A wide range of antiseptics have been used locally to control the bacterial flora in the treatment of retained placenta and the uterus following removal of the retained fetal membranes. These early drugs consisted of such products as charcoal, boric acid, acriflavine, bismuth subnitrate, bismuth formic iodide, bismuth thymol iodide, chlorine preparations, iodine in oil, silver oxide, bismuth formic iodide in oil, chlorophyll and bismuth and iodoform in oil (Bipp). This latter product imparted an odor to the milk that prohibited its use in dairy cattle. Various products containing sodium perborate have been

advocated to aid in the removal and treatment of retained placenta. On contact with tissue debris these products release much gas and cause foaming similar to that resulting from the use of hydrogen peroxide. These products are slightly irritating and probably should not be used in the uterus if the cervix is contracted. Because of their effect on tissue debris a number of enzyme products containing urea, yeast, pepsin, and papain have been advocated. It is doubtful if these varied preparations greatly alter the course of the disease.

Sulphonamides have been used locally in the uterus and have been approved by some veterinarians. Other veterinarians indicate that these drugs are rather insoluble, especially in a tablet form, and tend to settle in the apex of the horn and are of questionable value. Penicillin, streptomycin and tyrothricin have been used widely in the past in the local treatment of retained placenta. The former is usually quickly inactivated by penicillinase produced by the infective organisms in the uterus and the latter is rather irritating in large amounts. In recent years 1 to 3 gm. of the broad-range antibiotics such as oxytetracycline (Terramycin), Chlortetracycline (Aureomycin), Tetracycline, Furacin and others have been used locally in cases of retention of the fetal membranes. For immediate response these are used as an infusion in 200 to 1,000 ml. of saline or warm water. The boluses or powder produce a slightly slower response. These appear to be the first products used locally that definitely alter the course of the infection. The rate of putrefaction and lysis is greatly reduced. The usual fetid odor is largely eliminated. The retained membranes may tend to remain attached to the caruncles in the uterus for a slightly longer period. The use of these products in a case of septic metritis usually eliminates the local infection quite promptly and if used early, 24 to 36 hours after calving or as soon as the temperature becomes elevated or other signs of illness develop they usually bring about a prompt regression of the illness. After the use of **Aureomycin** in the uterus in 612 cows with retained placenta, only 2 cows developed acute metritis.^{5,27} In 31 cows with retained placenta manual removal was not attempted and 0.5 gm of **Aureomycin** was placed in the uterus every 1 to 2 days until the afterbirth dropped away. This took 2 to 10 days, with an average of 5.2 days. Subsequent conception rates were excellent.²² It was recommended that manual removal not be attempted. After treating 508 cows with retained placenta in various ways, one study reported that cows receiving local tetracycline intrauterine medication had a lower conception rate than those cows not receiving medication. If medication was initiated it was better to wait until 36 hours or more postpartum. Whether the retained membranes were removed or al-

lowed to drop away had no effect on subsequent fertility.⁴⁶ Conception rate on the first service was higher, 70 percent vs 40 to 50 percent, and days from parturition to conception were lower, 86 vs 91 to 110 days, in cows treated with intrauterine oxytetracycline within 72 hours of calving and the placenta was not removed than in cows receiving no medication. Removal of the placenta definitely lowered the conception rate at first service.⁴

Observations and reports have shown that hormones, sulfonamides, and antibiotics are rapidly absorbed from the uterus into the bloodstream.^{8b,50b} This systemic effect is further reason for the topical use in the uterus of these easily administered products. If large doses of antibiotics are placed locally in the uterus, the milk from treated cows should not be put in the supply for about 72 hours.

If symptoms of septic metritis develop with retention of the fetal membranes, sulfonamides administered orally, or sulfonamides and/or antibiotics administered parenterally are of great value along with supportive treatment with saline and glucose solutions, and possibly blood transfusions intravenously as described under the treatment of septic metritis. As in horses, laminitis often accompanies septic uterine infections in cattle but is not as obvious. The local treatment of the uterus should be very gentle and manual removal of the placenta should not be attempted. In rare cases a severe anaerobe or necrophorus infection may invade the uterus and these infections are usually fatal. In Europe in areas where anaerobe infections are common antiserum is usually administered after a dystocia. If severe straining is present with retained fetal membranes, epidural anesthesia should be given and the uterus and birth canal carefully and gently examined. In most cases the straining is due to a severe vulvitis or vaginitis, and these should be treated. Rarely it may be due to an invagination of the uterine horn. Tenesmus may also be associated with rabies in endemic areas.

It is recommended that all cows affected with retained placenta be examined 20 to 30 days after removal of the afterbirth to determine if involution of the uterus is proceeding normally and that postpartum metritis or pyometra is not present. If this is not done the cow may fail to show estrum and 90 days or more after parturition the disease condition will be diagnosed too late to prevent a serious delay in conception. Permanent sterility may result. The owner should be advised that many older cows affected with retained placenta should not be bred until 90 days after parturition. This time interval is usually necessary for proper involution and overcoming of the infection in the diseased uterus. In valuable cows the involution and return of the uterus to normal can be checked by periodic examinations during this period. If

the uterus is completely involuted, no genital discharge is present and regular estrous cycles are occurring, cows with a history of retained placenta at the last parturition may be bred at 60 days postpartum with a good conception rate. All cattle having a persistent mucopurulent discharge from the vulva following retained placenta should be reexamined and treated.

Retained Placenta in the Mare is probably less common, from 2 to 10 percent, and more variable than in the cow.⁶⁷ Probably the same factors responsible for retention of the placenta in the cow also are present in the mare. The infection most commonly observed in association with retained placenta in the mare is *Streptococcus zooepidemicus* but many other organisms may be involved, especially the gram-negative ones that produce endotoxins and histamines. Many genital infections in the mare are related to vulvar defects leading to pneumovagina. In some mares air and infectious organisms may be aspirated through the cervix into the uterus during the act of windsucking. Infection also gains entrance to the uterus following foaling, when the mare gets up. A rush of air often fills the dilated genital tract and uterus and the membranes draw debris from the bedding into the uterus. Straw and shavings or sawdust are the worst offenders. It was suggested that Tartan or a similar covering over a cushioning material would greatly reduce uterine infection after foaling.³ If the mare remains recumbent after foaling, until the placenta is about ready to drop away, the uterus is more contracted and less air is aspirated. The rush of contaminated air into the uterus after foaling might play an immediate role in the retention of the afterbirth. Retained placenta more commonly accompanied the large draft foals than the light horse foals.³³ A lack of breeding and foaling hygiene might possibly explain why some draft mares are more likely to have retained placenta than are Thoroughbred mares. Repeated breedings during one heat period or the breeding of infected mares or infected stallions may cause retained placenta. Placentas weighing over 14 lbs. in light mares were usually associated with infections of the uterus, and a chorion that was characterized by necrotic areas and edema.³³ Retained placenta is probably less common in mares because of the simple, diffuse type of placentation and the strong uterine contractions aiding the separation of the villi from their maternal crypts and expelling the detached membranes. It is interesting that the physiologically expelled placentas of most mares, as in cows, are inverted. This apparently is due to the fact that the allantois chorion first separates from the rapidly contracting apices of the uterine horns and passes into the birth canal before it is separated from the uterine body. Retained placenta in the mare is likely to occur

following abortion and prolonged gestation.^{69b} Probably the causes for retention of the afterbirth in the mare are infection, uterine inertia and other factors similar to those affecting cattle.

Symptoms. Physiologically the equine fetal membranes are expelled within 0.5 to 3 hours after parturition but it is fairly common to have the fetal membranes not drop away until 8 to 12 or more hours later without any observable symptoms of illness. Strong uterine contractions in the mare after foaling and just before expulsion of the placenta are often accompanied by signs of abdominal pain, recumbency, and colic.² The mares that retain their afterbirths exhibit no such pains and appear normal, content, eat and drink, and suckle their foals. Slow expulsion of the placenta may be due to uterine inertia or exhaustion following expulsion of the fetus. The onset of delayed expulsion is indicated by the mare developing colicky pains followed by the dropping away of the membranes in from 10 to 20 minutes. In a few nervous mares it is necessary to tie up or cut off the hanging retained placenta so that it will not frighten the mare into kicking and otherwise possibly injuring the foal. In dystocia the fetal membranes may be detached and wrapped around the fetus. The rapid separation of the fetal membranes probably accounts for the early death of the fetus in many equine dystocias. Retained fetal membranes can usually be observed hanging from the vulva. Occasionally the placenta may partially fall away and the apex or tip of the placenta will remain in the nongravid horn especially if the apex is thickened and edematous. The weight of the placenta or the mare stepping on it may rip it away, leaving the tip of the nongravid horn in the uterus. This piece of placenta may act as a focus of infection often resulting in a severe metritis and secondary laminitis the third to seventh day after foaling. The afterbirth of each mare should be carefully examined after it falls away, to make certain no portion of the placenta remains in the uterus. Most cases of laminitis occurring after foaling are due to metritis often associated with a portion of the placenta being retained and floating in a uterus filled with fetid fluid. Uterine invagination or intussusception, usually of the nongravid horn into the uterine body, may accompany retention of the fetal membranes in the mare but it is seldom of a serious nature.^{25,30} The prognosis of retained placenta in the mare is usually good.

Treatment. It is generally recommended that removal of the placenta in the mare not be attempted for at least 12 hours after foaling.^{8a,30,33} No treatment until 20 to 24 hours after foaling was recommended if the mare continues to eat, has a normal temperature and the pulse rate remains normal. With retained placenta it is common

practice to administer 2 to 4 ml. of oxytocin, 20 to 40 units, subcutaneously or intramuscularly every 2 to 3 hours starting the fourth to twelfth hour after foaling. Vandeplassche⁶⁷ recommended the administration of 40 to 60 units of oxytocin in 500 to 1000 ml of saline by slow intravenous drip over a period of 1 to 2 hours as a more physiologic way in which to give the hormone. This treatment is successful in about 75 percent of the cases.⁶⁷ The placenta was often passed during this period. It may be necessary to administer a tranquilizer to control mild colic and pain associated with the uterine contractions produced. In most cases the afterbirth drops away within a few hours or before 24 hours have elapsed. Injections of **Aureomycin**, tetracycline or Terramycin, 1 to 3 mg. per pound of body weight daily, intravenously; or the intramuscular injection of 3 to 6 million units of aqueous penicillin daily and 5 gm. of streptomycin twice daily may be indicated to control infection for 2 to 4 days.

After 12 to 24 hours postpartum the veterinarian, in a scrupulously clean manner, should administer a tranquilizer, bandage or have the tail held out of the way and scrub the perineum of the mare with soap and water. His hand and arm enclosed in a sterile surgical glove and sleeve is inserted into the birth canal and the allantois chorion is grasped. By means of gentle traction and twisting on the fetal membranes to form a "rope," uniform traction may be applied to the fetal membranes as the hand is very gently forced between the endometrium and chorion in the places where it is still attached. It should be recognized that any direct manipulation of the endometrium may be damaging to it. The entire placenta, including the tips of the horns, should be carefully removed. If necessary, examine the placenta after removal to be certain that the removal is complete. A more conservative and gentle approach, which has much to recommend it, consists of inserting the hand inside the allantois chorion and gently massaging it away from the endometrium.⁵⁹ If removal does not occur promptly, supportive treatment should be given and the mare reexamined and treated 4 to 12 hours later.

Another method to remove an equine retained placenta without manual intervention has recently been described.¹⁴ After preparing the mare as described above the gloved hand enters the vagina and gently draws the chorioallantois out of the vulva. The torn ends of the cervical star portion are gathered together and a stomach tube is placed through the opening into the allantoic cavity. Two to 3 gallons of warm dilute povidone iodine solution, 4 ounces/gallon, are slowly pumped into the cavity to distend it. The hand around the membranes and tube prevent this solution from escaping. The distended

uterus stimulates the mare to attempt to expel the solution. These efforts may be augmented by the injection of 40 IU of oxytocin. The exposed fetal membrane is held and the solution is squeezed back into the uterus as the chorioallantois is slowly released. This is repeated frequently. It usually takes about 15 to 20 minutes for the complete release of the placenta which comes out intact including even the microvilli of the chorioallantois.

In one mare the author observed retained fetal membranes that remained firmly adherent to the endometrium for 72 hours without any adverse effect on the mare. Older local treatment consisted of inserting into the uterus a pint of oil. It is probable that the more stable but soluble broad-range antibiotics of the tetracycline and furacin groups would be of greater value in the local treatment of the uterus in mares, as in cows. Intrauterine therapy may be continued daily or every other day for 2 to 4 days until the uterus is well-involuted and the infection is largely overcome. It is highly desirable to administer tetanus antitoxin and probably oxytocin to a mare following removal of a retained placenta. Temporary skin clips or sutures may be placed in the upper two-thirds of the vulvar lips within several hours after foaling if the afterbirth has not been dropped and even after removal of a retained placenta in the mare to prevent aspiration of air into the genital tract.²⁵ At present douching of the uterus after removal of a retained placenta is considered a questionable practice although former workers advocated the general use of this technique. If the uterus is filled with fetid fluid this should be removed by siphoning through a sterile rubber tube. The danger of laminitis should always be considered. Ice packs should be placed on the feet and antibiotics given locally and parenterally until uterine infection subsides. Antihistamines and phenylbutazone might also be administered. Some advocate the use of stilbestrol, 30 to 60 mg., or estradiol, 3 to 6 mg., and ergonovine, 1 to 3 mg., intramuscularly daily for several injections. Large repeated doses of the glucocorticoids should not be given these mares.

Retained Placenta in the Ewe and Doe is handled in a manner similar to that in the cow except that removal from inside the uterus is seldom possible. If signs of elevated temperature, anorexia, and depression indicative of septic metritis are exhibited, parenteral injections of antibiotics, estrogens, oxytocin and antihistamines are recommended. Manual treatment is limited to occasional gentle traction on the hanging portion of the membranes. Some veterinarians introduce a broad-range antibiotic capsule or tablet used for enteric infections in calves into the uterus after carefully cleansing the ex-

ternal genitalia. The placenta usually drops away within 2 to 7 days.

Retained Placenta in the Sow is uncommon. It is usually impossible to determine if retention has occurred except by the symptoms of septic metritis, prostration, and a prolonged purulent vulvar discharge containing placental shreds. This condition has been reported² as a cause of fatal metritis, however this has rarely if ever been reported in the United States. Since retained placenta is most likely to occur after a dystocia with prolonged labor it would be advisable in these cases to save the expelled fetal membranes, count the umbilical cords, and to give oxytocin 1 to 3 ml., after relieving the dystocia. When septic metritis does occur because of a retained placenta, administration of stilbestrol, 10 to 20 mg. and the daily injection of intramuscular forms of antibiotics, such as 3,000,000 units of aqueous or oily preparations of penicillin, 1 to 2 gms. of streptomycin or 1 gm of intramuscular **Terramycin**, tetracycline, or **Aureomycin** are indicated. Intrauterine infusions of broad range antibiotics have been used by some veterinarians. A sterile AI catheter or a horse catheter may be used. The value of this type of therapy in the postpartum sow has not been proven. Good nursing is essential.

Retained Placenta in the Bitch and Queen is uncommon. It is seen most often in toy breeds in which dystocia or prolonged labor has occurred. In any such suspected case parenteral antibiotics should be administered at once and continued for several weeks. If the placenta is not expelled in 12 to 24 hours an acute metritis may result and unless it is treated early or a hysterectomy performed promptly, it usually is fatal in 4 to 5 days due to a necrosis of the uterine wall in the region of the placental attachments and peritonitis. Once toxic symptoms have developed in septic metritis in bitches due to retained placenta, the prognosis should be very guarded. The presence of a dark green vulvar discharge more than 12 hours after parturition is a symptom of retention of fetal membranes. If retained placenta occurs during whelping or is noticed within the first day afterwards, the retained membranes may be gently withdrawn from the birth canal and uterus with the finger. A pair of forceps padded with gauze or cotton may be rotated in the genital tract to wind up the membranes and remove them. In the small bitch the uterus might be palpated and massaged over the retained membrane to help to force the latter through the cervix. This might be repeated in several hours if unsuccessful initially.² In toy bitches after whelping and especially after dystocia a small dose of 1/2 to 1 cc., 10 to 20 units, of oxytocin may prevent retained placenta. If the bitch is valuable an attendant could watch her during whelping and save the

placentas to make certain all are expelled. If septic metritis is present, with a vulvar discharge, elevated temperature, rapid pulse, and anorexia the prognosis is guarded and treatment with antibiotics parenterally, as well as supportive treatment similar to that in other animals, should be given. Careful infusion of a small amount, 30 ml., broad-range antibiotic solution into the uterus might be indicated with a small soft rubber catheter. Injections of oxytocin may be of value. Supportive therapy with fluids is desirable. Laparo-hysterectomy might be considered but should be performed early.

Septic Metritis Following Parturition may occur with or without retention of the fetal membranes and is observed usually within 1 to 10 days after parturition in all species. The etiology of septic metritis is probably similar to that of retention of the fetal membranes. It usually is associated with a uterine atony or inertia. Highly pathogenic types of organisms are present in the uterus and they or their toxins are absorbed into the circulation, producing severe general symptoms associated with septicemia, endotoxemia, and pyemia. The organisms most commonly present are coliform organisms, **Coryn. pyogenes**, hemolytic staphylococci, **Ps. aeruginosa**, proteus, hemolytic streptococci, and in rare cases clostridia. These severe infections are characterized by a fetid, red, watery uterine fluid that is very toxic and depressing to the animal. This condition usually follows emphysema of the fetus, severe torsion of the uterus with the presence of a dead and possibly emphysematous fetus, and other conditions associated with a uterine inertia such as dropsy of the fetal membranes, fetal anasarca, fetal gigantism, twinning, peritonitis due to traumatic gastritis and retention of the fetal membranes. In many cases it may follow rough improper removal of a retained placenta. Probably most veterinarians in large animal practice can cite several instances in which septic metritis and even death followed the injudicious removal of a retained placenta in a cow when the owner insisted upon its being removed. Septic metritis may follow a prolonged dystocia especially if a difficult fetotomy operation has been performed. It may follow a prolapsed uterus or invagination of the tip of the uterine horn associated with trauma and infection of the endometrium. Occasionally it may result by extension from a necrotic vaginitis. It may occur in all species through the introduction of infection by unsanitary practices during the relief of dystocia or removal of a retained placenta. In bitches and sows it may occur from neglect at the time of parturition or trauma to the uterus with forceps, or accidentally allowing one or more placentas or fetuses to remain in the uterus and macerate. The use of cortisone without antibiotics by farmers soon after calving for the treatment

of ketosis may favor metritis.⁵⁵

The symptoms of septic metritis following parturition are very similar in all species of animals. Retention of the fetal membranes is frequently observed; in the cow the placentomes are usually greatly swollen and the fetal cotyledons firmly attached to the maternal caruncles. In the mare a piece of the placenta, often a portion from the nongravid horn, is retained and found in the body or nongravid horn of the uterus. The animals exhibit anorexia and dullness. The pulse is rapid, in the cow from 80 to 120 per minute, and usually weak. The body temperature in the cow may be elevated during the early phase of the disease. In advanced cases the cow's temperature may be either normal or subnormal. The latter condition usually occurs shortly before death of the animal. The cow is less apt to show a prolonged elevation of body temperature than are the other animals. The animal will shiver and its extremities are cold. The respirations are rapid and shallow; the eyes may be sunken; the hair coat is rough; and there is a rapid loss of weight. In severe cases there is a marked atony of the digestive tract. The feces may be hard and firm or may be black, oily, fetid, and liquid in character especially in the cow. A marked drop in milk flow or agalactia occurs in all species and the newborn will exhibit signs of malnutrition or starvation. There is usually a reddish, watery, fetid discharge from the vulva. The genital passageways are likely to be swollen and inflamed. Straining may be present or absent before the examination but during or after the examination it is generally present. In many cases of septic metritis with secondary enteritis in the cow, a rectal examination, especially if not performed gently, results in straining or tenesmus. The tenesmus may be very persistent and is definitely undesirable and exhausting to the cow. Rectal examinations should usually be confined to cows with no evidence of rectal irritation or enteritis. In some cows having septic metritis without a retained placenta the cervix may be quite contracted. Vaginal examination may reveal a normal vagina and clear, or only slightly cloudy, vaginal mucus, yet the uterine contents may be toxic and fetid, and occasionally toxic enough to cause death. The uterus in nearly all cases is atonic or flaccid. The walls are usually thin and in some cases, especially in bitches and queens, may be very friable or even necrotic, especially the placental sites. Peritonitis may be present due to extension of the infection through the uterine wall with symptoms of abdominal tenderness or soreness, abdominal distension, slight to moderate tympany of the rumen due to atony of the digestive tract, an arched back, stiff, slow gait, and tense abdominal muscles. The cow may exhibit a characteristic expiratory grunt due to the peritonitis.

