crl:(MON)BR strain.

Genetics

There is a low amount of genetic variability present in laboratory gerbils compared to wild gerbils as a result of their origination from a few founder animals (Razzoli et al., 2003). Recently, Neumann et al. (2001) identified the first polymorphic dinucleotide repeat loci in Mongolian gerbils by a microsatellite technique. These studies demonstrated that there has been minimal genetic variability identified in the Mongolian gerbil used in research, even though there are several different lines or strains. Razzoli et al. (2003) confirmed these results using an amplified fragment length polymorphism technique to characterize and detect strain-specific polymorphisms in gerbils. Prior to these studies, relatively few genetic studies had been performed.

The common agouti or mixed brown Mongolian gerbil stock is used in research and sold as pets. The agouti has given rise to black (Cramlet et al., 1974; Waring and Poole, 1980), albino (Hedges, 1977), piebald, dove, cinnamon, and a "hairless" mutant (Alderton, 1986; Matsuzaki et al., 1989b). An inbred strain (Mon/Tum) is also available (Brain, 1999). There are also seizure-sensitive and seizure-resistant lines of gerbils (Loskota et al., 1974).

At the time of publication, Mongolian gerbils are commercially available in the United States from Charles River Laboratories, Inc., Wilmington, MA and Harlan, Indianapolis, IN.

ANATOMY, PHYSIOLOGY, AND BEHAVIOR

Basic Features

Gerbils have several unique anatomical and physiological features. Mature gerbils are smaller than rats, but

FIGURE 52.1 Size comparison between an adult rat (top), gerbil, and mouse.

FIGURE 52.2 Male and female gerbils are easily differentiated by the male's greater anogenital distance and pigmented scrotum (left, female; right, male).

larger than mice (Figure 52.1). Adults of both sexes vary between 11.5–14.5 cm in body length with males weighing an average of 100 grams and females weighing an average of 87.5 grams (Kramer, 1964). Body weights vary among colonies and this variation may be a genetic phenomenon as well as a dietary factor (Arrington et al., 1973). In adults, the sexes are easily differentiated by the male's longer anogenital distance, prominent testicles, and pigmented scrotum (Figure 52.2). Females have four pair of mammae, two inguinal and two thoracic, and the urethra is located outside the vagina (Wagner and Farrar, 1987).

External Features

External anatomical features are depicted in Figure 52.3. Cranial characteristics are consistent with saltatorial rodents. They have broad, short heads with prominent ears and large, black, slightly bulging eyes. Most

FIGURE 52.3 External anatomy of the gerbil. (A) Lateral view. (B) Dorsal view. (C) Ventral view.

mice and rats have longer, extended faces. The large eyes are an adaptation found in nocturnal animals, and their vision is very well developed (Alderton, 1986). Gerbils show active periods during day and night, and use both rod- and cone-based vision.

Gerbils generally have reddish brown fur with black outer tips on their backs, but coat color can vary from tan to gray, with a gray or creamy white undercoat. The tail is covered with fur that is short at the base and progressively becomes longer and bushy toward the tip of the tail. The tail length ranges from 10.0–19.3 cm (Norris and Adams, 1972c).

Musculoskeletal System

The hindlimbs are elongated, and the forefeet are relatively small. The hindlimbs are very muscular, and

aid in the gerbil's ability to jump considerable distances in proportion to their size. Gerbils use jumping or hopping as a form of ambulation (Brain, 1999). Gerbils' hind paws are not equipped with friction pads or opposable toes, and the soles are covered with fur; therefore, they cannot climb like mice (Roger and Polioudakis, 1977).

Special Senses

The gerbil's sense of smell is very keen and well developed. Gerbils have been shown to use a variety of odors as discriminative social cues from urine, ventral sebaceous glandular secretions, and Harderian gland secretions (Halpin, 1974; Thiessen et al., 1976; Thiessen and Yahr, 1977). Mongolian gerbils are attracted to saliva and use salivary cues to discriminate between siblings and non-siblings, and females use oral cues in the selection of sociosexual partners (Smith and Block, 1991). The Harderian gland functions as a potential site for immune response, serves as a part of the retinal–pineal axis, acts to cushion the eyeball, secretes lubrication for the eye, and is a source for pheromones and thermoregulatory lipids (Johnston et al., 1983; Sakai, 1981). Harderian gland secretions, comprised of lipids, proteins, and protoporphyrin, are carried by an excretory duct to the medial aspect of the nictitating membrane. These secretions bathe the eye and conjunctival space and are transported down the nasolacrimal duct, exiting at the external nares. The Harderian secretions are mixed with saliva and spread over the pelage during grooming (Thiessen, 1977).

Compared with mice, gerbils possess a much higher proportion of cones to rods. Since the gerbil retina is not exclusively rod-dominated, it is a valuable model for *in vitro* studies of retinogenesis (Bytyqi and Layer, 2005).

The tympanic bullae are prominent, giving the gerbil remarkable hearing with a high frequency peak of 50 kHz (Johnson and Marcotti, 2008).

Digestive System

The dental formula is 2 (incisors 1/1, canines 0/0, premolars 0/0, molars 3/3) = 16. The incisors are hypsodont (long crown) and elodont (continuously growing and erupting teeth that do not develop anatomical roots). The molars in gerbils are brachydont (short crown), rooted, anelodont (limited growth period) and cease to grow in mature animals. They are prone to dental caries, periodontal disease, and can develop incisor malocclusion (Field and Sibold, 1999).

The Mongolian gerbil's liver enzymes which are involved in cholesterol metabolism and hepatic cholesterol ester storage differ from those found in other rodents and make the gerbil an excellent model for hypercholesterolemia research (Norris, 1987; Temmerman et al., 1989). The gerbil's serum cholesterol

level is very sensitive to increased dietary cholesterol. Gerbils are resistant to atheromatous changes on high-cholesterol diets, but they can develop hepatic lipidosis and cholesterol gallstones when fed these diets (Vincent et al., 1979).

Circulatory System

Approximately 40% of Mongolian gerbils have an incomplete circle of Willis that allows for a reliable development of focal cerebral ischemia which is used to study the pathophysiology and treatment of ischemic stroke (Başkaya et al., 1999). When one carotid artery is ligated, a cerebral infarct on the side ipsilateral to the ligation is formed (Vincent et al., 1979). Gerbils have less collateral blood supply to the brain compared to mice and rats (Vincent et al., 1979).

Respiratory System

The respiratory system is very similar to other rodents in that gerbils do not appear to have respiratory bronchioles in the lung (Bal and Ghoshal, 1988). The right lung is composed of four lobes, while the left lung has three lobes (Williams, 1974).

Genitourinary System

Since they are desert animals, gerbils have several characteristics that have allowed them to adapt to dry environments. Gerbils have an excellent ability for thermoregulation, and they have a high level of heat tolerance. They have a unique water metabolism in that they require very little water to function (Winkelmann and Getz, 1962). Gerbils can obtain sufficient water from their diet and their kidneys have a highly efficient urine-concentrating capacity to ensure adequate hydration (Goyal et al., 1988). The ratio of long-loop nephrons to short-loop nephrons in gerbils is high. Ninety-six percent of their nephrons are long loop which allows them to efficiently concentrate their urine (Ichii et al., 2006). The digestive system is also very efficient at absorbing and retaining water, and water can be stored in fat cell layers. Gerbils produce and excrete a small amount of concentrated urine and dry feces per day (Alderton, 1986); therefore they require less frequent cage changing than other laboratory rodents.

Other Characteristics

The internal anatomy of Mongolian gerbils was investigated and described in detail by Williams (1974). He demonstrated that the anatomy of the gerbil and the albino laboratory rat is similar except for some minor

FIGURE 52.4 The thymus persists in adult gerbils (arrow).

FIGURE 52.5 Gerbils have large adrenal glands for their weight when compared to rats and mice (arrows).

variations. These include a lack of a preputial gland, the presence of a gall bladder, and 12 pairs of ribs in gerbils (Williams, 1974).

Gerbils have an unusually large thymus and adrenal glands compared to other rodents of similar size (Figures 52.4 and 52.5). The thymus is persistent in adults (Wagner and Farrar, 1987). The adrenal gland weight

FIGURE 52.6 There is a significant sex difference in the size of the ventral sebaceous gland, located in the shaved areas of these gerbils (left, female; right, male).

when compared to the body weight is approximately three times the size of the adrenal gland in rats (Cullen et al., 1971; Holmes, 1985). The significance of these anatomically enlarged structures is not known (Schwentker, 1963), although the enlarged adrenal glands are thought to contribute to their unique water conservation ability (Wagner and Farrar, 1987). The adrenal cortex produces equal amounts of corticosterone and 19-hydroxycorticosterone (Drummond et al., 1988). Unlike a rat, an adrenalectomized gerbil cannot be maintained by providing supplemental sodium (Cullen et al., 1971).

Both sexes have distinct mid-ventral abdominal sebaceous glands, which are used for territorial marking. The male sebaceous gland is twice the size of the female gland (Figure 52.6). At puberty in males, the gland becomes orange and produces an oily, musky scented secretion (Clark, 1984).

Physiology

Selective normal mature gerbil physiological parameter and hematological and serum chemistry values are listed in Tables 52.1, 52.2 and 52.3, respectively. The data reported are compiled from literature using average values with sexes combined. There is a limited amount of hematological and clinical chemistry data available in gerbils. Ruhren (1965), Mays (1969), Dillon and Glomski (1975), and Gattermann (1979) conducted studies and reported original data in gerbils. The blood volume of a Mongolian gerbil is approximately 7.7 ml/100 g. The red blood cell half life is approximately 9.9 days, which is short in comparison with that of other rodents (Womack, 1972). Young gerbils can have up to a 40% increase in circulating, stippled red blood cells and reticulocytes compared to adults (Ruhren,

TABLE 52.1 Basic Biological Parameters of Gerbils

Chromosome number	44
Life span (years)	2–5
Number of mammary glands	4 pairs: 2 thoracic, 2 inguinal
Birth weight (g)	2–4
Mature body weight (g)	65–100 (males) 55–85 (females)
Body temperature (°C)	37–38.5
Dental formula	2 (1/1, 0/0, 0/0, 3/3)
Food intake (g/day/100 g weight)	5–7
Water intake (ml/day/100 g weight)	4–7
Urine volume (ml/day)	Few drops to 3–4 ml
Heart rate	260–600
Respiratory rate	70–120
Sexual maturity	9–12 weeks for both sexes
Estrous cycle	4–6 days; postpartum estrus is present
Gestation	24–26 days
Number of litters in lifetime	6 or more
Litter size	1–12 (average 5)
Eyes open	16–20 days
Weaning	21–24 days

(Adapted from Clark, 1984; Field and Sibold, 1999; Harkness and Wagner, 1983).

1965; Smith et al., 1976). Gerbils have lower hematocrit values than mice, and have higher blood lipid values than rats (Mays, 1969). Sexual dimorphism in hematocrit, hemoglobin, total leukocyte count, and lymphocytes has been reported (Dillon and Glomski, 1975; Mays, 1969). Mays (1969) demonstrated that there were significant differences between males and females in phosphorus and uric acid levels. Serum cholesterol levels are higher than other rodents, even when gerbils are fed diets containing normal levels of fat (Roscoe and Fahrenbach, 1962).

Select Normative Values

Basic biological values are presented in Tables 52.1, 52.2, and 52.3 (adapted from Clark, 1984; Field and Sibold, 1999; Harkness and Wagner, 1983; Wagner and Farrar, 1987). Similar and additional data are presented in the sections on Normative Values; and Clinical Biochemistry and Hematology.

Behavior

Gerbils are quiet animals that are generally docile, easy to handle, and seldom bite. They are quite

TABLE 52.2 Hematological Parameters

Cholesterol (mg/dl)	90–151

(Adapted from Clark, 1984; Field and Sibold, 1999; Harkness and Wagner, 1983).

curious as demonstrated by their increased activity in an open field test and decreased thigmotrophic or “wall hugging” behavior compared to mice (Oldham and Morlock, 1970). In nature, gerbils live in family groups in complex burrows. Their compulsive burrowing behavior extends into the laboratory setting as well, and in many cases they will scratch at the sides and bottoms of cages in their attempts to burrow (Brain, 1999; Field and Sibold, 1999). Other normal activities include gnawing,

making nests, and nibbling on food continually to support their bursts of energy (Bradley and Pence, 1995). While primarily nocturnal, they are active during daylight hours, too, alternating periods of intense activity with sleep or rest (Brain, 1999; Thiessen and Yahr, 1977). They do not hibernate, but may exhibit estivation, depending on the species (Bradley and Pence, 1995).

Gerbils are territorial, and will mark almost any object in their environment by depositing a pheromone with their ventral sebaceous gland (Thiessen and Gray, 1971, 1974) (Figure 52.6). This enlarged, specialized gland is under the control of gonadal hormones (Glenn and Gray, 1965). Animals of both sexes which have higher androgen levels are more frequent markers and have an advantage in hostile encounters (Swanson et al., 1978; Thiessen et al., 1968a). In males, the gonadal androgens act on the medial preoptic area of the brain (Commings and Yahr, 1984; Thiessen and Yahr, 1970). In the female there is contradictory information regarding the influence of estrogen and progesterone on marking behavior (Thiessen and Lindzey, 1970; Wallace et al., 1973; Whitsett and Thiessen, 1972). Male gerbils scent mark more frequently than females (Lindzey and Carbonell, 1968) and gerbils with black coat color tend to mark more often than those with brown coat color (Turner and Carbonell, 1984). Marking behavior in males is used for exploration, establishing social dominance, and identifying territory (Thiessen and Yahr, 1970). In females, scent marking is used for exploration and is also important for identification and for the attraction between mother and young (Dagg and Windsor, 1971; Wallace et al., 1973). Males also urinate and defecate to mark their territory. Only groups of males that are raised together are compatible as adults and will defend their territory as a group. Once a family unit (male and female, or parents with a litter) is established, the gerbils will viciously attack intruders.

Pair bonding between male and female gerbils occurs; however, gerbils may not be completely monogamous (Brain, 1999; Robinson, 1978). Mating usually occurs at night, and the male will mate with the female several times. Both males and females will build a nest and care for the young (Elwood, 1975).

Gerbils make a drumming sound by thumping their hindlegs rapidly on the cage floor to signal a warning or excitement, or during courtship by the male (Brain, 1999).

Food hoarding is also a natural behavior in gerbils with females serving as the primary food hoarders. Castration of male gerbils will increase hoarding behavior indicating that hoarding is inversely related to androgen levels. In one experimental setting where a pair of gerbils was provided with a ten foot square room with a closet, the female gerbil gathered and stored approximately 50 pounds of food in the closet (Thiessen and Yahr, 1977).

MANAGEMENT, HUSBANDRY, AND COLONY HEALTH

Maintaining a well-managed gerbil colony requires attention to many aspects of animal care. Animal well-being is dependent on appropriate housing conditions, from the micro-environment (cage) to the macro-environment (holding room and facility). Animals must receive appropriate nutrition, and veterinary oversight must be provided to ensure an effective preventive medicine and health-monitoring program. Finally, documentation is essential to ensure that procedures are being followed as designed and to comply with national regulations.

Housing Systems

Caging designed for other rodents (e.g. hamsters and rats) is generally adequate for gerbils, and solid-bottom, bedded caging is preferred (Brain, 1999; Field and Sibold, 1999; Harkness and Wagner, 1983; Moore, 1995; Olfert and Cross, 1993). Recommended cage dimensions vary and may be subject to national regulations. For example, the Canadian Council on Animal Care (Olfert and Cross, 1993) proposes a floor area per animal of 116cm² and 15cm cage height, while the Committee for the Purpose of Control and Supervision on Experiments on Animals (CPCSEA) in India recommends a floor area of 64.5cm² (up to 60g) to 122.5cm² (over 100g) and a height of 12cm. Although the gerbil is a United States Department of Agriculture (USDA)-covered species, neither the Animal Welfare Act Regulations (9CFR Part 3 nor the *Guide for the Care and Use of Laboratory Animals* (Guide)) (National Research Council, 2011) provide standards for cage sizes for gerbils in the United States. Others have recommended that adult gerbils have 36in²/230cm² of floor space per animal and 6in/15cm of internal cage height and that breeding pairs with litters should have 180in²/1300cm² of floor space (Harkness and Wagner, 1983).

Bedding types used for gerbils are the same as those used for other rodent species. These include chopped corncob, hardwood chips, cellulose fiber, and other commercially available beddings. In addition to absorbing wastes, bedding may be used as a burrowing substrate, or a separate substrate such as sand may be provided. Pine bedding is not recommended as it causes matting and greasiness of the fur (Brain, 1999; Field and Sibold, 1999) as well as the induction of hepatic drug-metabolizing enzymes (Vesell, 1967).

Gerbils do best when housed in groups established prior to puberty. Introducing new cagemates into an established group, or re-introducing former cagemates who have been separated for more than 14 days, may precipitate fighting (Harkness and Wagner, 1983; Moore, 1995; Olfert and Cross, 1993). One method of pairing

unfamiliar adults is to allow them to recover from anesthesia in a neutral cage (Harkness and Wagner, 1983). Male gerbils raised in isolation exhibit increases in social sniffing, aggression, and anxiety compared with group-reared males (Shimozuru and Kikusui, 2008).

Environmental Conditions

Recommendations for environmental conditions for gerbils are similar to those for rats and mice. Temperature recommendations range from 64–79°F/18–26°C (typically 72 ± 2°F/22 ± 1°C). A 12-h light: 12-h dark cycle is appropriate for general housing, but a longer 14-h light: 10-h dark cycle is desirable for breeding colonies (Field and Sibold, 1999; Moore, 1995). Cold temperatures and/or short light cycles (e.g. 5°C, 8-h light: 16-h dark) may elicit physiological changes related to winter survival mechanisms such as increased basal metabolic rate and non-shivering thermogenesis (Li and Wang, 2005). Relative humidity should be maintained at 30–70% RH; however, rough hair coats have been reported to occur at humidity levels greater than 50% RH (Field and Sibold, 1999; Harkness and Wagner, 1983; Moore, 1995). Housing areas should be kept quiet, because sudden noises may elicit epileptic seizures. The *Guide* (National Research Council, 2011) recommends 10–15 air changes per hour as a general standard for animal holding rooms.

Cage enrichment devices for gerbils that are not made of a sturdy material will be quickly destroyed by the gerbils' natural chewing activities. Stainless steel and PVC materials have been recommended in the form of "toys", cups, tubes, and other shelters (Field and Sibold, 1999). However, it has been suggested that providing shelters may result in differences in behavior, maturation rate, and adrenal weights (Moore, 1995). Nesting material is used readily but may be chewed and incorporated into the cage bedding. Heavier material such as thick cardboard tubing can provide shelter and a chewing substrate which will last longer than other nesting materials (Batchelder, personal communication). Naturalistic environmental enrichment such as sand and stones has been recommended. Sand or deep bedding allow expression of the animals' burrowing behaviors (Field and Sibold, 1999). Sand bathing is an important part of the gerbil behavioral repertoire (Tortora et al., 1974), but providing sand may not always be practical in the laboratory setting.

Gerbils in solid-bottom caging generally have the bedding replaced once or twice a week, depending on factors such as cage density or the presence of newborn pups. Since gerbils are a desert species, they produce little urine and dry feces, which may allow a decreased frequency of bedding changes relative to other species (Moore, 1995). Typically, bedding is changed and solid-bottom cages are sanitized on the same schedule,

while animals in wire-bottom cages may have the cage sanitized less often. The *Guide* recommends that primary enclosures and accessories (including lids and feeders) be sanitized at least every 2 weeks (National Research Council, 2011).

Sanitization may be performed by hand or in automated equipment. Detergent and hot water (143–180°F/62–82.2°C) are used to remove soil and disinfect the equipment. Care must be taken to rinse all chemical residue from the caging before use (Committee for the Purpose of Control and Supervision on Experiments on Animals, 2010; National Research Council, 2011). Cages, accessories, and bedding may be autoclaved if a sterile environment is desired (Field and Sibold, 1999).

Nutrition

Gerbils are adapted to live in arid conditions in the wild. Their diet is primarily seeds, and a large portion of their water intake is derived from their food. Although they can live for extended periods without supplemental water, provision of fresh water is generally recommended for animals in captivity. Reproduction may be decreased if water is restricted (Yahr and Kessler, 1974). Supplementation with natural feeds such as vegetables and grains is not necessary, but they may be provided as a treat.

Zeman (1967) proposed a semi-purified diet as a basis for research into the nutritional requirements of gerbils. However, very little work has been published since then, and the specific nutritional requirements of gerbils remain largely undetermined. They are generally considered to be similar to those of the rat, and gerbils are usually maintained by ad libitum feeding of commercial diets formulated for rats or mice. Diets should contain at least 16% protein. Harkness and Wagner (1983) recommend 22% protein and 2–5% dietary fat. Gerbils appear to have a higher need for magnesium than rats, as levels below 1 g/kg diet may result in alopecia and increased susceptibility to seizures; 1.5 g/kg diet is recommended. Gerbils are also susceptible to developing elevated blood and liver cholesterol when fed an excess of fat or cholesterol in the diet (Brain, 1999; Subcommittee on Laboratory Animal Nutrition, 1995). Gerbils are not coprophagic when fed a nutritionally complete diet (Field and Sibold, 1999; Otken and Scott, 1984).

Weanling gerbils may have difficulty reaching food provided in a cage-lid feeder. If necessary, food may be placed in a dish on the cage floor.

Breeding

It is relatively easy to determine the sex of adult gerbils. The male is distinguished by its longer anogenital

distance, prominent genital papilla, and pigmented scrotum (Figure 52.2). Gerbils become sexually mature at 9–12 weeks of age. Females have a 4–6-day estrous cycle and are spontaneous ovulators. They are sexually receptive for 12–15 hours, and mating often occurs several times. Males thump their feet as a courtship display. A vaginal plug is present after ejaculation, but usually disappears by the following morning (Brain, 1999). Gestation is 24–26 days, and litter size averages five pups (range 1–12). Larger litters may necessitate fostering some of the pups to another lactating female gerbil or even to a lactating rat (Brain, 1999; Moore, 1995). Both parents participate in building a nest and caring for the young, although during post-partum estrus the male may be more interested in mating than in child-rearing (Prates and Guerra, 2005). Arrington et al. (1973) reported that 47% of females become pregnant at this time. As in mice, gestation during lactation may be prolonged due to delayed implantation (Brain, 1999; Norris and Adams, 1981). Pups are about 2.5 g at birth, are altricial, begin eating solid food at about 14 days of age, and are weaned when they reach 21–24 days of age. Handling and cage changing should be minimized during the breeding and peri-partum periods to reduce the chance of females abandoning their pups.

Gerbils may be bred as pairs or as harems with 2–3 females per male. However, they may form monogamous pairs, mating for life. After the loss of one mate, it may be difficult to introduce a new one to the survivor (Norris and Adams, 1972a). Pairs are usually established at about 6–7 weeks of age (Moore, 1995), although Brain (1999) suggests animals reproduce sooner if paired at 2–3 months of age. Animals may fight or fail to mate if they were not previously housed together. Females which mature earlier (vaginal opening before 25 days of age) have been reported to be more productive breeders than later-maturing females (Brain, 1999). Female gerbils housed as a single-sex group show decreased incidence of estrus whereas pairing with a male will result in estrus by day 3 in 44% of females (Meckley and Ginther, 1974). Pseudopregnancy has been known to occur, lasting a shorter period (14–18 days) than pregnancy (Brain, 1999). Gerbils have a relatively high incidence of cystic ovaries which may affect breeding production (Norris and Adams, 1972b). Wu (1974) has described artificial insemination in the gerbil, and Mochida and Wakayama (2005) describe gerbil embryo cryopreservation with subsequent implantation and live births.

Colony Health

Maintaining a healthy gerbil colony is a matter of good husbandry and sanitation, screening of any new animals brought into the colony, and appropriate veterinary medical care and oversight. Routine health monitoring is

recommended to detect any unwanted agents that may arise in the colony.

Animals being brought into an established colony should be obtained from a reliable source and have documentation that they do not carry any infectious agents excluded by the institution. Shipping containers should be disinfected before bringing into the facility, in case the outside surfaces were contaminated during transport. Animals should be checked for general health upon receipt, and in some cases – especially if obtained from a non-commercial or untested source – may be subjected to a quarantine period to ensure absence of unwanted infectious agents before introduction into the general population.

Similarly, any tissues or biologicals that will be introduced into the colony should be screened for infectious agents prior to use (Rehbinder et al., 1996). This can be done by Mouse Antibody Production testing or by screening with a panel of polymerase chain reaction (PCR) tests.

Gerbils have not been reported to be susceptible to spontaneous viral diseases. Nevertheless, they can be screened for viruses that may infect other species, including zoonotic viruses. These include lymphocytic choriomeningitis virus (LCMV), pneumonia virus of mice (PVM), minute virus of mice (MVM), parainfluenza virus, hantavirus, coronavirus, reovirus, Sendai virus, and simian virus 5 (Charles River Laboratories, 2009; Rehbinder et al., 1996).