Perimetritis or peritoneal involvement with the uterine infection may occur naturally or be produced by heroic or too vigorous treatment of a severely infected and inflamed uterus. Rectal examination on these cases in cows may reveal early fibrin deposition and adhesions present between the uterus and the adjacent abdominal viscera. If this is found, the operator should terminate the examination at once, or the peritonitis and adhesions may be made worse, leading to severe peritonitis, abscess involvement of the adjacent structures, marked adhesions around the uterus, broad ligaments, ovaries and oviducts, or even death. Arthritic symptoms, with swelling and stiffness of the joints, particularly the hock, fetlock and knee joints, may occur especially in the cow, ewe and sow. Acute laminitis in all large animals may also be present making the animal reluctant to rise and stand. The animal may be very weak, staggering, or prostrate and show symptoms of paresis and inability to rise. Since under these conditions the extremities are usually cold, this disease in the cow may easily be confused with milk fever. A mild to strong reaction to the Ross test for the presence of ketones may develop on testing the urine of cattle with septic metritis. This may be due to ketosis as a complication of the disease but more often it is caused by the severe anorexia. The blood count usually develops a marked shift to the left, together with a marked drop in the total white blood cell level during the early stages of the condition. During the recovery stage the white blood cell count shifts to the right, with a leukocytosis developing. Occasionally secondary complications of pneumonia, and laminitis in the mare, cow, sow, and ewe, and in all species pyemia with arthritis, liver, brain, or lung abscesses or endocarditis or myocarditis may develop especially if the condition is prolonged. Rough removal of the placenta, or lacerations of the endometrium encountered in prolapse of the uterus may allow organisms to localize in the uterine wall and cause an abscess.

A careful differentiation should be made between septic metritis and other conditions, such as traumatic gastritis, gastroenteritis, hemorrhagic septicemia pneumonia, parturient paresis, laminitis, and mastitis which may cause paraplegia, reluctance or inability to stand and illness at parturition. The course of septic metritis usually lasts from 2 to 6 days, with recovery or death occurring within that time. In the cow a prolonged course may extend over a period of from 1 to 2 weeks. The prognosis may be guarded to poor in many cases unless treatment is begun early before the uterus is severely damaged, peritonitis develops and the animal becomes extremely toxic. Failure to respond to treatment, persistent straining or complications such as mastitis and

pneumonia tend to make the prognosis grave. The prognosis for the future breeding life of the animal may be poor in severe cases as well as in cases of perimetritis, ovaritis or abscesses of the uterine wall. If recovery occurs conception may be delayed due to severe chronic metritis.

The treatment of septic metritis should be conservative. Massage and douching of the uterus, attempts to remove the retained fetal membranes should seldom if ever be performed in cases of septic metritis, or the animal's condition may become critical. Septicemia and toxemia should be overcome before these manipulative procedures are used. In early cases oxytocin, 30 to 50 I.U. in large animals or 10 to 30 I.U. in small animals may be of some value in producing tonus in the atonic uterus. Usually if the condition is severe hormones are of questionable or no value. If the uterus is filled with a large amount of fetid fluid this should be gently siphoned off. Siphoning the uterus in large animals should be done very carefully with a sterile soft rubber hose or horse catheter since the uterine wall may be very friable and easily ruptured. In the mare and bitch, if a portion of the placenta is lying in the uterus it should be removed in as gentle a manner as possible. One to 3 gm. of the broad-range tetracycline derivatives such as **Aureomycin**, **Terramycin**, tetracycline or furacin placed in the bovine or equine uterus in a solution or in a readily soluble form may be of great value in controlling the infection locally and even systemically by absorption from the uterus.⁵⁵ Antibiotics and possibly sulfonamide therapy are indicated parenterally. The antibiotics such as procaine penicillin, 3,000 to 6,000 units per pound of body weight daily and streptomycin, 5 gms. per 1,000 pounds twice daily, intramuscularly; Terramycin, or tetracycline intravenously; or in large animals except the horse; intramuscularly, at a rate of 1 to 3 mg. or more per pound of body weight, daily, are of definite value. The older sulphonamides given orally, or intravenously, may be used alone or with other antibiotics. Other supportive therapy such as saline and glucose solutions, and blood may be administered daily. Calcium gluconate seems of value especially in the early cases and may increase the tone of the uterus, but large doses given too rapidly to toxic cattle may cause death. **Pyribenzamine** or other antihistamines may be of value. Forced feeding may be helpful. Good nursing in a suitable stall or other equally comfortable environment is essential. If possible the large animal should be on green pasture each day or provided with fresh-cut green feed and with whole oats or other coarse feeds to tempt and encourage it to eat. If straining is present epidural anesthesia should be used to control it until the cause of the condition is determined

and corrected. A drop in pulse rate, an increase in appetite, an improvement in the tone of the uterine wall, a change in the exudate from a watery to a mucoid consistency are all favorable symptoms indicating that the animal is responding to therapy. Treatment should be continued until the animal has safely recovered and septic symptoms have subsided. This should take place before actively treating the uterus and removing the retained fetal membranes in the cow. It may be advisable to let the afterbirth drop away. In the mare septic metritis is more likely to cause laminitis, than in the cow, ewe or sow.

The application of ice packs to the mare's hooves, antihistamines and phenylbutazone, are indicated as preventive therapy in septic metritis. Laminitis may also follow metritis in the cow, ewe, and sow but is usually less severe and may be unnoticed until months later when deformity of the hooves becomes evident.

Postpuerperal Metritis may be observed from the time of parturition to 2 to 8 weeks or more postpartum in all species. It may persist as a chronic metritis for months or occasionally pyometra with anestrus and persistence of the corpus luteum may occur in the cow. There are no septic or general symptoms of illness accompanying this metritis. In most cases there is a reddish-brown or grey, mucopurulent, occasionally fetid discharge from the vulva. Later a creamy-yellow or grey discharge from the uterus and vulva usually mats the hair on the tail and buttocks. The condition is probably caused by many of the bacteria, especially **C. pyogenes**, that cause a retained placenta or septic metritis but either the infection is milder or the animal's resistance and the tone of the uterus are better. It may follow the development of infection in the uterine lochia during involution of the uterus. It may occur following retention of the fetal membranes or a necrotic piece of membrane or caruncle that has remained in the uterus. Occasionally it may be associated with a piece of the fetus, such as a hoof, left in the uterus and which has become a focus of infection. In mares it may follow a vulvar tear or laceration after foaling which causes persistent penumovagina and chronic metritis. Usually a cervicitis and vaginitis accompany the metritis, as by extension the infection from the uterus involves these structures. Rectal examination in cases of postpuerperal metritis reveals a larger than normal uterus undergoing a delayed involution. Uterine tone is fair but the uterine wall is thick and heavy. There may be from one-half pint to several gallons of mucopurulent material in the uterus of large animals. Vaginal examination may reveal some of this pus lying in the vagina. As late as two weeks after parturition the cervix in the cow with metritis is usually relaxed and dilated enough to admit

one finger. The uterine exudate is mucoid in character rather than watery as in septic metritis. Since postpuerperal metritis usually follows a retained placenta the veterinarian will find it advisable to reexamine valuable cows or mares 2 to 5 weeks after a parturition associated with retention of the placenta and treat the metritis and delayed involution of the uterus if they are present. In valuable cows a routine genital examination is usually performed in 3 to 5 weeks after parturition, even though retained placenta did not occur, to make certain that involution of the uterus is normal and that metritis is not present. There is evidence in mares and cows that probably 100 percent of parturient animals have infectious organisms invade the uterus for a short period of several days or more after expulsion of the fetus. At the time of the first estrus, at 5 to 12 days in the mare and 12 to 18 days in most cows, these infections are overcome and eliminated. In animals in which the first estrus is delayed or in animals failing to eliminate the infection, the infection persists as a mild to moderate metritis. With each subsequent estrous period more of these mild metritis or endometritis cases recover.^{59,70}

The prognosis in most of these cases is good. Many animals would recover without treatment but recovery time might be prolonged and conception delayed. Neglected postpuerperal metritis may progress into pyometra, chronic endometritis or cervicitis, and delayed or permanent infertility may result.

Treatment of these cases should start early, and repeated examinations and treatment at 1- to 3-week intervals may be indicated. Douching of the vagina of the cow with a gallon of hot, 120 to 130° F., mild antiseptic solution of chlorine, a soapy antiseptic, dilute **Lysol**, or other mild antiseptic 2 to 3 times a week stimulates uterine contractions, and washes the purulent exudate from the vagina. Intrauterine douching should be done gently, using only a soft rubber catheter, so that the endometrium is not traumatized. The exudate is thinned by the introduction of small amounts of a mild antiseptic solution, and then removed by siphoning. If the exudate is very thick, an enzyme like streptococcic dornase or pancreatic trypsin may be used to thin it and thus make it easier to siphon out. The recommendation in most of these cases is to avoid vigorous massage of the uterus or the removal of the corpora lutea in cows, since otherwise adhesions and perimetritis or ovaritis may develop. If the uterus is massaged this should be done gently. Antibiotics, and other antiseptics, such as 1 to 5 ml. of Lugol's solution or 10 to 20 ml. of **Betadine** in 100 ml. of saline or water, may be introduced into the uterus for local treatment of the infection. Large or prolonged doses of estrogen should be avoided lest cystic ovaries or the

transfer of infection through the oviducts with ovaritis and adhesions result. Estrogens should not be used in the dairy cow. Presently the prostaglandins such as F_{2a} or prostaglandin analogues are used to evacuate the uterus when a corpus luteum is present. Breeding of the animal should be delayed until the uterus and cervix are normal and 2 to 3 normal estrous periods have elapsed. Most affected cows should not be bred until 90 days or more after parturition although some may be normal and be bred at 60 to 80 days (See Metritis and Endometritis, Chapter XIII). In bitches, queens, and sows parenteral treatment of postpuerperal infections with courses of antibiotics and oxytocic agents are indicated to assist recovery. In rare cases laparotomy and hysterotomy with douching and infusing of the uterus with antiseptics and antibiotics might be undertaken.²¹ The mare may be treated similar to the cow except irritating infusions should not be used. If the mare or cow develops pneumovagina the Caslick operation should be performed. Because of the long period between lambing and breeding most ewes recover from postpuerperal metritis without treatment.

Lactation Failure, Hypogalactia or Agalactia, Mastitis-Metritis Agalactia (MMA) Syndrome of Sows is a heterogeneous disease complex with many possible causes. In this regard it resembles the postparturient paraplegic or downer syndrome in cows. Based on exhaustive reviews of this disease syndrome,^{40,68b} the name MMA is probably a misnomer. Much research on this syndrome over the past 20 years has shown that metritis is not a contributing factor in most cases and mastitis is not always a contributing factor. This syndrome of lactation failure affects 10 to 15 percent of sows farrowing in the midwest and is a contributing cause for the loss of 20 percent of the baby pigs due to starvation, hypoglycemia, overlaying and pig scours.

Lactation failure syndrome appears to be contagious but cannot be produced experimentally with regularity. The general categories of causes can be classified under infectious agents, managerial deficiencies related to nutrition, housing and stress, endocrine imbalances and possibly heredity for lactational ability.^{11,40,53,58,65,66a,68b}

E. coli and **Klebsiella** are commonly associated with mastitis and lactation failure. The latter organism has been associated with wood products used as bedding as in cattle. As with cattle, damp contaminated farrowing crates or houses can result in "bacteria-build-up" and be a cause for mastitis.^{68b} Endotoxins from these gram-negative organisms when injected into postparturient sows produce symptoms of the syndrome. These endotoxins may come from the mammary glands or the digestive tract. In the latter they may be associated with underfeeding, overfeeding or altered feeding practices with constipation.

Other bacterial agents have been associated with the agalactia syndrome including **Streptococci**, **Aerobacter**, **Citrobacter**, **Actinobacillus**, **Clostridia**, **Pseudomonas**, **Proteus**, **Mycoplasma** and **Staphylococcus**.

Endocrine studies of sows with lactation failure have revealed an elevated estrogen level 48 hours post partum in hypogalactic sows compared to normal sows. Serum prolactin levels were much lower than normal sows post-farrowing. Plasma cortisol levels were higher and thyroxine values were lower in affected sows. Evidence was presented of altered oxytocin release, increased engorgement of the udder and reduced ability to maintain blood glucose levels in affected sows.⁴⁰ Further correlation of these studies with management practices, infectious processes and heredity are needed to explain the pathogenesis of this multifaceted syndrome.

Overfeeding of the preparturient sow especially with finely ground feed and underfeeding causing hypoglycemia have been associated with this syndrome. But extensive studies have not revealed or demonstrated any uniform fault or deficiency in feeding practices. In fact the disease was observed with all commonly used feeding systems. Although selenium deficiency and hypocalcemia have been reported as possible causes for this syndrome, the evidence is not conclusive. Exercise on pasture during gestation is highly desirable. Sows that are susceptible to this lactation failure syndrome have been reported. It is possible that selection for lowered back fat and increased growth rate may favor the development of strains hereditarily susceptible to this disease.

On necropsy examination of affected sows, mastitis limited to a few areas of certain glands was found in 65 percent of the sows.⁴⁰ A mild metritis was present in 3 of 18 affected sows. Although all these above predisposing factors may be categorized as stress factors, further studies are needed to elucidate the complex interplay of the various causative etiologies.^{68b}

The clinical signs of lactation failure syndrome include: depression, anorexia, elevated body temperature, increased respiratory and heart rates, infrequent defecation, reluctance to rise and to allow nursing. These signs occur within 1 to 3 days after farrowing. Signs of mastitis may be evident or lactation failure can occur without systemic involvement of the sow. The pigs show signs of discontent by excessive running around and vocalizing. They become gaunt, weak and emaciated and are often crushed by the sow who is irritable and gets up and down frequently.

Treatment consists of providing feed for the malnourished piglets until milk flow is re-established in the affected sow or gilt. This can be done by placing piglets

with other recently farrowed piglets on another sow or feeding baby pig formula (SPF-Lac, Borden) or a formula of one quart cow's milk, one ounce white syrup or honey and one ounce of cream or corn oil. Piglets should be fed fresh warm formula every 1 to 3 hours for the first several weeks in amounts of about 10 percent of their body weight daily. Piglets should be left with the sow so as she returns to milk they may suckle.

The affected sow or gilt should be given oxytocin 30 to 50 I.U. at 3 to 4 hour intervals along with broad-spectrum antibiotics and possibly glucocorticoids to combat the endotoxin. Some veterinarians also give the sow estradiol and promazine tranquilizers. Preventive procedures should be directed at reducing stress. Avoid sudden changes in feeding and management. Handle sows quietly. House to avoid overheating and excessive humidity. Place sows in the farrowing house early enough so they become accustomed to it. Feed balanced coarse-textured mildly laxative grain ration with bran or beet pulp at a rate of 2 to 3 lbs. twice a day. Keep sows lean, don't let sows get overly fat.^{2,65} Feeds containing estrogenic mycotoxins should be avoided.⁴⁹ A daily exercise period during the periparturient period is desirable. Farrowing houses should be thoroughly cleaned and disinfected and allowed to stand empty for 1 to 2 months between farrowings and farrowing periods in a house should be limited to 3 to 4 weeks to avoid "bacteria build-up." Vigorous culling of affected sows is recommended. There is some evidence that lactation failure might be decreased by using prostaglandins to induce parturition after day 111 of gestation (See Chapter VI). Feeding high levels of antibiotics for a week before and after farrowing or the use of polyvalent autogenous vaccines to control infections have not proven to be uniformly of value.^{53,68b}

Agalactia in sows and mares associated with the ingestion of ergot or ergot-like alkaloids or mycotoxins (fescue) has been reported.^{1,38} This should be considered in a differential diagnosis in dams showing no systemic clinical signs other than agalactia along with a more excitable temperament. The active principal of ergot from the grain may be transmitted through the milk to the piglets resulting in gangrene of the ears and tails. In mares on certain fescue pastures in Missouri an increased incidence of agalactia was reported as a serious problem.

Postpartum metritis syndrome in cattle was described in 1963³¹ and has been seen with increasing frequency in many dairy herds in the Northeast especially as herd numbers increase and as production rises. It is becoming a serious problem especially in the free-stall herds with over 100 cows and where the cows never are placed on pasture. There are many similarities between

this postparturient syndrome in cattle and the postparturient agalactia in swine.

The postparturient metritis syndrome in cattle herds is characterized by a high incidence of retained placenta and subsequent metritis. Even in cows and heifers in which retained placenta does not occur, a postpartum metritis will develop. A few cases of metritis may exhibit septic symptoms but nearly 100 percent of the cows that calve during the Fall and Winter stabling season will exhibit a chronic metritis with a persistent yellowish discharge of pus that lasts for several months, a delayed involution of the uterus, a lowered conception rate and a calving interval that is increased from about 13 months to 15 to 17 months. Often an abnormally long period of anestrus follows calving. A few cases develop a persistent pyometra. In the early stages of the infection a wide variety of organisms are cultured but after several months *C. pyogenes* is the principal organism found. Economic loss is due mainly to delayed conception and culling because of infertility.

From his studies the author agrees that the postparturient metritis syndrome is principally a problem of sanitation in the barn, the free stalls, the exercise yards, and especially the calving stalls.³¹ In many instances calvings and postpartum involution of the uterus are normal for a period of a month or more at the start of the calving season. Then after one or two cases of retained placenta and metritis occur nearly every cow that freshens in these barns and calving stalls becomes infected (See Retained Placenta in Cows). In some herds with this problem nearly every calf born in these infected calving stalls will develop scours and die unless prophylactic antibiotic treatment is given as soon as the calf is born. Sometimes the owners in treating the cows prophylactically by placing antibiotics into the uterus may spread the virulent infection that has been established in the barn and calving stalls. Frequently this may only occur in a herd for one year. When the cows are turned to pasture or when a period of 2 to 3 months passes with no cows calving the infection will disappear. In large herds calving the year around the condition may remain a problem for years. If dry cows and pregnant heifers are removed from the herd and kept separate from the herd, calve at pasture or calve in a clean, noninfected environment and kept there for about 7 to 10 days this metritis syndrome will stop. To solve this problem some farmers have built portable 10' x 10' calving stalls that can be thoroughly disinfected between calvings and can be moved to clean ground after each calving. It is obvious that more study in the field in problem herds is needed to determine the sanitation needs and management practices to control this metritis syndrome in a practical way. Possibly by proper

construction, suitable isolation, adequate disinfection and rest after each calving, stalls could be constructed as have farrowing houses, that are adequate for the needs of intensive dairy farming.