Health monitoring for agents likely to cause disease in gerbils is primarily directed toward bacterial and parasitic agents. It is recommended that gerbil colonies be screened for *Clostridium piliforme* (Tyzzer's disease) and for *Salmonella* spp. They may also be screened for *CAR* bacillus, *Bordetella bronchiseptica*, *Pasteurella* spp., *Beta Streptococcus* spp., *Streptococcus pneumoniae*, *Pseudomonas* spp., *Klebsiella* spp., *Helicobacter* spp., *Citrobacter rodentium*, and *Corynebacterium kutscheri*, which may less commonly cause disease in gerbils, or be transmitted to other species (de la Puente-Redondo et al., 1999; Glage et al., 2007). Screening for *Staphylococcus aureus* may generate positive results without disease being present, but the organism can be associated with some conditions such as nasal dermatitis (Charles River Laboratories, 2009; Rehbinder et al., 1996; Solomon et al., 1990).

Screening should also be performed for the more common parasites including *Demodex merionis* mites and pinworms such as *Syphacia* spp. or *Dentostomella translucida* (Wightman et al., 1978). Other possible parasitic agents include *Hymenolepis diminuta* and *Hymenolepis nana*, *Giardia* spp., *Entamoeba muris*, *Eimeria* spp., *Encephalitozoon cuniculi*, *Toxoplasma gondii*, *Spiroplasma* spp., and intestinal flagellates.

Screening may be performed using colony animals and/or using dedicated sentinel animals, most often

animals exposed to soiled bedding and/or caging from colony animals. Mice have been used as sentinels in gerbil colonies as they are susceptible to lymphocytic choriomeningitis virus, coronavirus, Sendai virus, pneumonia virus of mice, and Reovirus 3, as well as to *Syphacia* and bacterial pathogens (Batchelder, personal communication).

Record Keeping

Several types of records are important in the maintenance of a gerbil colony, including animal records, facility records, breeding records, and regulatory records.

Identification records and health records are two types of animal records. Each animal should be able to be identified as to source, birth date, receipt date, sex, animal use protocol, responsible investigator name, and any identifying information such as an ear tag or microchip number. These records help ensure that the appropriate animal, and the correct animal, is used in an experimental procedure. Health records can include examination records at the time of receipt, surgical and experimental procedure records, and records of any individual health issues and treatments the animal may have received.

Facility records consist of documentation that appropriate husbandry and sanitization procedures have been followed. These are commonly kept as a check-off sheet that lists daily, weekly, and other scheduled tasks which are marked off as they are completed. Other facility records include cage wash and autoclave validation, feed receipt and expiration dates, pest control documentation, environmental parameters such as light, temperature, and humidity, etc.

Breeding records are essential to the maintenance of any breeding colony. An animal's genealogy should be able to be traced, and records should be kept on the breeding success of both males and females. Daily records, such as birth and weaning dates, and long-term records such as planned breeder replacement are necessary to keep breeding at top efficiency. Unless inbreeding is desired, careful records will help avoid mating close relatives.

Additional records may be required by regulatory agencies in the country where the animals are being kept. Such records might include animal receipt and transfer records, disposition records, and documentation concerning the research for which the animals were used. Animals which are sick or which die unexpectedly may be expected to have additional documentation such as individual medical or necropsy records. Records may be needed to document research oversight activities such as approval of protocols involving gerbils, facility inspections, and animal care program reviews. Regulations may also stipulate how long such records need to be

retained. Those involved with research using gerbils should be familiar with the regulations for their particular location.

BASIC EXPERIMENTAL METHODS

Gerbils have been used as experimental models in a number of areas of biomedical research. They are relatively easy to maintain and to handle. Experimental methods used for gerbils are similar to those used in other rodents such as mice and rats.

Handling and Restraint

Gerbils are generally non-aggressive and can easily be handled with little risk of being bitten. They may be moved using cupped hands, or may be lifted gently by the base of the tail. Care must be taken to grasp the tail base only (Figure 52.7), since the skin on more distal parts of the tail may pull off easily (Donnelly, 1997). If more secure restraint is needed, gerbils may be grasped by the loose skin on the back of the neck (Figure 52.8). With this grasp, they may be oriented in any position; however gerbils dislike being held on their backs and may struggle in this position (Moore, 1995).

Mechanical restraint devices designed for mice or small rats may be used for gerbils. Again, care must be taken to grasp the tail only at the base when placing the animal in the device to prevent a degloving injury.

A number of chemical agents used in other species are also used to sedate gerbils for handling. These include diazepam (5mg/kg IM or IP), ketamine (100–200mg/kg IM), medetomidine (100–200µg/kg IP or SC), midazolam (5mg/kg IM or IP), or xylazine (2mg/kg IM)

(Flecknell, 2009; Hawk et al., 2005). Acepromazine has been reported to induce convulsions in gerbils (Harkness and Wagner, 1983) and is not recommended in this species. A short-acting inhalant anesthetic such as isoflurane or sevoflurane may also be used to effect for brief chemical restraint. Atropine (0.02–0.05mg/kg SC, IM, or IV) or glycopyrrolate (0.01–0.02mg/kg IM or SC) may be used to decrease salivary and bronchial secretions (Hawk et al., 2005).

Identification

Gerbils may be identified by cage cards, ear tags or notches, indelible markers, or microchip implantation. Tattooing is another option, but is less useful in gerbils than in mice and rats due to the presence of hair on the paws and tail.

Sampling Techniques

Several sites may be used for blood collection in the gerbil. Use of the lateral tail vein may be facilitated by warming the tail to promote blood flow and by placing pressure on the vein at the base of the tail. Methods for

FIGURE 52.7 When restraining a gerbil by the tail, only the base of the tail should be grasped to avoid degloving injuries.

FIGURE 52.8 Gerbils may be restrained by the scruff of the neck.

FIGURE 52.9 Blood collection from the retro-orbital sinus.

FIGURE 52.10 Blood collection by cardiac puncture.

bleeding from the lateral saphenous vein and from the submandibular vein have also been reported (Golde and Gollobin, 2005; Hem and Smith, 1998). For a small amount of blood, a toenail may be clipped short, or the tip of the tail (1–2 mm) may be transected. Care should be taken to control hemorrhage, the tail tip should only be used once or twice to avoid damage to the coccygeal vertebrae, and anesthesia is recommended. Larger volumes of blood may be collected by retro-orbital puncture (Figure 52.9), jugular venipuncture (Palm and Hollander, 2007), or cardiac puncture; all of these procedures should be performed under anesthesia, and cardiac puncture (Figure 52.10) should be terminal because of the risk of pericardial hemorrhage and cardiac tamponade. The maximum volume for blood withdrawal which has the least scientific impact on the gerbil's physiologic response is 0.77 ml/100 g body weight (Diehl et al., 2001; Moore, 1995).

Urine collection is difficult due to the very small volume of urine produced by the gerbil, variously reported as a few drops to 3–4 ml/day (Brain, 1999; Moore, 1995). If urine cannot be collected by expressing the bladder or by free catch, a metabolism cage may be used. Care should be taken that the small amount of urine does not evaporate from the collection chamber.

FIGURE 52.11 Measuring the gavage needle to the level of the last rib.

Compound Administration

Oral administration of compounds is most commonly accomplished with the use of a ball-tipped gavage needle, as used in other small rodents. The length of the needle should be checked against the side of the animal to the level of the last rib to ensure it is not so long as to bypass the stomach (Figure 52.11). The needle should slide easily into the stomach (Figure 52.12); any resistance may indicate the needle is located in the trachea and it should be withdrawn and redirected. Animals may also be dosed orally by the use of medicated feed or water. If this method is used, the animals' food and water consumption should be monitored to ensure that the drug is not causing the feed or water to be unpalatable. Decreased consumption may lead to underdosing.

The most common site for intravenous (IV) injection in the gerbil is the lateral tail vein (Figure 52.13). Injection may be facilitated by warming the tail to promote blood flow and by placing pressure on the vein at the base of the tail to dilate the vessel. A 23-gauge or smaller needle should be used (Field and Sibold, 1999). Cutdown procedures have been described for intravenous dosing using the jugular vein (Palm and Hollander, 2007) and the femoral vein (Pérez-García et al., 2002).

FIGURE 52.12 Oral gavage using a ball-tipped dosing needle.

FIGURE 52.14 Intramuscular injection into the thigh muscles.

FIGURE 52.13 Intravenous injection in the lateral tail vein.

FIGURE 52.15 Subcutaneous injections may be given under the loose skin over the gerbil's back by tenting the skin and inserting the needle parallel to the body wall.

Intramuscular (IM) injections are given in the muscles of the thigh ([Figure 52.14](#)), with care being taken to avoid the sciatic nerve. The volume of the IM injection should be small enough to avoid muscle damage and pain. Volumes over 0.1 ml should be split between two sites.

Most subcutaneous (SC) injections are given under the loose skin over the neck and shoulders of the gerbil ([Figure 52.15](#)). The skin is tented and the needle is inserted parallel to the body wall to avoid injecting into deeper tissues.

Gerbils may be dosed intraperitoneally (IP) in the caudal left or right abdomen, similar to other small rodent species. However, because gerbils may struggle if held on their backs, they should be restrained in a

vertical position while dosing ([Figure 52.16](#)). Extra care should be taken to draw back on the syringe to ensure the needle has not entered the bowel or bladder prior to injecting.

Other routes of dosing include topical, intradermal, intranasal, and cerebroventricular. Any substance used for parenteral dosing should be sterile and pyrogen-free ([Moore, 1995](#)).

If dosing is performed repeatedly, the animal should be monitored closely for any complications. Depression, dyspnea, hunched posture, abdominal splinting, or signs of pain or irritation at an injection site should be brought to the attention of the veterinary staff.

FIGURE 52.16 An intraperitoneal injection is given while holding the gerbil in a vertical position.

An alternative to repeated parenteral injections is the implantation of an osmotic pump. These devices are designed to be implanted subcutaneously or intraperitoneally, and will subsequently provide a steady-state dose of compound for up to several weeks.

Euthanasia

Methods for euthanasia should be selected based on the recommendations of the AVMA ([American Veterinary Medical Association, 2007](#)), the experimental parameters, and operator comfort with the procedure. Common methods include carbon dioxide inhalation, overdose of an anesthetic agent (e.g. pentobarbital 100–150 mg/kg IP), use of a commercial injectable euthanasia agent, or physical methods such as decapitation or cervical dislocation. The latter two methods should be performed under anesthesia unless scientifically justified and approved by the Institutional Animal Care and Use Committee. Less commonly used methods include microwave irradiation and exsanguination/perfusion under anesthesia. All methods require training and proper equipment in order to be performed humanely.

VETERINARY CARE AND DISEASES

Veterinary Care

Gerbils are excellent subjects for laboratory animal research as they are susceptible to bacterial, viral, and parasitic pathogens that affect humans and other species, yet they have very few of their own diseases. Some of the most common conditions seen in laboratory gerbils are related to handling, husbandry, or keeping the gerbils until old age. In general, veterinary practices used in providing health care for other laboratory rodents are also appropriate for laboratory gerbils.

Meeting gerbils' specific housing and husbandry needs will help keep them healthy. Gerbils' hind legs are longer than their front legs and they like to stand erect on the hind legs. To accommodate this behavior, the floor to lid height of gerbil cages needs to be sufficient for the gerbil to stand. Gerbils should be housed in solid-bottom caging with bedding at least 3–5 cm deep to allow for burrowing behavior. Gerbils also exhibit gnawing behavior and need to have non-toxic, hard materials on which to gnaw.

Gerbils must be picked up by the base of the tail to avoid the skin on the tail degloving. They should have their incisors and claws checked periodically to make sure that both are being worn down. Claws can be clipped if they are too long. A rough-surfaced object such as a stone or a bathroom tile can be placed in the cage for the gerbils to wear down their claws as well as to use for normal marking behaviors. Gerbils exhibit shredding behavior and should be provided with autoclaved cardboard, hay, straw, paper, or tissue. Gerbils are burrowing animals and sometimes will resort to stereotypic digging in the corner of the cage. A man-made burrow may be used in a laboratory setting. One example utilizes clear and opaque sections with an access tunnel ([Waiblinger, 2010](#)).

Gerbils need to have a substrate to remove the lipids that they place on their hair coat during self-grooming. In the wild, gerbils use sand baths, and they will use them in the laboratory if provided (Tortora et al., 1974). If gerbils exhibit a dirty, ungroomed hair coat, consider changing the type and amount of bedding, make sure the relative humidity is less than 50% and consider lowering the temperature of the room.

Common Diseases

Epilepsy

Gerbils may have spontaneous seizures secondary to stress such as handling, cage change, abrupt noises, or changes in the environment. Generally, gerbils will recover from these seizures after 30–90 seconds without treatment, and appear to have no long-lasting effects.

Tail Slip

Gerbils that are picked up by the tip or middle of the tail are very susceptible to skin degloving (Donnelly, 1997). Gerbils should always be picked up by the base of the tail or by cupping the hands. Tails that have been degloved can be surgically amputated.

Nasal Dermatitis (Sore Nose, Facial Eczema)

This is a common skin condition of gerbils which likely has a multifactorial etiology. Clinical signs start as erythema at the nares and develop into facial alopecia, dermatitis, and scab formation. Some cases can develop into a moist dermatitis involving the head, forelimbs, and chest. This condition has been reported to be most common in young weanling gerbils (Field and Sibold, 1999).

Gerbils release a complex mixture of pigments and lipids from the Harderian gland during self-grooming. The material is excreted at the nares and is mixed with saliva and spread over the gerbil's hair coat. Harderian exudates are normally removed from the gerbil's pelage by sand bathing (Harriman and Thiessen, 1983; Thiessen, 1988). Two studies have shown that Harderian secretions which act as primary skin irritants are a factor in the development of nasal dermatitis. Removal of Harderian glands or housing animals on sand either prevented lesions or caused improvement in existing lesions, while animals with intact Harderian glands and reduced opportunity to groom or sand bathe developed or maintained existing lesions (Farrar et al., 1988; Thiessen and Pendergrass, 1982).

Staphylococcus spp. have been implicated in the development of this condition. One paper reports *S. aureus* as the bacteria most commonly cultured from the nasal area of affected animals, although *S. aureus* was also cultured from non-affected gerbils (Bresnahan et al., 1983). Another study reported that *S. xylosus* was the predominant species isolated from all gerbils, most commonly from the nasal area, and the only species isolated from the nasal area of gerbils with clinical signs of nasal dermatitis (Solomon et al., 1990).

Cystic Ovaries

Cystic ovaries are seen commonly in female gerbils over 1 year of age (Norris and Adams, 1972b). Clinical signs include symmetrical alopecia, abdominal swelling, lethargy, anorexia, dyspnea, and reduced fertility. In 1982, Norris and Adams showed that female gerbils older than 700 days had a 79% rate of cystic ovaries in gerbils with two ovaries and a 40% rate of cystic ovaries in gerbils with one ovary. They also showed that removing one ovary in a gerbil does little to affect overall reproductive performance (Norris and Adams, 1982).

Less Common Diseases

Bacterial

Although there have been reports of bacterial diseases in laboratory gerbils in the past, animals can be purchased today that are free from antibodies to *Clostridium piliforme* and are culture-negative for *Salmonella* spp., *Bordetella bronchiseptica*, and *Pasteurella pneumotropica*. The most common bacterial threat to a high-quality research colony is helicobacter.

There have been reports of laboratory and pet gerbils infected with *Clostridium piliforme*, the etiologic agent for Tyzzer's disease (Motzel and Gibson, 1990; Port et al., 1971; Vincent et al., 1975). Gerbils usually exhibited diarrhea or sudden death. Necropsy findings included multi-focal hepatic necrosis. In 1984, Waggle et al. experimentally induced Tyzzer's disease in gerbils and showed that they were highly susceptible to the disease. Strittmatter (1972) eliminated the disease in gerbils by cross-fostering gerbil offspring to unaffected mice.

In 2005, Bergin et al. reported a case of two laboratory gerbils with fatal *Clostridium difficile* enteritis. The gerbils were being treated for helicobacter infection with antibiotic wafers containing amoxicillin, metronidazole, and bismuth subsalicylate. There is also one report of a fatal epidemic of *Citrobacter rodentium* affecting nine gerbils (de la Puente-Redondo et al., 1999).

In 2009, Tappe et al. reported a new species of the genus *Streptococcus* which was cultured from the oropharynx of Mongolian gerbils. The new name proposed for these Gram-positive, catalase-negative, chain-forming cocci is *Streptococcus merionis* sp. nov. There were no clinical signs reported in the gerbils.

Gerbils are natural carriers of multiple species of helicobacter (Bergin et al., 2005). Glage et al. (2007) reported rederivation of *Helicobacter hepaticus*-infected gerbils by Caesarean section and cross-fostering on non-infected mice.

Viral

No naturally occurring viral diseases of gerbils have been published.

Parasitic

Parasites rarely cause clinical problems in the laboratory gerbil, and are excluded from major commercial gerbil suppliers. Wightman et al. (1978) reported finding *Syphacia obveleta* and *Dentostomella translucida* in gerbils. They showed that *S. obveleta* can be transmitted from gerbil to mouse, mouse to gerbil, and gerbil to gerbil, while Ross et al. (1980) showed that *Syphacia muris* is similarly easily transmitted between gerbils, rats, hamsters, and mice. Wilkerson et al. (2001) reported that using fenbendazole-medicated feed was the only practical and reliable way to eradicate pinworms in

gerbil colonies. In 1970, Lussier and Loew reported a naturally occurring case of *Hymenolepis nana* in Mongolian gerbils, while in 1975, Vincent et al. reported the recovery of *Hymenolepis diminuta* from gerbils. *Demodex merioni* mites have been reported in gerbils with alopecia, dry skin, and ulcerations. Animals who are already debilitated are at most risk for developing mite infestations (Rollin and Kesel, 1995).

Other Diseases

Antibiotic Sensitivity

Gerbils are very sensitive to dihydrostreptomycin. Wightman et al. (1980) reported that an injection of 50 mg caused mortality in 80–100% of gerbils weighing 55–65 grams. Two gerbils given a commercially available treatment to eradicate helicobacter developed a necrohemorrhagic enteritis. It was determined that the amoxicillin component caused an overgrowth of *Clostridium difficile* (Bergin et al., 2005).

Neoplasia

There are a number of surveys about neoplasia in laboratory colonies of Mongolian gerbils (Meckley and Zwicker, 1979; Ringler et al., 1972; Vincent and Ash, 1978; Vincent et al., 1975). Neoplasia has been most often reported in gerbils over 3 years of age (Matsuoka and Suzuki, 1995). Commonly reported tumors are squamous cell carcinoma of the ventral marking gland in males and ovarian granulosa cell tumors in females. In surveys, adrenocortical tumors, cutaneous squamous cell carcinoma, malignant melanoma, and renal and splenic hemangiomas are the next most commonly reported tumors. Other tumors that have been reported include astrocytoma, craniopharyngioma, and systemic mastocytosis (Guzman-Silva, 1997; Guzman-Silva et al., 1988; Kroh et al., 1987; Rembert and Johnson, 2001). In 1997, Campos et al. reported a variety of epithelial-type neoplasias in the ventral prostrate of 18-month-old gerbils. Tumors included prostatic intraepithelial neoplasias, microinvasive carcinomas, and adenocarcinomas.

Chronic Interstitial Nephritis

This condition is considered an old-age change. Gerbils will exhibit clinical signs of polyuria, polydipsia, and weight loss. On gross exam the kidneys will be shrunken and pitted (Bingel, 1995).

Aural Cholesteatoma

Older gerbils can spontaneously develop cholesteatomas in the ear canal which resemble the human condition. Clinical signs include scratching, head tilt, and circling. The incidence appears to be age-related (Fulghum and Cole, 1985; Schiffer et al., 1986).

GERBILS AS EXPERIMENTAL MODELS

Gerbils have unique characteristics which make them appropriate for a number of animal models. Classically, gerbils have been used in research involving stroke, parasitology, infectious diseases, epilepsy, brain development and behavior, and hearing.

Stroke (Cerebral Ischemia)

In mammals the circle of Willis is comprised of a communication of arteries at the bottom of the brain consisting of the internal carotid arteries, anterior cerebral arteries, anterior communicating arteries, posterior communicating arteries, posterior cerebral arteries, and basilar arteries. This structure provides for alternate blood flow to the brain in case one artery becomes occluded. Levine and Payan (1966) first identified gerbils as having an anatomical anomaly of the circle of Willis with no communication between the posterior cerebral arteries. This has been termed an incomplete circle of Willis. Researchers found that ligating the left carotid artery of the gerbil caused acute cerebral ischemia much more consistently than when performing the same ligation in the rat (Wexler, 1972). In 1974, Levy and Brierley performed a study on gerbils to assess the cerebrovascular anatomy and communications in the gerbil brain by injecting colored dye into the aorta. Based on evaluating ten male gerbils from an unspecified source, these authors concluded that each of the gerbil's carotid arteries is divided into an anterior, middle, and posterior cerebral artery. They found that the basilar artery communicated with the carotid artery in all gerbils, that the posterior cerebral artery was a branch of the carotid, and that there was no single posterior communicating artery.

As gerbils were more frequently used for stroke research, more information about their cerebrovascular anatomy became available. It was determined that not all gerbils have an incomplete circle of Willis and that "stroke-prone" and "stroke-resistant" gerbils could be identified (Delbarre et al., 1988; Kitagawa et al., 1989; Pelliccioli et al., 1995). Considerable variability was found both in the extent of damage after bilateral artery occlusion and in the percentage of stroke-prone gerbils in a population. The percentage varied between the sexes (males 42.9% stroke-prone, females 26.7%) (Hall et al., 1991) and by the source of the animals (Breuer and Mayevsky, 1992; Laidley et al., 2005; Seal et al., 2006).

Methods to define stroke-prone gerbils include examination of retinal blood flow after ligation of the carotid artery (Delbarre et al., 1988), measurement of the diameter of the common carotid artery before and after temporary ligation (Kitagawa et al., 1989), survival

after unilateral carotid artery occlusion (Pelliccioli et al., 1995), and determination of the presence and diameter of the posterior communicating artery (Seal et al., 2006).

Despite the fact that the anatomy of the gerbils' circles of Willis cannot be considered uniformly lacking in posterior communicating arteries, gerbils continue to be used as a common animal model for stroke, with the two-vessel occlusion being considered the simplest (Small and Buchan, 2000). Laboratory animal veterinarians that work with gerbils as stroke models need to be aware that this difference in cerebral vascular anatomy could lead to variable or conflicting results.

Parasitic Diseases

Gerbils seem to be very well suited to host parasitic infections from other species and are therefore a popular animal model for a wide variety of parasites. Many parasitic genera have been described in experimental studies of infection, susceptibility, pathology, immunology, and chemotherapy.

Cestodes

Gerbils are alternative definitive hosts for *Echinococcus granulosus* (Conchedda et al., 2006). Gerbils have also been used as an animal model for *Echinococcus multilocularis* (Kamiya and Sato, 1990) as well as *Echinococcus vogeli* (Matsuo et al., 2000).

Although the Mongolian gerbil is not a natural host for *Rodentolepis nana*, it can be experimentally transmitted to gerbils that are given dexamethasone daily (Vianna and deMelo, 2007). Gerbils have also been experimental hosts for *Hymenolepis diminuta*, *Taeniasolium*, *Taenia saginata*, *Taenia asiatica*, and *Taenia crassiceps* (Avila et al., 2005; Chang et al., 2006; Johnson and Condor, 1996; Kamiya and Sato, 1990; Sato et al., 2000).

Nematodes

Gerbils can also serve as experimental hosts for a number of nematode parasites. These include *Haemonchus contortus*, *Toxocara canis*, *Strongyloides stercoralis*, *Strongyloides papillosus*, *Aspiculuris tetraptera*, *Syphacia obvelata*, *Dentostomella translucida*, and *Baylisascaris procyonis* (Akao et al., 2003; De Jesús-Gabino et al., 2009; Lok, 2007; Pinto et al., 2003a, 2003b; Zanandrea et al., 2008).

One of the most important uses of gerbils in biomedical research is for the study of filarid nematodes, which include *Brugia malayi*, *Brugia pahangi*, *Loa loa*, and *Litomosoides sigmodontis* (Lim et al., 2004; Mand et al., 2006; Shigeno et al., 2006; Wanji et al., 2002). Gerbils have been experimentally infected with these filarid nematodes to study the immunology, antigenicity, and life cycles of the parasites. Serologic tests and treatment

regimens have been developed by using these models (Hübner et al., 2009; Lim et al., 2004; Shigeno et al., 2006).

Trematodes

Gerbils have been used to study all aspects of the trematode life cycle including infectivity and immunology as well as to study potential treatments. These trematodes include *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, *Schistosoma magreboweie*, *Echinostoma caproni*, and *Opisthorcis viverrini* (Adam et al., 1993; Boonmars et al., 2009; Chisty et al., 2002; Mahler et al., 1995; Ogbe, 1983; Sato and Kamiya, 2001). Gerbils are also a good host for the avian schistosome, *Austrobilharzia variglandis* (Bacha et al., 1982).

Protozoa

Gerbils are good animal models for intestinal *Cryptosporidium parvum* infection and for gastric infection with *Cryptosporidium andersoni* and *muris* (Kvác et al., 2009). Immunosuppressed gerbils have been reported to be infected with *Cryptosporidium hominis* (Baishanbo et al., 2005).

Gerbils have been identified as a model for infection with *Giardia lamblia* (Belosevic et al., 1984; Faubert et al., 1983). Gerbils were used to develop the fecal antigen test for giardiasis (Moss et al., 1990). Gerbils can also be experimentally infected with *Giardia duodenalis* (Araújo et al., 2008).

Viral Diseases

Borna Disease

This is caused by a negative-strand RNA neurotropic virus which causes acute or subacute encephalitis in horses and sheep. This virus has been linked with schizophrenia and other affective disorders in humans (Rott et al., 1985). Borna disease is considered a model for studying neuronal plasticity, as the virus can persist in the CNS and cause changes in brain cell function (Gonzalez-Dunia et al., 2005). The gerbil is the definitive animal model for Borna disease. Newborn gerbils are very susceptible to intracranial infection with Borna virus resulting in inflammatory reactions in the brain as well as evidence of viral persistence in the brain (Nakamura et al., 1999).

Swine Hepatitis Virus

In 2009, gerbils were identified as the first animal model for swine hepatitis virus. Gerbils inoculated intraperitoneally with hepatitis E virus became infected, with viremia and virus shedding in the feces for 4 weeks. Additionally, the virus could be found in the liver of the infected gerbils (Li et al., 2009).

La Crosse Virus

This is an arbovirus that is one of the most common causes of pediatric arboviral infection in the US (Haddow and Odoi, 2009). In 1996, researchers at the University of Wisconsin discovered that Mongolian gerbils were an ideal animal model for La Crosse virus studies. Gerbils were susceptible to infection, survived, and developed viremia and neutralizing antibody titers following exposure by intramuscular injection and by the bite of infected mosquitoes. Moreover, they are attractive to mosquito vectors (Osorio et al., 1996).

Other Viruses

Gerbils are able to be infected with encephalomyocarditis virus, with viral replication evident in the heart and pancreas (Matsuzaki et al., 1989a). The young gerbil has also been identified as the first animal model of Rift Valley fever encephalitis that was uniformly fatal without causing lesions outside of the CNS (Anderson et al., 1988). During the summer of 2003, three gerbils were shown to be infected with monkey pox virus after being exposed to the virus from an infected Gambian giant rat (Kulesh et al., 2004). Newborn gerbils have been shown to be a better model for Puumala virus transmission than rats or mice (Lokugamage et al., 2003). Newborn gerbils can also be experimentally infected with reovirus 3 with histopathologic lesions noted in the brain and pancreas (Yukawa et al., 1993).

Bacterial Diseases

Helicobacteriosis

The gerbil is favored by many researchers as an animal model for *Helicobacter pylori* research because, when infected, the gerbil develops severe gastritis and gastric ulcers. These ulcers do not heal spontaneously but do respond to therapeutic treatment. This is similar to human infection with *Helicobacter pylori* (Peek, 2008). Gerbils also can develop gastric adenocarcinoma secondary to chronic helicobacter infection (Franco et al., 2008; Tsukamoto et al., 2007; Watanabe et al., 1998).

Listeriosis

The Mongolian gerbil is an animal model for listeriosis, the disease resulting from infection with *Listeria monocytogenes* (Blanot et al., 1997). The gerbil has two cell receptors which are similar to the human, InlA-E-cadherin and InlB-Met. These cell receptors work with *L. monocytogenes* surface proteins to facilitate entry into the cells (Disson et al., 2009).

Leptospirosis

The gerbil has been identified as a good animal model to study pulmonary hemorrhage as a consequence of

severe leptospirosis infection. More importantly, the gerbil mimics the human in its response to the infection by producing increased amounts of platelet-activating factor acetylhydrolase (Yang et al., 2009).

Borreliosis

Gerbils have been used in research on vaccines for *Borrelia burgdorferi*, the etiologic agent for Lyme disease (Preac-Mursic et al., 1992).

Epilepsy (Seizures)

Gerbils are considered a good model for inherited epilepsy. Gerbils will display spontaneous, recurrent generalized seizures beginning at about 6 weeks of age (Buckmaster and Wong, 2002; Loskota and Lomax, 1975). Mongolian gerbils were first identified as a new animal model of inherited seizures in 1968 (Thiessen et al., 1968b). Immediately thereafter a number of papers were published regarding gerbils and seizures (Kaplan and Mizejeskic, 1972; Loskota et al., 1974, 1975).

In the 1970s Loskota started a selective breeding program at UCLA to develop seizure-sensitive and seizure-resistant gerbils. Selective breeding of three pairs of seizure-sensitive gerbils, originating from Tumblebrook Farm in Massachusetts, for 18 generations resulted in the creation of the seizure-sensitive gerbil. The seizure-sensitive gerbils were identified as WJL/UC and seizure-resistant gerbils as STR/UC (Loskota et al., 1974).

Mongolian gerbils continue to be used as a model of inherited epilepsy. It is now known that the seizure-sensitive gerbils have abnormalities that involve the GABAergic synaptic transmission in the brain (Hwang et al., 2004; Kang et al., 2001; Kwak et al., 2005). The entire mechanism of how and why seizures occur continues to be under investigation.

Brain Development and Behavior

Since the 1980s, the gerbil has been widely used in studies of brain growth and development, neural plasticity, behavior, and normal and pathological aspects of aging (Cheal, 1986). Examples include studies of changes in the muscarinic receptors in the gerbil thalamus from age 6–36 months (Pilar-Cuellar et al., 2008), effects of periadolescent sensory stimulation on neural development (Lehmann et al., 2009), and ontogeny of the dopamine innervations in the nucleus accumbens (Lesting et al., 2005). Behavioral studies include reports of neonatal separation that results in behavioral and biochemical differences in adult gerbils (Jaworska et al., 2008) and studies of the effects of the father in gerbil developmental behavior (Piovanotti and Vieira, 2004). Lee et al. (2009, 2010a, 2010b) have studied neurochemical changes in the gerbil brain, especially the hippocampus, as it relates

to aging. As gerbils are an important model for hearing research there is also interest in the development of specific parts of the brain that relate to hearing, such as age-related changes in the medial nucleus of the trapezoid body and in the lateral superior olive (Gleich and Strutz, 2002; Gleich et al., 2004).

General Neuroscience

Gerbils have been used extensively in neuroscience research. It has been found that gerbils are more homologous to humans in the tachykinin NK-1, 2, 3, receptor activity and affinity as compared to rats and mice (Griffante et al., 2006; Leffler et al., 2009). A new model, gerbil foot tapping, has been developed as a fear-related response. Gerbils injected with NK-1 agonists in the brain develop a fear-related foot-tapping behavior (Bristow and Young, 1994; Sundqvist et al., 2007). Gerbils have also been used as animal models of anxiety in the elevated plus maze and Black/White Box tests (Bridges and Starkey, 2004; Heldt et al., 2009), and to evaluate the anxiolytic properties of rose odor inhalation (Bradley et al., 2007). Gerbils have been used in the forced swim test which has predictive validity for the evaluation of novel anti-depressants (Wallace-Boone et al., 2008). In 2009, Gaese et al. published a report using Mongolian gerbils for acoustic startle and prepulse inhibition studies.

Auditory Research

Mongolian gerbils are a common animal model in auditory research as gerbils have human-like low-frequency hearing (Engel, 2008; Wetzel et al., 2008). Gerbils have been used as an animal model of auditory neuropathy and it has been shown that there is the potential for use of stem cells to cure some hearing loss (Matsuoka et al., 2007).

Miscellaneous Disease Models and Research Uses

Iron Overload

The gerbil is the first animal model found for the human disease hemochromatosis. In the experimental gerbil model histopathologic lesions in the heart and liver are very similar to the human disease. The model is created by once- or twice-daily injections with iron dextran (Carthew et al., 1993). The gerbil iron-overload model continues to be used to further elucidate the mechanisms of the disease as well as to explore potential therapies (Al-Rousan et al., 2009; Kaiser et al., 2003; Otto-Duessel et al., 2008).

Cholesteatoma and Otitis Media

Just as gerbils have been used widely in acoustic and auditory basic research, they have also been found to be an animal model for cholesteatoma, a benign tumor of the middle ear. The animal model is most commonly created by surgical ligation of the gerbil's auditory duct (Choufani et al., 2007; Kim and Chole, 1998). Gerbils are also commonly used for studies of infectious otitis media. In the induced model the gerbils are usually infected with *Streptococcus pneumoniae* (Soriano et al., 2000), although *Haemophilus influenza* (Ponte et al., 1999) and *Moraxella catarrhalis* (Fulghum and Marrow, 1996) have also been used.

Prostate Gland Biology

Gerbils have been used as an animal model for the study of androgen receptors in the prostate gland (Campos et al., 1997; Cordeiro et al., 2008).

Dental Research

Gerbils are used as experimental models to correlate the periodontium's biological response to various mechanical stresses, as the periodontal ligament was shown to be highly sensitive to occlusal alterations (Iyomasa et al., 2008). Gerbils have also been used as animal models for dental caries (Fitzgerald and Fitzgerald, 1966).

INTRODUCTION

The Egyptian fat-tailed jird (jird) (Figure 53.1) has been housed in zoological collections since its discovery in 1880. It has only been within the last decade or so that the species has become increasingly popular among exotic pet hobbyists. Many pet owners are intrigued by the unusual appearance of the tail and the gentle disposition of this species. Captive-bred jirds are now available for purchase in pet stores within the United States and Europe, where they may be referred to as “duprasi” or “fat-tailed duprasi.” Despite the jird gaining recognition and movement globally, much remains unknown regarding basic biologic and physiologic data. These rodents have a rounded body with long fluffy agouti-colored fur on the dorsum and white on the ventrum. They have a highly distinctive, blunt, sparsely haired, club-shaped tail which has been established as an effective site for the development of cutaneous leishmaniasis.

History

Pachyuromys duprasi were first discovered in Algeria by French zoologist Fernand Lataste in 1880 (Lataste, 1880). The Egyptian subspecies (*P.d. natronensis*) was first described in 1903 by William Edward De Winton.

FIGURE 53.1 Adult Egyptian fat-tailed jird, *Pachyuormys duprasi natronensis*.

Taxonomy

The jird is in the genus *Pachyuromys*, subfamily Gerbillinae, family Muridae, and order Rodentia. *P. duprasi* is the only species within this genus. *Pachyuromys* appear phylogenetically closely related to *Desmodilliscus* (Brauer’s gerbil) and together they comprise a new tribe taxonomically (Chevret and Dobigny, 2005). Although there is considerable debate among taxonomists, currently there are three geographically distinct forms of this species: Libyan (*P. duprasi*), Egyptian (*P. d. natronensis*), and Algerian (*P. d. faroulti*). The Egyptian subspecies can be distinguished from the nominate (Algerian) form by its lighter hair coat. The Greek roots of the genus name, *Pachyuromys* (“Pachy” = “thick”, “uro” = “tail”, “mys” = “mouse”), provides those who have never seen this animal an idea of what it might look like and highlights the animal’s most distinguishing physical feature.

Geographical Distribution

Jirds are found in North Africa from Algeria to Egypt. The Egyptian subspecies lives along the Mediterranean coastal desert. They usually inhabit rocky or sandy areas with sparse vegetation and live in simple burrows which they excavate to a depth of 1m (Figure 53.2).

FIGURE 53.2 Wild jird burrow (upper left) with desert beetle exoskeletons (lower right) in Wadi Natroun, Egypt.

Jirds have also been observed residing in tunnels excavated by other rodent species. They are described in the wild as being nocturnal mammals which become active at dusk (Osborne and Helmy, 1980). Much remains unknown about the breeding and dietary habits of wild jirds but they are believed to be omnivorous, eating both plants and at least two species of desert beetles from the Tenebrionidae family (*Adesmia* sp. and *Pimelia* sp.) (Osborne and Helmy, 1980).

Origin

The Naval Medical Research Unit No. 3 (NAMRU-3) in Cairo, Egypt began work in December 1996 to establish a purpose-bred jird colony to mitigate the confounding potential of unknown variables (such as age, health status, and nutritional factors) associated with wild-caught research subjects, and to avoid harming the local ecosystem with ongoing trapping. Wild-caught jirds were used from the Wadi El Natroun area of the western margin of the Nile Delta to found the colony. A government-authorized local hunter caught jirds using either surface live traps or by excavating their tunnels. Initially, 24 juvenile jirds (12 males and 12 females) were brought to NAMRU-3 and served as the foundation colony. Additional wild-caught jirds were added to the colony in 2000 and 2003. Since 2003, NAMRU-3 has had a closed, self-sustaining colony.

ANATOMY, PHYSIOLOGY, AND BEHAVIOR

Anatomy

External Features

The Egyptian fat-tailed jird is mouse-like with well-developed hind legs and forelegs that can be used as hands. The eyes and ears are large and vibrissae well-developed. The coat is very dense and soft. The palmar and plantar aspects of the feet are partially haired. Dorsal hairs are pale agouti with blackish tips. The lateral aspects are agouti and both the ventrum and feet are white.

The average jird lifespan is 2–4 years. The body of the adult jird is 148–183 mm long, and its tail is 55–62 mm long. In the wild, their adult body weight typically ranges from between 22–44.6 g (Hoath, 2003; Osborne and Helmy, 1980). Captive adult males are approximately 25% heavier than adult non-gravid females (Table 53.1). Adult captive jirds are approximately twice the size of their wild counterparts. This could result from several factors, including ad libitum feeding in captivity, access to calorie-dense feed instead of calorie-restricted natural diets, decreased exercise, genetic selection, and metabolic

changes related to environmental conditions such as temperature and humidity.

The tail is relatively thick and club-shaped, bicolored, and like the body has an agouti dorsal surface and white ventral surface, and no apical brush. Histologically, the tail is well-vascularized and comprised of abundant adipose tissue. Because of the sparse hair on the tail, skin color can readily be assessed. Thus the tail is a good location to assess for oxygenation and capillary refill time (CRT). The tail also is usually “plump” in healthy adult animals and “thinner” in immature animals, lactating females, and sick animals. The skin over the tail is taut in well-hydrated animals and “wrinkled” in dehydrated jirds. Although fighting is uncommon, the tail is usually the site towards which bite wounds are directed.

Dentition

Dental morphology has been studied in detail (Osborne and Helmy, 1980; Petter, 1956) and the overall dentition pattern is similar to that of murid rodents. Some noteworthy features of *Pachyuromys* which help distinguish it from other Gerbilline genera include the presence of grooves on the anterior surfaces of the upper incisors and simple third molars which lack folds. The adult enamel pattern has been noted to be more similar to *Meriones crassus* than *Gerbillus* sp.

Skeletal System

The morphology of the skull of jirds has been well-characterized (Hoath, 2003; Osborne and Helmy, 1980). The skull is elongate with very large and prominent auditory bullae. The external auditory meatus is also large. A large suprameatal triangle is a distinguishing characteristic of this species. The meatal lip is prominent, and an accessory tympanum is present. Other identifying features of the skull of the jird include presence of complete zygomatic processes and a poorly differentiated supraorbital ridge.

TABLE 53.1 Biological Data for the Captive Egyptian Fat-Tailed Jird (*Pachyuromys duprasi natronensis*)

Adult body weight (male)	80–82 g
Adult body weight (female)	55–61 g
Birth weight	2.4–2.6 g
Life span	2–4 y
Adult food consumption	5 g/d
Adult water consumption	5 ml/d
Gestation period	20–22 d
Litter size	1–7 pups (3.1 pups on average)
Weaning age	21–28 d

Mammary System

Conspicuous rows of nipples (four pairs: one thoracic, one abdominal, and two inguinal) are visible on the ventrum of the female jird by 16 days of age. Nipples are not visible on males. This dimorphic feature can be used in proper sex determination.

Genitourinary System

Male jirds lack preputial glands and have a single pair of unusually small ventral prostate glands. Vesicular glands are lobed medially and along the acutely edged greater curvatures. The subterminal flexures of the vesicular glands are rounded and smooth (Voss and Linzey, 1981). Jirds are reported to produce post-copulatory vaginal plugs but unlike other common laboratory rodent species, plugs can be challenging to visualize consistently and their absence should not imply an unsuccessful breeding attempt (Héron-Royer, 1891; Lataste, 1882).

Physiology

Serum Biochemistry Parameters

Serum biochemical parameters have been determined for a number of analytes, using a serum chemistry analyzer, in healthy adult male and female jirds under chemical sedation (Table 53.2). Serum concentrations of amylase and glucose are significantly different in male versus female jirds. Amylase was significantly higher in males (mean, 1380 μ /L) than in females (mean, 1214 μ /L). Mean blood glucose was significantly lower in male jirds (193 mg/dl) compared with females (247 mg/dl). Values for globulin, creatinine, alanine aminotransferase, alkaline phosphatase, albumin, and total protein were not significantly different in male and female jirds. In captivity, despite ad libitum feeding of the same diet to both sexes, adult males grow to about 25% greater average body weight than adult non-gravid females (Felt et al., 2008). Weight difference among wild jirds of different sexes had not been noted previously (Capello, 2003; Hoath, 2003; Osborne and Helmy, 1980).

Hematological Parameters

The normal parameters have been determined for a number of hematological indices for adult male and female healthy jirds under chemical sedation (Table 53.3). Leukocytic and erythrocytic indices are not significantly different between the sexes. Platelet counts are similar between the sexes as well, but mean platelet volume (MPV) is significantly higher in females than males. The baseline hematological laboratory reference ranges along with serum biochemical established parameters permit for individual and overall colony health monitoring.

Behavior

Wild jirds tend to live in small groups but have also been found to live solitarily. They are described as nocturnal, becoming active at dusk (Hoath, 2003; Osborne and Helmy, 1980), but in captivity they appear to sleep and awaken intermittently throughout the day and night. Captive jirds spend considerable time burrowing. They tend to build a simple cup-shaped nest which they usually share with all of their cage mates. PVC plastic mouse tunnels (Bio-Serv, Inc., Frenchtown, NJ) are readily used as shelter when provided.

When a male and female are ready to breed, they will focus their attention on one another almost exclusively. They often vocalize emitting high-pitch squeaks, and they stand on their hind legs and appear to wrestle. It remains unclear if this behavior is a component of the courtship process or the copulation act itself. Internal cage height should be at least 6 inches to accommodate "standing" if breeding is desired. Unlike *Meriones* sp., which have a strong pair bond and are often described as monogamous, proven jird breeders will accept and successfully mate with unfamiliar conspecifics (Donnelly and Quimby, 2002).

In the wild, omnivorous jirds are successful hunters. Captive jirds will display active hunting behavior when offered live food items, such as mealworms or crickets.

Cannibalism has been reported to be a common expected behavior encountered in captive animals (Osborne and Helmy, 1980). This occurs very rarely in laboratory-reared animals and is probably confined to primiparous females.

MANAGEMENT, HUSBANDRY, AND COLONY HEALTH

Housing Systems

Caging Systems

Jirds are successfully housed and bred in conventional and individually ventilated rodent caging systems. Cages with dimensions of 12.1 in long $\times$ 12.1 in wide $\times$ 7.4 in high have been successfully used. Breeding pairs, nursing dam, or four males or females can be co-housed without aggressive behavior in a 144-sq-inch solid-bottomed cage. Smaller cage sizes have not been evaluated. They adapt well to sipper tube-equipped water bottles.

Bedding

Unlike many gerbilline species, jirds can be housed on sterilized hardwood bedding without access to a sand substrate and will remain free of any dermatological health problems. Jirds produce small quantities

of urine daily, despite ad libitum availability of water. Their pelleted stool, although very hard and dry, is similar in shape and size to that of rodents of a comparable size. The bedding remains odorless for several days and cage changes are typically performed once a week.

Environmental Conditions

Ventilation

Ventilation requirements are similar to those for the mouse and other rodent species. Use of individually ventilated cage systems does not negatively impact reproductive capabilities.

Temperature and Humidity

Jirds can be housed at temperatures of 17.8–22.2°C (64–72°F), similar to those used for other rodents. They are sensitive to temperatures above 35°C (95°F). Humidity range of 35–50% is well-tolerated, but humidity values greater than 50% have been reported to result in a rough

and damp hair coat in *Meriones* sp. (Harkness and Wagner, 1995). Ringtail has not been a condition identified in jirds. Nasal dermatitis, which has been associated with high humidity in other gerbilline species, has not been observed in captive *Pachyuromys duprasi*.

Illumination

A typical light:dark cycle of 12:12h throughout the year is adequate for both the breeding colony and the research animals. Incandescent light (approximately 400lux) 1 meter above the floor has not induced any clinical or histological evidence of vision or reproductive problems.

Enrichment

Nestlets (Ancare Corp., Bellmore, NY) and/or cotton balls are readily used by jirds to line the nest in which they sleep and give birth. Co-housed jirds usually share the nest. PVC plastic mouse tunnels (Bio-Serv, Inc., Frenchtown, NJ) can also be used as shelter.

Sanitation

The routine sanitation practices used in laboratory animal facilities are adequate to ensure healthy laboratory jirds. Cage changes are typically performed weekly, unless pups are present. In this case, spot cleaning may be performed as needed and complete cage changing should be delayed until pups are at least 10 days old.

Nutrition

Feed Type

Jirds are successfully maintained on pelleted rodent feed with 18% protein and 11% fat (Purina LabDiet, St. Louis, MO).

Nutritional Requirements

Jirds thrive on commercial rodent ration. Fresh vegetables such as carrots and cucumber can be placed on the cage floor once a week as part of the enrichment program. Like hamsters, some jirds prefer food on the floor and may refuse to take it from the hopper even if it is the only available food source in the cage. After weaning, young animals are given food both on the cage floor and in the hopper. Animal care staff must ensure that young jirds are eating during the transition from floor feeding to hopper feeding. Most animals transition to using a feed hopper by the time they are 5 weeks old. If an approved supplier is available, meal worms and crickets can be offered; these seem to be preferred food items.

Water

Jirds adapt well to sipper tube equipped water bottles filled with acidified water (pH 2.8). Water should be provided *ad libitum*. Unlike other desert-dwelling rodents such as the kangaroo rat (*Dipodomys* sp.), compulsive water drinking behavior and a subsequent diabetes insipidus-like disease have not been observed in this species (Donnelly and Quimby, 2002).

Breeding

Reproductive Biology

Jirds are paired according to compatibility, health status, and size. Jirds are placed together in a clean, neutral cage and must be observed for several minutes to ensure compatibility. If fighting is observed within the first few minutes, animals should be immediately separated. Animals from unsuccessful matings have been successfully paired with other mates. Compatible pairs are kept together for approximately 1 week. The male is removed and placed in same-sex group housing or individual housing. Females are allowed a minimum of a 4-week rest interval between weaning and subsequent mating attempts. Unlike *Meriones* sp., which have

FIGURE 53.3 Adult male jird.

FIGURE 53.4 Adult female jird.

a strong pair bond and are often described as monogamous, proven jird breeders will accept and successfully mate with unfamiliar conspecifics. After weaning, the offspring can be housed with same-sex littermates or individually, if littermates are not available.

Like other rodents, males have a greater distance between the urogenital and anal openings than do females (Figures 53.3 and 53.4). When adult males are held upright, there is a prominent bulge of the caudal body due to the large descended testicles within the scrotum (Figure 53.3). Only females have visible nipples after 16 days of age; these are also helpful in sex determination.

Unlike wild jirds which have been described as having a seasonality to breeding (Osborne and Helmy, 1980), captive jirds breed successfully all year. Females and males reach sexual maturity at 8 weeks of age and reach peak performance at 1 year. Compatible pairs have been reproductively successful for 3 years.

FIGURE 53.5 Newborn captive jirds in a cup-shaped nest.

FIGURE 53.6 Pair of 10-day-old jird pups. Furred with adult hair pattern, non-ambulatory, and eyes still closed.

Breeding System

Random breeding methods are used to maintain outbred stock. Inbreeding has not been initiated; instead, systematic mating of cousins is used in an attempt to preserve heterozygosity, since this is thought to be better than random mating in smaller populations (Festing, 2003). The jirds can be divided into four groups and a circular mating system used. Members of one group are mated with members of another group, and their offspring constitute a third group. As more generations are produced, inbreeding and homozygosity will gradually increase within the colony.

Care of Young

Jirds have a gestation period of 20–22 days with litters of 1–7 pups (average is three pups per litter). Newborns weigh 2.4–2.6g (Figure 53.5); they double their weight by day 7, and triple their weight by day 14. Hair growth begins by week 1, and the adult hair coat pattern (Figure 53.6) becomes obvious by week 2. Pups usually begin to crawl by day 12 and open their eyes by day 16. Pups begin to eat pelleted food, if offered on the cage floor, by 21 days of age and are fully weaned by 28 days. More than 90.2%

FIGURE 53.7 Typical growth rate of captive male and female jirds.

of pups reach weaning age. Juveniles continue to gain weight until they are 16–20 weeks old (Figure 53.7).

Colony Health

Preventive Medical Strategies

Routine traditional rodent quality assurance and sentinel methods can readily be applied to this species and colony health can be monitored through the placement of dirty bedding sentinels (jirds) in each room and periodic scheduled serological, microbiological, parasitological, and pathological screening.

Record Keeping

Conventional cage cards and breeding records adapted from those used for mice have proven satisfactory for maintaining jird colony records.

DISEASES

Introduction

Properly maintained laboratory jirds, in general, lead lives that are largely free of infectious diseases. Dental disease and neoplasia are the most common health issues encountered and seem to be confined to aged animals. Both can result in significant morbidity and mortality.