Preventive treatment of cows in a herd where postparturient metritis develops in nearly every cow is generally not satisfactory. Autogenous bacterins or commercial polyvalent vaccines have been tried without success. Injections of oxytocin after calving seem to have little or no effect. Parenteral injections or local intrauterine infusions or capsules of broad range antibiotics after calving have limited value and then only in possibly preventing some cases of septic metritis. In one experiment where two 500 mg. of neomycin sulfate boluses were inserted into the uterus of cows within 24 hours of calving the number of services per conception were greater in the treated than in the control cows.²⁶ As an aid to hastening the recovery of the chronic metritis and delayed involution of the uterus, estrogen injections or 3 to 10 mg. of estradiol and intrauterine antibiotics and/or weak Lugol's solution, 2 to 5 ml. of Lugol's solution in 100 ml. of water, infused into the uterus at biweekly or monthly intervals has proven helpful. Although proper management, exercise, and clean, noninfected isolation facilities for the parturient cow are more difficult for the farmer to provide, at present it is the best way to control this economically costly metritis syndrome.

Puerperal Laminitis is most likely to occur in the mare and may be commonly seen in the cow, ewe, and sow. Twenty-four percent of 170 cases of bovine laminitis occurred within 2 to 3 days of calving.^{50a} It usually occurs secondary to a septic metritis. In the mare the placenta may tear away, leaving the apex of the allantois chorion in the nongravid horn. This placental remnant acts as a focus of infection and the uterus fills with a fetid, watery exudate. Laminitis is apparently caused by the septic uterine contents and possibly the histamines released and results in symptoms similar to those in laminitis of digestive origin. Usually 2 to 4 days after parturition the animal begins to exhibit a foundered gait characterized by the hind legs being placed well forward under the body in order to remove the weight from the even more severely affected forelimbs. The hooves are hot to the touch and the digital artery has a strong, hard pulse. The animal may lie down continually, standing for only short intervals, or rarely it may refuse to lie down. Weight loss is rapid. The prognosis is fair if treatment is begun early. Any animal with hooves with severe retained placenta or septic uterine infection should be treated early to prevent the possibility of laminitis developing. Treatment consists of the administration of an antihistamine in repeated doses plus the application of

ice packs to the feet or having the animal stand in cold water. The author prefers alternate hot and cold packs and placing the animal on a firm supportive bedding such as sand. The placenta of any valuable mare should be examined after expulsion by the veterinarian or, if he is intelligent and informed, by the owner to make certain that none of the placenta has remained in the uterus. If laminitis develops in a mare or other animal several days post partum, the uterus should be treated as for septic metritis by gently removing the exudate and placenta if present. Antibiotics may be used in the uterus and parenterally along with injections of oxytocin. The uterus should be examined and treated again if necessary in 24 to 48 hours and therapy continued until recovery results. Phenylbutazone or similar nonsteroid antiinflammatory drugs and possibly tranquilizers make the affected mare more comfortable and speed recovery by allowing moderate exercise to promote circulation in the hooves.

Puerperal Tetanus may occasionally occur in the mare and cow. It is possible in any species. All mares with dystocia, retained placenta and metritis and prolapsed uteri should be vaccinated promptly with tetanus antitoxin or toxoid. In the cow, even though of unusual occurrence, puerperal tetanus is the most common form of the disease. It often follows retained placenta and postpartum metritis. Unsanitary handling of a retained placenta when the uterus or birth canal may be traumatized predisposes to tetanus in the cow and mare. The afterbirth drops out a short distance when the cow lies down and becomes contaminated and when the cow rises foreign material on the placenta is drawn into the genital tract. Tetanus is usually observed one to four weeks after parturition. In many cases a post-*puerperal* metritis is present. If possible the uterine exudate should be removed and the cow or mare treated as for an ordinary case of tetanus resulting from external wounds, that is, by the administration of large doses of tetanus antitoxin, penicillin and tranquilizers. Estrogens or prostaglandins, if a corpus luteum is present, should be injected to evacuate the pus from the uterus. Constant, careful, quiet nursing is essential. The prognosis is guarded but recovery may occur if the cow is treated early with an indwelling uterine catheter to infuse the uterus with about 50 to 100 ml of penicillin-streptomycin mixture daily and inject 5,000 units of tetanus antitoxin followed by 1500 units daily for a number of days. A tranquilizer and laxative may also administered as needed.³⁶

Uterine Abscess, or pyometra with cervical or vaginal obstruction, may occasionally follow severe septic metritis, dystocia, and necrotic cervicitis or vaginitis that cause an atresia of the birth canal. It is seen in all species, but most commonly in the cow and mare. During the early stages no external symptoms may be evident

but after several weeks to a month or more the uterus becomes so greatly distended with pus that it may cause a distention of the abdomen. Usually intermittent straining and frequent urination are present. On rectal and vaginal examination the enlarged fluctuating uterus can be felt protruding into the pelvic cavity and the stenotic or closed portion of the genital canal may be palpated. Adhesions between the vagina and uterus may be present, so that an incision can be safely made through the vaginal wall into the uterus to drain off the pus. In one mare so treated by the author about 15 gallons of pus were removed. Symptoms of shock developed following the removal of this large volume of pus. The uterine abscess may break into the rectum or vagina. The animals occasionally recover, but their breeding life is ended. This condition should be distinguished from an abscess of the uterine wall which is a small, localized lesion.

Infections of the Cervix, Vagina and Vulva

Postpuerperal Cervicitis due to trauma, mild lacerations, infectious material from the uterus passing through the cervix, infection by extension from the vagina, or infection from a retained placenta or material carried into the genital tract on the placenta, is common in animals. It is observed most commonly in the cow and in association with a metritis or vaginitis after calving. The good blood supply, large mucus glands in the cervix, and the folded mucous membrane make severe injury, necrosis, and atresia of the cervix rare except in the mare. If cervicitis is present in the mare the gentle introduction of mild oily antiseptics or antibiotic infusions into the uterus and gentle dilation of the cervix with the gloved fingers may prevent stenosis occurring. This should be repeated until the cervicitis has been corrected. As long as a metritis is present local treatment of the cervix is usually ineffective. Once involution of the uterus takes place and the uterus rids itself of infection, the cervix also recovers unless a vaginitis, pneumovagina, or a greatly enlarged chronically infected ectropic cervix persists. Treatment for postpuerperal cervicitis is the same as treatment for metritis or vaginitis. The prognosis is usually good.

Postpuerperal Vaginitis and Vulvitis may occur with or without a concurrent metritis. Following parturition either a severe necrotic vaginitis and vulvitis or a mild catarrhal inflammation of these structures may develop.

Necrotic Vaginitis, Vestibulitis and Vulvitis is observed most often in dairy and beef heifers having a narrow small birth canal that caused dystocia. The fetus may have been expelled without aid after a difficult, prolonged parturition or traction may have been necessary. These factors, especially the latter, result in trauma, lac-

eration, excessive pressure, and abrasion of the vulvar and vaginal walls. The mucosa of the vagina and vulva may be further irritated by the presence of a retained placenta, a metritis, or a torn or ruptured perineum allowing infection to enter the vulva and vagina. Pressure necrosis of the vulvar and vaginal mucous membranes is often observed following the removal of an emphysematous fetus by traction or after a prolonged fetotomy without proper lubrication in a heifer or cow. In rare cases necrotic vaginitis may be due to douching with too irritating or strong an antiseptic. Occasionally a severe necrophorus infection of the vagina may occur.

The symptoms of necrotic vaginitis and vestibulitis are usually observed 1 to 4 days after parturition and last for 1 to 2 weeks or more depending on the severity of the lesions. There is usually an arched back, elevated tail, anorexia, and rapid loss of weight. The animal may exhibit either no straining, straining that is intermittent and mild and only observed at the time of urination or defecation, or nearly continuous straining with air being sucked into the vagina and forcibly expelled. The vulva, vestibule and vagina may be very swollen, due to a perivulvar and perivaginal phlegmon. A fetid, reddish, watery fluid is present. The pulse rate is usually elevated. The body temperature may be moderately elevated. Parting of the vulvar lips reveals a necrotic, diptheritic inflammation of the vestibule and vagina, usually most severe at the vulvo-vaginal border. The necrotic portion of the mucous membranes sloughs, and the exposed submucosal tissues granulate and eventually heal with a cicatrix. In an acute case, the passage of the hand through the inflamed vulva and vagina of the cow is likely to cause bleeding. This act is very painful to the animal and because of the swollen dry tissues is usually difficult to perform. Straining is probably due to the vestibular and vulvar inflammation and irritation and possibly the accompanying vaginal swelling or phlegmon, since there are many sensory nerves in the vulva and vestibule but few if any in the vagina. Straining due to vulvitis, vestibulitis and vaginitis should be differentiated from that caused by dystocia, an undiagnosed, retained fetus, rabies, or other conditions which might cause straining.

In some of these cases of vulvitis, vestibulitis and vaginitis, no matter how they are handled, marked stenosis or even atresia of the vagina may occur resulting in a distention of the cranial portion of the vagina due to pus or mucus. In advanced chronic cases, even the cervix and the uterus may be distended with 2 to 3 gallons of a mucopurulent material if infection persists, or of mucus alone if no infection is present. The prognosis is fair to good in mild cases treated early. In severe cases that are neglected the prognosis is guarded. If necrosis is extensive, straining constant, and the animal is extremely

debilitated, death may result. In cases of severe vaginal or vestibular atresia—fortunately uncommon—the future breeding life is usually terminated.

The treatment of necrotic vaginitis should be gentle and conservative. Oily bland antiseptics such as 4 to 6 ounces of bismuth formic iodide or antibiotics, in oil, together with the broad range antibiotics, may be introduced in a gentle manner into the cranial portion of the vagina 2 to 3 times a day. As this infusion is expelled it coats the inflamed mucous membranes. If swelling, phlegmon, elevation of the temperature, and rapid pulse rate are present, parenteral administration of antibiotics and/or oral or intravenous administration of sulfonamides are indicated daily for 4 to 6 days or until recovery is evident. If in the cow, retained fetal membranes are hanging through the vulva they should be removed if this can be done easily and without injury to the vulva and vagina. In most cases the placenta is fastened securely and must be allowed to remain and drop away later. If the membranes are heavy and hang nearly to the floor they should be cut off at the hocks so the added weight does not aggravate the vulvitis and induce straining. If straining is present, the use of one of the longer-lasting epidural anesthetics such as lidocaine to which a small amount of adrenaline solution has been added to retard its rate of absorption. This may be given twice daily or more often if necessary. Sometimes procaine penicillin may be used epidurally as a fairly long-acting local anesthetic. The administration of tranquilizers is helpful in controlling pain and tenesmus. Elevation of the rear parts may be helpful. In mild cases of vulvitis and vaginitis with straining, some local anesthetic ointments containing butesin picrate or benzocaine have been used but difficulty has occurred in applying these to a moist mucous membrane and their effect is questionable.

If tenesmus is severe and accompanied by marked sucking and blowing of air into and out of the vagina, the dorsal two-thirds to three-quarters of the vulva should be tightly sutured after administration of epidural anesthesia. This prevents ballooning of the vagina with air and precludes the accompanying irritation and straining. This treatment with other supportive treatments described usually promptly controls the straining. The sutures holding the vulvar lips together may be removed in 4 to 7 days. In rare cases it may be indicated to insufflate the abdominal cavity with air to prevent tenesmus.⁶³ Control of severe straining is essential to prevent rapid loss of weight, weakness, early exhaustion, and even death. Repeated treating and dilating of a necrotic vagina is not indicated, inasmuch as this procedure prolongs recovery time, increases the inflammatory reaction in the vagina, and produces additional scar tissue. Fol-

lowing healing, breeding may be advised if the stenosis is not severe. At the time of parturition it may be necessary to dilate the stenotic portion of the vagina. In many cases, however, due to the relaxation of the vaginal wall and surrounding tissues, mild stenoses disappear at the time of parturition. If the stenosis is severe and breeding is desired this might be accomplished by artificial insemination with cesarean section at the time of parturition. Most severe cases of stenosis of the vagina are slaughtered. Outbreaks of blackleg have been reported in sheep following lambing where the organism, *C. festeri*, invades the damaged vulvar tissues.¹¹

Catarrhal Vaginitis and Vulvitis occurs following or with retained placenta, puerperal metritis, or injuries to the vulva causing pneumovagina. Following parturition this generally is characterized by a persistent mucopurulent discharge from the vulva. The prognosis is good. Dilute, warm vaginal douches, using 200 ppm Betadine solution, dilute Lysol or other soapy aromatic antiseptics, or saline or sodium bicarbonate, are indicated. These may be repeated at 1- to 3-day intervals. If the vulva is torn it should be sutured, to prevent pneumovagina. If puerperal metritis is present the vaginitis may persist in a mild form until the discharge of uterine exudate ceases. In some cases when only a vaginitis is present one to three weeks after parturition, some oily antibiotics or antibiotics in ointment form may be placed in the vagina to aid in overcoming the infection.

Paraplegia in the Parturient Cow, The "Downer Cow" and "Fat Cow Syndrome" ("Atypical Milk Fever," "Creeper" or "Alert Downer")

The cow that fails to rise after calving or dystocia, the cow that goes down and is unable to rise late in gestation

or soon after parturition or the cow that goes down with parturient hypocalcemia and fails to respond to treatment cause a perplexing diagnostic problem for the veterinarian. All too often many of the following conditions are lumped together without adequate and careful attempts to make an accurate diagnosis and called a "downer cow," a "creeper," an "alert downer" or a cow with "atypical milk fever." Most of these cases reflect the disease state present in the cow entering the periparturient period and the stresses and injuries developing during this period. Each case should be studied carefully. A complete physical examination of each system of the animal should be performed despite the fact the animal is recumbent. Since diseased states occurring around calving may be serious an early diagnosis, treatment, and recovery is desirable from the standpoint of the animal's future production of milk and/or calves.

Overconditioned dry cows, often fed excessive amounts of corn silage high in energy, have an increased susceptibility to metabolic and infectious diseases including milk fever, ketosis, displaced abomasum, retained fetal membranes, secondary metritis, mastitis, and foot and joint diseases that are loosely described under the "fat cow syndrome." If these animals are unable to rise for a period of a few hours pressure damage to muscles and nerves may occur. In some herds with this nutritional problem brought on by poor management the morbidity rate may reach 50 to 90 percent and the mortality rate may reach 20 percent or more.^{7,9}

The "downer cow" syndrome can be regarded as a common complication of parturient hypocalcemia that is preventable to a significant extent by either preventing milk fever or giving early treatment when the standing cow initially shows inappetence, mild depression and cold extremities.⁹ In a recent study 16 normal healthy cows confined by halothane anesthesia in sternal recumbency on the right side for 6 to 12 hours developed pressure damage including ischemic necrosis of muscles and sciatic and peroneal nerve lesions. Eight of the 16 cows were able to rise within 3 hours after anesthesia but the other 8 cows remained recumbent until death or euthanasia.^{4a,b}

A check-list of factors and possibilities to consider in the diagnosis of paraplegia before, at and after parturition includes:¹¹

A—Metabolic and/or Nutritional Disturbances

1. Parturient paresis, hypocalcemia, milk fever.
2. Tetany, hypocalcemia and/or hypomagnesemia including grass and transport tetany.
3. Ketosis, usually postparturient.
4. Debility, cachexia, or weakness—due to starvation, senility, acute or chronic wasting dis-

eases including internal or external parasitisms and Johne's Disease.

5. Zenker's degeneration of muscle—due to a lack of selenium, vitamin E, and the presence of other factors including poor quality hay and muscle stress following a lack of exercise or following vigorous attempts to rise in cows with milk fever, nerve paralyses, or cows that are cast.

B—Traumatic and/or Physical Injuries—These often occur during attempts to rise especially where the footing is slippery or in cows affected with parturient hypocalcemia resulting in pressure damage to muscles and nerves.^{4a,b}

1. Paralyses—due to injuries to the obturator, L6-sciatic, peroneal, gluteal, femoral, and brachial nerves or compression of spinal cord. Besides a severe injury, lymphosarcoma and abscesses may also produce spinal cord compression.^{12,14}
2. Dislocation of the hip or sacroiliac joints,^{1,10} (See Figure 101). The latter is seen in young cows, under 5 years of age, often after a dystocia.
3. Fractures of the leg, pelvis, spine, and skull.
4. "Cast" often associated with myositis, Zenker's degeneration, tendinitis, arthritis, muscle asthenia and ischemia, phlebitis and thrombosis, and contusions.
5. Rupture of the gastrocnemius muscle, usually secondary to Zenker's degeneration.
6. Exhaustion from attempts to rise or exertion from dystocia may produce a circulatory crisis, low blood pressure and myocarditis.¹³ This may be related to a lack of exercise.
7. Hemorrhage, anemia, or shock as in rupture of the uterine or pelvic blood vessels in torsion or prolapse of the uterus, laceration of the genital tract, transportation in advanced pregnancy, violence during foaling in mares, abomasal or duodenal ulcers, coccidiosis, anaplasmosis, leptospirosis and postparturient hemoglobinuria.

C—Infectious Diseases or Inflammatory Processes

1. Septic metritis, with or without a retained placenta or a vulvar discharge.
2. Septic mastitis.
3. Peritonitis, or pericarditis, secondary to traumatic gastritis, uterine rupture or abomasal ulcers with perforation.
4. Acute laminitis.

Figure 101. Dislocation of the sacroiliac articulation in a cow. This is occasionally seen in young dairy cattle following a difficult parturition.

5. Septic arthritis—knee, hocks, coffin joint.
6. Miscellaneous diseases—severe pyelonephritis, shipping fever, blackleg, anthrax, necrobacillosis, rabies, listeriosis, meningitis, and brain or cord abscess.

D—Digestive Disturbances, Diarrheas, Toxemias and Poisonings

1. Enteritis, severe diarrhea secondary to an intestinal stasis associated with hypocalcemia or grass tetany, winter dysentery, salmonellosis, virus diarrhea, etc.
2. Toxic indigestion due to overeating on fruit, grain, or spoiled forage.
3. Toxic indigestion of advanced pregnancy has been described⁵ as occurring in stabled dairy cows late in the winter confinement period and characterized by partial to complete anorexia, dullness, progressive emaciation and increased pulse rate. Normal activity of the gastrointestinal tract appears impaired possibly due to large gravid uterus. The recommended treatment consists of exercise, forced if necessary, intravenous fluid therapy, and mild laxatives orally. In a valuable cow cesarean section or induced parturition might be indicated.
4. Poisonings—plant, chemical, etc.

E—Miscellaneous Causes.

1. Hydrops allantois and/or amnii.
2. Lymphocytoma especially involving the spinal cord, heart, and abomasum.
3. "Maligner."
 4. Spastic syndrome ("stretches").
 5. Severe albuminuria and uremia secondary to nephritis (rare).

In making a differential diagnosis of the etiology for paraplegia, cows with infectious diseases may have an elevated body temperature and pulse rate. The latter is also elevated in digestive disturbances. Hypocalcemic states usually respond to calcium therapy intravenously or udder inflation although some response to calcium therapy may be observed in digestive disturbances. An expiratory grunt is often exhibited in cases of peritonitis. One or more of the following symptoms would be sufficient reason for questioning the diagnosis of parturient hypocalcemia in a cow: a pulse rate of 90 or more per minute, rapid respirations or respirations accompanied by an expiratory grunt, diarrhea, an attitude that is bright and alert, a nearly normal appetite, a body temperature of 102° F. or higher, a hot swollen udder, persistent tenesmus, and failure of expected response to adequate calcium therapy. Although these diseases and conditions are described and listed for cows many of them are applicable to mares, ewes, sows, and even bitches and queens.

Because of his exposure to frequent necropsies on so-

called "downer" cows the author is impressed with the frequency of physical and muscular lesions in these cases as well as the variety of the conditions found. A high incidence of muscle damage and tears together with a rising S.G.O.T. level in "downer" cows following parturient paresis was observed.^{3,4} The best procedure to follow to prevent "downer" cows is to control, prevent or provide early and prompt treatment of cows with hypocalcemia or parturient paresis.⁸ In certain herds in selenium deficient areas, the administration of selenium late in gestation might be indicated to assist in preventing Zenker's degeneration of muscle under the stress of calving or during parturient paresis.

The author is firmly convinced that obesity or excessive condition "the fat cow syndrome," is highly detrimental and dangerous to the parturient animal especially if it is coupled with a lack of exercise during the latter half of the gestation period. In cases of parturient paresis these two factors combine to greatly lower the cow's resistance to stress, to favor exhaustion and a "malinger-type" of attitude and to result in difficulty in rising with the production of secondary traumatic lesions. A 20 by 20 box stall with a dirt floor for excellent footing is highly desirable for large high-producing parturient dairy cows to avoid injury. Further proof of the possible effect of lack of exercise is the list of diseases of muscular organs that are most commonly observed in cattle in northeastern U.S. in the late winter or early spring months after a long period of confinement namely: displaced abomasum or torsion of the abomasum, prolapse of the vagina, prolapse of the uterus, retained placenta possibly related to uterine inertia, torsion of the cecum, intussusception of the intestine, torsion of the uterus, indigestion of advanced pregnancy and Zenker's degeneration of skeletal muscle. The incidence of these diseases is much lower

during the late spring or summer months when cows are on pasture and getting exercise.

Part II

INFERTILITY IN DOMESTIC ANIMALS

Although the problem of infertility in domestic animals has been studied for many years there has been a great surge of interest, activity, research, and investigation since 1940 when the widespread use of artificial insemination forcefully brought the problem of infertility in domestic animals, to the attention of farmers, veterinarians, animal husbandrymen, physiologists, endocrinologists and others. These basic studies on the problem have rapidly forwarded our knowledge of reproductive physiology in domestic animals. In the past 25 years basic and applied reproductive studies in all species of animals and man has been heavily supported by state and federal governments, as well as private foundations, because of the urgency of thoroughly understanding all areas of reproductive physiology so that effective methods may be devised to control the so-called population explosion. In that time there has also been rapid progress in the field of endocrinology. Nutritional studies have furthered our knowledge of infertility as related to the animal diet.

The losses due to sterility and delayed breeding in dairy cattle were estimated in 1960 to be about twenty million dollars per year in New York State.² While it is possible that the incidence of sterility and delayed breeding is increasing, it is more likely that in recent years, due to more general use of artificial insemination, gradually,

increased milk yield, higher value per cow, and increasing nutritional problems, farmers have become more conscious of their loss than they were formerly when a cow failed to conceive promptly. The average good cow should provide a farmer a net return of \$500 each year over feed costs. Each monthly delay in conception results in \$30 to \$60 loss to the farmer. Preventive medicine is a component part of the control of infertility and as such requires an adequate record keeping system not only for informational purposes but also for evaluation of performance and identification of deficiencies.

The studies initiated in the field of artificial insemination on the infertility problems in bulls and cows have done much in recent years to elucidate more clearly the importance of the bull in the overall problem of bovine infertility. These studies in cattle have in turn set the pattern and stimulated studies in the other species of animals.

In the past 20 years reproductive studies in horses, swine, dogs and cats have grown and expanded rapidly. The increased value of the large domestic animals and the realization by the owners that knowledge is available to greatly improve reproductive rates and reduce economic losses has increased the demand for skilled veterinary services.

Chapter XII

PHYSIOLOGY OF FEMALE REPRODUCTION

Reproductive Hormones

Reproduction is a luxury function of the body not physiologically necessary for the life of the individual and usually not performed until the animal reaches nearly adult size and nutritive supplies are ample for the nutrition of both the dam and fetus. Any adverse influence of environment, nutrition, stress or disease on the individual will, if severe enough, exert its influence on the reproductive system.

Reproduction in mammals is largely controlled by endocrine glands and the hormones they secrete. These influence all phases of reproduction. At least four temporary reproductive structures or organs elaborate various steroid or protein hormones; these are the ovarian follicle, the corpus luteum, the placenta and the endometrial cups in the mare. The hormonal regulation of reproduction is a complicated and carefully balanced system of checks and controls. The various hormones stimulate or inhibit each other and accordingly their effects on the animal's reproductive organs. The reproductive hormones play a major role in the initiation and regulation of the estrous cycle, ovulation, fertilization, preparing the uterus for the fertilized ovum, protecting, insuring and maintaining pregnancy, initiating parturition, and the development of the mammary gland and lactation. With a complex hormonal system controlling these many phases of reproduction, it is remarkable how seldom reproductive troubles are due to a breakdown of any portion of this mechanism. The nervous system, both central and autonomic, plays a secondary role in reproduction but one that is closely linked to the hormones produced. These nervous mechanisms in reproduction play a definite role in ovulation in those species in which ovulation is not spontaneous; with the period of sexual desire, or estrus and acceptance of the male and in such hormonal disturbances as nymphomania. Thus reproduction is under neuroendocrine or neurohumoral control. In many species of animals all phases of reproduction can take place even with the spinal cord severed in the lumbar region.

The reproductive hormones of each mammal are not species-specific in their effect; that is, the estrogenic hormone from women or mares when injected into a cow

produces the same effect as does the estrogenic hormone from the cow. All hormones are highly specific and selective in their action on the genetically-conditioned end, or "target," organ. The "target" organ with its receptors reacts promptly to a specific hormone to produce the substance or changes for which it has been genetically "programmed." Differences in the amounts of hormone required to produce specific effects occur between species, but the basic effects thus produced are often similar. A wide range of reactions to certain hormones exists.

Another important fact to recognize in the use of reproductive hormones is that hormones produced in a certain organ or gland do not, when injected, affect that organ or gland directly. In other words, endocrine disturbances of the ovary do not respond directly to the ovarian hormones, but if curable usually respond to the pituitary or uterine hormones. For example ovarian hormones act in a direct manner on the tubular genitalia and in an inhibitory manner on the anterior pituitary gland through their indirect effect on the central nervous system and hypothalamus. The amount of hormone, the frequency of dosage, and the time of injection in relation to the stage of the estrous cycle have profound influences on the effects produced.

Many external sensory stimuli act upon the central nervous system and hypothalamus and effect reproduction. These include: light, and sight mediated by the eyes, sound, or vocalization, mediated by the ears, smell mediated by the nose, state of nutrition, physical stimuli including cold and heat and the amount of work, stress as mediated by the release of glucocorticoids from the adrenal gland, tactile stimuli as obtained by mounting and intromission and possibly others. The olfactory stimuli have been called "pheromones."¹⁰ Certain drugs, as well as hormones, can effect the centers in the central nervous system and produce changes in reproductive physiology. In the central nervous system, spinal cord and hypothalamus are numerous interacting reflex arcs, and centers concerned with reproductive behavior and with production of releasing factors, peptides or neurosecretions that result in the release of the tropic hormones from the anterior pituitary gland after they pass to the

adenohypophysis through the hypophyseal portal system. Such centers, often located in or near the hypothalamus, also control the release of prolactin from the anterior pituitary gland and oxytocin and vasopressin from the neurohypophysis or posterior pituitary gland (see Figure 102). The blood supply to the hypophysis and hypophyseal portal system used to carry releasing factors or neuroendocrines from the hypothalamus to the adenohypophysis has been described.⁵

In the last 20 years much work has been done to elucidate the relationship of the hypothalamus and its releasing factors to the central nervous system and the adenohypophysis.^{3,6,8} These releasing factors (RF) are small peptides that like the other hormones are not generally species specific. The hypothalamic releasing factor or hormone in ACTH is CRH, corticotropin releasing factor; for TSH is TRH, for FSH and LH is GnRH, and for STH or GH is GRH. In regard to prolactin a hypothalamic factor inhibiting its release from the adenohypophysis, PIF or PRIF has been described. GnRH, gonadotropin releasing hormone, is a decapeptide that has been synthesized and produced commercially as "**Cystorelin**." GnRH is sometimes referred to as LHRH or LHRH/FSHRH because the single hormone acts on the adenohypophysis to release both luteinizing hormone (LH) and follicle stimulating hormone (FSH).⁶ Both GnRH ("Cystorelin") and human chorionic gonadotropin (HCG) are equally effective in the treatment of cystic ovaries in cows.^{3,6,8}

The principal or major endocrine gland controlling the reproductive organs and functions is the adenohypophysis. The pituitary gland is composed of two principal parts. The anterior lobe or adenohypophysis is quite vascular. Cells in this lobe produce the gonadotropic hormones and control the activity of the gonads. The posterior lobe or neurohypophysis is divided into the pars nervosa and pars intermedia. The latter structure is small and apparently of limited importance. The pars nervosa, the major portion of the posterior lobe, is attached to the floor of the third ventricle or hypothalamus by a stalk or infundibulum. Thus the anterior and posterior lobes of the pituitary gland are separate and distinct in origin, structure and functions. (See Figure 102.)

Anterior Pituitary or Adenohypophyseal Hormones

There are 6 major adenohypophyseal hormones that have been isolated and are obtainable in a nearly pure form at the present time:

ACTH—adrenocorticotrophic hormone.

Prolactin—this hormone promotes lactation and certain other metabolic and possibly gonadotropic functions.⁶

STH or GH—somatotrophic or growth hormone.

TSH or TTH—thyroid-stimulating or thyrotrophic hormone

FSH—follicle-stimulating hormone

LH—luteinizing and luteotropic hormone

MSH—melanocyte—stimulating hormone—this seventh hormone is of little importance
(FSH and LH are the gonadotropic hormones.)

All of these hormones are complex proteins in nature and are water-soluble. A review of the literature on the histology and physiology of the anterior pituitary gland reported that there were three principal cell types composing this endocrine gland; basophilic cells, acidophilic cells and chromophobe cells. FSH, LH, TSH, and probably ACTH are produced by certain basophilic cells. Somatotrophic or growth hormone and prolactin are produced in the acidophilic cells.^{3,6,8}

The adrenocorticotrophic hormone is essential for the maintenance and functioning of the adrenal cortex. It is sometimes called the "stress" hormone because it stimulates the production of glucocorticoids from the adrenal cortex. Besides its other functions, this latter hormone raises the blood sugar level and lowers milk production. This explains the value of ACTH and the glucocorticoid hormones in acetoneuria or ketosis. The adrenal cortex is capable of synthesizing the gonadal steroid hormones as well as the glucocorticoids. The effects of stress on the reproductive system have been reviewed.⁴¹ **The thyrotrophic hormone** is essential for the functioning of the thyroid gland and the regulation of metabolism by its stimulation of thyroxine production. **The somatotrophic or growth hormone** is concerned with body growth; moreover, it has been shown to be intimately concerned with udder development and lactation. Somatotropin causes growth of the long bones, affects protein metabolism by increasing nitrogen retention by the body, and markedly influences carbohydrate metabolism. This hormone in the cow is probably more concerned with lactation than is prolactin. Recent studies have shown that natural or recombinantly-derived bovine growth hormone when injected into cows the third month of lactation in daily doses of 25 mg increased milk production 10 to 13 percent and improved feed efficiency 9 to 15 percent.^{2a,c}

The two anterior pituitary hormones concerned with reproduction are FSH and LH, the gonadotropic hormones. Probably prolactin should not be listed as a gonadotropic hormone in domestic animals.⁸ **FSH or fol-**

Figure 102. Diagram of the Neuroendocrine Control of Reproduction in Female Animals.

Luteal-stimulating hormone is necessary for the growth of the Graafian follicles and the production of estrogens in the ovary. The secretion of this hormone was formerly thought to be inhibited only by progesterone from the corpus luteum, by testosterone from the interstitial cells of the testes, or by estrogen from the follicular cells and fluid. This was considered to be a "feedback" effect of the steroids on the central nervous system and hypothalamus preventing the secretion of GnRH. For this reason in castrated animals or postmenopausal women, the plasma levels of circulating FSH and LH are high. Recent studies have indicated that a nonsteroidal substance

in the follicular fluid has an inhibitory effect on FSH secretions and plasma levels in mares and ewes.^{28c} Luteinizing hormone (LH) is released in a pulsatile or episodic pattern or fluctuations.⁶ **LH, luteinizing or luteotropic hormone** causes ovulation and growth of the corpus luteum from the granulosa cells of the ruptured Graafian follicle. The basophilic delta cells of the anterior pituitary gland produce LH and probably FSH.^{3,6,8} The continued secretion of LH is necessary to maintain the corpus luteum and the secretion of progesterone to continue pregnancy in the cow. LH is probably luteotropic for all domestic animals.⁸ Prolactin is also luteo-

tropic. LH and probably FSH secretion and release can be stimulated by the drug, clomiphene.¹³ The following drugs can inhibit or prevent LH release and ovulation: antiadrenergic agents like dibenamine; anticholinergic agents like atropine; tranquilizers like chlorpromazine; psychic energizers like iproniazid; anticonvulsants, sedatives and anesthetics like barbiturates; and analgesics like morphine. These drugs act in a variety of ways on the cells of the C.N.S. to prevent or inhibit the release of LH. FSH and LH are synergistic in their action on the gonads. **Prolactin** is primarily involved in the initiation and possibly the maintenance of lactation. It is believed to be intimately connected with maternal instincts in mammals and broodiness in hens. It may be luteotropic in ewes.^{8,37}

Because of the many essential hormones produced by the anterior pituitary gland, it has been often called the "master gland" or "motor" of the endocrine system. In the light of recent studies this designation is questionable as it is obvious that the pituitary gland is controlled by the higher reproductive "centers" in the central nervous system. Clinical abnormalities of this gland produce many and varied effects. Since the hormones produced by this gland are complex proteins, they cannot be produced synthetically and have no effect when taken orally inasmuch as they are destroyed by the proteolytic enzymes in the digestive tract. DuVigneaud, however, won the Nobel Prize in chemistry in 1954 by synthesizing the neurohypophyseal hormones, oxytocin and vasopressin which are complex polypeptides made up of 8 amino acids. Other workers are busy studying the structure of other pituitary hormones and it is likely more may be synthesized. Repeated injections of heterologous anterior pituitary hormone products into animals may result in the production of antihormones, with the result that the injected hormone is neutralized or no longer effective. This is probably of little importance in most animals and seldom occurs unless repeated injections of these proteinaceous hormones obtained from animal sources are administered.^{7,32,42}

The adenohypophyseal content of LH is highest in cattle, sheep and cats and lowest in horses and man.⁸ Of the domestic animals, the cow and ewe secrete the greatest amount of prolactin. It has been shown that the timing of the release and the amounts of FSH and LH hormone released is very important in the initiation of ovulation and the number of ova released. The blood serum of castrates contains an increased amount of FSH because neither testosterone, estrogen, nor progesterone is inhibiting its secretion. Large prolonged injections of these latter steroid hormones suppress pituitary gonadotropic hormones and cause small, atrophic gonads. Smaller

doses of estrogens or progesterone may cause cystic ovaries. The urine and serum of pregnant women from about 30 to 60 days after the last menstruation and the serum of pregnant mares from about 40 to 120 days of gestation contain large amounts of gonadotropic hormone human chorionic gonadotropin (HCG) and pregnant mare serum gonadotropin (PMSG) or equine chorionic gonadotropin (ECG), respectively. In the mare this hormone is not excreted in the urine. In humans these gonadotropic hormones are produced in the chorion of the placenta and called chorionic gonadotropins; in the mare they are produced by the endometrial cups of the uterus, which originated from the chorionic cells, and are called equine gonadotropins.

The equine gonadotropic hormones from pituitary glands and pregnant mare serum are predominately follicle-stimulating in character although a small amount of LH is present.^{34a} Sheep and pig pituitary gonadotropic hormones are predominately luteinizing in character although some FSH is present. Chorionic gonadotropic hormone from the urine of pregnant women is almost entirely luteinizing in character.

The biologic sources of the gonadotropic hormones are: human chorionic gonadotropin, HCG, from the urine of pregnant women is sold under many trade names such as "Follutein" (Squibb), and is prepared and packaged in the dry state in a sealed glass vial. This is reconstituted with a saline solution before use. In liquid form it retains its potency for several weeks or months if kept at refrigerator temperature. In rare instances anaphylactic reactions are observed in animals into which this product is injected. These reactions are most common in animals previously treated with this form of gonadotropic hormone. Human menopausal gonadotropin HMG, from urine is also used as a source of gonadotropin high in FSH.^{4b} **Anterior pituitary gland** extracts or pituitary gonadotropic hormones, FSH and LH are prepared from the pituitary glands of sheep, horses and pigs. Some of the more common veterinary preparations are "Vetrophin" (Diamond), a sheep pituitary product; "P.L.H." (Armour); and equine pituitary gonadotropin products such as FSH (Armour). These are purified and prepared in sealed vials as a dry powder and reconstituted with a saline solution at the time of use. Anaphylaxis following the use of these products is unusual. **Equine gonadotropic hormone** or pregnant mare serum gonadotropin, PMSG or PMS or equine chorionic gonadotropin (ECG)^{34a} is serum that is collected approximately every 10 days, between 50 and 100 days of pregnancy in the mare. The concentration of hormone is about 50 R.U. per ml. Repeated doses of this may cause anaphylaxis, especially in the cow. In the mare, rare cases of Theiler's disease

or infectious hepatitis have been reported to occur from 50 to 70 days to as long as 120 days after the use of this crude equine serum product.

PMSG in the mare's blood is present at 37 to 42 days of gestation and reaches a peak concentration at 70 days.^{4b} Shetland ponies have a concentration of 335,000 I.U. per liter of serum between 55 and 76 days of gestation. This is about twice as high as larger horses that have serum concentrations of 50,000 to 100,000 I.U./liter. Mares with twin fetuses have double the serum levels, 240 I.U./ml. vs 100 I.U./ml. of mares carrying single fetuses. Mares carrying mule foals produce only one-eighth as much PMSG as mares carrying horse foals. The mucoid secretion in the endometrial cups of the mares may contain 5,000 to 210,000 I.U./gm. of PMSG. Peak concentrations of HCG in human urine occur at 50 to 70 days of gestation when 20,000 to 450,000 I.U. of HCG per 24 hours of urine is excreted. After this period about 10,000 I.U. HCG is excreted daily to near term.