Infectious Diseases

Viral Infections

Serological screening for several murine viral pathogens (Sendai pneumonia virus, mouse hepatitis virus, minute virus of mice, GD-7, reovirus 3, ectromelia,

K virus, mouse cytomegalovirus, mouse parvovirus, pneumonia virus of mice, polyomavirus, rotavirus (enzootic diarrhea of infant mice), hantavirus, mouse thymic virus, lymphocytic choriomeningitis virus and mouse adenovirus-1 (FL) and -2 (K87)) have been conducted on sentinel and wild-caught jirds repeatedly for several years. To date, serological evidence of infection has not been documented.

Bacterial Infections

Ciliated-associated respiratory bacillus (CAR) and *Mycoplasma pulmonis*, using serology and culture, have not been detected in the jird colonies despite long-term active surveillance. Specific screening for Tyzzer's (*Clostridium piliformis*), staphylococcal dermatitis or salmonellosis, which are known to occur in the Mongolian gerbil (*Meriones unguiculatus*), has also not yielded any positive animals.

COLIBACILLOSIS

Escherichia coli has been isolated from jirds that have died of septicemia. These animals were either found dead in their cage or severely moribund. Onset was very acute in all cases and there were no signs of external trauma. Suppurative metritis, typhlocolitis, and myocarditis were present in at least two of the cases.

KLEBSIELLOSIS

Klebsiella pneumoniae has been isolated from the blood, spleen, and liver of a jird that died suddenly and had evidence of hepatomegaly and splenomegaly. No other abnormalities were noted on necropsy.

SERRATIOSIS

Serratia marcescens was isolated from the blood and muscle tissue of a jird that died acutely. Severe rhabdomyolysis was noted in one of its distal hind legs. No other gross lesions were noted on necropsy or histopathology.

BARTONELLOSIS

A single case of severe acute pulmonary hemorrhage occurred in an adult wild-caught jird, which acutely developed severe dyspnea and was euthanized. *Bartonella* sp. was cultured from the blood. The organism is likely a novel species and seems to most closely genetically resemble a species isolated from the Tanezumi rat, *Rattus tanezumi flavipectus* (Ying et al., 2002). The affected jird's cagemates were also screened for the organism using blood culture and tested negative.

Parasitic Infections

PROTOZOA

Routine serological screening for *Encephalitozoon cuniculi* has not detected the presence of that pathogen

in jirds. An uncharacterized protozoal organism has been identified in the intestinal mucosa of several wild-caught jirds. In all cases, no lesions could be attributed to infection.

CESTODES

Adult *Hymenolepis diminuta* were found in the small and large intestines of wild-caught jirds. Eggs were detected by direct fecal smear and by fecal flotation with zinc sulfate. Parasites were eliminated by treating infected jirds with a single oral dose of niclosamide (10mg/100g body weight). The potential zoonotic health risk of this parasite should be considered when bringing wild-caught jirds into a facility.

NEMATODES

Adult pinworms, unspecified to date, have been found intraluminally in the gastrointestinal tracts of wild-caught jirds. Pinworm eggs can be isolated using a fecal flotation technique with zinc sulfate. Perianal tape tests of infected animals did not yield any eggs. Infected animals appeared healthy and no lesions were attributed to infection in animals that were screened by gross necropsy and histologically. Infection was eliminated using a subcutaneous dose of ivermectin (200µg per kg body weight) weekly for 3 weeks.

Eggs resembling *Strongyloides* have been detected occasionally on direct smears of feces from wild-caught jirds.

MITES

Wild-caught jirds have been found to be susceptible to colonization with *Pyroglyphis morganii* (Felt, 2009) (Figure 53.8). All jirds in the cage developed acute patchy hair loss and generalized pruritus. Direct examination, combing of fur, cellophane tape testing, and microscopic examination revealed that all jirds in the cage were infested with this mite. This species of mite had not previously been reported to infest mammals. Cage changes along with two doses of ivermectin (200µg per kg body weight) administered subcutaneously 14 days apart proved effective in eradicating the infestation. The fur grew back and pruritus subsided quickly following treatment of affected animals.

TICKS

Camel ticks (*Hyalomma drommedarii*) have been found feeding on wild-caught jirds.

Neoplasia

Several spontaneous neoplasms have been characterized previously in jirds (Rowe et al., 1974). Rowe found that 46% (11/24) of aged (>24 months) jirds developed spontaneous neoplasms. The incidence of neoplasia

FIGURE 53.8 Magnification 4x. Pyroglyphid adult mite, *Pyroglyphis morgani*, infesting captive jirds with alopecia and pruritus. The following anatomical structures have been identified: ● = chelicerae; ■ = pulvillus of tarsus; + = legs; ■ = setae.

in NAMRU-3's colony is less than 5%. The difference in rates may be due to variation among subspecies, as Rowe housed both *Pachyuromys duprasi* and NAMRU-3 source *Pachyuromys duprasi natronensis*. Age may have also been a factor, as many of the jirds in Rowe's colony were of unknown age and may have been older than the NAMRU-3 colony. Further, genetics may have been a factor, as the NAMRU-3 colony originated from 24 founding animals and the majority of Rowe's animals were wild-caught.

Lymphoreticular Neoplasms

Lymphoreticular neoplasms, especially thymomas and B-cell lymphomas, are encountered most commonly. Thoracic B-cell lymphomas may present with acute dyspnea and metastasize to the spleen.

Trichofolliculoma

A recurrent dermal mass appeared on the muzzle and nasal planum of a captive-born 2.5-year-old male jird. The initial mass was raised, circular and approximately 3mm in diameter (Figure 53.9). It was surgically excised and the excision healed normally. Histopathology of the mass was most consistent with a diagnosis of trichofolliculoma and excision seemed complete. Approximately 8 months post-excision the mass recurred and within 3 weeks was more than triple its original size (1cm diameter) (Figure 53.10). Histologically, the recurrent mass was once again diagnosed as a trichofolliculoma. Attempts to identify a possible underlying infectious cause (such as papillomatosis) using electron microscopy were

FIGURE 53.9 A 1½-year-old male jird with dermal mass prior to surgical removal.

FIGURE 53.10 The same jird with a recurrent dermal mass 8 months later. Compared to the initial mass, this mass grew rapidly and had an irregular surface with raised areas and some thorn-like projections.

unsuccessful. Trichofolliculoma is the only neoplasm of the skin reported thus far in jirds.

Other Neoplasms

The only reported neoplasm affecting the digestive system is gastric adenocarcinoma. Neoplasms affecting the genital system include uterine leiomyosarcoma and prostatic adenocarcinoma. Endocrine neoplasms include pancreatic islet cell adenoma and both adrenal adenomas and adenocarcinomas (Rowe, 1974).

Miscellaneous Diseases

Dental Problems

Frequently, older jirds (≥ 2 years) develop excessively worn upper incisors and periodontitis. Caretakers may first note that jirds are thin or their appetite is

FIGURE 53.11 Chondrodysplastic 4-week-old jird (right) with normal-sized littermate (left). Besides the diminutive size the affected jirds tend to have dome-shaped skulls and at 5–8 months of age develop difficulty ambulating.

diminished. In addition to recessed upper incisors and periodontitis, some jirds will present with concurrent elongated lower incisors presumably due to loss of occlusive contact. The condition is not reversible but can sometimes be managed effectively for several weeks through teeth trimming. Affected animals may also benefit nutritionally from offering fruits, vegetables, meal worms, and crickets in addition to the rodent chow. For jirds that are more than 2 years old and are housed long term, we recommend conducting oral examinations and weighing animals monthly. If substantial weight loss (>10%) is noted, the animal should be evaluated for worn upper incisors or elongated lower incisors. Although the affected jird's condition may improve with teeth trimming, the prognosis is considered grave and euthanasia is recommended if the crowns of the upper incisors recess to the level of the gum.

Maxillary and mandibular abscesses have been reported to occur in pet jirds (Capello, 2003). If a decision is made to treat, surgical debridement is recommended. Both the maxillary and mandibular molars, the source of the abscess, are almost impossible to extract, so recurrence is likely. Antibiotic therapy should also be considered.

Dwarfism (Chondrodysplasia)

Spontaneous dwarfism has occurred in this species. As adults, such jirds only reached approximately 25% of the normal body weight (see Figure 53.11). It is thought that this disease is genetic with an autosomal recessive mode of inheritance, as all dwarf jirds were born to normal-sized parents and had normal-sized siblings. Attempts to mate dwarf jirds to further characterize the mode of inheritance have proven unsuccessful to date. Besides their diminutive size and possible infertility, affected jirds have visible skull and limb deformities, but are capable of surviving well into adulthood. They begin showing difficulty ambulating when they

reach 5–10 months of age and this usually warrants euthanasia. Certain anatomical sites such as the ribs, proximal tibia, distal radius, and distal femur seem to be affected by chondrodysplasia more than others.

ANESTHESIA/ANALGESIA, EUTHANASIA, AND NECROPSY

Chemical Restraint

The jird is effectively immobilized using ketamine (100mg/kg) given intramuscularly; this provides approximately 30 min of sedation. Alternatively a cocktail of ketamine (30mg/kg), xylazine (6mg/kg), and acepromazine (1mg/kg) administered intraperitoneally (Felt et al., 2009) provides approximately 5–10 min of sedation. Inhalant isoflurane (1–4%) works very well in this species and should be used when conducting invasive or longer procedures. The jird is highly susceptible to hypothermia. Body temperature should be closely monitored and exogenous heat should be provided as necessary.

Euthanasia

The jird can effectively and humanely be euthanized by several methods including: inhalant carbon dioxide, intraperitoneally delivered pentobarbital, cervical dislocation (under sedation), and exsanguination via cardiac or jugular venipuncture (under sedation).

USE IN RESEARCH

Introduction

The general characteristics of the jird that lend well to it being a research subject are its unique anatomy, small size, docility, fecundity, and ease at which it appears to adapt to captivity (Felt et al., 2008). Specifically with regard to cutaneous leishmania research, inoculations and subsequent lesion development in the tail of *P. duprasi* may result in less pain or discomfort than for other established models (e.g., foot pad infection of mice and hamsters).

Historical Uses

The jird has been used to study thermoregulation and circadian rhythms which indicated that the homeostatic control of body temperature is exerted separately from the circadian control (Refinetti, 1998).

Auditory studies of jirds include those focused on neuronal anatomy (Muller et al., 1991), frequency

representation in the auditory brainstem nuclei (Muller, 1990) and cochlea (Muller et al., 1991), and low-frequency auditory sensitivity (Plassmann and Kadel, 1991).

Less commonly, this species has been used to study phylogenetic taxonomy (Benazzou et al., 1984); rodent reproductive physiology (Eisenberg and Isaac, 1963; Héron-Royer, 1891; Lataste, 1882); and cyclic transmission of protozoal infections (Jakel, 1995).

More recently, infectious disease studies have used the jird, specifically to study *Leishmania major* and *L. tropica* (Hanafi et al., 2000, 2007).

Leishmaniasis

The jird's tail and foot pads have been established as effective sites for the development of cutaneous leishmaniasis and study of Old World *Leishmania* spp. (Hanafi et al., 2000, 2007).

The BALB/c mouse has been successfully used for study of *L. major* and the Syrian hamster for the study of *L. major*, *L. donovani*, and *L. infantum*; however, until recently there has not been a model for *L. tropica* (Bray, 1987; Bastien and Killick-Kendrick, 1992) which is widespread throughout eastern and northern Africa, the Middle East, and large parts of Asia (AlSamarai and AIObaidi, 2009; Hay, 2009; Katakura, 2009; Parvizi et al., 2010; Toz et al., 2009). The Old World anthroponotic cutaneous leishmaniasis caused by *L. tropica* was a significant public health problem during the First Gulf War (1990–1991). Prevention and treatment of this infection has been limited due to lack of knowledge regarding the biological interactions with its vectors and the lack of an animal model for such studies.

Leishmania amastigotes mature in the sandfly gut to promastigotes (infective stage) which then migrate via the esophagus and transfer to a receptive host during a blood meal. The infective stage infects blood cells, particularly macrophages, and develops into the amastigote stage, which grows, reproduces, and infects more cells near the site of infection. Sand flies feeding on an infected host ingest amastigote-laden macrophages and continue the cycle. A study conducted at the NAMRU-3, Cairo, Egypt explored the feasibility of using the tail of the jird for *Leishmania* propagation. This study demonstrated that the jird tail was susceptible to infection with *L. major* (Hanafi et al., 2000) but was not as efficient as BALB/c mice, the established animal model for *L. major*. Surprisingly, *L. tropica* was unable to propagate in the tail of the jird. The preferred usual site for infecting animals with *Leishmania* spp. is the dorsal surface of the foot (Laison and Shaw, 1987) although footpad inoculations were often used in earlier studies. A follow-up study at NAMRU-3 involving inoculation of the jird's hind foot with cultured *L. tropica* metacyclic promastigotes established the jird not only as an effective animal

model but also as a possible natural rodent reservoir for *L. tropica* (Hanafi et al., 2007).

BASIC EXPERIMENTAL METHODS

Many of the common handling and restraint techniques and bi methodologies used for comparably sized rodents may be applied to the jird. In general this species is considered quite docile and rarely bites even when provoked. Minimal physical restraint for non-invasive examinations and procedures is usually adequate. The size, shape, and vasculature of the jird tail pose unique challenges when considering it as a site for vascular access.

Physical Restraint

A single pair of latex or nitrile gloves is adequate protection for the hands of personnel during handling. The jird can readily be lifted from the cage by closing cupped hands over the animal and gently scooping it into the palm of one hand. This method is suitable for non-invasive examinations or procedures and for cage transfers.

Another method for physically restraining the jird is to hold the base of the tail with the handler's dominant hand, and then firmly scruff the animal over the shoulders with the thumb and forefinger of the non-dominant hand, rotating the non-dominant hand, so the jird is laying in the palm with ventrum upward and placing the tail between the pinky finger and palm for added control. This technique leaves the handler's dominant hand available for other manipulations.

Sampling Techniques

Blood Sampling

A number of anatomical sites have been evaluated as venipuncture sites in this species (Felt et al., 2009). The submandibular vessels are not visible even with hair removal and the lancet technique inconsistently yields small blood volume amounts (<0.05ml). The lateral saphenous vein, although visible and easily punctured with a needle, yields a small amount of blood (0.05ml). The tail venipuncture technique presents unique challenges due to the size, shape, and abundant adipose tissue of the tail, which collectively serve to obliterate vessel visibility. The orbital venous sinus, jugular vein, and cardiac venipuncture are all preferred bleeding anatomical sites.

Orbital Venous Sinus

This procedure should be performed only on anesthetized animals. The animal is placed in lateral recumbency.

FIGURE 53.12 “Blind” jugular venipuncture technique in a jird. A rubber band, placed behind the incisors, was used to extend and stabilize the head of the jird. The needle is inserted 2–4 mm medial to the shoulder at a 30–45° angle at the level of the clavicle.

Scruffing, although not required, seems to stabilize the head and results in protrusion of the ocular globe which may facilitate accessibility. A capillary tube is inserted into the medial canthus and directed medially and posteriorly to the globe until it reaches the center of the orbit. The capillary tube is gently rotated until the sinus is punctured and blood flows. Following blood collection, the capillary tube is removed, the eyelids closed, and gentle pressure applied for several seconds to ensure hemostasis. Antibiotic and/or lubricating eye ointment can be applied to the eye. This technique is suitable for obtaining blood volumes less than 0.1 ml.

Jugular Vein

Jirds should be anesthetized or sedated for this procedure, which is performed blindly and therefore, immobility and positioning are critical for success (Felt et al., 2009). The anesthetized jird is placed in dorsal recumbency. The ventral neck and chest are shaved and then cleaned with 70% isopropyl alcohol or alternate disinfectant. A rubber band is placed behind the incisors to stabilize and extend the head and neck rostrally (Figure 53.12). Using a 1-ml syringe with a 25-gauge needle, blood can be collected blindly by inserting the needle (23–25 g) with the bevel up at approximately a 30–45° angle at the level of the clavicle and 2–4 mm medial to the shoulder. The needle is advanced cranially 2–3 mm under the skin, the desired volume of blood withdrawn, and the needle removed. Direct pressure is applied using a cotton ball, gauze pad, or cotton swab for 30 seconds to aid hemostasis. Additionally, this technique can be used as a successful exsanguination method for euthanasia, yielding up to 3 ml of blood.

Cardiac Puncture

Blood can readily be collected directly from the heart using identical techniques (dorsal and lateral

recumbency) employed in the mouse and rat. This procedure should be performed as a terminal procedure on anesthetized animals only and can also be used to exsanguinate animals with yields up to 3 ml.

Compound Administration

Oral, intramuscular, subcutaneous, and intraperitoneal compound administrations can readily be performed in the jird using techniques identical to those used for the mouse and rat. Non-invasive intravenous administration is technically challenging in this species. The lateral saphenous vein can be used. It is important not to use a blood flash in the hub of the needle to verify patency, but rather look for signs of extravasation during injection. The tail, submandibular and jugular veins can all be accessed via cutdown procedure.

INTRODUCTION

The focus of this chapter is to illustrate the use of a rodent, other than the mouse or rat, to serve as a model of an important human disease. Often, the idea of animal modeling suffers from a narrow focus on the species available for such work, and the goal here is to demonstrate the contributions of a lesser-known species. Thus, this chapter will provide limited information on basic species biology and husbandry and will instead concentrate on research uses.

Psammomys obesus is an animal model of the nutritionally induced type 2 diabetes-like model used in biological and medical research. *Psammomys* is a rodent belonging to the sub-family *Gerbillinae* living in the semi-desert regions of North Africa and the Middle East, from Morocco in the west, through Egypt and Israel, up to Arabia in the east (Osborn and Helmy, 1980).

Psammomys, first described by Cretzschmar in 1828, became renowned among the scientific community with the discovery that it was an excellent model for the study of human diabetes.

Diabetes in *Psammomys* was discovered by chance observation in desert rodents collected by the US Naval Medical Research Unit in Egypt in the 1960s. The animals were trapped on the sandy beaches of the Nile Delta and thought to be rats. They were trivially nicknamed “sand rats,” which is a misnomer because they are gerbils that belong to the family *Gerbillinae*. They should be referred to as *Psammomys*, according to the classification of Thomas (Pinshow, 1993; Thomas, 1902).

The *Psammomys* were sent to the laboratory of Schmidt-Nielsen at Duke University. Investigators there were the first to report that diabetes occurs in the majority of *Psammomys* maintained on a regular laboratory diet but not on a vegetable diet (Schmidt-Nielsen, 1964).

The diabetes ranged from mild hyperglycemia with hyperinsulinemia to hypoinsulinemia with ketoacidosis, which was a terminal stage with short survival (Haines et al., 1965; Miki et al., 1966). These early investigations were performed mostly on the first generation of Egyptian *Psammomys* because attempts to establish a multigeneration colony were not successful due to low reproductive capacity on the regular rodent diet. On this relatively high-energy diet, a large proportion of the animals gained excess weight with a characteristic superscapular hump and became insulin-resistant (Miki et al., 1967).

Psammomys attained additional interest when it was found to be an intermediate host of the parasite *Leishmania tropica* which is transmitted to humans by the sand fly, *Phlebotomus* sp. (Shafrir et al., 2006).

Cutaneous leishmaniasis in the Jordan Valley is maintained within the close association of *Psammomys* and sand fly *Phlebotomus papatasi*, which appear to be the exclusive host and vector species. The incidence of the disease was similar to the distribution of *Psammomys* colonies in the region, i.e., the plains of light stoneless soil. An infection rate of 93% was recorded in the very common *Psammomys*. All *Leishmania* isolates from *Psammomys* and from *Ph. papatasi* were identical to those from local human cases (Schlein et al., 1982).

Psammomys obesus is a unique polygenic animal model ideal for the study of obesity and type 2 diabetes. Unlike most other animal models used for obesity research, *Psammomys* displays a range of phenotypic characteristics, as might be expected for non-inbred progeny, when given free access to standard laboratory diet labeled as high-energy (HE) diet (Digestible energy – 2.93 kcal/g). Adult *Psammomys* have a wide range of body weight and body fat content that forms a continuous distribution.

The evolution of diabetes in *Psammomys* is gradual, as defined by Kalderon et al. (1986) and follows several defined stages: some animals remain normoglycemic and normoinsulinemic (stage A), others are hyperinsulinemic and normoglycemic (stage B), some develop overt insulin-resistant diabetes with hyperinsulinemia (stage C), and a small percentage develop consequential to the long-lasting hyperglycemia, severe decompensated diabetes, loss of beta cells and hypoinsulinemia (stage D). *Psammomys* are considered hyperglycemic when non-fasted blood glucose levels exceed 200 mg/dl, and considered hyperinsulinemic when non-fasted plasma insulin levels exceed 150 μ U/ml. Plasma insulin was measured by radioimmunoassay utilizing anti-human insulin antibodies and human insulin as standard. Dilutions of *Psammomys* serum and pancreatic insulin gave curves paralleling those of dilutions of human insulin. Cross reactivity with purified human insulin, used as standard, was 90–95% (Kalderon et al., 1986).

The speed of progression from stage A to the other stages depends on the amount of digestible energy in

the diet. On HE diet *Psammomys* progress from stage A to stage C within 7–28 days.

A genetic variability in diabetes susceptibility within the natural population has been observed. Several years ago a selection program was established in order to achieve divergent diabetes-prone (DP) and diabetes-resistant (DR) lines (Kalman et al., 1993; Ziv and Kalman, 2000). The DP line, 7–28 days following the transfer to HE diet, is characterized by hyperinsulinemia, and later by hyperglycemia.

Diet-induced “diabesity” (collusion of diabetes and obesity) in *Psammomys* involves attenuation of insulin action by inhibition of the tyrosine kinase essential for tyrosine phosphorylation of the insulin receptor substrate IRS-1 (Ikeda et al., 2001; Kanety et al., 1994; Shafrir, 1996), together with the increase in plasma triglyceride levels and augmentation of lipoprotein lipase activity (Chajek-Shaul et al., 1988). According to Coleman (Coleman, 1978) all these features lead to a metabolic state that is superimposed on a native “thrifty metabolism”, which might be seen as a peculiar natural adaptation to life in areas where only low-energy food is available.

SELECTION OF RELIABLE DIETS AND PSAMMOMYS LINES FOR DIABETES RESEARCH

In 1970 Adler established a *Psammomys* colony for medical research purposes at the Hebrew University Medical School in Jerusalem (Adler et al., 1976). The colony originated from ten pairs of *Psammomys* captured in the Dead Sea area. The colony was initially fed on the natural diet – the salt bush (*Atriplex halimus*). All animals fed this diet, which was supplied from the Dead Sea shore to the Jerusalem animal facility, maintained normoglycemia similar to their phenotype in the natural habitat. Animals from the colony served mainly for diabetes research, and were challenged by feeding them on regular laboratory rat diet, that for this species should be regarded as a diabetogenic diet.

In later stages it was decided to standardize the *Psammomys* diets, in order to enable diabetic research. For that purpose two diets were developed. The normoglycemic Mediterranean salt bush diet was replaced by an artificial low-energy (LE) *Psammomys* diet and the diabetic state was achieved by feeding the animals the HE diet. For composition and ingredients of both diets see Table 54.1. The major difference between both diets is in the digestible portion of the carbohydrates. The carbohydrate source of the LE diet derives mainly from alfalfa that has a high cellulose level, thus reducing carbohydrate availability to 59%. The carbohydrate source of the HE diet derives mainly from corn flour that contains a high starch level thus increasing carbohydrate availability to 77%.

TABLE 54.1 Composition, Energy, and Digestibility of *Psammomys* Diets

Components	HE diet		LE diet		Salt bush	
	%	Digestible portion	%	Digestible portion	%	Digestible portion
Protein	23.6	0.79	16.7	0.70	23.3	0.75
Fat	2.4	0.92	3.1	0.86	2.9	0.57
Carbohydrates	68.0	0.77	70.0	0.59	53.3	0.55
Ash	6.0		10.2		20.5	
Total digestibility		0.76		0.64		0.58
Total energy (kcal/g)	3.88		3.74		3.32	
Digestible energy (kcal/g)		2.93		2.38		1.92

HE diet major ingredients – ground wheat, ground corn, wheat middlings, dehulled soybean meal, corn gluten meal, soybean oil, calcium carbonate, brewers dried yeast, dicalcium phosphate, iodized salt. LE diet major ingredients – dehydrated alfalfa meal, barley, wheat bran, calcium carbonate, dicalcium phosphate, iodized salt.

**FIGURE 54.1** Evolution of Diabetes in *Psammomys* (DP & DR) on HE diet.

We used the HE diet to examine the diabetic potential of each individual, and to identify the diabetic and non-diabetic margins of the population. By using an assortative mating system based on a minimal inbreeding method (Baker, 1979) it was possible to separate the animals in the colony into two distinct lines differing phenotypically and genotypically: diabetes-prone (DP) and diabetes-resistant (DR) animals (Kalman et al., 1993). Details of the genotypic differences between the two lines are described later in this chapter and development of diabetes in the DP and DR lines is summarized in Figure 54.1. Animals to be mated were chosen according to phenotypic parameters (postprandial blood glucose levels of 200mg/dl and above for the DP breeders and 100mg/dl and lower for the DR breeders; plasma insulin levels of 100μU/ml and lower for the DR breeders). We isolated two lines that differ in their diabetic sensitivity without diluting their total genetic pool.

It should be noted that in addition to the composition of the HE diet, the physical characteristics (extruded versus pelleted) and the placement (on the bottom of the cage versus placing diet on the grid) influence both the rate of the development of hyperglycemia and the percentage of diabetic *Psammomys* in the colony. Extruded HE diet tends to be more diabetogenic than pelleted HE diet. Since the amount of diet that animals assume is similar on both diets, we assume that the difference in diabetogenicity is probably due

to the amount of energy the animal has to spend when chewing on the diet and to the fact that nutrient components become more available during the extrusion process. We have noticed that when *Psammomys* are fed the extruded HE diet, about 90% of DP animals become hyperglycemic within 14 days. When feeding *Psammomys* on pelleted HE diet, 80–90% of DP animals become hyperglycemic within 28 days.

The average life span of *Psammomys* is about 2 years (for DR animals fed HE diet and DP animals fed LE diet). When *Psammomys* from the DP line are transferred to the HE diet, they will become diabetic and survive on the HE diet for up to 3 months. They subsequently become hypoinsulinemic (stage D) and die within 10 days.

METABOLIC EFFICIENCY

In order to assess the difference between the two lines and to examine metabolic features related to the etiology of diabetes, we have compared blood glucose, plasma insulin, and plasma triglyceride levels in the two lines when fed on three different diets (*Atriplex halimus*, the Mediterranean saltbush, LE, and HE diets). The results following 14 days of *Psammomys* weaned and then fed for 14 days on the various diets are shown in Figures 54.2–54.5.

The marked difference between the two lines is evident by the development of hyperglycemia and hyperinsulinemia in the DP animals when fed the HE diet, while DR animals on both diets as well as DP animals on LE diet maintain normoglycemia and normoinsulinemia (summarized in Figure 54.6).

In our experiments animals reached stage C when the DP animals were fed the HE diet for 14 days. Our results indicated that when fed the HE diet, over 90% of the DP

FIGURE 54.2 Blood glucose levels in *Psammomys* from the DP line fed on various diets for 14 days.

FIGURE 54.4 Blood glucose levels in *Psammomys* from the DR line fed various diets for 14 days.

FIGURE 54.3 Plasma insulin levels in *Psammomys* from the DP line fed various diets for 14 days.

FIGURE 54.6 Development of diabetes in *Psammomys obesus*.

animals become diabetic within 7–28 days. In order to better understand the basis for the rapid evolution of diabetes in these animals, we have looked at several parameters including weight gain and obesity (Figure 54.7).

The different sensitivities to the development of diabetes between the DP and the DR lines may be caused by one or more factors: food intake, hepatic and

peripheral resistance, pancreas activity, or metabolic efficiency. To measure the metabolic efficiency, we followed animals during the period of their most rapid body growth after weaning (2.5–3.0g/day in males and 2.4–2.9g/day in females) and calculated metabolic efficiency as the relation between digestible energy intake and weight increment (Kalman et al., 1993).

FIGURE 54.7 Weight gain in *Psammomys obesus* from the DP and DR lines on various diets for 14 days.

TABLE 54.2 Effect of HE and LE Diets on Diet and Energy Consumption and Energy Utilization by *Psammomys obesus* from the DP and DR Lines

Diet	DP line		DR line
	HE	LE	HE
Diet consumed in 14 days (g)	125.9 ± 7.0	122.8 ± 2.7	122.5 ± 7.4
Feces secreted in 14 days (g)	26.8 ± 1.9	52.1 ± 1.2	16.1 ± 1.1
Digestible energy consumed in 14 days (kcal)	376.5 ± 21.1	274.5 ± 7.1	402.1 ± 24.2
Energy consumed for growth of 1.0g weight (kcal/g)	6.3 ± 0.2	6.0 ± 0.2	9.4 ± 0.3
Number of animals	20	27	10

FIGURE 54.8 Metabolic efficiency of *Psammomys obesus* from the DP and DR lines on various diets for 14 days.

There is no hyperphagia in either DP or DR lines when fed HE or LE diets; hyperglycemia is related to energy availability in the diet. The quantity of feces was significantly greater in animals fed the LE diet than in animals fed the HE diet, in line with the dietary carbohydrate digestibility (Table 54.2). The metabolic efficiency in DP line *Psammomys* fed all diets was 6.0–6.6 kcal/g of weight increase, whereas in the DR line, metabolic efficiency was 9.0–9.6 kcal/g of weight increase (Figure 54.8).

The essence of thrifty metabolism represents high metabolic efficiency that enables existence in an environment characterized by constant availability of

LE diets. The artificial laboratory condition of an ad libitum accessible HE diet creates a continuous input of energy and leads to hyperinsulinemia and hyperglycemia.

In other studies performed on a branch of the Israeli colony in Australia (Barnett, 1995), hyperphagia was reported in diabetic *Psammomys* fed a standard rat maintenance diet, but the weight gain did not exceed 15% of body weight. Differences between DP and DR lines are the result not only of their dietary-induced diabetes but also of other zootechnical and reproductive characteristics as described in the next section (Kalman et al., 1996).

MORPHOLOGY, PHYSIOLOGY, BREEDING PERFORMANCE, AND HUSBANDRY

Breeding Performance, Husbandry, and Sources

Breeding performance data for the DP and the DR lines collected over a period of 3 years are summarized in Table 54.3.

TABLE 54.3 Breeding Efficiency of *Psammomys obesus* from the DP and DR Lines. DP Line Animals were Fed the HE Diet, DR Line Animals were Fed the LE Diet

Criteria	DP	DR
Total number of breeding pairs	247	65
Number of sterile pairs	34 (14%)	15 (23%)
Average interval between first two litters (weeks)	7.0	7.5
Average age of female at first birth (weeks)	19.7	20.6
Average mating time (weeks)	39.2	29.8
Number of females that littered at least once	213	50
Number of females that littered at least three times	178 (84%)	34 (68%)
Number of females that littered at least seven times	61 (29%)	8 (16%)
Average number of litters/female	4.7	3.9
Average number of newborn/litter	3.3	3.2
Average number of newborn at first litter	3.2	3.3
Average number of weaned pups/litter	2.2	2.3
Average number of weaned pups at first litter	1.9	2.4
Average total of newborn/female	15.8	12.4
Average total of weaned pups/female	10.5	9.0

Breeding efficiency in *Psammomys* is low compared to outbred rats (Dietrich et al., 1973; Lutsky et al., 1984; Kalman et al., 1996). Number of newborn per female per week is about 0.4. About 75% of the newborn reach the end of weaning. Breeding efficiency of the DP line is higher than of the DR line due to differences in percentages of non-productive breeding pairs (14 vs. 23%) and in total number of litters per female (4.7 vs. 3.9) which increases the total number of newborn per female (15.8 vs. 12.4). Average size of litters in both lines is very similar (3.2 and 3.3).

In the *Psammomys* colony, the DR animals are maintained on HE diet and the DP animals, on LE diet. These are the most suitable conditions for the survival and breeding of the two lines (see Table 54.4).

Psammomys are very docile and are handled very easily. Animals are housed in a room with a typical ventilation rate of 15 air changes per hour, and under a light:dark cycle of 12:12h. Polypropylene cages with wire mesh lids are suitable primary enclosures. A breeding ratio is 1:1 is recommended for reproduction. When the litter is born, the male is separated and the female is left with the litter for 19–26 days. After weaning, the breeding pair is reformed and the litter is transferred to stock cages. Aspen shavings provide adequate bedding and should be changed weekly.

At the time of writing, *Psammomys* are available from the original Hebrew University breeding colony. A branch of the Israeli *Psammomys* colony is also maintained in Australia (Barnett et al., 1994a, 1994, 1995). An additional colony of *Psammomys* is maintained at the Food and Drug Administration, Washington, DC, on which beta cell studies and assessment of diabetic lenses were performed (Chennault et al., 2002; Katzman et al., 2004).

TABLE 54.4 Diet Type and Placement for Breeding Pairs and Stock Animals in DR and DP *Psammomys obesus* Lines

Genetic Line		Diet type	Diet placement
DR line	Breeding pair (monogamy) without litter	HE diet (Harlan Teklad 2018SC)	On the grid
	Breeding pair (monogamy) with litter	HE diet (Harlan Teklad 2018SC)	On the grid and on bottom of the cage
	Stock animals up to 2.5 months of age	HE diet (Harlan Teklad 2018SC)	On the grid and on bottom of the cage
	Stock animals over 2.5 months of age	HE diet (Harlan Teklad 2018SC)	On the grid
DP line	Breeding pair (monogamy) without litter	LE diet (Harlan Teklad 3084S)	On the grid
	Breeding pair (monogamy) with litter	LE diet (Harlan Teklad 3084S) plus	On the grid
		GP diet (Harlan Teklad 2040S)	On the bottom of the cage

	Stock animals up to 2.5 months of age	LE diet (Harlan Teklad 3084S)	On the grid

Morphological, Physiological, and Biochemical Data

In order to study zootechnical parameters of the DP line animals, we used the pelleted HE diet that slows down the development of hyperglycemia and prevents the extreme diabetic state (stage D).

The morphological, physiological, and biochemical data collected from 151 *Psammomys* from the DP line fed pelleted HE diet, 74 males (M) and 77 females (F), were studied. Biochemical, metabolic, and nutritional balance data of male and female *Psammomys* at various ages are presented in Tables 54.5 (males) and 54.6 (females). Food consumption was 14–16 g/day in male *Psammomys* and 12.5–13 g/day in female *Psammomys*. Water consumption was about 25 ml/day per animal.

Psammomys were weaned at 19–26 days and the growth curves of *Psammomys* fed the HE diet are

presented in Figure 54.9. The results indicated that the period of most rapid growth lasts until 65 days of age (2.5 g/day in males and 2.4 g/day in females). Weight increment slowed until the age of 120 days (1.4 and 0.8 g/day, respectively) and was almost non-existent thereafter. Average weight at maximal growth was 260 g for males and 220 g for females.

Tables 54.7 and 54.8 present morphological and hematological data of male and female *Psammomys*. On the basis of these data Table 54.9 presents the relative size of organs at different ages. Heart and white suprascapular fat are the only organs in which relative weight increased with age. All other organs remained unchanged or reduced their relative weight with age. The adrenal gland was the only organ with a significant difference in relative weight between males and females. Relative size of the kidneys was higher than in other rodents while relative size for the heart was smaller.

THE BASIS OF DIABETES IN PSAMMOMYS

Diabetes does not occur in *Psammomys* on the LE diet which is similar in its caloric value to the native food of this animal. Although the metabolic efficiency of *Psammomys* is similar on both LE and HE diets, diabetes

develops on HE diet because of the relative excess nutrient availability resulting in enhanced insulin secretion (Nesher et al., 1999). On HE diet, the transition from the normoin-sulinemic-normoglycemic stage A to the hyperglycemic stage C is often rapid, and may occur within 1–2 weeks.

To examine whether deficiency of bioactive insulin is a possible cause of the hyperglycemia we administered

subcutaneous implants supplying exogenous bovine insulin to stage D, insulin-deficient *Psammomys*. In this stage *Psammomys* have elevated post-prandial glucose and triglyceride levels, and also have elevated fasting blood glucose level (as opposed to stage C *Psammomys*, where fasting blood glucose levels and post-prandial triglyceride levels are not elevated). As shown in Figure 54.10, the effect of insulin became evident by the decrease of fasting glucose levels in four *Psammomys* from 393 ± 55 mg/dl to 107 ± 21 mg/dl and fasting plasma triglyceride from 683 ± 23 mg/dl to 210 ± 86 mg/dl. Blood glucose levels in the fed state remained high (418 ± 24 mg/dl) (Ziv et al., 1996).

The lack of endogenous insulin causes death in diabetic *Psammomys* within 10 days. Addition of the exogenous bovine insulin prevented death, extending their life for up to 60 days, which is the period of activity of the exogenous insulin implants.

To further study the effect of insulin we administered insulin to non-diabetic stage A *Psammomys* and to normal albino rats (Sabra outbred strain, Hebrew University, Jerusalem). At the same time, we started feeding them the HE diet (Ziv et al., 1996). Administration of exogenous insulin did not produce hypoglycemia and failed to prevent the development of hyperglycemia in *Psammomys* (Figure 54.11A). *Psammomys* fed the LE diet and receiving exogenous insulin did not become hypoglycemic despite a marked elevation in circulating insulin levels (Figure 54.11B).

In contrast to *Psammomys*, albino rats fed the HE diet remained normoglycemic, but exogenous insulin caused a pronounced fall in their blood glucose levels. Albino rats fed the LE diet also maintained normoglycemia but

exogenous insulin caused severe hypoglycemia and the death of all animals within 24h (Figure 54.12A). Insulin levels in rats both on LE and HE diets increased markedly as a result of exogenous insulin treatment, which, however, did not result in fatal hypoglycemia in rats on the HE diet (Figure 54.12B).

From this experiment we concluded that it is not the deficiency of insulin that causes hyperglycemia in *Psammomys* fed the HE diet. Further, hyperinsulinemia induced by exogenous bioactive insulin did not result in hypoglycemia even in normoglycemic *Psammomys* fed the LE diet. These results indicated the possible existence of primary insulin resistance in *Psammomys*.

To better define the nature of the insulin resistance and to assess the effect of exogenous insulin on basal hepatic glucose production (HGP) and total glucose disposal in stage A *Psammomys* maintained on the LE diet, a hyperinsulinemic, euglycemic clamp was performed. The clamp was carried out on both DP and DR groups of *Psammomys* and albino rats which were matched for weight. Results are shown in Table 54.10. The basal fasting glucose and insulin levels were similar in all animals. The hyperinsulinemia resulting from the infusion of an identical amount of human insulin was higher in *Psammomys* than in rats by 44–74%, most probably due to low hepatic clearance (Ziv et al., 1986). The HGP in albino rats and in both groups of *Psammomys* was similar in magnitude. However, in albino rats the HGP became almost completely suppressed by exogenous insulin (Ziv et al., 1996).

Psammomys obesus developed a pronounced insulin resistance both at muscle and liver levels when maintained on a high-energy laboratory diet as compared

FIGURE 54.10 Blood glucose and plasma triglyceride levels in *Psammomys obesus* from the DP line at stages C and D diabetes, fed the HE diet, with and without administered insulin.

with the native dietary regimen. This is evident from decreased muscle glucose uptake and lack of restraint of hepatic gluconeogenesis in the face of hyperinsulinemia (Ziv et al., 1986). Insulin-induced receptor activation, a prerequisite for intracellular signal transduction is inhibited in the hyperinsulinemic-hyperglycemic stage C, indicating that the resistance is located at the insulin receptor site (Ikeda et al., 2001; Kanety et al., 1994; Ziv et al., 1996).

We have demonstrated that the insulin resistance in *Psammomys* may be an inherent characteristic even in the normoglycemic-normoinsulinemic stage A animals on the LE diet. The ability of *Psammomys* to withstand the hypoglycemic effect of insulin implants could not be explained by massively increased hepatic gluconeogenesis or glycogenolysis. However, because hepatic phosphoenolpyruvate carboxykinase (PEPCK), the rate-limiting gluconeogenic enzyme, was reduced only

FIGURE 54.11A Effect of LE and HE diets and of exogenous insulin implants on blood glucose levels in *Psammomys obesus* from the DP line after 14 days of treatment.

FIGURE 54.11B Effect of LE and HE diets and of exogenous insulin implants on plasma insulin levels in *Psammomys obesus* from the DP line after 14 days of treatment.

FIGURE 54.12A Effect of LE and HE diets and of exogenous insulin implants on blood glucose levels in albino rats after 14 days of treatment.

FIGURE 54.12B Effect of LE and HE diets and of exogenous insulin implants on plasma insulin levels in albino rats after 14 days of treatment.

in part by hyperinsulinaemia, this indicates that gluconeogenesis was proceeding and could compensate for the insulin-induced peripheral glucose uptake. It is also conceivable that the scarcity of hepatic and muscle insulin receptors in this animal species (Kanety et al., 1994) and their compromised function in the presence of hyperinsulinemia did not result in an excessive plasma glucose removal. In contrast, the similar hyperinsulinemia in albino rats resulted in reduced hepatic gluconeogenic capacity and enhanced glycogenolysis, which

however did not appear to be sufficient to compensate for the insulin-stimulated tissue glucose uptake. Thus, a profound hypoglycemia was evident, particularly when the animals were maintained on the LE diet.

The use of rats as reference animals in parallel with *Psammomys* does not imply that they are control animals. Rather, they reflect a response of a different species population that is well adjusted to consumption of the HE laboratory diet and characterized by marked sensitivity to insulin.

TABLE 54.10 Results of Hyperinsulinemic Euglycemic Clamp in *Psammomys* and Albino Rats

Albino rat (<i>n</i> = 14)	<i>Psammomys</i> DR line (<i>n</i> = 4)	<i>Psammomys</i> DP line (<i>n</i> = 16)	
95.4 ± 3.6	93.6 ± 5.4	88.2 ± 3.6	Clamp plasma glucose (mg/dl)
116.2 ± 13.4	167.2 ± 72.8	202.5 ± 18.4	Clamp plasma insulin (μU/ml)
11.0 ± 0.5	8.9 ± 1.7	10.0 ± 0.6	Basal HGP (mg min ⁻¹ kg ⁻¹)
0.7 ± 0.3 ^a	4.2 ± 0.2	3.8 ± 0.4	Insulin HGP (mg min ⁻¹ kg ⁻¹)
39.0 ± 1.9 ^a	11.8 ± 2.1	16.0 ± 1.9	Total glucose transport (mg min ⁻¹ kg ⁻¹)

Values are means ± SEM for the number of animals indicated in parentheses.

Body weight of *Psammomys* and albino rats ranged between 150 and 190 g. Fasting plasma glucose of *Psammomys* and albino rats was from 75.6 ± 3.6 to 79.2 ± 3.6 mg/dl and plasma insulin was from 4.2 ± 1.7 to 5.6 ± 1.7 μU/ml. No significant difference for all values between DP and DR *Psammomys*.

Hyperinsulinemia was induced by infusing human insulin.

^a <0.001 for difference between albino rats and both *Psammomys* groups.

Our premise of liver and muscle insulin resistance as characteristic of *Psammomys* species was confirmed by quantitative data on HGP and total glucose transport (TGT) in hyperinsulinemic-euglycemic clamp studies. Insulin infusion decreased the HGP and increased the TGT, again demonstrating the effectiveness of the exogenous insulin. However, HGP was only partly reduced, whereas in albino rats HGP was almost completely abolished (Kalman et al., 1996). Lack of complete suppression of HGP in *Psammomys* was evident even at a higher and longer-lasting level of hyperinsulinemia than in the rats, confirming our previous assumption that gluconeogenesis in *Psammomys* treated with insulin implants is sustained despite hyperinsulinemia.

We have noted a high proportion of circulating proinsulin was observed particularly in the hyperglycemic-hyperinsulinemic stage C *Psammomys* (Gadot, 1994). The hyperproinsulinemia was elicited most probably by the pancreatic beta-cell overtaxation as a result of protracted hyperglycemia. This finding raised the question, "to what extent is the availability of biologically active insulin reduced to account for the hyperglycemia or whether hyperglycemia is caused mainly by the peripheral and hepatic resistance to the available active insulin?" It could be postulated that in the presence of a high proportion of proinsulin or partially split insulin (known to have minimal bioactivity) in *Psammomys*, the HGP could not be totally suppressed in vivo and the peripheral glucose utilization could not be adequately promoted, thus resulting in hyperglycemia. However, the experiments with exogenous insulin, derived either from implants or from infusion during clamp studies, indicated that the hyperinsulinemia elicited by the nutritional overload at stages B or C is able to suppress the HGP at least in part. Full suppression, as observed in the rats, could not be achieved because of the particular resistance of the *Psammomys* species rather than to insufficient levels of bioactive insulin resulting from the

change in the insulin/proinsulin ratio. Similar observations (Shafir, 1988) on incomplete suppression of HGP by porcine insulin were also observed in another group of *Psammomys*. Lack of total HGP suppression in *Psammomys* was evident in these hyperinsulinemic clamp studies even at plasma levels of infused insulin exceeding 6000 pmol/L.

It has previously been shown that hyperinsulinemia is detrimental to the activity of insulin receptors, and the density of liver and muscle receptors in randomly chosen *Psammomys* is low (Kanety et al., 1994). The difference in hyperglycemic response between the two selected lines may be related to the insulin secretion response of pancreatic beta cells of the animals fed the HE diet, the number of available insulin receptors, or the rate of liver clearance of circulating insulin.

The findings of limited suppressibility of HGP by hyperinsulinemia in *Psammomys*, contribute to the understanding of the metabolic condition in the desert environment. With meager nutrition any glucose derived from non-glucose precursors would be primarily targeted to the vital glucose-dependent tissues and the released insulin should not be able to shut off the gluconeogenesis. HGP in the desert environment is probably of survival value both in terms of preferential glucose channeling to non-insulin-dependent nervous tissues and conversion of the available glucose to energy storage, e. g. hepatic lipogenesis. It is quite possible that the adaptation of both animals and humans to plentiful nutrition either in laboratory conditions or as a result of affluence of the western lifestyle have attenuated or selected out the "inborn" insulin resistance characteristics of populations living in nutritional scarcity. Absence of gluconeogenesis restraint in such populations together with rich nutrient intake would lead to enhancement of insulin secretion, excessive lipogenesis followed by insulin resistance and hyperglycemia. This, and eventual obesity with potentiation of insulin

resistance, is well exemplified in *Psammomys* because of the abundant hepatic lipogenic capacity and adipose tissue triglyceride uptake (Kalderon et al., 1983; Ziv et al., 2008).

Beta cell apoptosis and necrosis following prolonged insulin resistance with hyperinsulinemia does not last long enough to compensate for insulin resistance and the associated hyperglycemia in stage C diabetes of *Psammomys* (Bar-On et al., 1999; Donath et al., 1999). The insulin content of beta cells in native *Psammomys* is low compared with that of other animal models of diabetes like the ob/ob mouse or ZDF rat in which the hyperglycemia is effectively compensated. As reported by Leibowitz et al. (2001), the gene expression in *Psammomys* associated with PDX-1 transcription factor is very low or absent and limits beta cell secretory function. The secretion pressure presumably leads to apoptosis and beta cell demise.

The "spontaneous" diabetes in *Psammomys* occurs as a result of prolonged maintenance on HE diet which in stage D is associated with massive beta-cell degranulation, loss of insulin, apoptosis, and necrosis (Like and Miki, 1967). Joerns et al. (2002) followed in detail the consecutive beta-cell changes during the progression from stages A–D on HE diet, involving a gradual loss of beta-cell insulin, glucokinase and GLUT2 transporter immunoreactivities. Ultrastructurally, different signs of necrotic destruction of pancreatic beta cells such as the pyknosis of nuclei and a massive vacuolization in the cytoplasm were seen accompanied by swollen mitochondria and dilated cisternae of the Golgi complex and of the rough endoplasmic reticulum. When the pancreas was removed from animals at stage D, beta cells exhibited apoptosis and DNA fragmentation (Shafir et al., 1999). Similar observations were reported by Donath et al. (1999) and Nesher et al. (1999).

There is no direct evidence for the involvement of gluco- or lipotoxicity in the necrosis of beta cells in *Psammomys*. An attempt to prevent the possible effect of advanced glycation end products or of nitrous oxide by including the glycation inhibitor, aminoguanidine in the hyperglycemic incubation medium was not effective in protecting beta cells of *Psammomys* from apoptosis (Donath et al., 1999). In *Psammomys* the prompt damage of beta cell architecture is probably the result of exhaustion due to the insulin hypersecretion prior to the eventual glucotoxic effect.

Psammomys in stage C diabetes show increased plasma proinsulin levels, up to one half of the circulating immunoassayable total insulin (Gadot et al., 1994). The inordinate secretion pressure may cause a swift exocytosis of immature insulin granules escaping prior to the C peptide cleavage. This indicates that the compensation of the delayed glucose removal and suppression of the hepatic gluconeogenesis attributed

to insulin is not effective because proinsulin has only a minute fraction of insulin activity. Actually, a high level of circulating proinsulin does not mean that its secretion is similar to that of insulin since the half-life of proinsulin is much longer than that of insulin (Glauber et al., 1986) but in effect very little true insulin is released into the circulation. Deficient insulin secretion, with increased proportions of insulin precursor molecules, is a common feature of type 2 diabetes and could result both from inappropriate beta cell function and reduced beta cell mass. Bendayan et al. (1993) reported that beta cells of hyperglycemic *Psammomys* are in a chronic high-secretory mode with loss of secretory granules and impaired processing of proinsulin by the convertases PC1 and PC2 as compared with normoglycemic animals. Leibowitz et al. (2002) stated that inadequate response of the preproinsulin gene by glucose may contribute to the failure of *Psammomys* to cope with the increased demand for insulin associated with caloric excess, leading to depletion of insulin stores and diabetes.