When the gonadotropic activity of the pituitary glands of man, horse, sheep, pig and ox were compared by assay on rats' ovaries highly sensitive to FSH the comparable percentages were 100, 35, 3, 2, and 1, respectively. When assayed on rabbits' ovaries highly sensitive to LH the comparable percentages were 100, 42, 62, 65, and 42, respectively. In the sheep, pig and cow FSH in the pituitary gland was low but LH was high. In the horse FSH and LH was high and in man FSH and LH were very high.

The principal use of gonadotropic hormones in animals is the administration of LH or luteinizing hormone in the treatment of nymphomania or cystic ovaries in cows to produce active corpora lutea and restore a normal estrous cycle. Other uses include the injection of luteinizing hormone at the time of estrus to hasten ovulation, or about 4 days after ovulation to increase the size of the corpus luteum and the amount of progesterone secreted. Injection of large doses of FSH or PMSG 4 to 5 days prior to estrus causes superovulation in the cow and ewe. The use of FSH to promote estrus in anestrus animals may be of value under certain limited conditions. Generally the results of this therapy for the treatment of anestrus have been poor. The value of gonadotropic hormones to produce descent of testes in cryptorchid animals is questionable. FSH and PMSG may be of value in producing estrus in sheep during the anestrus period in the spring and summer months and hastening the onset of estrus in lactating sows.

Protein hormones from the pituitary gland are ineffective if given orally because they are digested and broken down in the gut. They are water-soluble and may be given intravenously where they produce a rapid ac-

tion. These hormones given subcutaneously or intramuscularly are absorbed more slowly and provide a more prolonged effect. Protein hormones must be protected from thermal decomposition as they are heat-labile.

Posterior Pituitary or Neurohypophyseal Hormones

There are two neuroendocrine hormones secreted in the posterior lobe of the pituitary. **Oxytocin** produces its effect by contracting the smooth muscles such as those in the uterus, around the alveoli and lactiferous ducts of the mammary gland, and in the bladder and gut. This fraction of the posterior pituitary lobe was formerly called "obstetrical pituitrin." **Vasopressin** or "surgical pituitrin" causes contraction of the smooth muscle of the arterioles thus checking postpartum uterine hemorrhage and raising blood pressure. This is also an antidiuretic hormone, ADH. If ADH is deficient in the dog and cat,⁸ diabetes insipidus with symptoms of polyuria and thirst occurs. In this disease vasopressin is not present to regulate the water resorption from the glomerular filtrate in the kidneys.

Oxytocin and vasopressin or ADH are very similar in composition with 6 of the 8 amino acids in these two hormones being similar. Posterior pituitary hormone or extract is a stable extract of the posterior pituitary lobe containing both fractions, oxytocin and vasopressin. A combination of both fractions, rather than one alone, seems to give as good or better results than oxytocin alone for most conditions treated in the veterinary field. However, since oxytocin is produced synthetically, it is the one now generally available commercially for use in animals. These hormones are protein in nature and water-soluble. They are stable and are usually packaged in liquid form with a concentration of 10 or 20 U.S.P. (I.U.) units of each fraction per ml of the solution. Evidence of anaphylaxis following injection of oxytocin or vasopressin is rare in animals but it was seen occasionally when the former crude hormone extract was injected intravenously in the mare.

The posterior lobe hormones are produced by neurons or cells in the hypothalamus. The posterior lobe proper composed of terminal nerve endings only stores and releases the oxytocin and vasopressin. The posterior pituitary gland, or neurohypophysis, of the goat contains 10 to 15 units and a cow gland contains 30 to 40 units or more of oxytocin.²⁶ The half-life of oxytocin or vasopressin in the body is short, only 1 to 2 minutes. However, there are forms of ADH that slowly release small amounts after injection to control diabetes insipidus. The posterior lobe cells filled with a fine granular material,

release into the blood stream, by means of cell processes extending into the posterior lobe, the hormone represented by this granular material. This is an anatomical means of passing the hormone through the blood-brain barrier. The posterior lobe is not a distinct organ or gland but is a collection of terminal cell processes which store and release the hormone produced by the cells in the hypothalamus.^{6,8}

The principal use of oxytocin is to hasten the contraction and involution of the uterus after a dystocia or prolapse of the uterus. When used immediately after parturition, it may be of some value in the prevention of retained placenta. If oxytocin is to be used, it is essential that it be administered soon after parturition since by 48 to 72 hours the effects are slight as compared to the marked contractions produced within 12 hours or so after parturition when the uterus is still sensitized by the presence of many oxytocin receptors stimulated to develop by the estrogens produced by the placenta late in pregnancy.¹² For hastening involution of the uterus, oxytocin is superior to "Lentin" or the other ecbolics with the possible exception of ergonovine which acts more slowly. Oxytocin causes contraction of the smooth muscle or myoepithelial cells in the alveoli of the udder, to produce milk ejection or "let down" in heifers or cows that because of pain or for other reasons refuse to "let down" their milk even after stimulation of the udder by massage. The term "let down" is probably not proper because it infers the cow has voluntary control of milk ejection which she does not have. If 10 units or more are given intravenously the action is very rapid, with prompt "let down" within 30 to 60 seconds. Within this time the intra-cistern pressure increases from 30 to 40 mm to 60 to 70 mm of Hg. Under natural conditions, fright, pain or excitement apparently antagonizes, slows, or prevents the release of oxytocin by the posterior pituitary gland by a central nervous system block to oxytocin release or possibly by the release of epinephrine which causes a vasoconstriction preventing oxytocin from reaching the myoepithelial cells. In sheep and goats oxytocin release and milk ejection is not necessary for satisfactory milking.

The Ovarian Hormones

The hormones produced by the ovaries are: the estrogens, the progestogens, the androgens, and a nonsteroid hormone, relaxin. The first three are steroid hormones that are also produced by testes, adrenal cortices, and the placenta.^{13,30} The precursor for all steroids is pregnenolone which is derived from cholesterol.⁶ The further

biosynthesis of the steroid hormones proceeds to progesterone—testosterone—estradiol—estrone. In the circulation the steroids appear to be bound to binding proteins or globulins. The steroids are inactivated in the liver by conjugation.

The estrogens are steroid substances with the ability to produce estrum when injected parenterally into female animals, even in the spayed female. **Estradiol** and **estrone** are the natural biologic estrogens produced in animals by the cells of the theca interna of the Graafian follicle or the placenta.² The follicular fluid of a mature bovine Graafian follicle contains about 50 to 90 micrograms of estradiol per 100 ml of fluid. The amount of fluid averages 2 to 3 ml. per follicle. Estradiol from the Graafian follicle produces the clinical signs of estrum in the domestic animal. These include growth and keratinization of the vaginal epithelium, especially in bitches and queens, increased vascularity, edema, and growth of the endometrium, uterus and cervix, and increased sensitivity and amplitude of contraction of the uterine muscles. Under its influence the cervix relaxes and goblet cells in the cervix and anterior vagina secrete a large amount of clear viscid mucus in the cow and lesser amounts in the other species. The vulva relaxes and becomes edematous; this is especially noticeable in the bitch and sow. Estrogens increase the rate of migration of leucocytes into the uterine lumen and thus increases the bactericidal activity of the uterus during estrum. Thus the genital tract sensitized by the estrogens is in a state of readiness for copulation, which in turn stimulates the release of oxytocin. The greatly increased uterine contractions and characteristic mucus of estrum favor the rapid transfer of spermatozoa to the pavilion of the oviduct, and the viability and capacitation of the spermatozoa in the female reproductive tract. Certain reproductive tissues can't grow unless stimulated by estrogen. The uterus, vagina and mammary gland are tissues that are hormone dependent. Acting through the central nervous system, estradiol produces the typical clinical signs of estrum, including the female's acceptance of the male. Gonadal hormones not only bring sexual behavior to expression at estrus they also produce a differentiation or organization of neural tissues, before or soon after birth, that establishes the basic femininity, or masculinity of the individual animal.⁴³

Estradiol is responsible for the secondary sex characteristics of the female. It causes the growth of the duct system of the mammary gland. It has a definite effect on the deposition and distribution of body fat and it hastens the ossification of the epiphyses of the bones. Near the time of ovulation estradiol reaches a high enough level in the body to suppress FSH production and by

stimulating the release of GnRH and LH promotes ovulation.^{3,8} The high level of estrogens in the plasma of pregnant sows between 20 and 30 days of gestation comes from the blastocysts.^{3,6} During pregnancy the placenta produces an increasing amount of estrogen, especially the last several weeks before parturition that promotes the rapid growth of oxytocin receptors in the myometrium and mammary gland.¹² At this period estrogen initiates uterine tonus by stimulating the release of prostaglandins F_{2a} and potentiates the effects of the latter and oxytocin on uterine contractions,⁶ sensitizes the uterine muscle to oxytocin, relaxes the cervix, vagina and vulva, and the pelvic ligaments. Following parturition the level of estrogens drops rapidly. Estrogens are secreted in increasing amounts in the urine of the mare after 100 to 120 days of gestation as estrone and estriol and other forms. These are recovered as a commercial, biologic source of estrogens. The major urinary estrogen excreted in the cow is estradiol.³⁰ During gestation the action of a low physiologic level of estrogens on the pituitary gland may be necessary to help maintain the corpus luteum by stimulating the release of LH. The presence of progesterone during pregnancy prevents the occurrence of estrum.²

Being steroid in nature, the estrogens are soluble in oil and therefore are usually administered intramuscularly or subcutaneously. Estrogens may be implanted subcutaneously or intramuscularly in the form of a pellet, from which the estrogens are absorbed slowly over a period of several months. To be successful, this procedure requires a nearly sterile technique because if infection is introduced excessive connective tissue is built up around the pellet and absorption might be prevented. Other estrogenic preparations for injection are the aqueous suspension of fine particles of estrogen and the solution of estrogens in an alcoholic base or "Repositol" which precipitate when injected into the body tissues or come in contact with water. Following intramuscular injections of the aqueous suspension and "Repositol" products the fluid is rapidly absorbed, leaving fine particles of estrogen as a modified type of implant. These preparations are easier to administer but due to the fine size of the estrogenic particle it is absorbed faster than when in pellet form. Consequently injections must be repeated about every 5 to 10 days. The esterification of an estrogen will also reduce its rate of absorption and thus prolong its action. For example, the effects of stilbestrol in oil last 24 to 36 hours while the effects of estradiol dipropionate will last 24 to 48 hours and estradiolcyclopentylpropionate in oil, "E.C.P." (Upjohn) and estradiol valerate (Squibb) are effective over a period of 72 to possibly 96 hours or longer. In humans and animals

with a simple stomach, such as the dog and cat, the estrogens, like stilbestrol, may also be administered orally. Low levels of estrogens, such as 10 mg/day of stilbestrol, added to the ration of feeder cattle and sheep will increase the rate of gain and growth compared to rations not containing this hormone. The naturally-occurring estrogen, estradiol, is more rapidly destroyed than is stilbestrol when given orally.¹¹ All animals can absorb estrogens fed in their ration. Estrogens may be applied by inunctions and absorbed through the skin or from the uterus after intrauterine infusions.

There were formerly two types of estrogens available commercially; the naturally-occurring estrogens such as estradiol, estrone and estriol produced from natural sources such as the urine of pregnant mares and women, from the adrenals and testes of stallions and from the human placenta and amniotic fluid; and stilbestrol or diethylstilbestrol synthesized from various coal-tar derivatives and other steroids. Presently all types of estrogenic compounds are synthesized chemically for commercial purposes. In animals both compounds, estradiol and stilbestrol, are equally effective and desirable. While in humans estradiol is preferred because there are fewer undesirable side reactions. Milligram for milligram estradiol is about 10 times as potent as stilbestrol. Therefore a 50 mg. injection of stilbestrol is approximately equivalent to a 5 mg injection of estradiol. The U.S. Food and Drug Administration has banned the use of stilbestrol and other estrogenic growth promotants because of public health implications. A few steroidal nonestrogenic compounds as implants have been cleared for this latter use in animals.

The estrogens are probably the most widely-used hormones in veterinary medicine. They are used to evacuate the uterus in cases of a mummified fetus or pyometra in cattle, and to produce therapeutic abortion in all species. By increasing the uterine blood supply, increasing the contraction of the uterine muscles, and stimulating epithelial growth and the flow of mucus they aid in the treatment of such conditions as postpartum metritis and retained placenta. Estrogens have been shown to have a definite effect on the uterus and uterine infection by their ability to prevent, reduce, and overcome infection in the uterine cavity^{2,35} by their action on stimulating the passage of leucocytes and bactericidal substances from the leucocytes into the uterus.^{9,22,23} When administered soon after an undesired service, estrogens prevent conception by their effect on the oviduct and uterus and the transport of the fertilized ova by either tubal "locking" of ova or the expulsion, death or failure of implantation of the early embryo. All of these effects on the tubular portion of the genital tract characterize the action of estrogens.

The estrogens have also been used widely to produce signs of estrus in anestrus animals. This action is to be expected since proper doses of estrogens produce estrus or acceptance of the male even in spayed females. This artificial estrus cannot be regarded as physiological since ovulation does not occur unless the estrogen is given at the time in the estrous cycle at which ovulation would normally occur. Large or moderate doses of estrogens given at the time of estrus or ovulation often cause infertility because of their adverse effects on ova transport. Injection of estrogens in large doses over a period of time in virgin heifers or dry cows usually produces varying degrees of mammary development and lactation. The peak of production following the estrogenic initiation of lactation follows a week or two after the estrogen is withdrawn and milking has begun. This phenomenon is also observed occasionally in the natural state in newborn heifers and prepubertal heifers due to excessive assimilation of estrogens from the placenta or production of estrogen by the endocrine glands. Large doses of estrogen after parturition inhibit lactation and relieve congestion of the udder. It is also used in bitches at the end of their pseudo-pregnant period to relieve udder congestion and possibly other symptoms of pseudocyesis. Because of its effect on the muscles and epithelium of the genito-urinary system it is used in low doses in dogs affected with urinary incontinence. The estrogens are occasionally used in ointment form for their stimulating effect on epithelial tissues in obscure skin ailments or to produce cornification of the vaginal epithelium in certain types of vaginitis.

Excessive, prolonged or improper dosing with estrogens will produce cystic ovaries or nymphomania in cattle, abortion, atrophy of the ovaries and cessation of the estrous cycles. In cattle and sheep estrogens will cause the regression of the corpus luteum probably by suppressing LH secretion, by exhausting the LH levels in the adenohypophysis or by stimulating the release of prostaglandins. In the sow and horse estrogens prolong the life of the corpus luteum. Large amounts of estrogen produce edema of the vulva, excessive relaxation of the pelvic ligaments and other supporting structures, predisposing to prolapse of the vagina and rectum, and fractures of the pelvic bones. In the bitch excessive or prolonged doses of estrogens can produce a fatal anemia due to their toxic effect on bone marrow or cause cystic endometrial hyperplasia with secondary metritis and pyometra.

In animals the level of the gonadotropins in the pituitary, the length of the heat period, and estrogen threshold and excretion during estrus are strikingly parallel. The following order, from high to low is reported:

man, horse, hog, sheep and cow.²

Progesterone or the corpus luteum hormone, is a steroid hormone produced by the granulosa cells and by the corpus luteum. In many species the secretion of progesterone by the follicle begins before ovulation occurs¹³ and is continued by the mature corpus luteum since the half-life of progesterone in the blood is only 3 to 5 minutes^{8,17a,24,27} in cows and mares. Progesterone is also produced by the adrenal cortex and the placenta. Following ovulation the corpus luteum develops from the granulosa cells of the Graafian follicle and is maintained by the luteinizing (LH), luteotrophic or gonadotropic hormone of the anterior pituitary gland.^{9,39} Under the stimulation of the luteotropic hormone, the lutein cells produce progesterone. Progesterone secretion by the corpus luteum regulates the estrous cycle by inhibiting estrus and the ovulatory surge of LH and plays other important roles in the reproduction of domestic animals.³⁹ The corpus luteum is essential throughout pregnancy in the cow, doe, sow and bitch but for less than full term in the mare, queen and ewe. In these latter species the progesterone produced by the placenta maintains the latter stages of pregnancy.¹⁸

Progesterone causes the growth of the glandular system of the endometrium of the uterus and the uterine secretions ("milk") from the endometrial glands for the nutrition of the ovum, and the attachment of the embryo. It maintains pregnancy by producing a favorable environment for the survival of the developing embryo and inhibiting the motility of the uterus. By causing an inhibition of the LH and FSH or gonadotropic hormones from the anterior pituitary gland, it prevents estrus, ovulation, and the occurrence of the estrous cycle and maintains pregnancy. However enough FSH is released so that follicles may form even during the luteal phase of the estrous cycle, and also during early gestation in some domestic animals especially the mare. Even ovulation often occurs during these two periods in the mare. Research has indicated that progesterone may act with estrogen to stimulate ovulation by promoting the release of LH.³ Small amounts of progesterone injected during early estrus in the cow hasten ovulation.²⁰ Progesterone probably acts with estrogen in most species to cause signs of estrus and acceptance. If progesterone from a previous corpus luteum is lacking, the first ovulation is usually characterized by a "silent" heat. This is seen in the early part of the breeding season in sheep, in prepubertal heifers, and in the postpartum period in the cow.⁸ The endometrium and uterus, when under the influence of progesterone during the luteal phase of the cycle, are much more susceptible to infection and provide a favorable environment for bacterial development.^{2,35} Pro-

gesterone causes the development of the alveolar system of the udder. Following the first half of the period of pregnancy in women and in animals such as the mare and ewe, progesterone for the maintenance of pregnancy is produced by the placenta, and the corpus luteum becomes small and inactive. In other species, such as the cow, sow and doe, the corpus luteum is essential during most if not the entire period of pregnancy in order to prevent abortion inasmuch as apparently little progesterone is secreted by the placenta.³⁹ Because of its ability to inhibit keratinization of the vagina, to prevent sensitization of the uterus, and to prevent estrus, progesterone secreted by the placenta and corpus luteum prevents or possibly counteracts the action of estradiol also produced in large amounts during late pregnancy. In the nonpregnant bitch and queen progesterone produces changes characteristic of pseudopregnancy. The radioimmunoassay is a highly sensitive test for progesterone in milk and plasma that has been described under pregnancy tests in cows, does and mares (see Chapter II). This test is quite accurate at 21 to 23 days post service especially in nonpregnant cows. Progesterone concentrations in dairy products are associated with the milk fat levels.¹⁷

Progesterone is produced synthetically. Progesterone is prepared in an oily base, in a "Repositol" form, or in finely-divided particles in an aqueous base. The oily preparation is effective for 24 to 48 hours when injected intramuscularly; while the latter preparations are effective for about 3 to 7 days since the finely divided particles precipitate in the tissues.