The possible involvement of islet amyloid polypeptide (IAPP) in insulin depletion of diabetic *Psammomys* was also investigated. The immunoreactivity of pancreatic IAPP and insulin were considerably weaker in stage C diabetic *Psammomys* compared with normoinsulinemic group A. Plasma IAPP and insulin were significantly elevated suggesting co-excretion as a result of pancreatic beta cell overstimulation (Leckstrom et al., 1997).

It may be concluded that *Psammomys* represents a good model to address questions related to the role of insulin resistance and beta cell failure in nutritionally induced diabetes. Continued consumption of the HE diet thus imposes a gradually rising insulin resistance, resulting in depletion of pancreatic insulin stores, with increased proportion of insulin precursor molecules in the pancreas and the blood. Impaired processing of preproinsulin to the increased insulin needs is an important cause in diabetes progression (Leibowitz et al., 2002). Changes in beta cell mass do not correlate with pancreatic insulin stores and are unlikely to play a role in disease initiation and progression. The major culprit is the inappropriate insulin production with depletion of insulin stores as a consequence.

Psammomys of 1–12 months of age, and which are fed LE diet from weaning and transferred at different ages to HHHhhE diet, demonstrated that sensitivity to the development of diabetes increases from weaning to 5 months of age and decreases thereafter (Kalman et al., 1998; Ziv et al., 1999). At 5 months of age, the obesity factor measured as the proportion of epididymal fat weight to total body weight, is highest, while the proportion of other organs to total body weight remains unchanged (Figure 54.13). In animals older than 7–8 months, the potential to develop diabetes and obesity decreases.

FIGURE 54.13 Changes in percentage of diabetic animals, epididymal fat and liver relative weight in male *Psammomys obesus* from the DP line at various ages after being switched to the HE diet for 5 weeks.

These changes are in correlation with the decrease in fertility of *Psammomys* from both DP and DR lines.

THE RELEVANCE OF PSAMMOMYS TO DIABETES RESEARCH

Psammomys represents an excellent model to test compounds attenuating diabetes in stages B or C since they are reversible to stage A diabetes following treatment. Stage D, in which the beta cells are already compromised, is not amenable to treatment. Vanadyl sulfate was effectively used to prevent the hyperglycemia and hyperinsulinemia of *Psammomys* maintained on the HE diet (Shafrir et al., 2001). Administration of 5mg/kg of vanadyl sulfate for 5 days resulted in a prolonged restoration of normoglycemia and normoinsulinemia and muscle GLUT4 transporter as well. Pretreatment with vanadyl sulfate significantly delayed the onset of hyperglycemia. Rosiglitazone administered to *Psammomys* on HE diet at 20mg/kg for 2 weeks also normalized the hyperglycemia and markedly reduced the hyperinsulinemia. The glucose metabolism in peripheral tissues was not the primary target of the beneficial effect of rosiglitazone but this thiazolidinedione prevented the damage to pancreatic beta cells and loss of insulin, thus enabling insulin secretion to compensate for the peripheral insulin resistance (Hefetz et al., 2006).

Among other beneficial treatments of *Psammomys*, administration of nicotine was shown to decrease the food intake and body weight in *Psammomys* via a non-leptin-dependent pathway (Sanigorski et al., 2002). A

sustained hypoglycemic effect was obtained by electroacupuncture (Shapira et al., 2000). Improvement was also obtained following treatment with an analog of glucagon-like peptide (GLP-1) acting like an incretin promoting the beta cell insulin secretion and availability (Uckaya et al., 2005). Novel peptides modulating a G-protein-coupled kinase had an anti-diabetic effect in *Psammomys* as well as in *db/db* mice and ZDF rats (Anis et al., 2004). An oral agent S15261 L-isomer of 2-([2-methoxy-2-[3-(trifluoromethyl)phenyl]ethyl]amino)ethyl-4-(2-([2-(9H-fluorenyl)acetyl]amino)ethyl)benzene preventing the beta cell lesion in the HE maintained *Psammomys* and restored the integrity of beta cell cytoarchitecture. Metabolic and anti-atherogenic effects were obtained by long-term administration of benfluorex in dyslipidemic insulin-resistant *Psammomys* (Marquie et al., 1997a, 1997b).

As already stated, *Psammomys obesus* exhibits muscle insulin resistance due to impaired insulin signaling pathway inhibition evident by reduced tyrosine kinase activity (Ikeda et al., 2001; Kanety et al., 1994; Shafrir et al., 1996). An overexpression of the enzyme protein kinase isoform epsilon (PKC ϵ) was found in *Psammomys* muscle (Ikeda et al., 2001), which prevented the tyrosine phosphorylation on the IRS-1 insulin receptor substrate by inhibiting phosphorylation of serine residues (Mack et al., 2008). Further, prevention of the detrimental serine phosphorylation on IRS-1 was achieved by using a competitive inhibitory peptide Kce-12 isolated from the catalytic domain of PKC (Niv et al., 2004), thereby abrogating the insulin signaling impediment and restoring normoglycemia in *Psammomys* maintained on the HE diet. Damage and loss of insulin in

FIGURE 54.14 Blood glucose lowering by intraperitoneal injections of peptide Kce-12, indicated by arrows. Mean $\pm$ SE for groups of eight female *Psammomys obesus* maintained on the HE diet.

FIGURE 54.15 Beta cell insulin replenishment after treatment with Kce-12. Left: Islet cell from untreated diabetic *Psammomys obesus* on HE diet. Arrows indicate vacuoles. Right: Islet cell from treated diabetic *Psammomys obesus* on HE diet. Note the strong immunostaining of insulin and disappearance of vacuoles.

pancreatic beta cells on HE diet were also prevented by the inhibitory peptide (Mack et al., 2008) as presented in Figures 54.14 and 54.15. The anti-diabetic peptide Kce-12, and similar peptides copied from the catalytic region of the PKC molecule may lead to a functional therapeutical modality preventing the overnutrition-induced insulin resistance and diabetes.

THE GENETIC BASIS OF PSAMMOMYS DIABETES

The genetic predisposition of the DP line of *Psammomys* determines the development of “diabetes”, a collusion of diabetes and obesity (Shafir, 1996) in animals only when they are maintained on a HE diet, whereas the DR animals do not develop these untoward changes. The roles of genetic factors on one hand and dietary conditions on the other seem to be similar in humans and thus render development of type 2 diabetes in *Psammomys* an excellent model for the study of this multifactorial disease.

In order to better understand the genetic background of diabetes in *Psammomys*, a backcross generation (BC₁) was formed by crossing F₁ males with females of the DP line. The resulting progeny were assessed for blood glucose on high-energy (HE) diet. A clear bimodal distribution of blood glucose was observed; normoglycaemic and hyperglycemic at a 1:1 ratio (Hillel et al., 2005).

This distribution of progeny suggested that a major gene may be involved in the transition from normoglycemia to hyperglycemia, while the level of the blood glucose within each mode may be affected by more than one gene and by environmental factors. If this hypothesis is true, it implies that the selected DR line is homozygous for the dominant allele, the selected DP line is homozygous for the recessive allele, and that the F₁ is heterozygous for this single putative gene. In such a case, when F₁ individuals are backcrossed to the DP line, one should expect a bimodal distribution among the BC₁ progeny at a ratio of 1:1 between the resistant and the prone modes. In fact, we used the backcross to the DP line rather than to the DR line or to both lines since we hypothesized that the hyperglycemic animals are more likely to be homozygous recessive.

The mode of inheritance of nutritionally induced diabetes in DR *Psammomys* was investigated following the transfer from LE to HE diet. *Psammomys* selected for high or low blood glucose were used as two parental lines. At weeks 1–9 after weaning, a clear bimodal distribution, different from unimodal distribution, of blood glucose was observed, normoglycemic and hyperglycemic at a 1:1 ratio. This ratio is expected at the first backcross generation for traits controlled by a single dominant gene. From week 0 (prior to transfer to HE diet) until week 8, the hyperglycemic individuals were significantly heavier (4–17%) than the normoglycemic ones. The bimodal blood glucose distribution in BC₁ generation, with about equal frequencies in each mode, strongly suggests that a single major gene affects the transition from normo- to hyperglycemia. The wide

range of blood glucose values among the hyperglycemic individuals (180–500 mg/dl) indicates that several genes and environmental factors influence the extent of hyperglycemia. The DR allele appears to be dominant; the estimate for the dominance ratio is 0.97.

Our main conclusion is to challenge the accepted convention of polygenic development of insulin resistance and type 2 diabetes. We have shown that, in an established dietary regimen defined by us, a major gene comes into play. This gene may mask what might be a polygenic-based phenomenon in another environment. Thus, what may be polygenic in one environment with a neutralized major gene may be monogenic in another environment where that gene becomes expressed. Such an idea may have large implications to the human situation where individuals overconsume. We propose that a major monogenic factor initiates type 2 diabetes, which may be followed by, or associated with, nutritionally and/or environmentally evoked factors. This possibility may apply to the development of type 2 diabetes in animals and humans alike.

WORLDWIDE RESEARCH USING PSAMMOMYS

Diabetes in *Psammomys* originating from Algeria was described by Marquie et al. (1991a, 1991b). Approximately 40% of the animals developed the diabetes syndrome, with a few dying in ketosis. Other investigations in the Algerian *Psammomys* concerned the seasonal variations in the ultrastructure and production of testosterone-dependent proteins in the seminal vesicles and the role of glucose and insulin in the regulation of collagen synthesis in aortic smooth muscle cells (Aouichat-Bouguerra et al., 2001; Gernigon-Spychalowicz, 1992; Gernigon-Spychalowicz et al., 1997). A lack of physiologic changes in the activity of the hepatic enzyme glucose-6-phosphatase was established in the Algerian *Psammomys* (Koceir et al., 2003). An additional colony of *Psammomys* is maintained in Food and Drug Administration premises in Washington, DC, on which beta cell studies and assessment of diabetic lenses were performed (Chennault et al., 2002; Katzman et al., 2004).

A branch of the Israeli *Psammomys* colony has also been maintained by the Collier group in Australia (Barnett et al., 1994a, 1994b; Collier et al., 1997). It was observed that insulin resistance and hyperinsulinemia appear before weight gain, followed by adipose tissue accretion and diabetes. Tissue triglyceride deposition was driven by the ample hepatic lipogenesis, which continues unabated despite insulin resistance. With regard to the genetic characteristics it is of interest that the product of a hypothalamic gene termed 'BEACON' (Collier et al., 2000; Walder et al., 2002a)

was found to increase the food intake and body weight after intracerebroventricular injection. It also induced a two-fold increase in hypothalamic neuropeptide Y expression. The Australian investigators have discovered a TANIS gene assumed to be responsible for a link between type 2 diabetes and inflammation (Walder et al., 2002b). They also identified a mitochondrial intramembranal protease, known as presenilin-associated rhomboid-like protein (PSARL) to be associated with insulin resistance and possibly a new candidate gene related to development of type 2 diabetes (Walder et al., 2005).

Psammomys from the Israeli colony have also been maintained by Thora Bodvarsdottir and colleagues at the Novo-Nordisk Department of Pharmacology in Denmark. An important observation of this group was the development of the pancreas in the known propensity for agenesis in the presumed absence of the homeobox gene 1 (PDx-1) (Leibowitz et al., 2002). However, in spite of possible deficiency of PDx-1 the pancreas developed almost normally, similarly to *Muridae* species, and the sequence and expression of the Neurogenin-3 gene exhibited a highly conserved pattern (Vedtofte et al., 2007).

One of the recent developments in diabetology is the treatment of patients with incretin-like compounds activating insulin secretion by the intestinal glucagon-like peptide (GLP-1). Protection of this peptide and others like liraglutide requires inhibition of the intestinal enzyme dipeptidyl peptidase (DPP-4). Liraglutide administered to diabetic *Psammomys* significantly reduced the blood glucose often to normal levels in the majority of animals, whereas the inhibition of DPP-4 by vidagliptin neither reduced the blood glucose, nor affected the pancreatic insulin content. Thus, liraglutide decidedly improved the glycemic control of diabetes by improving the pancreatic insulin secretion while the vidagliptin was ineffective in *Psammomys* (Vedtofte et al., 2009).

COMPLICATIONS OF DIABETES IN PSAMMOMYS

Of the complications affecting long-term hyperglycemic animals, cataracts are the foremost (Hackel et al., 1965; Kohler and Knospe, 1980; Kuwabara and Okisaka, 1976), and are prominent after 2–4 months on the HE diet. Retinal damage is also evident due to degeneration of dopamine neurons (Larabi et al., 1991). With respect to cataracts, Gutman et al. (1976) found that the activity of the enzyme galactokinase is very low in *Psammomys* red blood cells and ocular tissues, with or without cataracts. This suggests that the formation of cataracts is due to consumption of the

calorie-rich diet and conversion of glucose and galactose to sorbitol or galactitol, followed by their accumulation in the presence of hyperglycemia. Treatment of *Psammomys* with acarbose resulted both in reduced glycemia and raised activity of aldose reductase with a significant prevention of cataract development (Cohen-Melamed et al., 1995). It was also found that treatment with lipoic acid reduced the hyperglycemia and increased the glutathione content in association with reduced incidence of cataract development (Borenshtein et al., 2001).

Microangiopathy characterized by thickening of the intima and deposition of glycosaminoglycans was seen in the Algerian *Psammomys* (Marquie et al., 1991b) and degeneration of the intervertebral discs with spondylosis was noted in the Jerusalem colony (Silberberg, 1988; Silberberg et al., 1979). Old *Psammomys* exhibited a tendency of hepatic malignancy (Ungar and Adler, 1978), and uterine neoplasms (Czernobilski et al., 1982). Various ontological deficiencies were found in *Psammomys* by Sichel et al. (1999), Perez et al. (2002), and Sohmer et al. (2004). Although *Psammomys* excrete highly concentrated urine (Jamison et al., 1979), various stages of nephropathy were observed in those with diabetes (Scherzer et al., 2000).

Neonatal malformations were observed in newborns of diabetic *Psammomys* females, the pregnancy of which is somewhat longer, 27 days versus 26 days (Patlas et al., 2006). Litter size average is reduced, and the newborns have smaller crown-rump lengths and lower birth weights. Neurodevelopmental parameters (e. g., first turnover, hair appearance, and eye opening) are delayed by 2–3 days. From the fourth week of life they become diabetic, even on the LE diet.

CONCLUDING REMARKS

Psammomys in its native habitat is a healthy animal with a metabolic-endocrine system that is adjusted to desert life on a low-caloric-density diet, thus enabling reasonable survival. *Psammomys* is not hyperphagic; however, when high HE nutrition becomes available, it is predisposed to diabetes, obesity, and beta cell overtaxation. This predisposition is due to feedback inhibition of the insulin-signaling pathway, involving serine phosphorylation and stoppage of tissue glucose transport but not lipogenesis. This ill adaptation to nutrient excess is an outstanding example of the "thrifty gene" effect as described by Wendorf and Goldfine (1991) and it therefore represents a suitable model for studying the mechanism of predisposition to insulin resistance and metabolic syndrome in human populations that evolve from scarcity to abundance in nutritional intake.

INTRODUCTION

We have endeavored to develop a formulary that includes drugs in common use within the laboratory animal community. This formulary is limited to the species relevant to this volume, with particular emphasis on rabbits, guinea pigs, hamsters, and degus. There is limited published information available for the other minor rodent species covered in this text. This formulary is not meant to be all-inclusive. There are many other excellent published sources that cover laboratory animals and other exotic species.

This formulary is divided into five major areas within each species. These areas include analgesics /sedatives,

anesthetics, anti-infectives, parasiticides, and a miscellaneous category. It must be noted that the vast majority of the drugs listed have not been approved by regulatory authorities for use in the species covered in this formulary. It is also important to note that few of the drugs have undergone formal studies to determine their efficacy, pharmacokinetics, or pharmacodynamics. Thus most drug dosages listed in this formulary are based on clinical observation and experience, or extrapolated from limited scientific data. Extrapolation to other species may be considered using allometric scaling (Hawk et al., 2005). Before any of the referenced doses are used in animals, it is the responsibility of the reader to study the source citation to understand how the listed dose was determined.

Abbreviations

bid	twice daily	prn	as needed
h	hour	q	every
IM	intramuscular	qid	four times daily
IN	intranasally	s	second
IP	intraperitoneal	SC	subcutaneous
IU	international unit	sid	once daily
IV	intravenous	tid	three times daily
kg	kilogram	U	unit
l	liter	µg	microgram
lb	pound	%	g/100 ml
mg	milligram		
ml	milliliter		
PO	per os		
ppm	parts per million		

Drugs are listed in alphabetical order by their generic name within each category. When multiple drugs are listed, the dose and route are listed in the same order as the drug names.

RABBIT (*ORYCTOLAGUS CUNICULUS*)

Analgesics and Sedatives

Generic name	Dose and route	Comments	Reference
Acepromazine	5 mg/kg IM		Flecknell, 1987
Acepromazine	2 mg/kg IM		Bauck, 1989
Acepromazine	1–2 mg/kg IM		Harkness and Wagner, 1983
Acepromazine	0.5–1 mg/kg IM	Dosage for vasodilation with minimal sedation	Morrissey et al., 2004
Acepromazine, codeine elixir	1 ml elixir/100 ml drinking water PO		Wixson, 1994
Acetaminophen	200–500 mg/kg PO		Gillett, 1994
Alfentanil	0.03–0.07 mg/kg IV	Intraoperative analgesia with 45 min duration	Wixson, 1994
Alphaxalone-alphadolone	9–12 mg/kg IM		Flecknell, 1987
Alphaxalone-alphadolone	6–9 mg/kg IV	Possible high mortality (Flecknell, 1987)	Green, 1982
Aminopyrine	50 mg/kg PO		Jenkins, 1987
Antipyrine	100 mg/kg IM, IP, or SC		Borchard et al., 1990
Antipyrine	500 mg/kg PO		Borchard et al., 1990
Antipyrine	100 mg/kg PO		Jenkins, 1987
Aspirin	100 mg/kg PO	Suggested q4h	Flecknell, 1991
Aspirin	400 mg/kg SC or PO sid		Harkness and Wagner, 1983
Aspirin	80–160 mg PO bid		Harvey, 1995
Aspirin	20 mg/kg PO sid		Marangos et al., 1994
Aspirin	10–100 mg/kg PO q8–24h		Morrissey et al., 2004
Buprenorphine	0.02–0.1 mg/kg IV or SC bid		Carpenter et al., 1995
Buprenorphine	0.02–0.0 mg/kg IM, IV, or SC q8–12h		Flecknell, 1985; Jenkins, 1987

(Continued)

Analgesics and Sedatives (Continued)

Generic name	Dose and route	Comments	Reference
Buprenorphine	0.01–0.05 mg/kg IV or SC q6–12h		Flecknell, 1991
Buprenorphine	0.01–0.05 mg/kg IM, IV, or SC q6–12h		Heard, 2009
Buprenorphine	0.025 mg/kg PO bid	Post nephrectomy	Rhody, 2006
Buprenorphine	0.5–0.75 mg/kg SC	Pre emptive analgesia	Sklenka et al., 2006
Buprenorphine	0.5 mg/kg per rectum bid	Analgesia	Huerkamp, 1995
Buprenorphine	0.01–0.05 mg/kg SC q6–8h	Relief from ileus, gastric stasis (Note: relief for severe pain, but repeated usage may cause ileus, GI hypomotility)	Reusch, 2005
Buprenorphine, acepromazine	0.5 mg/kg SC, 0.03 mg/kg SC	Sedation for immunizations	Halliday et al., 2004
Butorphanol	0.1–0.5 mg/kg IM, IV, or SC q4h	More sedative effect than buprenorphine, effective as preanaesthetic/preemptive analgesia	Carpenter et al., 1995
Butorphanol	0.1–0.5 mg/kg IV q4h		Flecknell, 1989
Butorphanol	0.5–2 mg/kg IM or SC qid		Harvey, 1995
Butorphanol	0.1–0.5 mg/kg SC	Analgesic for surgical thoracoscopic implantation of tumor	Kreuter et al., 2008
Butorphanol	0.1–0.5 mg/kg SC or IV q2–4h	Relief from ileus, gastric stasis	Reusch, 2005
Butorphanol, acepromazine	1 mg/kg IM, 1 mg/kg IM		Flecknell, 1996
Carprofen	1.5 mg/kg PO bid		Flecknell, 1996
Carprofen	3 mg/kg IV		Grint et al., 2006
Carprofen	4 mg/kg SC sid		Heard, 2009
Carprofen	1.5 mg/kg PO bid		Heard, 2009
Carprofen	1–2.2 mg/kg PO sid		Morrissey et al., 2004
Carprofen	2–4 mg/kg SC, IV, or PO sid	Relief from ileus, gastric stasis	Reusch, 2005
Chlorpromazine	1–20 mg/kg IM		Carpenter et al., 1995
Chlorpromazine	25 mg/kg IM	May produce myositis	Canadian Council on Animal Care, 1984
Diazepam	2 mg/kg IV		Flecknell, 1987
Diazepam	4 mg/kg IM or IP		Flecknell, 1987
Diazepam	5–10 mg/kg IM or IP		Green, 1982
Diazepam	5–10 mg/kg IM		Hrkness et al., 1983
Diazepam, xylazine	1 mg/kg IV, 3 mg/kg IV	Bolus for anesthetic induction	Hatch et al., 1988
Fentanyl	25 µg/h transdermal patch	Up to 72 hours, pharmacokinetic profile affected by hair removal method	Foley et al., 2001
Fentanyl/droperidol	0.17 ml/kg IM		Canadian Council on Animal Care, 1984
Fentanyl/droperidol	0.15–0.17 ml/kg IM		Lewis et al., 1972
Fentanyl/fluanisone	0.5 ml/kg IM		Jenkins, 1987
Flunixin	1–2 mg/kg IM or SC bid		Heard, 2009

(Continued)

Analgesics and Sedatives (Continued)

Generic name	Dose and route	Comments	Reference
Flunixin	1–3 mg/kg IM or SC sid or bid	Contraindicated with renal disease, does not appear to cause GI ulceration	Krempels et al., 2000
Flunixin	1.1 mg/kg IM or SC suggested bid	Use no more than 3 days (Carpenter, 2005)	Liles et al., 1992
Haloperidol	0.2–0.4 mg/kg IM bid		Iglauer et al., 1995
Hydromorphone	0.1–0.2 mg/kg IM, IV, or SC q6–8h		Johnston, 2005
Ibuprofen	10–20 mg/kg IV suggested q4h		Flecknell, 1991
Ibuprofen	2.0–7.5 mg/kg PO q12–24h		Morrissey et al., 2004
Indomethacin	12.5 mg/kg PO		Keller et al., 1988
Ketamine	30 mg/kg IM	Should be administered with other agents	Bauck, 1989
Ketamine	15–20 mg/kg IV	Should be administered with other agents (Hernandez-Divers, 2005)	Gillett, 1994
Ketamine	20–50 mg/kg IM	Should be administered with other agents, 60 min of sedation (Hernandez-Divers, 2005)	Gillett, 1994
Ketamine, acepromazine	25 mg/kg IM, 0.7 mg/kg IM	Anesthetic induction	Sklenka et al., 2006
Ketamine, diazepam	Diazepam 0.2–0.5 mg/kg IV, then Ketamine 10–15 mg/kg IV to effect	Sedation, use with isoflurane for anesthetic	Heard, 1993
Ketamine, diazepam	15 mg/kg IM, 0.3 mg/kg IM	Anesthesia, follow with isoflurane	Millis et al., 1992
Ketamine, diazepam	20–30 mg/kg IM then 0.5 mg/kg IV at 5–10 min	Anesthesia for dentistry	Hillyer, 1994
Ketamine, diazepam	20–30 mg/kg IM, 1–3 mg/kg IM		Hillyer, 1994
Ketamine, diazepam	20–40 mg/kg IM, 1–5 mg/kg IM		Heard, 2004
Ketamine, medetomidine	15 mg/kg IM, 0.250 mg/kg IM		Grint et al., 2006
Ketamine, medetomidine, buprenorphine	35 mg/kg IM, 0.5 mg/kg IM, 0.03 mg/kg IM	Anesthetic induction and pre surgical analgesia	Difilippo et al., 2004
Ketamine, midazolam	15 mg/kg IM, 3 mg/kg IM		Grint et al., 2006
Ketamine, midazolam	25 mg/kg IM, 5 mg/kg IM		Sireve et al., 2008
Ketamine, xylazine	0.75 ml (two parts 100 mg/ml ketamine: one part 20 mg/ml xylazine)/kg IM	Anesthetic induction	Kreuter et al., 2008
Ketamine, xylazine, buprenorphine	35 mg/kg IM, 5 mg/kg IM, 0.03 mg/kg IM	Anesthetic induction and pre surgical analgesia	Difilippo et al., 2004
Ketoprofen	3 mg/kg IM		Flecknell, 1996
Ketoprofen	3 mg/kg IM or SC sid		Heard, 2009
Ketoprofen	1 mg/kg IM		Perrin et al., 1990
Medetomidine	0.300–0.500 mg/kg	Reverse with atipamezole	Aeschbacher, 1995
Medetomidine	0.100–0.500 mg/kg IM or SC	Reverse with atipamezole	Flecknell, 1996
Medetomidine	0.250 mg/kg IM	Reverse with atipamezole	Ko et al., 1992
Medetomidine, Ketamine	0.35 mg/kg IM, 5–20 mg/kg IV 15 minutes after medetomidine	Anesthesia, surgical depth approximately 19 min	Hellebrekers et al., 1997

(Continued)

Analgesics and Sedatives (Continued)

Generic name	Dose and route	Comments	Reference
Medetomidine, Ketamine	0.1 mg/kg IV, 20 mg/kg IV 20 minutes after medetomidine	Anesthesia sufficient for cerebrospinal fluid spinal tap and cardiocentesis	Raekallio et al., 2002
Medetomidine Propofol	0.35 mg/kg IM then 3 mg/kg IV	Anesthesia; surgical depth approximately 11 min	Hellebrekers et al., 1997
Meloxicam	0.2 mg/kg PO sid	Used chronically for osteoarthritis, dental abscess, osteomyelitis, and postoperative pain, palatable (Hernandez-Divers, 2005)	Grint et al., 2006
Meloxicam	0.1–0.3 mg/kg PO or SC sid		Hawkins, 2006
Meloxicam	0.2 mg/kg IM or SC sid		Heard, 2009
Meloxicam	0.3 mg/kg PO sid		Heard, 2009
Meloxicam	0.1–0.5 mg/kg PO or SC q12–24h		Johnston, 2005
Meloxicam	1.5 mg/kg PO sid	Can be given up to 5 days, safe dose, efficacy not shown but suspected	Turner et al., 2006
Meloxicam	0.5 mg/kg PO bid for 10 days	Pain relief for retrobulbar abscess	Martinez-Jimenez et al., 2007
Meloxicam	0.12 mg/kg PO sid for 7 days	Post nephrectomy	Rhody, 2006
Meloxicam	0.1–0.6 mg/kg SC or PO bid	Relief from ileus, gastric stasis	Reusch, 2005
Meperidine	10–20 mg/kg IM or SC q2–3h	Analgesia	Flecknell, 1991
Meperidine	5–10 mg/kg SC, IP q2–3h	Analgesia	Flecknell, 1991
Meperidine	5–25 mg/kg SC, IM, IV	Analgesia	Gillett, 1994
Meperidine	0.2 mg/ml drinking water	Analgesia	Huerkamp, 1995
Meperidine	10 mg/kg IM or SC q2–3h	Analgesia	Jenkins, 1987
Midazolam	2 mg/kg IV		Flecknell, 1987
Midazolam	4 mg/kg IM or IP		Flecknell, 1987
Midazolam	0.5–2 mg/kg IM, IP, or IV		Flecknell, 1996
Midazolam, fentanyl/ fluanisone	1–2 mg/kg IV, 0.3 ml/kg IM	Infuse with 2–5 µg/kg/min IV fentanyl for long term anesthesia	Flecknell, 1996
Midazolam	2 mg/kg IM or IV		Morrissey et al., 2004
Midazolam	2 mg/kg IN		Robertson and Eberhart, 1994
Midazolam	1–2 mg/kg IM		Paul-Murphy, 2007
Meloxicam	0.12 mg/kg PO sid for 7 days	Post nephrectomy analgesia	Rhody, 2006
Morphine	5 mg/kg IM or SC q2–4h		Flecknell, 1985; Jenkins, 1987
Morphine	2–5 mg/kg IM or SC q2–4h		Flecknell, 1991
Nalbuphine	1–2 mg/kg IV q4–5h		Flecknell, 1989
Nalbuphine	1 mg/kg IP or SC		Flecknell, 1996
Nalbuphine	0.1 mg/kg IV		Flecknell, 1996
Naloxone	0.01–0.1 mg/kg IM, IV	Narcotic reversal	Hernandez-Divers, 2005
Oxymorphone	0.1–0.2 mg/kg IM or IV		Cantwell, 2001
Oxymorphone	0.05–0.2 mg/kg IM or SC q8–12h		Heard, 2009

Analgesics and Sedatives (Continued)

Generic name	Dose and route	Comments	Reference
Paracetamol (acetaminophen)	50 mg rectal suppository	Post procedure pain relief	Papaioannou et al., 2004
Paracetamol (acetaminophen)	25 mg PO bid	Post procedure pain relief	Papaioannou et al., 2004
Paracetamol (acetaminophen)	10–20 mg/kg IM or SC q4h	Post procedure pain relief	Flecknell, 1985; Jenkins, 1987
Pentazocine	5 mg/kg IV q2–4h		Flecknell, 1991
Pethidine	10 mg/kg IM or SC q2–3h		Flecknell, 1987
Piroxicam	0.3 mg/kg PO q48h		Flecknell, 1996
Piroxicam	0.2 mg/kg PO tid	Analgesia, NSAID	More et al., 1989
Promazine	1–2 mg/kg IM, IV	Preanesthetic	Gillett, 1994
Propofol	2–3 mg/kg IV for induction after premedication, maintain with approximately 1 mg/kg IV q15 min		Hernandez-Divers 2005
Tramadol	10 mg/kg PO sid		Johnston, 2005
Tramadol	> 11 mg/kg PO q4–6h	Variable absorption orally, 11 mg/kg did not reach plasma concentrations needed for analgesia based on humans	Souza et al., 2008
Xylazine	1–3 mg/kg IM		Flecknell, 1987
Xylazine	1–5 mg/kg IM or SC		Armeno et al., 2002
Xylazine	3–5 mg/kg IM		Harkness and Wagner, 1983
Xylazine	5 mg/kg IM		Hughes, 1981
Yohimbine	0.2–1.0 mg/kg IM, IV	Xylazine reversal	Hernandez-Divers, 2005

Anesthetics

Generic name	Dose and route	Comments	Reference
Chloralose	80–100 mg/kg IV	1 % solution	Green, 1982
Diazepam	2 mg/kg IV	Surgical anesthesia	González-Gil et al., 2004
Fentanyl, medetomidine	8 µg/kg IV, 0.300 mg/kg IV		Flecknell, 1996
Fentanyl/droperidol	0.4 ml/kg SC		González-Gil et al., 2003
Fentanyl/droperidol	0.1–0.5 ml/kg IM		Green, 1982
Fentanyl/fluanisone, diazepam	0.3 ml/kg IM, 1–2 mg/kg IP or IV		Flecknell, 1996
Fentanyl/fluanisone, midazolam	0.3 ml/kg IM, 2 mg/kg IM or SC		Armeno et al., 2002
Fentanyl/fluanisone, midazolam	0.3 ml/kg IM, 1–2 mg/kg IP or IV		Flecknell, 1996
Fentanyl/fluanisone, midazolam	0.3 ml/kg IM, 2 mg/kg IV	For long-term anesthesia follow with fentanyl 2–5 µg/kg/min IV	Flecknell, 1996
Ketamine	44 mg/kg IM		Weisbroth and Fudens, 1972
Ketamine	50 mg/kg IM	For immobilization	Flecknell, 1987
Ketamine	25 mg/kg IN	Light surgical anesthesia	Robertson and Eberhart, 1994

Generic name	Dose and route	Comments	Reference
Trimethoprim sulphadoxine	48 mg/kg SC	Coliobacillosis, May cause tissue necrosis SC (Hernandez-Divers, 2005)	Reusch, 2005
Trimethoprim/sulfadiazine	30 mg/kg SC sid	May cause tissue necrosis SC (Hernandez-Divers, 2005)	Bauck, 1989
Trimethoprim/sulfadiazine	0.2 ml/kg of 240 mg/ml solution bid		Flecknell, 1987
Trimethoprim-sulfamethoxazole	30 mg/kg PO bid		Reusch, 2005
Trimethoprim-sulfamethoxazole	15 mg/kg PO bid	Dosed on sulfa concentration	Bauck, 1989
Tylosin	10 mg/kg IM, PO, or SC bid		Hernandez-Divers, 2005
Tylosin	10 mg/kg PO or SC bid		Morrissey et al., 2004
Vancomycin	50 mg/kg IV tid		Nicolau et al., 1993

Parasiticides

Generic name	Dose and route	Comments	Reference
Amprolium	1 ml of 9.6% solution /7kg sid for 5 days		Hernandez-Divers, 2005
Amprolium	5 ml of 9.6% solution/gallon drinking water PO for 5 days		Hernandez-Divers, 2005
Carbaryl powder	5% powder topical	Can be diluted 1:1 with talc	Harkness and Wagner, 1983
Fenbendazole	50 ppm mixed in food PO for 5 days		Duwel and Brech, 1981
Fenbendazole	20 mg/kg PO sid for 5 days		McKellar, 1989
Fenbendazole	10–20 mg/kg PO repeated in 10–14 days	Pinworm, <i>Passalurus ambiguus</i>	Reusch, 2005
Fenbendazole	10–20 mg/kg PO	Repeat in 14 days	Morrissey et al., 2004
Fipronil	Not recommended	Not recommended by manufacturer (see MSDS)	
Fipronil	Not recommended	Toxic	Morrissey et al., 2004
Imidacloprid	Topical	Cat dose, once each month	Morrissey et al., 2004
Imidacloprid, moxidectin	10 mg/kg topical, 12 mg/kg topical	Apply as a spot-on	Hansen et al., 2005
Ivermectin	200–500 µg/kg SC or PO		Harvey, 1995
Ivermectin	400 µg/kg SC		McKellar et al., 1992
Ivermectin	200–400 µg/kg SC or PO		Messonnier, 1994
Ivermectin	200–400 µg/kg SC	Repeat in 10–14 days	Carpenter et al., 1995; Morrissey et al., 2004
Lasalocid	120 ppm in feed	Coccidiosis	Harkness and Wagner, 1995
Lime sulfur	2.50% topical	Dip every 7 days	Morrissey et al., 2004
Lufenuron	30 mg/kg PO q30d		Morrissey et al., 2004
Malathion	0.50% topical	Sponged two times each week	Russell et al., 1981
Mebendazole	10 mg/kg PO sid for 5 days		McKellar, 1989

(Continued)

Parasiticides (Continued)

Generic name	Dose and route	Comments	Reference
Metronidazole	20 mg/kg PO bid for 10 days		Carpenter et al., 1995
Nicarbazin	125 ppm PO	Mixed in food for 30 days	Sorribas et al., 1992
Niclosamide	150 mg/kg PO		Williams, 1976
Phenothiazine	1 g PO	Place in 50 g molasses-treated feed	Siegmund, 1979
Piperazine	100 mg/ml drinking water PO		Hagan and Gorham, 1976
Piperazine	500 mg/kg PO sid for 2 days	As adipate	Morrissey et al., 2004
Piperazine	0.5 mg/kg PO	As adipate; sid for 2 days	Brooks, 1979
Piperazine	200 mg/kg PO	As citrate: repeat in 14 days (Morrissey et al., 2004)	Harkness and Wagner, 1983
Praziquantel	5 mg/kg SC		McKellar, 1989
Praziquantel	10 mg/kg PO		McKellar, 1989
Praziquantel	5–10 mg/kg PO	Cestodes, trematodes	Reusch, 2005
Praziquantel	5–10 mg/kg IM, PO or SC	Repeat in 10 days	Carpenter et al., 1995
Pyrantel pamoate	5–10 mg/kg PO	Repeat in 14 days	Morrissey et al., 2004
Pyrethrin	0.50% topical	Dust	Russell et al., 1981
Selamectin	6 mg/kg topical		Morrissey et al., 2004
Selamectin	6 or 18 mg/kg topical	Apply once or twice 28 days apart	McTier et al., 2003
Sulfadimethoxine	50 mg/kg PO sid, then 25 mg/kg PO sid for 10–20 days	Coccidiosis	Morrissey et al., 2004
Sulfamerazine	100 mg/kg PO or 0.05–0.15% in drinking water	Coccidiosis	Gillett, 1994
Sulfamethazine	100 mg/kg PO sid 0.77 g/L drinking water 0.5–1.0% in feed	Coccidiosis	Gillett, 1994
Sulfamethoxine	50 mg/kg PO on day 1, then 25 mg/kg PO sid × 10–20 d		Brown, 1996
Thiabendazole	50 mg/kg PO sid, repeat in 3 weeks		Hernandez-Divers, 2005
Thiabendazole	100 mg/kg PO sid for 5 days		McKellar, 1989
Thiabendazole	50–100 mg/kg PO sid for 5 days		Morrissey et al., 2004
Thiabendazole	25 mg/kg PO		Williams, 1976
Thiabendazole	50 mg/kg PO repeated 10–14 d	Pinworm, <i>Passalurus ambiguus</i>	Reusch, 2005
Toltrazuril	25 ppm in drinking water (or 25 mg/kg PO) q24h × 2 days, repeat after 5 days	Coccidiosis	Harcourt Brown, 2002
Trimethoprim-sulfamethoxazole	30 mg/kg PO bid for 10 d	Intestinal coccidiosis	Reusch, 2005

Trimethoprim/sulfamethoxazole	15 mg/kg PO bid	Dosed on sulfa concentration	Bauck, 1989
Tylosin	100 mg/kg PO sid	Use with caution (Ness, 2005)	Flecknell, 1987
Tylosin	10 mg/kg IM or SC sid	Use with caution (Ness, 2005)	McKellar, 1989
Tylosin	100 mg/kg PO sid for 21 days	Use with caution (Ness, 2005)	Russell et al., 1981
Tylosin	2–8 mg/kg PO or SC bid	Use with caution	Morrissey et al., 2004
Vancomycin	20 mg/kg PO	By gavage	Boss et al., 1994

Parasiticides

Generic name	Dose and route	Comments	Reference
Amitraz	1.4 ml topical	Treat every 7 days	Morrissey et al., 2004
Amitraz	Topical	Use half the strength of the dilution directions; sponge on or dip every 2 weeks; may be lethal	Harvey, 1995

(Continued)

Parasiticides (Continued)

Generic name	Dose and route	Comments	Reference
Fenbendazole	20 mg/kg PO sid for 5 days		Morrissey et al., 2004
Fipronil	7.5 mg/kg topical q30–60d		Morrissey et al., 2004
Ivermectin	200–400 µg/kg SC	Repeat in 10–14 days	Morrissey et al., 2004
Lime sulfur	2.5% topical	Dip every 7 days	Morrissey et al., 2004
Metronidazole	70 mg/kg PO tid		Morrissey et al., 2004
Niclosamide	500 mg PO	Mix in 150-g food	Burke, 1979
Niclosamide	100 mg/kg PO	Once; repeat in 2 weeks	Russell et al., 1981
Piperazine	3–5 mg/ml drinking water PO	As adipate; 7 days on, 7 days off	Russell et al., 1981; Morrissey et al., 2004
Piperazine	10 mg/ml PO	As citrate: in drinking water – for 7 days, off 5 days, on 7 days	Unay and Davis, 1980
Piperazine	10 mg/ml PO	As citrate; give 2 ml	Unay and Davis, 1980
Praziquantel	6–10 mg/kg PO or SC	Repeat in 10 days	Morrissey et al., 2004
Pyriminyl pamoate	0.8 mg/L in drinking water PO for 30 days		Frost and Van Hoosier, 1977
Selamectin	6 or 18 mg/kg topical		Fisher et al., 2007
Sulfadimethoxine	25–50 mg/kg PO sid for 10–14 days		Morrissey et al., 2004
Thiabendazole	100 mg/kg PO sid for 5 days		Morrissey et al., 2004

Miscellaneous

Generic name	Dose and route	Comments	Reference
Atropine	0.02–0.05 mg/kg IM, IV, or SC		Canadian Council on Animal Care, 1984
Atropine	0.1–0.4 mg/kg IM or SC		Morrissey et al., 2004
Cimetidine	5–10 mg/kg IM, IV, PO or SC q6–12h		Morrissey et al., 2004
Cisapride	0.1–0.5 mg/kg PO bid		Morrissey et al., 2004
Dexamethasone	0.5–2 mg/kg IM, IV, or SC		Morrissey et al., 2004
Digoxin	0.05–0.1 mg/kg PO		Morrissey et al., 2004
Diphenhydramine	1–2 mg/kg PO or SC		Morrissey et al., 2004
Doxapram	5–10 mg/kg IV		Flecknell, 1987
Furosemide	2–10 mg/kg PO or SC bid		Morrissey et al., 2004
Glycopyrrolate	0.01–0.02 mg/kg SC		Morrissey et al., 2004
Meprobamate	100 mg/kg IM		Melby et al., 1976
Metoclopramide	0.2–1 mg/kg IM, PO, or SC bid		Morrissey et al., 2004
Naloxone	0.01–0.1 mg/kg IP or IV		Flecknell, 1987
Oxytocin	0.2–3 IU/kg IM, IV, or SC		Morrissey et al., 2004
Prednisone	0.5–2.2 mg/kg IM, PO, or SC		Morrissey et al., 2004
Sucralfate	25–50 mg/kg PO		Morrissey et al., 2004

(Continued)

Miscellaneous (Continued)

Generic name	Dose and route	Comments	Reference
Thyroxine	0.1 mg	Suspend in 10 ml water. Place 1 ml of suspension, place into 50 ml drinking water	Harvey, 1995
Vitamin A	500–5000 IU/kg IM		Morrissey et al., 2004
Vitamin K	1–10 mg/kg IM prn		Morrissey et al., 2004

DEGU (OCTODON DEGUS)**Analgesics and Sedatives**

Generic name	Dose and route	Comments	Reference
Acepromazine	0.5–1 mg/kg IM	Pre anesthetic dose	Johnson-Delaney, 1996
Aspirin	100–200 mg/kg PO q6–8h		Johnson, 2002
Aspirin	50–100 mg/kg PO q4h prn		Johnson-Delaney, 1996
Butorphanol	0.2 mg/kg IM		Johnson-Delaney, 1996
Butorphanol	0.2 mg/kg SC		Powers et al., 2008
Diazepam	1–2 mg/kg IM or IP		Johnson-Delaney, 1996
Flunixin	2.5 mg/kg SC q12–24h		Johnson-Delaney, 1996
Meperidine	10–20 mg/kg IM or SC qid		Johnson, 2002
Meperidine	10–20 mg/kg IM or SC q3–4h		Johnson-Delaney, 1996

Anesthetics

Generic name	Dose and route	Comments	Reference
Ketamine	44 mg/kg IP		Johnson, 2002
Ketamine	40 mg/kg IM		Johnson-Delaney, 1996
Ketamine, acepromazine	40 mg/kg IM, 0.5 mg/kg IM		Johnson-Delaney, 1996
Ketamine, diazepam	20–40 mg/kg IM, 1–2 mg/kg IM		Johnson-Delaney, 1996
Ketamine, xylazine	35–40 mg/kg IM, 4–8 mg/kg IM		Johnson-Delaney, 1996
Ketamine, xylazine	90 mg/kg IM, 10 mg/kg IM		Suckow et al., 1996
Pentobarbital	30 mg/kg IV		Johnson-Delaney, 1996
Pentobarbital	35–40 mg/kg IP		Johnson-Delaney, 1996
Thiopental	40 mg/kg IV		Johnson-Delaney, 1996
Yohimbine	0.5–1 mg/kg IV		Johnson-Delaney, 1996

Anti-Infectives

Generic name	Dose and route	Comments	Reference
Amikacin	2 mg/kg IM, IV, or SC tid		Johnson, 2002
Amikacin	2–5 mg/kg IM or SC q8–12h		Johnson-Delaney, 1996

(Continued)

Anti-Infectives (Continued)

Generic name	Dose and route	Comments	Reference
Amoxicillin	Not recommended	Toxic	Johnson-Delaney, 1996
Ampicillin	Not recommended	Toxic	Johnson-Delaney, 1996
Cephaloridine	10–25 mg/kg IM or SC q8–24h		Johnson-Delaney, 1996
Chloramphenicol palmitate	30–50 mg/kg PO bid		Johnson, 2002
Chloramphenicol palmitate	10 mg/30 ml drinking water PO		Johnson, 2002
Chloramphenicol palmitate	50 mg/kg PO bid		Johnson-Delaney, 1996
Chloramphenicol succinate	30–50 mg/kg IM or SC bid		Johnson-Delaney, 1996
Chlortetracycline	50 mg/kg PO bid		Johnson-Delaney, 1996
Doxycycline	2.5 mg/kg PO bid		Johnson-Delaney, 1996
Enrofloxacin	5–10 mg/kg IM, PO, or SC bid		Johnson, 2002
Enrofloxacin	4.4 mg/kg SC sid for 7 days		Powers et al., 2008
Enrofloxacin	2.5–5 mg/kg IM, PO or SC bid	Limit injections	Johnson-Delaney, 1996
Gentamicin	2–5 mg/kg IM or SC q8–12h		Johnson-Delaney, 1996
Gentamicin	2 mg/kg IV		Johnson-Delaney, 1996
Griseofulvin	25 mg/kg PO sid for 28–40 days	Not for use in pregnant animals	Johnson-Delaney, 1996
Metronidazole	10–40 mg/kg PO sid		Johnson-Delaney, 1996
Neomycin	15 mg/kg PO bid		Johnson, 2002
Neomycin	15 mg/kg PO sid		Johnson-Delaney, 1996
Oxytetracycline	50 mg/kg PO bid		Johnson, 2002
Oxytetracycline	1 mg/ml in drinking water PO	Prepare in drinking water	Johnson, 2002
Penicillin	Not recommended	Toxic	Johnson-Delaney, 1996
Sulfadimethoxine	10–15 mg/kg PO bid		Johnson-Delaney, 1996
Sulfamerazine	1 mg/ml in drinking water PO	Prepare in drinking water	Johnson-Delaney, 1996
Sulfamethazine	1–5 mg/ml drinking water PO		Johnson-Delaney, 1996
Tetracycline	50 mg/kg PO bid		Johnson-Delaney, 1996
Tetracycline	0.3–2 mg/ml in drinking water PO	Prepare in drinking water	Johnson, 2002
Trimethoprim/sulfadiazine	30 mg/kg IM or SC bid		Johnson-Delaney, 1996

Paraciticides

Generic Name	Dose and route	Comments	Reference
Carbaryl	5% powder topical	Dust lightly once each week for 3 weeks	Johnson-Delaney, 1996
Fenbendazole	20 mg/kg PO sid for 5 days		Johnson-Delaney, 1996
Ivermectin	200–400 µg/kg SC or PO	Repeat in 7–14 days	Johnson-Delaney, 1996
Piperazine	2–5 mg/ml in drinking water PO	As citrate, 7 days on, 7 days off, repeat	Johnson-Delaney, 1996
Praziquantel	5–10 mg/kg IM, PO, or SC	Repeat in 10 days	Johnson-Delaney, 1996
Thiabendazole	50–100 mg/kg PO sid for 5 days		Johnson-Delaney, 1996

Miscellaneous

Generic name	Dose and route	Comments	Reference
Atropine	0.05 mg/kg IM or SC		Johnson-Delaney, 1996
Calcium EDTA	30 mg/kg SC bid		Johnson-Delaney, 1996
Dexamethasone	0.5–2 mg/kg IM, IP, IV, or SC		Johnson-Delaney, 1996
Doxapram	2–5 mg/kg IV		Johnson-Delaney, 1996
Furosemide	5–10 mg/kg bid, PO, SC, IV		Johnson-Delaney, 1996
Glycopyrrolate	0.01–0.02 mg/kg SC	For control of mucus secretions	Johnson-Delaney, 1996
Magnesium hydroxide, simethicone	1 ml PO prn	Diovol Plus®	Johnson-Delaney, 1996
Metoclopramide	0.5 mg/kg IM or SC tid	Motility enhancer	Johnson-Delaney, 1996
Oxytocin	0.2–3 IU/kg IM, IV, or SC		Johnson, 2002
Oxytocin	0.5–1 IU IM, IV, or SC	Total dose per animal	Johnson-Delaney, 1996
Prednisone	0.5–2 mg/kg PO		Johnson-Delaney, 1996
Vitamin B ₁	0.02–0.2 ml/kg		Johnson, 2002
Vitamin B ₁	1 mg/kg PO	Prepare in food	Johnson-Delaney, 1996
Vitamin K	1–20 mg/kg prn	Route not indicated, listed as IM in Johnson, 2002	Johnson-Delaney, 1996

OTHER SPECIES

Analgesics and Sedatives

Species Name	Generic name	Dose and route	Comments	Reference
Patagonian cavy (<i>Dolichotis patagonum</i>)	Buprenorphine	0.02 mg/kg IV		Joyner et al., 2004
Patagonian cavy (<i>Dolichotis patagonum</i>)	Butorphanol	2 mg/kg IM	Pre-medication for anesthesia	Joyner et al., 2004

Anesthetics

Species Name	Generic name	Dose and route	Comments	Reference
Cotton rat (<i>Sigmodon hispidus</i>)	Ketamine, acepromazine	25 mg/kg IM, 2.5 mg/kg IM		Prince, 1994
Brush mice (<i>Peromyscus boylii</i>), California Meadow voles (<i>Microtus californicus</i>), Chipmunks (<i>Tamias spp.</i>), Deer mice (<i>Peromyscus maniculatus</i>), Dusky footed wood rats (<i>Neotoma fuscipes</i>), Kangaroo rats (<i>Dipodomys californicus</i>), Pinon mice (<i>Peromyscus truei</i>)	Ketamine, medetomidine	50 mg/kg IP, 1 mg/kg IP	For examination and skin biopsy, response to deep toe pinch not eliminated, add 0.5% proparacaine hydrochloride ophthalmic drops for retro-orbital bleeding	Hahn et al., 2005
Djungarian hamster (<i>Phodopus campbelli</i>)	Ketamine, xylazine	40 mg/kg IP, 4 mg/kg IP	Surgical plane of anesthesia in 3-day-old pups, 30 minutes, no recovery tested	Vella et al., 2004
Cotton rat (<i>Sigmodon hispidus</i>)	Ketamine, xylazine, acepromazine	22 mg/kg, 10 mg/kg, 5 mg/kg	Route not indicated	Niewiesk and Prince, 2002

Anti-Infectives

Species Name	Generic name	Dose and route	Comments	Reference
Patagonian cavy (<i>Dolichotis patagonum</i>)	Trimethoprim-sulfamethoxazole	30 mg/kg PO bid	Post surgery	Joyner et al., 2004

Miscellaneous

Species Name	Generic name	Dose and route	Comments	Reference
Brush mice (<i>Peromyscus boylii</i>), California Meadow voles (<i>Microtus californicus</i>), Chipmunks (<i>Tamias</i> spp.), Deer mice (<i>Peromyscus maniculatus</i>), Dusky footed wood rats (<i>Neotoma fuscipes</i>), Kangaroo rats (<i>Dipodomys californicus</i>), Pinon mice (<i>Peromyscus truei</i>)	Atimpacezole	5 mg/kg IP	Reversal of medetomidine	Hahn et al., 2005

OUTLINE

Rabbits (<i>Oryctolagus cuniculus</i>)	1232	Other rodents	1238
Guinea pigs (<i>Cavia porcellus</i>)	1233	<i>Degu (<i>Octodon degus</i>)</i>	1238
Hamsters	1234	<i>Naked mole rat (<i>Heterocephalus glaber</i>)</i>	1239
<i>Syrian (<i>Mesocricetus auratus</i>)</i>	1234	<i>Deer mouse (<i>Peromyscus maniculatus</i>)</i>	1239
<i>Chinese (<i>Cricetulus griseus</i>)</i>	1235	<i>Dormice (<i>Graphiurus</i> spp.)</i>	1240
<i>European (<i>Cricetus cricetus</i>)</i>	1235	<i>Kangaroo rat (<i>Dipodomys</i> spp.)</i>	1241
<i>Djungarian (<i>Phodopus</i> spp.)</i>	1236	<i>Cotton rat (<i>Sigmodon hispidus</i>)</i>	1241
Gerbils (<i>Meriones unguiculatus</i>)	1236	<i>Sand rat (<i>Psammomys obesus</i>)</i>	1242
Chinchillas (<i>Chinchilla laniger</i>)	1237	References	1243

The purpose of this chapter is to provide supplemental normative values and references for a number of the species which are covered in detail earlier in this book. Basic hematology and many other values are provided in the individual chapters for these species. In providing the tables below, we have used discretion to select values which are most likely to be useful for the laboratory animal veterinarian or research scientist. However, for many species, some values may not be widely applicable to contemporary housing and husbandry conditions. When possible, peer-reviewed publications were used as the source of the values unless such references were not found. When values for some animals were unavailable in the published literature direct communications from individuals utilizing those species or various websites

were used as the source of information. In those cases, reference values may be presented here which have limited documentation or are anecdotal in source, such as those values found in an unreferenced website.