Progesterone is used to prevent or control habitual abortion due to an actual or possible progesterone deficiency. It may be used to promote conception the first 20 days of gestation in the cow. In the mare, ewe, cow, sow, bitch and queen, progesterone or synthetic progestogens can be injected or fed orally and prevent estrus from occurring by suppressing the release of the gonadotropic hormones, for as long as the injections or feeding are continued.³⁹ However, conception rates at the estrus following its withdrawal have been lower than in non-treated animals. Progesterone has been used experimentally to maintain pregnancy in animals in which the corpora lutea have been removed. If injections are continued beyond the normal length of gestation, prolonged gestation and fetal death may result. Progesterone has a "calming or tranquilizing" as well as an antiandrogenic effect and has been used for a variety of aggressive or antisocial behavior problems in dogs, cats, mares and stallions by the author and others.²¹

Relaxin is a water-soluble polypeptide hormone apparently present in the ovaries, probably the corpus lu-

teum, placenta and uterus during the late stages of gestation and is responsible, along with estrogen, for the relaxation of the pelvic ligaments and cervix necessary for parturition in sows, ewes, cows and possibly dogs.^{3,5,8} In the pregnant guinea pig and gopher it is able to cause resorption of the pelvic symphysis. This relaxation effect is brought about by an enzymatic depolymerization of the ground substance or collagen.

Prostaglandin (PG) was first described in 1934 after it was found in human semen. Prostaglandins are potent biologic agents found in many body tissues. Since they usually act locally, they don't usually conform to the classic definition of a hormone. Phospholipids in cell membranes give rise to arachidonic acid, a fatty acid which is the precursor for the major prostaglandins F_{2a} and E_2 . Glucocorticoids can inhibit the formation of arachidonic acid from phospholipids. Aspirin, phenylbutazone and other nonsteroidal anti-inflammatory agents can inhibit the formation of prostaglandins from arachidonic acid. Other important and highly active metabolites of the arachidonic cascade^{2a,11,19} are the thromboxanes, prostacyclins, and the leukotrienes that, together with the prostaglandins, produce a variety of effects on the reproductive, circulatory, respiratory and other systems and cause inflammatory reactions in joints and other tissues. Prostaglandins are even present in the corpus luteum.¹⁹

Prostaglandins play a number of important roles in reproduction including: gonadotropin release, ovulation in certain species, regression or luteolysis of the corpus luteum to control the estrous cycle, produce uterine motility and contraction, oxytocic effects, at parturition and in sperm transport.^{3,5,8,11,39b} Prostaglandins are also involved in cervical "ripening" and relaxation at the time of parturition in mares, ewes and women. In the periparturient sow postaglandin (PGF_{2a}) is released from the placenta and uterus causing luteolysis of the corpus luteum and a decline in plasma progesterone together with a marked rise in relaxin, and a further rise in prolactin and estradiol.^{25a} In most large domestic animals prostaglandin is elevated for a number of hours before parturition but in the mare its elevation closely coincides with delivery.¹¹

The uterine prostaglandins are produced by the endometrium from arachidonic acid under the influence of estrogens and oxytocin. The regulation of the estrous cycle by the luteolytic effect of the uterine formation of prostaglandin is a complex mechanism that differs between species. Prostaglandins are short-lived and after they enter the general circulation they are metabolized very rapidly by enzyme action. The prostaglandins used for luteolysis and estrus synchronization have no effect on the

ovum, ovulation, sperm cells or the fertility of the subsequent breeding that occurs 2 or 3 to 10 days after the injection in the mare, cow, ewe and doe.¹¹ The prostaglandins do not cause luteolysis in sows until after the twelfth day of the estrous cycle⁸ and they are even more limited in value in the bitch and queen for synchronizing estrus.

After ovulation in the cow, ewe, sow and mare the corpus luteum matures rapidly and produces progesterone that prevents estrus for the duration of the cycle. Prostaglandins can only cause luteolysis of the mature corpus luteum after about the fifth or sixth day after ovulation in the cycling cow, doe, mare and ewe. In the cow, ewe and doe, endogenous prostaglandin F_{2a} from the endometrium travels to the corpus luteum by passing from the uterine vein to the ovarian artery which lie in close apposition. In the cow one-fifth of the required systemic dose of prostaglandin if infused into the uterus will cause luteolysis by this local pathway.²⁸ In the mare this local venoarterial pathway is not present so prostaglandin from the endometrium reaches the corpus luteum by the systemic circulation. In both instances the prostaglandin constricts the blood supply to the corpus luteum and acts directly on the luteal cells to produce luteolysis.^{5,8,6,11,17b,19,28} If the animal conceives then the early embryo or blastocyst secretes hormones or substances that prevents the formation of prostaglandins in the endometrium and maintains pregnancy by the persistence of the corpus luteum, often called "maternal recognition of pregnancy." Similar persistence of the corpus luteum is observed in chronic uterine infections or pyometra,^{39b} hysterectomy performed during the luteal phase of the cycle and in rare cases of congenital hypoplasia of the endometrium and caruncular areas in heifers in which the endometrium is unable to produce prostaglandins.

A number of techniques or agents have been shown to induce the secretion of prostaglandins in cycling and even pregnant animals and cause the involution or luteolysis of the mature corpus luteum. In the mare these include: manual dilation and manipulation of the cervix, natural breeding of a mare after administering a large dose of estrogen, douching the uterus with 500 ml. or more of physiological saline^{5,39b} and taking an endometrial biopsy. These techniques probably stimulate the release of prostaglandin by the equine endometrium and a normal estrus occurs within 3 to 10 days. In the cow these procedures include: injecting daily doses of oxytocin between the second and sixth day of the cycle,^{8,19,39b} injecting 5 to 10 mg. of estradiol valerate when a mature corpus luteum is present either during an estrous cycle or during early pregnancy, introducing an infectious agent, an irritating solution such as weak Lugol's iodine or an

intrauterine device (IUD) within a few days after estrus and the resulting stimulation of the endometrium causes a release of prostaglandin and the development of a short 8 to 10 day estrous cycle. It is possible that in exogenous estrogen therapy that LH release from the anterior pituitary gland is also suppressed. It is also possible the introduction agents into the uterus or dilating the cervix introduces bacteria from the caudal reproductive tract into the uterus resulting in endometritis and prostaglandin release.

A number of stable prostaglandins (PGs) and their analogues have been produced commercially and are used therapeutically to cause luteolysis of the mature corpus luteum after the fifth or sixth day postovulation to produce estrus or estrus synchronization or abortion in the mare, cow, ewe, doe and sow.^{3,4,39b,40} (See Chapter V.) Prostaglandins are not effective when the corpus luteum is immature and developing. PGs are also used to evacuate the contents of the uterus in pyometra of the cow and bitch, and a mummified bovine fetus. Prostaglandins are also used, especially in sows, to induce parturition (See Chapter VI) and to treat "persistent" corpora lutea or "pseudopregnancy" in mares.^{11,39b} The prostaglandins available commercially have now been officially approved for use in lactating dairy cows. These products include: "**Prostin**," "**Lutalyse**" from Upjohn Company which is prostaglandin F_{2a} (dinoprost tromethamine) for mares and cows, respectively, with suggested doses of 5 to 15 mg. (10 mg.) for mares, 15 to 35 mg. (25mg.) for cows, and 7 to 15 mg. (10 mg.) or less in ewes, does^{11,33} and sows. In mares this product causes mild to moderate side-effects lasting for up to one hour of sweating, increased heart and respiratory rate, defecation, urination and discomfort due to increased peristalsis.^{28b} Other prostaglandin analogues that do not cause these side-effects include: "**Equimate**" (fluprostenol, ICI 81,008) from Haver Lockhart Lab with a dose rate for mares of 250 ug; "**Synchrocept**" (prostaglandin, RS 9390) from Diamond Lab with an equine dose rate of 2 mg., and "**Estrumate**" (cloprostenol, ICI, 80996) presently from Imperial Chemical Industries with a bovine dose rate of 500 ug. and for ewes and does 125 ug.

After the injection of prostaglandins into mares, cows, and ewes or does that are cycling normally and have a mature corpus luteum, after 5 to 7 days postestrus, the corpus luteum regresses and a normal fertile estrus usually occurs. In mares this is 3 to 12 days later with most mares showing estrus within 2 to 5 days and ovulation 6 to 12 days after the injection. In ewes and does estrus usually occurs 2 to 3 days post injection.³³ In cows estrus usually occurs 2 to 5 days later or at about the same time as they would if the corpus luteum had been expressed

manually.^{5,6,8,11,19} Estrus synchronization is generally more precise after two treatments with prostaglandins, in the mare 12 to 14 days apart, in the cow 10 to 12 days apart, in does 11 days apart and in sheep 8 to 11 days apart. In mares 2,500 IU of HCG may be injected 6 days after the prostaglandin to promote or "pinpoint" ovulation which usually occurs 24 to 48 hours later.¹¹

Other Endocrine Glands

Other endocrine glands that are associated with reproduction are the thyroid, adrenal, and the pineal gland. Pheromones also exert endocrine effects on reproduction.

The thyroid gland secretes thyroxine and triiodothyronine, composed of iodinated amino acids, under the regulation of the thyrotropic or thyroid stimulating hormone from the basophilic beta cells in the anterior pituitary gland after release by TRH from the hypothalamus. Thyroxine and triiodothyronine have been synthesized. The latter is more active and potent.¹³ The thyroid gland contains large amounts of iodine. In humans hypothyroidism is believed by many to be associated with sterility, infertility and abortion. Thyroid activity is necessary for normal reproductive functions. In the United States thyroid abnormalities such as goiter are most common in the iodine-deficient areas around the Great Lakes and the northeastern part of the country. Goiter or an enlarged thyroid is produced by excessive stimulation of the thyroid gland by TSH when the gland cannot meet the body's need for thyroxine. Hypothyroidism causes a low metabolic rate that is believed to have an adverse effect on human fertility and pregnancy and often is associated with obesity.

Since thyroxine and triiodothyronine are quite expensive when obtained from animal sources or synthesized, and because there has been little work to show the need of these in various sterility or impotency problems in animals, its use is limited. Some veterinarians have indicated thyroprotein may benefit males and even females that lack libido. This could be related to overconditioning. An iodinated casein was developed with about a 3-percent thyroxine potency. "Protamone" contained thyroxine and triiodothyronine.⁸ This has been marketed by the Cerophyll Laboratories in Kansas City, Missouri. In daily doses of 1 gm per 100 lbs. of weight it may be fed to livestock, in which it produces a definite increase in the basal metabolic rate, as shown by an increase of 5 to 20 percent in milk production together with a higher percentage of milk fat in lactating dairy animals (Chapter IV). Because of the cost, dangers and restrictions associated with its feeding to increase milk production, the use of thyroprotein has been limited. It causes a marked

loss in weight in fat animals. Preliminary clinical studies in cattle suggest thyroprotein or triiodothyronine may be of value in certain types of female infertility such as "silent" estrus,⁸ or prolonged infertility associated with a steer-like appearance. In males, especially old, fat males, it may increase their activity and reduce their weight. In some males this may result in some improvement in sexual desire. However, the same purpose can usually be accomplished by restricting the rations and increasing exercise. The use of iodinated casein for reproductive diseases in livestock appears limited. Thyroid function tests are now available, although costly, for domestic animals.⁸

The adrenal gland, composed of the medullary and cortical portions, secrete hormones that have profound effects on other body systems and functions and thus may indirectly affect reproduction.⁴¹

The adrenal medulla secretes adrenalin, or epinephrine, which has been synthesized; it is protein in nature and water-soluble. This hormone stimulates the sympathetic nerves, whether the sympathetic nerve of the organ is excitatory or inhibitory. In cows adrenalin may prevent the normal "let down" of milk by preventing oxytocin release from the posterior pituitary lobe. It causes a relaxation of the estrogenized uterine muscle in the cow. In other species it may cause contraction of the gravid or nongravid uterus. Epinephrine has been used by some veterinarians to control hemorrhage following the manual removal of the corpus luteum in the cow, but there is no pharmacologic justification for its use in this condition.

The adrenal cortex secretes steroidal hormones, such as corticosterone or cortisol that control glycogenic activity and protects the individual against various stresses, and desoxycorticosterone or mineralo-corticoids that control electrolyte and water metabolism. These hormones have no direct effect on the reproductive organs but glucocorticoids in moderate or large doses may cause abortion or premature birth, especially late in gestation in the cow, ewe and doe. The adrenal cortex, which originates from mesodermal cells closely related to the embryonic gonadal cells,⁴¹ secretes androgens, estrogens and progesterone in small amounts.⁸ Progesterone is a precursor of cortisol. Stress factors on the female cause an increased secretion of cortisol mediated by CRH from the hypothalamus and ACTH from the anterior pituitary gland. Transport stress significantly increased the occurrence of estrus in sows.⁴¹ Increased ACTH may be a factor in the cause of bovine cystic ovaries. High levels of cortisol from the fetal adrenals is closely associated with the onset of parturition in the cow and ewe. In rare instances tumors of the adrenal cortex may secrete sufficient androgens to cause masculinization or virilism in

a female. In the cow, because of the increased demands of the body for cortical hormones during gestation and the first third of the lactation period, the adrenal cortex is usually larger than normal for that length of time.

The pineal gland or body, attached in most animals by a short-stalk to the roof of the third ventricle of the brain is thought to be an endocrine gland in animals like the horse and sheep that are seasonal breeders. Current reviews^{5,6} reported that although much more research is necessary, evidence indicates that the pineal gland, stimulated by light by neural pathways from the eye, may secrete melatonin or a polypeptide. In mares melatonin acts as an inhibitor, or in ewes^{32b} as a stimulator of the gonadotropic centers of the hypothalamus to regulate the breeding season in these photoperiodic species. Intramuscular injection of 2.5 mg of melatonin daily into ewes hastened the onset of the fall breeding season or extended the length of the breeding season in the spring.^{32b}

Pheromones are odoriferous substances, external "chemical messengers," that, although they don't meet the definition of a hormone, serve as communication media between animals.^{5,8} The sex pheromones come from modified skin glands like the preputial glands in the boar and the glands at the base of the horns in bucks. The urine apparently contains pheromones in dogs, cattle, swine and sheep, as well as saliva in boars, as do other skin glands of the external genitalia and other body regions in the dog and horse. The development of these pheromones occurs with puberty and the production of estrogens and testosterone. A pheromone present in the vaginal secretion of bitches in estrus that attracts dogs and stimulates them to mount the bitch is methyl p-hydroxybenzoate.^{18b} The flehmen stance observed in horses, and ruminants is believed to provide the vomeronasal organs, with their sensitive odor receptors in the nasal passages, concentrated pheromone laden air from the urine or perineal region by closing the external nares. Tongue movements in cattle prior to the flehmen stance may force fluids, that often contain urine from estrous females being "teased," from the oral cavity into the incisive pits and fissures and into vomeronasal organ.^{25a} These olfactory stimuli along with other acoustical, visual and tactile stimuli provide both the female and male animals information on the sexual state of the other that is transmitted to the brain and hypothalamus. These odors present at estrus can be recognized by other species.^{25b}

The hormones concerned with reproduction in the male animal are described in Chapter XVIII.

Puberty

Puberty may be defined as the age or time at which the generative organs become functional and reproduc-

tion may occur. Puberty does not signify full or normal reproductive capacity, which develops later. In the male, puberty is indicated, along with other secondary sex changes, by the ability to copulate and produce sperm. In the female animal, it is characterized by the appearance of estrus and ovulation. The time of onset of puberty in animals is greatly modified by environmental and genetic factors. A high plane of nutrition hastens the onset of estrus especially in cattle and horses. A low plane of nutrition or deficiencies of various nutrients as well as disease factors will delay puberty. Exposure to stress conditions especially during the cold months of the year delay the onset of puberty. In certain animals such as sheep which have a limited breeding season puberty does not occur until that season, at which time the animal may be nearly fully grown. Inbreeding tends to delay puberty while crossbreeding tends to hasten its occurrence. Brahman and Zebu cattle reach puberty 6 to 12 months later than the European (*Bos taurus*) breeds. The larger breeds of cattle and horses tend to have a later onset of puberty than the smaller breeds.^{3,6,8,4,6,15,16} The age at puberty was less variable than the weight in gilts on a high and low plane of nutrition. In 3 groups of 21 calves each, fed on the following three levels of nutrition, 140 percent, 100 percent, and 60 percent, as based on Morrison's standards,^{13,14} the heifers on the high level of nutrition reached puberty with the first estrus at an average of 37.4 weeks of age weighing 580 lbs., the heifers on the average level of nutrition reached puberty at 47 weeks of age weighing 597 lbs., and heifers on the low level reached puberty at 65 weeks weighing 502 lbs.

The attainment of puberty is a slow, gradual process. Graafian follicles must attain a fairly advanced stage of development before the gonadotropins are effective. Puberty depends upon the release of the gonadotropic hormones from the anterior pituitary gland. Injection of these hormones into prepubertal animals may cause precocious sexual maturity. The gradual nature of the processes leading to puberty is cited in the human, in which secondary sex characteristics develop before menstruation occurs, and menstruation takes place for a period of time before ovulation occurs.^{2,1} In 53 Holstein heifers with a mean interval from birth to the first ovulation of 296 days and a mean weight of 609 lbs, "silent" estrus was exhibited in 74 percent of the heifers at the time of their first ovulation.⁷

Puberty in most of our domestic animals, especially those reared and fed under the most artificial conditions occurs much earlier than does sexual maturity or full or normal reproductive capacity. Most animals that normally give birth to 2 or more young at a time are less fecund immediately after puberty than they are later.^{2,1}

Yearling ewes usually have only one lamb. Primiparous gilts usually have smaller litters than 2- to 4-year-old sows. Fertility denotes the ability to produce young, while fecundity denotes the number of young produced. Fertility is reached at puberty but fecundity increases with age to maturity and then later in life decreases. Early fertility and high initial fecundity usually indicates that an animal will have a good reproductive record in the future.

Because of environmental influences, frequently estrum occurs at such an early age that if conception occurred parturition would be disastrous due to the small size and lack of development of the dam. Young female animals should not be bred until their body development ensures a normal gestation and parturition. Heifers should probably be bred according to size and weight rather than by their age. Puberty is more closely related to weight than age in domestic animals, except swine. Dairy cattle usually reach puberty when their body weight is 30 to 40 percent of adult weight, beef cattle 45 to 55 percent and sheep 40 to 60 percent of adult weight.⁶ Small breeds reach puberty earlier than large breeds.⁸ It has been recommended that Holstein and Brown Swiss heifers not be bred until they weigh about 750 lbs., Ayrshires about 650 lbs., Guernseys about 550 lbs., and Jerseys about 500 lbs.⁹ Heifers may reach this size from 10 to 24 months of age depending upon feeding levels and management practices. Rapid pubertal growth in Holstein heifers started during the seventh month after birth. By the tenth month this rapid growth of the genital tract terminated and subsequent growth was much slower.³ By proper feeding and management it may be possible by early breeding of heifers at 10 to 15 months of age and mares at 2 years of age to produce one additional calf or foal per female.

At the onset of puberty the gonadotropic hormone levels rise due to an increase in amplitude and frequency of periodic pulses or releases from the anterior pituitary gland. This rise is followed by gradual increases in levels of the gonadal steroids, estrogens and testosterone. Antral follicles must have formed to get this latter response in the female. Ovulation requires a high level of estrogen to cause an LH or gonadotropic surge.⁶ In the cow and ewe and possibly the mare, a "silent" estrus and ovulation may precede the first observed estrus.^{3,8} Some workers believe a small amount of progesterone from a regressing corpus luteum is necessary along with the estrogen from a mature follicle to produce psychic estrus.⁸ Based on rectal palpation and careful observation of 37 peripuberal heifers,⁸ signs of behavioral and physiological estrus without standing for mounting and without ovulation were observed 38 times before the first standing estrus. The cycles were all the same approxi-

mate duration, 20 days, despite the following conditions. Of the 245 cycles studied 7 percent had a silent estrus, 25 percent had a nonstanding estrus and 68 percent had a standing estrus. Anovulation occurred in 14 percent of the cycles, cystic follicles in 11 percent, cystic corpora lutea in 14 percent and normal corpora lutea in 61 percent of the cycles. Anovulation was associated with the signs of first estrus in nearly 50 percent of the heifers and then declined rapidly at subsequent cycles. Some anovulatory follicles progressed to cystic follicles. A normal corpus luteum was detected at the first estrus in 35 percent of the heifers and increased in subsequent cycles. Thus anovulation may be responsible for failure of conception.

Control of puberty in animals is presently largely limited to nutritional and environmental factors. Other lesser factors might include control of the photoperiod in seasonal breeders, heterosis or breed selection and social-sexual interactions between males and pubertal females. The hastening of the onset of puberty in gilts and possibly heifers by the presence of males is largely conditioned by the male sexual odor or pheromone present in the urine and by stimulation of the hypothalamic-pituitary axis.^{5a,b} The use of sex steroids and gonadotropic hormones to hasten the onset of puberty have not as yet proven to be practical or successful.^{2,5}

The onset of puberty in the domestic animals is as follows:

Horses—10 to 24 months, average 18 months of age, depending on the breeding season.

Cattle—6 to 18 months. Heifers in rare instances may come in estrum as early as 3–4 months of age, or if kept in a cold environment on a low level of nutrition, the first estrum may not occur until 24 months of age. In Brahman heifers puberty occurs at 19 to 27 months of age.¹⁵

Sheep—6 to 12 months, usually in the fall but depending on the breeding season.

Swine—5 to 8 months, average 6 months.

Dogs—6 to 12 months, average 7 to 10 months.

Cats—6 to 16 months, average 11 to 12 months, depending on the breeding season.³

Since puberty occurs before conception, normal gestation and parturition can take place, most well-grown dairy heifers are not bred until they are 14 to 18 months of age. Beef and poorly-grown dairy heifers may be bred from 18 to 24 months of age. Fillies should not be bred until 2, or preferably 3, years of age. Gilts, unless well grown, should not be bred before they are 8 to 9 months of age. Ewe lambs under 12 months of age should not be bred. It is generally considered undesirable to breed bitches on their first estrum or bitches or queens before

they are a year old. Following breeding of the pubertal animal, the nutritive level during the first gestation should be adequate to continue normal growth and development so by the time of parturition complications such as dystocia do not occur.

The Estrous Cycle

In all species of domestic animals that have reached puberty there is a definite physiologic functional rhythm of the reproductive system, called the estrous cycle. Although each species has its own peculiarities regarding their estrous cycle pattern, basically all are similar. The estrous cycle lasts 16 to 17 days in the ewe, 20 to 21 days in the cow, doe and sow and 21 to 23 days in the mare.⁶ The estrous cycle is commonly divided into 4 phases or periods that blend one into the other. Some authors prefer to divide the estrous cycle into two periods the **estrogenic or follicular phase** comprising proestrus and estrus and the **progestational or luteal phase** comprising metestrus and diestrus.^{3,5,6,8}

Proestrus is an ill-defined period during which the Graafian follicle is growing under the influence of FSH and producing increasing amounts of estradiol. There are increases in the growth of cells and cilia lining the oviduct, in the vascularity of the uterine mucosa, and in the thickness, edema and vascularity of the vaginal epithelium, with cornification occurring in some species, such as the bitch and queen. In the bitch, the increased endometrial vascularity is characterized by bleeding. In the bitch and sow the vulva becomes definitely edematous and swollen. There is a gradual relaxation of the cervix and an increased secretion of viscid, slimy mucus from

Figure 103. Heifer in Estrus—Standing to be Mounted.

Figure 104. Normal Genital Tract of a Heifer in Estrus—Note maturing follicle in the right ovary and regressing C. L. in the left ovary. (Courtesy K. McEntee.)

the goblet cells of the cervix and anterior vagina and from the uterine glands. In the cow and mare, the sticky, dry mucus of the preceeding period changes during proestrus to a milky, viscid mucus, and finally to a clear, transparent, stringy mucus late in the proestrous period. There is an increased excretion of estrogen in the urine and a beginning decrease of progesterone in the blood.³ The corpus luteum is undergoing rapid vacuolization, degeneration, and decrease in size in the mare, cow, ewe, doe and sow. The marked increase in growth of the epithelial tissues, of the activity of the musculature of the reproductive tract, of the secretion of mucus, and of the vascularity of the endometrium and vaginal mucosa is spoken of as the building-up period. It is produced by the secretion of increasing amounts of estradiol. Late in this phase of the cycle the female animal usually exhibits interest in the male.

Estrus is the fairly well-defined period characterized by sexual desire, immobility in the presence of, and the acceptance of the male by the female domestic animal. (See Figures 103 and 104.) This period begins with the time of the first acceptance and ends with the last acceptance of the male. During this period the female will usually seek out and accept the male. The Graafian follicle is large and mature. The ovum undergoes certain maturational changes. Estradiol from the maturing Graafian follicle produces changes in the tubular genital tract that reach their culmination in this period. The uterine tubes are tonic, the epithelium mature, and the cilia are active; contraction of the uterine tubes is occurring; and the fimbriated end of the uterine tube is assuming a close affinity to the Graafian follicle. Increased amounts

of tubal fluid is being secreted. The uterus is erect, turgid, and some species, edematous. The blood supply to the uterus is increased; the mucosa is growing rapidly, and mucus is secreted. The vaginal and cervical mucus is greatly increased. The mucosa is pink and congested, due to the increased vascularity. The cervix is relaxed and slightly edematous. The mucosa of the vagina is greatly thickened with many cornified epithelial cells being desquamated in certain species, such as the bitch and queen. The vulva is relaxed and edematous in all species, but most noticeably in the bitch and sow. Strings of mucus may hang from the vulva and tail of the cow. Toward the end of this period there may be an increase in leucocytes migrating into the uterine lumen. In domestic animals the elevation of estrogen to a peak in the absence of progesterone triggers the release of luteinizing hormone, the LH surge, near the onset of estrus that causes ovulation a day or so later.^{3,6,8} In most species the rupture of the mature ovisac or ovulation occurs toward the end of this period of estrum. In the cow and ewe ovulation occurs about 24 to 30 hours after the onset of estrus, 35 to 45 hours in sows, 4 to 6 days in mares,⁶ 24 to 48 hours in bitches and 24 to 30 hours after coitus in the queen. In certain species that do not ovulate spontaneously, such as the cat, rabbit, and ferret, ovulation does not occur until coitus and/or mounting takes place; hence in the queen estrum may be prolonged 7 to 10 days in the absence of a male. The acceptance of the male during estrum is due to the influence of estradiol on the central nervous system, producing the characteristic behavior patterns of receptivity in the various female animals. Female as well as male sexual behavior patterns are not sex-specific and that under certain conditions each exhibits the behavior patterns of the other.¹³

Metestrum or postestrum is a poorly defined period following estrum during which the corpus luteum grows rapidly from the granulosa cells of the ruptured follicle under the influence of the luteinizing hormone (LH) of the anterior pituitary. Metestrum is largely under the influence of progesterone produced by the corpus luteum. The presence of this hormone, by inhibiting the secretion of FSH by the pituitary gland, prevents the development of more Graafian follicles and the immediate development of another estrum. During metestrum in some species the epithelium of the vagina loses most of its new growth through desquamation. In the cow, during the early part of metestrum the epithelium over the caruncles of the uterus is very hyperemic and some capillary hemorrhage occurs. This is called postestrua or metestrua bleeding or "menstruation." This is not similar to true menstruation in primates which occurs at the time of progesterone withdrawal and is associated with a loss of the superficial layers of the endometrium. In cattle postes-

trual bleeding is associated with estrogen withdrawal. The mucous secretion decreases and the glands of the endometrium grow rapidly. Toward the middle to the end of metestrum the uterus becomes rather soft and pliable, due to a relaxation of the uterine muscle. In bitches and queens this stage includes the pseudopregnant period. In the species having diestrual cycles, including the cow, ewe, doe, sow and mare, the length of metestrum is about equal to the time it takes for the ova to reach the uterus or about 3 to 6 days. In the bitch and queen the pseudopregnant period may last about 50 to 60 days and 30 to 40 days, respectively, after which the corpora lutea regress and an anestrus of varying length occurs. In the queen that is not bred ovulation and corpus luteum development doesn't occur and the follicles become atretic. Several cycles of this sort may occur in the cat before a period of anestrus sets in. Bitches and queens do not have diestrual periods.

Diestrum is the longest phase or period of the estrous cycle in domestic animals including the cow, ewe, doe, sow and mare. The corpus luteum is mature and the effects of progesterone on the reproductive tract are marked. The endometrium becomes thicker and the glands hypertrophy. The cervix is constricted and the vaginal mucus is scant and sticky. The mucous membrane of the vagina is pale. The uterine muscle is relaxed. Late in this period the corpus luteum begins to show retrogressive changes and gradual vacuolization. The endometrium and its glands atrophy or regress in size. Beginning development of the primary and secondary follicles and finally proestrus occurs. In certain species that are not polyestrous, anestrus may occur.

Anestrus, when referred to in connection with the physiologic estrous cycle, is usually characterized by quiescent, functionless ovaries and reproductive tract. Anestrus is eventually followed by proestrus. Anestrus is observed physiologically in most mares during the winter months and in the ewe during the late spring and summer months. In the bitch and queen a physiologic anestrus period lasting several months may occur two or three times a year. The term anestrus is used, therefore, to differentiate it from diestrus, which lasts only a week or so and is characterized in the cow, sow, and other polyestrous animals by a mature corpus luteum. During anestrus in the mare the uterus is small and flaccid. The cervix is usually slight to very relaxed and the vaginal mucus is scanty and sticky. The vaginal mucosa is pale and the cervix is pale. Some follicular activity of the ovaries may develop but a mature follicle and ovulation seldom occur during the anestrus period.

The relative lengths of these various periods of the estrous cycle in domestic animals are approximately as follows:^{3,8}

	Estrum	Metestrum
Cow	12 to 24 hours	3 to 5 days
Mare	4 to 7 days	3 to 6 days
Sow	2 to 4 days	3 to 4 days
Ewe	1 to 2 days	3 to 5 days
Bitch	9 days (4-12)	
Queen	8 days without coitus ² 5 days with coitus ³	

	Diestrum	Proestrus
Cow	13 days	3 days
Mare	6 to 10 days	3 days
Sow	9 to 13 days	3 days
Ewe	7 to 10 days	2 days
Bitch	75 days (51-82) ¹	9 days (3-16)
Queen		2 days (1-3)

¹Anestrus—125 days (15-265) follows pseudopregnancy.

²Days to next estrus—14 to 21.

³Days to next estrus—42 (30-75).

(See also the Reproductive Tables at the end of this Chapter.)

Animals may be divided into three classes according to their estrous cycles. **Monestrous** animals are those animals having one estrous cycle per year. These are usually wild animals. **Polyestrous** animals are the domestic animals such as the cow, sow, and mare that have frequent periodic estrous cycles throughout the year. During the late fall and winter months the mare, especially the pony mare,⁵ usually has an anestrus period without estrous cycles. **Seasonal polyestrous** animals are those, like the ewe, that have periodic estrous cycles during only certain seasons of the year. The bitch and queen are more nearly like the monestrous animals. The bitch may have 2 to 3 periods of estrus each year. Three estrous periods per year are not uncommon in small breeds of dogs. The queen may have several heat periods in succession if coitus does not occur. These recurring episodes may occur two or three times a year. This arbitrary classification of animals as monestrous, polyestrous, and seasonally polyestrous must not be taken as entirely accurate and precise.

Excellent nutrition and environment may cause bitches to show estrus at any month in the year, and more frequently than once or twice a year. In mares, these factors may result in successful service during any month in the year. In ewes, recent work reveals a probable subclinical abortive estrual cycle present in most ewes during anestrus, especially the latter part of this phase. Certain breeds of sheep such as the Dorset and Merino regularly have

two seasonal polyestrous periods in both the spring and fall. The fall season is more fertile than the spring and summer, and a greater percentage of ewes are cycling.^{3,21} Thus the present classification may be more a clinical than an actual classification. In swine and bitches and in most queens much of the lactation period is usually characterized by a lack of estrus, termed "lactational anestrus." This postpartum, "anestrus" period is prolonged in cows nursing calves.^{5,25}

Factors Affecting the Reproductive or Estrous Cycle

Factors influencing the onset of estrous cycles of domestic animals are many and varied and irregularities, especially in the length of the cycle, are frequently observed by veterinarians and farmers. These abnormal estrous cycles may commonly be a cause of infertility. The failure of mares to have normal estrous cycles was one of the most important causes of infertility in that species.⁸ Some of these irregular estrous cycles are due to definite and known causes while others still remain to be completely explained. The causes of irregular estrous cycles include:

Nutritive state—Any severe degree of inanition or starvation caused by a lack of TDN or energy or any nutritive deficiencies, especially those causing a loss of appetite such as phosphorus, cobalt, possibly iron, copper, iodine, protein and others, may impair or prevent the secretion of gonadotropic hormones by the pituitary gland and result in a failure of the estrous cycle. In cows anestrus, possibly due to the above deficiencies, may be associated with a low P.C.V. or hemoglobin below 9 mg/100 ml. of blood. In humans it is well known that starvation causes a cessation of the estrous cycle and amenorrhea before other body disturbances appear. In rats a 15 percent loss of body weight may stop the estrous cycle. In a nutrition experiment at Cornell, in which sodium chloride was withheld from cows for long periods, the animals became very thin and cachectic and estrous cycles ceased.

Seasonal Influences and Light: Most animals in the natural or wild state are usually seasonal breeders and parturition generally occurs in the spring and summer when the weather is most favorable for the young and when food is most abundant for the dam. Although domestication has altered this pattern in some animals, the natural tendency remains.

The horse and fur-bearing animals tend to come into estrus and breed during the spring months under the influence of increasing daylight. Even in the cow, which is polyestrous, the best breeding months in the northern

hemisphere are May, June, and July and the poorest December, January, and February.¹⁸ The reverse condition is seen in ewes and does in the northern hemisphere; most breeds come into estrus under the influence of decreasing daylight and are fall breeders. This seasonal breeding trait is regulated by the effect of light, through the medium of the eyes, possibly the pineal body, the hypothalamus and the anterior pituitary gland.^{5,11,2,5,21} The effect on the animal of the total daily amount of light is important in controlling the onset of the estrous cycle and breeding season of mammals. This is called sexual photoperiodicity. A recent report on light and its effect on the gonadotropic hormones in seasonal breeders shows that the length of the daylight period necessary for sexual stimulation does not require that light must stimulate the nervous system the whole light period. Light is most efficient at only a precise period of the 24 hour daylight through dark cycle. This sensitive period varies in the different species but apparently occurs 10 to 20 hours after dawn and requires a specific period of one to several hours of light.⁶ Further study of this phenomena is indicated for sheep, horses and possibly cats.

Animals taken from one hemisphere to the other change their breeding seasons in accordance with the amount of daylight. Ewes and does confined experimentally in a darkened shed for increasing periods of time during the summer months developed estrous cycles earlier than normal. The length of estrus decreased and the length of diestrus increased in horses toward the summer months, or the end of the breeding season.⁸ Gradually increasing the total daily hours of light up to 16 hours per day by artificial means will hasten the onset of estrous cycles by 40 to 60 days in mares in the spring of the year (See Chapter XIV, Infertility in the Mare). Possibly this amount of continuous light may not be necessary. At the beginning or end of the breeding season, cycle lengths in ewes were more often longer or shorter than the average of 14 to 19 days.²⁶ Similarly in mares abnormalities of the estrous cycle are seen most commonly early in the spring during the transitional period and late in the breeding season with excessive estrous signs frequently observed early in the season. In the seasonal breeders that respond to increasing or decreasing daylight there is a refractory period that occurs at the end of the breeding season.²¹

Temperature—the influence of environmental temperature has less direct effect than has the amount of light on reproduction in animals. It has been hypothesized that excessive heat during the summer months, causing decreased thyroid activity, may indirectly reduce reproductive efficiency in swine, possibly cattle and sheep. This has also been shown to be caused by the effect of

heat on the very early developing embryo. In the bull and ram "summer sterility" is due largely to the adverse effect of prolonged atmospheric heat on spermatogenesis. Excessive exposure to cold, together with a reduced feed intake during the winter months, may cause failure of the estrous cycle in young growing animals or animals on a borderline of nutritive intake, since this intake must largely be used to maintain the animals' body temperature and necessary activities. By using a temperature-controlled room kept at a temperature of 45–48° F the onset of the estrous cycle in ewes was stimulated so they came into estrus 20 to 50 days earlier than control ewes subjected to the same amount of light but kept in summer atmospheric temperatures.¹⁰ This was also effective in improving or maintaining the fertility of rams. Estrous periods in dairy cattle in the northern half of the U.S.A. are about 18 hours long,¹⁵ while in the Gulf States they are shorter, about 12 hours.¹² It was also noted that the length of the estrous cycle in cattle under hot conditions increased to 25 days as compared to 20 to 21 day cycles in cooler weather.¹¹

Age—In cattle and swine, the young female usually has a slightly shorter length of estrus and estrous cycle than has the adult animal. The ewe lamb will not show estrus until the fall hence the sexual cycles in this species depend more upon the season than upon the pubertal age of the young female. Senility accompanied by defective teeth and marked weight loss, often results in a cessation of the estrous cycle or anestrus. Old age itself is relatively seldom a cause for reproductive failure. Senile changes, such as the menopause in women, seldom occur in animals. Whereas cessation of reproduction in women is associated with a particular age at which the oocytes in the ovaries are largely depleted, this apparently is uncommon in animals.

Character of work—Horses that are worked or raced hard frequently do not develop regular estrous cycles until the severe work schedule is stopped and they are rested, preferably on pasture for several months. Cows that are very heavy producers of milk may not have estrous cycles for 3 to 4 months or more following parturition due to a negative energy balance. Thus, heavy continuous work is a stress that can result in anestrus.

Transportation stress in ewes⁶ and in gilts⁹ induced follicular growth and ovulation in a large number of animals within 4 to 6 days. This phenomena was not reproduced with ACTH injections but severe stress did cause cystic corpora lutea in the ewes. Estrus signs failed to occur in some ewes due to the absence of a regressing corpus luteum with the presence of some progesterone. The author has observed a similar reaction in some transported mares and cows.

Systemic diseases—Severe chronic wasting diseases, such as Johne's disease, tuberculosis, mange, actinomycosis of the jaw, severe parasitisms, and other diseases cause a severe negative energy balance, debility, emaciation and cessation of the estrous cycle.

Pathology of the uterus or cervix is a frequent cause for irregularities of the estrous cycle. In cattle such conditions as pyometra, fetal maceration, mummification of the fetus, and rarely mucometra may cause failure of estrum, and a persistence of the corpus luteum, with a cessation of estrual cycles. A similar effect may be produced experimentally by hysterectomies in cows, swine, does and ewes.²⁷ Early death of the embryo within 20 to 60 days after conception may cause symptoms of apparent failure of the estrual cycle.