The normative values presented here, like all published values, may have been influenced by the laboratory test, animal source, animal genotype, age, gender, blood sampling method, use of anesthesia, or feed or housing conditions of the animals tested. Some normative values may have been derived from feral or newly confined animals. For this reason, it is always recommended that control tests be run concurrently with tests for animals which are suspected to be ill, prior to making final diagnostic conclusions or selecting treatment regimens.

RABBITS (*ORYCTOLAGUS CUNICULUS*)

	Value	Reference
ADULT WEIGHT		
Male	4.5 kg	Suckow et al., 2002
Female	4.5 kg	Suckow et al., 2002
LIFE SPAN		
Usual	5–6 years	Carpenter et al., 2001
Maximum Reported	15 years	Harkness and Wagner, 1995
Surface area (cm ²)	$9.5 \times \text{BW (in g)}^{2/3}$	Harkness and Wagner, 1995
Chromosome number	44	
Water consumption	120 ml/kg/day	
Food consumption	33–60 g pelleted diet/kg BW	Quesenberry and Carpenter, 2004
Body temperature	38.5–39.5°C	Suckow et al., 2002
Dental formula	2(I 2/1, C 0/0, PM 3/2, M 2–3/3) = 26–28	Suckow et al., 2002
Vitamin C requirement	High levels can lead to renal disease	Suckow et al., 2002
Digits	5 front, 4 rear	Richardson, 2000
GI transit time	4–5 hours	Suckow et al., 2002
PUBERTY		
Male	6–7 months	Quesenberry and Carpenter, 2004
Female	4–9 months	Hrapkiewicz and Medina, 2007
Breeding season	Spring (longer days, warmer temperatures)	Quesenberry and Carpenter, 2004
Gestation	31–32 days	Brewer, 2006
Litter size	7–9 per litter	Suckow et al., 2002
Birth weight	65 g	Brewer, 2006
Eyes open	10 days	Brewer, 2006
Weaning	8 weeks	Brewer, 2006
Number of mammary glands	8 or 10	
Heart rate	200–300 beats/min	Suckow et al., 2002
BLOOD PRESSURE		
Systolic	90–130 mmHg	Suckow et al., 2002
Diastolic	80–90 mmHg	Suckow et al., 2002
Respiration frequency	32–60/min	Suckow et al., 2002
Tidal volume	4–6 ml/kg body weight	Suckow et al., 2002
Minute volume	0.6 liter/min	Suckow et al., 2002
Stroke volume	0.49 ± 0.16 ml	Suckow et al., 2002

GUINEA PIGS (CAVIA PORCELLUS)

	Value	Reference
ADULT WEIGHT		
Male	900–1000 g	Harkness et al., 2002
Female	700–900 g	Harkness et al., 2002
LIFE SPAN		
Usual	4–5 years	Harkness and Wagner, 1995
Maximum reported	6–7 years	Harkness et al., 2002
Surface area (cm ²)	200–680 g— $9.2 \times (\text{BW in g})^{2/3}$ 700–830 g— $10.1 \times (\text{BW in g})^{2/3}$	Liu, 1988
Chromosome number	64	Makino, 1948
Water consumption	10 ml/100 g BW/day	Harkness et al., 2002
Food consumption	6 g/100 g BW/day	Harkness et al., 2002
Body temperature	37.2–39.8°C	Harkness et al., 2002
Dental formula	2(I 1/1 C 0/0 PM 1/1 M 3/3) = 20	
Vitamin C requirement	10 mg/kg/day, pregnant 30 mg/kg/day	Quesenberry and Carpenter, 2004
Digits	4 front, 3 rear	Harkness and Wagner, 1995
GI transit time	13–30 hours	Harkness and Wagner, 1995
PUBERTY		
Male	3–4 months	Harkness et al., 2002
Female	2–3 months	Harkness et al., 2002
Breeding season	Non-seasonally polyestrous	Quesenberry and Carpenter, 2004
Gestation	68.8 days	Goy et al., 1957
Litter size	2–5	Harkness and Wagner, 1995
Birth weight	45–115 g (pups less than 60 g rarely survive)	Harkness et al., 2002
Eyes open		
Weaning	21 days	Harkness et al., 2002
Heart rate	230–380 beats/minute	Harkness et al., 2002
BLOOD PRESSURE		
Systolic	80–94 mmHg	Harkness et al., 2002
Diastolic	55–58 mmHg	Harkness et al., 2002
Cardiac output		
Respiration frequency	42–104/min	Harkness and Wagner, 1995
Tidal volume	2.3–5.3 ml	Harkness and Wagner, 1995
Plasma		
pH	7.17–7.53	Harkness et al., 2002
CO ₂	18–26 mM/L	Harkness et al., 2002
CO ₂ pressure	21–59 mmHg	Harkness et al., 2002

HAMSTERS

There are over 20 hamster species worldwide; however the majority used in research are Syrian and

Chinese. Focus in this section will be on these two species, as well as the European and Djungarian, for which some aspects of normative biology have been investigated.

Syrian (*Mesocricetus auratus*)

	Value	Reference
ADULT WEIGHT		
Male	110–140 g	Hankenson and Van Hoosier, 2002
Female	110–140 g; females larger than males	Hankenson and Van Hoosier, 2002
LIFE SPAN		
Usual	1.5–2 years	
Maximum reported	3 years; female may be markedly shorter	Hankenson and Van Hoosier, 2002; Bernfield et al., 1986
Chromosome number	44	
Water consumption	30 ml/day	
Food consumption	10–15 g/day	
Body temperature	36.2–37.5°C	
Dental formula	2(I 1/1 C 0/0 PM 0/0 M 3/3) = 16; erupted at birth	
PUBERTY		
Male	6–8 weeks (85–110 g)	
Female	8–12 weeks (95–120 g)	
Gestation	15–18 days	Field, 1999
Litter size	4–12	
Birth weight	2–3 g	
Eyes open	15 days	
Weaning	21 days (35–40 g)	Bernfield et al., 1986
Heart rate	280–412 beats/min	Bernfield et al., 1986
BLOOD PRESSURE		
Systolic	150 mmHg	Johnson-Delaney, 1996
Diastolic	100 mmHg	Johnson-Delaney, 1996
Respiration frequency	33–127/min (average = 74/min)	Bernfield et al., 1986
Tidal volume	0.6–1.4 ml	Field, 1999
Plasma		
pH	7.45–7.51	Field, 1999

Chinese (*Cricetulus griseus*)

	Value	Reference
ADULT WEIGHT		
Male	39.3–45.7 g	Hankenson and Van Hoosier, 2002
Female	39.3–45.7 g	Hankenson and Van Hoosier, 2002
LIFESPAN		
Usual	2.5–3.0 years	
Chromosome number	22	
Water consumption	11.4 ml/100 g BW/day (M); 12.9 ml/100 g BW/day (F)	Thompson, 1971
PUBERTY		
Male/female	8–12 weeks	Yerganian, 1958
Gestation	20.5 days	Yerganian, 1958
Litter size	4.5–5.2	Festing, 1972
Birth weight	1.5–2.5 g	
Weaning	21–25 days	Yerganian, 1958

European (*Cricetus cricetus*)

	Value	Reference
ADULT WEIGHT		
Male	300–400 g	Anonymous, 2010a
Female	300–400 g	Anonymous, 2010a
LIFE SPAN		
Usual	2.6 years (M); 2.8 years (F)	
Chromosome number	22	
Water consumption	5 ml/100 g BW	
Food consumption	2.9 g/BW (summer); 1.8 g/100 g BW (winter)	
PUBERTY		
Male	60 days	Mohr et al., 1973
Female	80–90 days	Mohr et al., 1973
Breeding season	Summer	
Gestation	18–21 days	
Litter size	6–9	Reznick-Schuller et al., 1974
Weaning	25 days (75 g)	

Djungarian (*Phodopus* spp.)

	Value	Reference
ADULT WEIGHT		
Male	18–25 g	Hankenson and Van Hoosier, 2002
Female	18–25 g	Hankenson and Van Hoosier, 2002
LIFE SPAN		
Usual	0.75–1.25 years	
Maximum reported	2 years	Lawrie and Megahy, 1991
Chromosome number	28	
Breeding season	Photoperiod critical	
Gestation	18 days	
Litter size	1–9	Pogosianz, 1975
Weaning	21 days	

GERBILS (*MERIONES UNGUICULATUS*)

	Value	Reference
ADULT WEIGHT		
Male	65–100 g	Harkness and Wagner, 1995
Female	55–85 g	Harkness and Wagner, 1995
LIFE SPAN		
Usual	3–4 years	Harkness and Wagner, 1995
Surface area (cm ²)	$10.5 \times (\text{BW in g})^{2/3}$	Harkness and Wagner, 1995
Chromosome number	44	
Water consumption	4–7 ml/100 g/day	Harkness and Wagner, 1995
Food consumption	5–8 g/100 g/day	Harkness and Wagner, 1995
Body temperature	37.0–38.5°C	Harkness and Wagner, 1995
Dental formula	$2(I\ 1/1\ C\ 0/0\ P\ 0/0\ M\ 3/3) = 16$	Quesenberry and Carpenter, 2004
Digits	5 front, 4 rear	
GI transit time	5.8 hours	Kobayashi et al., 2009
PUBERTY		
Male	10–12 weeks	Hafez, 1970
Female	9–12 weeks	Hafez, 1970
Breeding season	Non-seasonal polyestrus	Hafez, 1970
Gestation	24–26 days	Hafez, 1970
Litter size	4.5 (1–12)	Marston and Chang, 1965
Birth weight	2.5–3.5 g	Hafez, 1970
Eyes open	16–20 days	Hafez, 1970

(Continued)

GERBILS (*MERIONES UNGUICULATUS*) (Continued)

	Value	Reference
Weaning	21 days	Hafez, 1970
Heart rate	Average 360 beats/min (range 260–600)	Harkness and Wagner, 1995
BLOOD PRESSURE		
Mean	78–100 mmHg	Laas, 1984
Respiration frequency	Average 90/min (range 70–120)	Harkness and Wagner, 1995
Plasma		
pH	7.249–7.405	Laas, 1984
CO ₂ pressure	30–44 mmHg	Laas, 1984

CHINCHILLAS (*CHINCHILLA LANIGER*)

	Value	Reference
ADULT WEIGHT		
Male	400–500 g	Quesenberry and Carpenter, 2004
Female	400–600 g	Quesenberry and Carpenter, 2004
LIFE SPAN		
Usual	10 years	Quesenberry and Carpenter, 2004
Maximum reported	20 years	Quesenberry and Carpenter, 2004
Chromosome number	64	Hrapkiewicz and Medina, 2007
Food consumption	21 g/day	Hrapkiewicz and Medina, 2007
Body temperature	37–38°C	Quesenberry and Carpenter, 2004
Dental formula	2(I 1/1 C 0/0 PM 1/ 1 M 3/3) = 20	Quesenberry and Carpenter, 2004
Digits	4 front, 3 rear	Kraft, 1987
PUBERTY		
Male	8 months	Quesenberry and Carpenter, 2004
Female	8 months	Quesenberry and Carpenter, 2004
Breeding season	Seasonally polyestrus (November–May)	Quesenberry and Carpenter, 2004
Gestation	105–118 days	Quesenberry and Carpenter, 2004
Litter size	1–6 (2 is usual)	Quesenberry and Carpenter, 2004
Birth weight	30–50 g	Quesenberry and Carpenter, 2004
Eyes open	At birth	Quesenberry and Carpenter, 2004
Weaning	6–8 weeks	Quesenberry and Carpenter, 2004
Heart rate	100–150 beats/min	Quesenberry and Carpenter, 2004
Respiration frequency	45–65/min	Hrapkiewicz and Medina, 2007

OTHER RODENTS

Degu (*Octodon degus*)

	Value	Reference
ADULT WEIGHT		
Male	180–250 g	
	170–300 g	
Female	180–250 g	Lester et al., 2005; Donnelly and Quimby, 2002; Cadillac et al., 2003; Najecki and Tate, 1999
	170–300 g	
	250 g for breeders	
LIFE SPAN		
Usual	3–5 years	Lester et al., 2005; Edwards, 2009
	7–10 years	
Maximum reported	9 years	Lee, 2004
Chromosome number	58	Woods and Boraker, 1975
Water consumption	10–40 ml/day	Edwards, 2009
Food consumption	57.8–94.2 g/kg BW/day	Edwards, 2009
Body temperature	36.0–37.9°C	Woods and Boraker, 1975
Dental formula	2(I 1/1 C 0/0 PM 1/1 M 3/3) = 20	Woods and Boraker, 1975
Digits	5 front, 5 rear	Woods and Boraker, 1975
GI transit time	5.1–5.2 hours	Edwards, 2009
PUBERTY		
Male	6 months	Altmann et al., 1994; Weir, 1970
Female	6 months	Altmann et al., 1994; Weir, 1970
Breeding season	Seasonal induced ovulators	
Gestation	84–90 days	Weir, 1970; Rojas et al., 1982
	90 days	
Litter size	1–10, average 5–7	Mabry et al., 1988; Reynolds and Wright, 1979
Birth weight	14 g	Reynolds and Wright, 1979
Eyes open	At birth	Mabry et al., 1988
Weaning	14–28 days	Donnelly and Quimby, 2002; Edwards, 2009
	4–6 weeks	
Heart rate	274 beats/min	Long, 2007
Respiration frequency	123/min	Long, 2007; Tomasco et al., 2010
	196–264/min	
Tidal volume	0.14–0.22 ml/g	Tomasco et al., 2010

Naked Mole rat (*Heterocephalus glaber*)

	Value	Reference
ADULT WEIGHT		
Male	29–38.8 g	Jarvis and Sherman, 2002
Female	35–80 g	Jarvis and Bennett, 1991
LIFE SPAN		
Usual	22 years	O'Connor et al., (2002)
Maximum Reported	28	O'Connor et al., (2002)
Chromosome number	60	Deuve et al., 2008
Water consumption	Acquired from food	Urison and Buffenstein, 1994
Food consumption	5–8 g/40 g BW	Goldman et al., 1999
Body temperature	30.0–32.0°C	Johansen et al., 1976
Dental formula	2(I 1/1 C 0/0 M 0/0 M 3/3) = 16	Hamilton, 1928
Digits	5 front, 5 rear	Mabry et al., 1988
PUBERTY		
Male	1 year	O'Connor et al., 2002
Female	1 year	O'Connor et al., 2002
Breeding season	Year round	Jarvis and Sherman, 2002
Gestation	76–84 days	Wood and Mendez, 2010; Maree and Faulkes, 2008
Litter size	1–24 pups, average of 10–19; 5.1–17.5	Wood and Mendez, 2010; Jarvis and Sherman, 2002
Birth weight	1–2 g	Jarvis, 1991
Weaning	5 weeks	Jarvis and Sherman, 2002
Number of mammary glands	9–15, 11–12	Sherman et al., 1999; Segelken, 1999
Heart rate	60–100 beats/min	Anonymous, 1998
BLOOD PRESSURE		
Systolic	140–155 mmHg	Anonymous, 1998
Diastolic	100–145 mmHg	Anonymous, 1998

Deer mouse (*Peromyscus maniculatus*)

	Value	Reference
ADULT WEIGHT		
Male	20.15–20.85 g	Hayssen, 2001
Female	20.15–20.85 g	Hayssen, 2001
LIFE SPAN		
Usual	5.5 years (<i>P. leucopus</i>)	Burger and Gochfeld, 1992
Maximum reported	8 years	Linzey, 1998
Chromosome number	48	Arakaki et al., 1970

(Continued)

Deer mouse (*Peromyscus maniculatus*) (Continued)

	Value	Reference
Water consumption	2.65 g	French, 1962
Food consumption	2.54 g	French, 1962
Body temperature	36.6°C	Nowak and Paradico, 1983
Dental formula	2(I 1/1 C 0/0 PM 0/0 M 3/3) = 16	Bunker, 2001
Digits	4 front, 5 rear	Cabrera, 2010
PUBERTY		
Male	7–8 weeks	Hygnstrom et al., 2010
Female	35–49 days	Nowak and Paradico, 1983; King, 1968
Breeding season	Year round indoors Spring through fall in cooler climates	Hygnstrom et al., 2010
Gestation	22.4–25.5 days	Kirkland and Layne, 1989
Litter size	4–4.3 1–11; average 4–6	Botten et al., 2001; Forrester, 1975; Baker, 1983
Birth weight	2 g	Bunker, 2001
Eyes open	15 days	Bunker, 2001
Weaning	25–35 days	Bunker, 2001
Heart rate	650–900 beats/min	Rosenmann and Morrison, 1974
BLOOD PRESSURE		
Systolic	Males 114–162 mmHg Females 103–123 mmHg	Turney and Lockwood, 1986

Dormice (*Graphiurus* spp.)

	Value	Reference
ADULT WEIGHT		
Male	18–20 g	West, 2010
Female	18–20 g	West, 2010
LIFE SPAN		
Usual	3 years	West, 2010
Maximum reported	4 years	West, 2010
Dental formula	2(I 1/1 C 0/0 PM 0-1/0-1 M 3/3) = 16-20	West, 2010
PUBERTY		
Female	6–8 weeks	West, 2010
Breeding Season	Year round in captivity	West, 2010
Gestation	Approximately 4 weeks	West, 2010
Litter size	4 Average	West, 2010
Weaning	4–6 weeks	West, 2010
Heart rate	180–200 beats/min	West, 2010

Kangaroo rat (*Dipodomys* spp.)

	Value	Reference
ADULT WEIGHT		
Male	40–50 g	Lancaster, 2000
Female	40–50 g	Lancaster, 2000
LIFE SPAN		
Usual	2–5 years	Anonymous, 2010b
Maximum Reported	9.8 years	Lancaster, 2000
Water consumption	Liquid water not required on seed diet	Anonymous, 2010b; Soholt, 1975
Food consumption	2–5 g/day (temperature-dependent)	Soholt, 1975
Body temperature	37°C	Wunder, 1974
Dental formula	2(I 1/1 C 0/0 PM 1/1 M 3/3) = 20	Vaughan et al., 1999
Digits	4 rear	West, 2010
PUBERTY		
	60–84 days	West, 2010
Breeding season	January–August	West, 2010
Gestation	28–32 days	West, 2010; Eisenberg and Issac, 1963
Litter size	1–6; average of 3	West, 2010; Eisenberg and Issac, 1963
Birth weight	3–8 g	West, 2010
Eyes open	2 weeks	Allen, 2010
Weaning	21–29 days	West, 2010; Eisenberg and Issac, 1963
	15–25 days	
Heart rate	417 beats/min	Soholt et al., 1973
Respiration frequency	90–125/min	Gardner, 2010
Tidal volume	150–170 ml	Gardner, 2010

Cotton rat (*Sigmodon hispidus*)

	Value	Reference
ADULT WEIGHT		
	70–200 g	Niewiesk and Prince
	80–310 g	Faith et al., 1997
LIFE SPAN		
Usual	23 months	Jimenz, 1969
Maximum reported	3 years	Jimenz, 1969
Surface area (cm ²)	$47.66 + 2.476 \times \text{BW (g)} - 0.006 \times \text{BW (g)}^2$	Ohwada and Katahira, 1993
Chromosome number	52	Prince, 1994
Water consumption	16.6–16.8 ml/day	Savabieasfahani et al., 1998
Food consumption	11.24–11.32 g/day	Savabieasfahani et al., 1998

(Continued)

	Value	Reference
Body temperature	36.4–36.6°C	Kirksey et al., 1975
Dental formula	2(I 1/1 C 0/0 PM 0/0 M 3/3) = 16	Faith et al., 1997
Digits	5 front, 5 rear	Hygnstrom et al., 2010
PUBERTY		
	40–60 days	Nowak, 1999
Male	8 weeks	Jackson, 1997
Female	30–50 days	Evans, 1981
Breeding season	Year round in captivity	Faith et al., 1997
Gestation	27 days	Donnelly and Quimby, 2002
Litter size	1–12 mean 5–7	Donnelly and Quimby, 2002
Birth weight	6.5–8 g	Donnelly and Quimby, 2002
Eyes open	24 hours	Donnelly and Quimby, 2002
Weaning	5 weeks	Faith et al., 1987
Respiration frequency	256–300/min	Eichelberger et al., 2004
Tidal volume	0.8 ml/g BW	Trias et al., 2009

Sand rat (*Psammomys obesus*)

	Value	Reference
ADULT WEIGHT		
Male	190–260 g	Adler et al., 1985; Kalman et al., 1996
Female	157–200 g	Adler et al., 1985; Kalman et al., 1996
LIFE SPAN		
Usual	3 years	Biagi and Myers, 2004
Maximum reported	3.2 years	Weigl, 2005
Chromosome number	46	Mostafa et al., 2006
Water consumption	22–28 ml/day	Kalman et al., 1996
Food consumption	Various custom diets, including 12–16 g/day of pellets 6.4 g of <i>Altriplexhalimus</i> (salt bush) or 7.0 g of Alfalfa pellets	Adler et al., 1985; Kalman et al., 1996; Sanigorski et al., 2002; Cope, 2010
Body temperature	37.3–38.8°C	Ben-Porat et al., 1976
Dental formula	2(I 1/1 C 0/0 PM 0/0 M 3/3) = 16	Ulmansky et al., 1984
PUBERTY		
Male	28–56 days	Windmill et al., 2007
Female	100 days	Anonymous, 2010c
Breeding season	January–April in wild	Cope, 2010

(Continued)

Sand rat (*Psammomys obesus*) (Continued)

	Value	Reference
Gestation	26 days	Patlas et al., 2006
Litter size	3	Kalman et al., 1996; Patlas et al., 2006
Birth weight	7.2 g	Patlas et al., 2006
Eyes open	1 week	Biagi and Myers, 2004
Weaning	19–26 days	Kalman et al., 1996
Heart rate	Average 310 beats/min 276–292 beats/min	Horowitz and Meiri, 1993; Hilzenrat et al., 1996
BLOOD PRESSURE		
Mean	79–88.4 mmHg	Hilzenrat et al., 1996
Cardiac output	84–100 ml/min	Hilzenrat et al., 1996
PLASMA		
Blood pH	7.362–7.430	Frenkel et al., 1972
CO ₂ pressure	27.6–33.4 mmHg	Frenkel et al., 1972