Endocrine disturbances often affect the estrous cycle. Cystic ovaries in cattle are frequently a cause for cessation of the estrous cycle. Nymphomania or cystic ovaries in animals are also characterized by irregularities in the estrous cycle and by frequent or continuous estrum. Following calving, ovulations are often associated with a "silent" estrum. This is also observed in ewes and does at the outset of the breeding season and in heifers reaching puberty. It is believed that some of these "silent" estrums are due to an imbalance of estrogens and progesterone with the latter often lacking.^{17b} Short estrous cycles in the cow, long or irregular periods of estrum or lack of estrum, or long diestrous periods in the mare^{3,5,8} are probably of endocrine origin, but the causes for these abnormal long estrous cycles are not fully understood. A long estrous cycle of 25 days was produced in cows infused with an iodine solution on day 15 of the cycle.^{22,23} This was probably due to a lack of prostaglandin caused by damage to the endometrium. Short estrous cycles of 8 to 14 days in cattle have been produced experimentally by infusing the uterus with bacterial contaminants or viral agents such as IBR-IPV at the time of service, infusing the uterus with irritating iodine compounds about the third to sixth day after estrus, injecting large doses of oxytocin from day 2 to day 7 of the cycle, or surgically implanting a foreign object into the horn corresponding to the ovary containing the corpus luteum about the second or third day of the cycle. It is believed that these treatments affect the luteolytic mechanism especially by their stimulation of the production of prostaglandin by the uterine endometrium and possibly by inhibiting the release of L.H. and failure to grow and maintain the corpus luteum.^{15,19,22,23} Large doses of L.H. given during the middle and last week of the estrous cycle may prolong the corpus luteum and the cycle (See Chapter XIII, Infertility in Cattle). In rare cases pituitary, ovarian, and adrenal tumors and their production or inhibition of secretion

of certain hormones may cause marked changes in the estrous cycle.

Miscellaneous causes for irregularities in the estrous cycle include the individual variations between animals in each species. The individual variations are usually minor. However, Brahman and Zebu cattle may have very short estrous periods of only 3 to 6 hours. Copulation usually occurs at night. Pregnancy causes a prompt physiologic cessation of the estrous cycles. The presence of the ram, stallion, buck or boar hastens the onset of estrum when the male is placed with the females late in the anestrus season. This stimulating effect on the release of gonadotropic hormone is probably mediated by visual, auditory and olfactory stimuli to the hypothalamus.^{3,5,4,7}

Thus it can be seen that although the reproductive cycles of domestic animals are primarily under endocrine control they are greatly influenced by the external environment which acts through the central nervous system and the hypothalamus to initiate and regulate the release of tropic hormones from the adenohypophysis.^{3,5,4,8,1,20}

Coition or Copulation

Coitus or the act of copulation, includes the insertion of the erect penis into the vagina, intromission, and the subsequent ejaculation of semen. This takes place only during estrum in the domestic animals. An exception to this occurs in certain barren mares early in the breeding season that exhibit a prolonged period of acceptance punctuated occasionally by true estrum and ovulation. During coitus semen is ejaculated into the vagina and onto the external os of the cervix in the cow, ewe, doe and woman. In the sow most of the semen usually is ejaculated into the uterus since the long narrow penis of the boar enters and "locks" into the cervix.^{6b} During coitus in the bitch, vaginal and uterine contraction waves aid the intrauterine deposition of semen.³ In the mare the penis may be forced against the relaxed dilated cervix and some semen might be ejaculated into the cervix or uterus. At the time of coitus in the mare there is a negative uterine pressure capable of drawing about 80 ml. of fluid into the uterus through the relaxed cervix.⁵ This negative uterine pressure is observed clinically when examining infected, "windsucking" mares especially at the time of estrum. The insertion of the speculum causes a sudden ballooning of the vagina and sometimes the uterus. Bubbles of mucopurulent material may be seen being drawn into the cervix. At the time of intromission the mare can be observed to take a deep inspiration and draw up her abdomen to produce this negative pressure. Us-

ally after an equine service at which time 50 to 100 ml. or more of semen is ejaculated, only 10 or 15 ml. can be recovered from the vagina. This fact is of importance in explaining the cause for infertility in "windsucking" infected mares.⁵ Examining the vagina with a speculum just before service is not advised as this act causes ballooning of the genital tract and prevents the negative pressure normally produced at coitus by the penis sealing the vulva, from drawing the semen into the uterus. More work is necessary on this interesting observation. In the ram the processus urethrae does not enter the external os of the cervix of the ewe during coitus but is responsible for forcibly spraying semen over the cervix and cranial portion of the vagina.⁴

The duration of coitus in cattle and sheep is only a few seconds. In horses copulation is longer, lasting 10 to 30 seconds. In swine copulation takes 3 to 8 minutes with an average of about 5 to 7 minutes. In the dog coitus takes 15 to 30 minutes; the bulbus glandis enlarges slowly, until it is large enough to dilate the caudal portion of the vagina. The sphincter muscles of the vestibule and vulva then contract and the male is unable to withdraw the penis until the bulbus glandis is reduced in size. The male dog usually dismounts and faces away from the bitch during the latter part of copulation.³ In the cat coitus lasts 2 to 5 minutes. (See Chapter XVIII, Infertility in Male Animals.)

It is rather interesting that the structure of the penis is somewhat related to the duration of foreplay and coitus.^{2,2} In ruminants with a fibroelastic type of penis with small vascular sinuses, foreplay and coitus are very brief and the amount of semen ejaculated is small. In animals such as dogs, horses and primates the penis is characterized by extensive vascular sinuses and foreplay and coitus are of moderate to long duration. The exception to this observation is the boar that has a fibroelastic type of penis. The large amount of semen ejaculated in the boar may be a factor causing the prolonged period of coitus in this species. The dog and stallion also have fairly long copulatory periods and they also ejaculate relatively large quantities of semen.

The dangers of coitus to the female animal include the possibility of young, small heifers and fillies or even older females being injured by large or overweight males. These injuries may include fracture of the pelvis, spine, or limbs; dislocation of the hips; muscle or tendon sprains; or injuries to the limbs, udder, or teats. These injuries may be avoided by using smaller males, a breeding rack, or artificial insemination. In both the mare and cow the vagina is shorter than the length of the male's penis, but at the time of coitus the vagina stretches. In spite of this, occasional lacerations and trauma may be produced and

cause swelling, hemorrhage, discharge, and straining following coitus. In rare instances the penis of a bull or stallion may actually rupture the vagina of the female and cause a perivaginal inflammation or abscess with signs resembling acute traumatic reticulitis. Fatal peritonitis may rarely be observed especially when heifers are bred on pasture by a mature bull or large vigorous stallions are bred to small mares. Vaginal and hymenal lacerations with bleeding after service by a stallion occur more commonly during the peak of the breeding season because more mares are bred; the stallions are more experienced and require greater stimulation for ejaculation because of frequent services so thrust deeper with more vigor.

Occasional cases of vaginal rupture and penetration of the peritoneal cavity in the heifer and mare may not result in death, especially if the damage is diagnosed promptly. Treatment consists of stopping further services for a month or more and providing stall rest and tranquilization if signs of colic or discomfort is present. The mare should be given antibiotics and tetanus antitoxin. If signs of shock develop, cortisone and possibly intravenous fluids should be administered. If the mare has pneumovagina the vulva should be promptly sutured.^{6a}

When large stallions are bred to small mares, or when a vigorous stallion with a large penis is bred to average-sized mares, a stallion roll, or if this is not available a double roll of cotton, may be placed against the stallion's abdomen in front of the sheath to prevent too-deep penetration of the penis. In mares with a small vulva it may be necessary to lubricate the vulva to facilitate insertion of the penis. Vaseline or the ordinary water-soluble, neutral, tragacanth gum lubricating jellies are satisfactory. These lubricants should not contain antiseptics. Occasionally feces and other dirt particles are introduced into the vulva and vagina at the time of service and cause irritation and infection.

In a mare with a tipped or horizontal vulva, occasionally the erect penis of the stallion may slide over the vulva and enter the rectum, causing a rupture of the rectal mucosa or the rectal wall. This is called "false entry" and may produce a rapidly fatal peritonitis or a pelvic diverticulum that fills with feces and causes severe straining. This is favored in mares with a vulva that has been sutured by the Caslick technique and not opened sufficiently prior to service. A rectal examination immediately prior to service should not be performed as it stretches the sphincter muscles of the anus of the mare permitting the penis to readily enter the rectum. False entry may also occur in the sow, ewe, doe and cow but apparently it causes little harm in these species. In the

mare if the diverticulum is in the pelvic region caudal to the peritoneum, gentle, regular enemas of physiologic saline or antiseptic solution should be given to keep the diverticulum free of feces until healing takes place. Antibiotics and tetanus antitoxin parenterally are indicated. False entry can be prevented by proper handling of the stallion at the time of service to make certain by manual direction, that the penis enters the vulva.

Occasionally the withers of the mare may be lacerated by the teeth of a stallion or jack at the time of coitus. This can be prevented by muzzling the stallion or by placing a heavy pad over the withers of the mare. Many horsemen believe the stallion has given a "poor service" when he dismounts and the penis on being withdrawn brings with it an ounce or more of semen. Holding the stallion on the mare a little longer allows the size of the glans penis to be reduced and less semen withdrawn. This condition would be more likely to occur if the genital tract was ballooned with air before service, so that the semen was not drawn into the uterus but remained in the vagina. There is no proof that these occasional so-called "poor services" fail to result in conception.

Rarely a mare or cow may have a stenosis of the vagina due to a previous injury or to a hereditary defect of the vulva or vagina, such as "white heifer disease" with an imperforate hymen. In these animals coitus usually results in vaginal or vulvar lacerations and straining. The author has observed two gilts and a sow that died a few days to a week after natural service with severe peritonitis caused by the boar's penis entering the urethra and bladder and passing into a ureter where it caused a rupture about 2 to 3 inches cranial to the bladder. All of these females had cystitis with signs of straining, bloody urine, a swollen vulva, depression and anorexia shortly after an apparent normal copulation. The author has observed and others^{2b} reported cystitis and pyelonephritis in a heifer and a gilt following AI when the semen had been introduced into the bladder. The heifer had a segmental aplasia of the vagina.

Sodomy or carnal intercourse between man and the lower animals is of little importance to the veterinarian, since ordinarily this does not result in injury or disease to the larger animals. In small female animals such perversion may result in injury to the animal's genital canal.

Sadism or sexual perversion in some humans, usually male, may cause them to injure or mutilate, with sharp or solid objects such as broom handles and pointed sticks, the genital organs of animals especially the vagina or rectum of female animals such as mares, cows, goats or sows. Whenever the veterinarian is confronted with a case of injury to the genital organs or rectum of an animal he should attempt to determine the cause, keeping

this possibility in mind, especially if several similar injuries are diagnosed. These injuries are most often perpetrated when the animal is in estrum. Injuries of this type are rarely produced by coitus or by accident but must be caused by some person, usually of low or abnormal mentality, who has access to the animals when no one else is present.⁷

Ovogenesis or Oogenesis

The ovary, besides secreting the necessary gonadal hormones, produces ova. Oocytes are developed similarly in all domestic animals.^{3,5,6,8} Early in the first weeks of embryonal development the primitive large germ cells called primordial germ cells can be identified in the caudal extraembryonal entoblast or yolk sac.⁹ These primordial germ cells migrate by ameboid movement from the yolk sac across the dorsal mesentery to the genital ridges.^{1,2} This migration occurs in porcine and bovine embryos about 24 and 35 days of gestation, respectively.⁴ In a few more days the gonadal sex can be distinguished by the formation of the superficial tunica albuginea and the central location of the germinal cells, spermatogonia, in the primitive testes and the peripheral location of the oogonia in the primitive ovary.⁹ These oogonia multiply by mitosis after sexual differentiation and enter the prophase of the first meiotic divisions when they are called oocytes. The number of oocytes produced may be determined by the level or amount of FSH in the embryo.⁹ Oogenesis is the transformation of oogonia into oocytes. Oogenesis is completed before or shortly after birth in all domestic mammals.^{3,10,14} Sexual differentiation occurs at 30 days of gestation in the feline and porcine embryos, 35 days in the ovine embryo and 45 days in the bovine embryo.⁹ The period of oogonial mitoses, the end of which signifies the end of the major portion of the period of oogenesis, are 32 days of gestation to 37 days after birth in cats, 30 days of gestation to 7 days after birth in swine, 35 to 90 days of gestation in sheep and 45 to 110 days of gestation in cattle. At the end of this period of oogenesis the oocytes enter the first meiotic prophase where they pass through the leptotene and zygotene stage into the pachytene stage. In this stage the ova are surrounded by a single layer of follicular epithelium and these are called primordial follicles.

Thus at birth all female calves and lambs are born with their full complement of oocytes in primordial or older follicles and these are never replenished but only decrease in number during the life of the animal. Bovine oocytes may rest in this pachytene phase for years if the primordial follicle does not grow.⁶ In most species this

resting stage where the oocyte is in the primordial follicle is the dictyate stage.^{7,8,9,10}

In the late dictyate stage as ovulation time approaches, follicle growth and maturation occur. The ovum itself will grow and triple in size in order to provide nutrition for early divisions of the fertilized ovum (See Table 16).

Three types of follicles present at birth and throughout the life of animals are,^{3,4} primordial follicles in which the oocyte is surrounded by a single layer of follicle cells, growing follicles in which the oocyte is surrounded by two or more layers of follicle cells, and vesicular follicles having antrums or fully-formed vesicles. The numbers of germ cells or oocytes in the ovaries of individual cattle is highly variable ranging from 0 (complete sterility) to 700,000. Of 69 cattle examined from birth to

two years of age about 25 percent had 42,000 (0 to 73,000) germ cells, about 60 percent had 137,000 (76,000 to 218,000) germ cells, and about 15 percent of the cattle had 325,000 (223,000 to 724,000) germ cells.^{3,4} The numbers of primordial follicles in cattle remained fairly stable around 140,000 until about 4 to 6 years of age and then declined rapidly thereafter to 25,000 at 10 to 14 years and to near zero at 20 years of age. From 60 days after birth to 10 to 14 years of age the numbers of growing follicles per bovine animal averaged about 150 to 250 and the number of vesicular follicles 25 to 30. In cows over 15 years of age these numbers declined to 70 and 12, respectively. Normal vesicular follicles predominated up to 10 years of age in cows but after that time atretic vesicular follicles were in greater numbers. Two

Table 16. Developmental States in the Maturation of the Ovum*

Chromosome Number		Time Period	
Mitosis	2N	Primordial germ cells	Migrate to gonadal area in bovine embryo
			from 25–35 days of gestation
Meiosis		Oogonia	Multiplication occurs in bovine embryo
			from 45–110+ days of gestation
		Oogonia A	
		Oogonia A (resting)	
		Oogonia B	
		Oocytes, primary	
		Prophase I (1st maturation division)	
		Leptotene stage	
		Zygotene stage	
		Pachytene stage—bovine species	
	4N	Diplotene stage—porcine species	Resting stage

			Ova transport to uterus
	2N	Zygote	
			Atresia of nonovulating follicles

*After Rajakoski, Henricson and Rajakoski, Kennelly and Foote, Erickson (1965) and Mauleon.

**In bitches and probably mares the 1st polar body is released after ovulation and the 2nd polar body is usually not released unless fertilization occurs. This is probably why the canine ova remain in the oviduct 5 or more days.

***The male and female pronuclei in the rabbit duplicate chromosomes before syngamy thus the fertilized ovum is tetraploid for a very short period until the two-cell stage occurs.¹³

20-year-old cows that had produced 16 and 17 calves, respectively, were considered to be sterile at slaughter with one cow being anestrus and the other showing irregular cycles. The numbers of primordial follicles in these two cows were 100 and 2000, growing follicles 80 and 50 and vesicular follicles 10 and 7. Thus these old cows were approaching the menopausal state that occurs in women. Women had an ovarian oocyte population of 200,000 to 400,000. During the postmenopausal years a complete disappearance of oocytes occur.⁵

Since during the lifetime of a 10-year-old cow producing a calf each year about 30 to 50 ova might be ovulated it is obvious that most oocytes degenerate and die in a process called follicular atresia. Although degeneration of oocytes and follicular atresia may occur in the prenatal period in cattle, germ cell quality in primordial follicles remains high until 6 to 8 months of age and then it declines rapidly thereafter until at 4 years of age and older most oocytes or primordial follicles are in an obvious degenerative state. The process of bovine follicular atresia and oocyte degeneration is a very protracted process extending over a period of years.⁴ Oogonia and oocytes in the first stages of meiotic prophase disappear or degenerate during prenatal and early postnatal periods.^{3,9} Only those oocytes in the pachytene through dictyate stages remain into later life.

Further evidence was presented that following puberty the average bovine female has only approximately 240 oocytes in growing or vesicular follicles upon which she is dependent for the production of fertile ova throughout the rest of her life.⁴ Since the numbers of these growing or vesicular follicles was closely correlated with the total number of primordial follicles there may be a relationship between germ cell numbers and fertility in females. When the ovaries of fertile and infertile 5-year-old cows were compared, the average numbers of primordial, growing, and vesicular follicles present were 119,000 and 18,000; 78 and 35; and 211 and 54, respectively.⁴ In a study on genetic hypoplasia of the ovaries in Swedish Highland cattle normal yearling cattle had an average total of about 50,000 primordial follicles in both ovaries (range 6,000 to 100,000). Heifers with a unilateral partial hypoplasia and unilateral total hypoplasia had 23,000 and 19,000 primordial follicles, respectively, in both ovaries.^{11,12} Of 7 heifers with one ovary completely hypoplastic and the other ovary partially hypoplastic, two heifers had no primordial follicles and five had 100 to 400. In heifers with bilateral total hypoplasia, no primordial follicles were present. Animals with less than 500 primordial follicles did not ovulate. Animals with one hypoplastic ovary had definitely fewer Graafian fol-

licles than normal heifers and were more infertile. In freemartin cattle the gonads have no germ cells.³

Folliculogenesis and Ovulation

Under the influence of the gonadotropic hormones FSH and LH, especially the former, vesicular or Graafian follicles grow and develop. This development occurs in fetal animals, young animals prior to puberty, and even during the pregnancy period. Follicular growth and development culminating in the mature Graafian or vesicular follicle and ovulation occurs only in nonpregnant animals after puberty during a reproductive cycle under the influence of the gonadotropic (FSH-LH) hormone. However horses frequently ovulate during early gestation and diestrus and cows may very rarely do so. The exact mechanisms governing the follicles that mature and ovulate and those that fail to mature and ovulate but regress and become atretic are not understood.

Without the Graafian follicle and the secretion of estrogens and progesterone including some androgens from the granulosa and theca cells under the influence of FSH and LH, signs of estrus would be lacking, ova could not be released and corpora lutea could not form. Growth of the primordial follicles, those where the oocyte is surrounded by a single layer of epithelial cells gives rise to growing or secondary follicles and vesicular follicles or those with antrums called Graafian follicles. In Graafian follicles the oocyte has reached the dictyate stage of development in the cow.^{6,25} By this time the connective tissues around the growing follicle have organized into the theca which consists of an outer zone of stroma cells called the theca externa, and an inner zone of epithelial-like cells called the theca interna which later secretes steroid hormones including estrogens. As growth continues, the antrum forms and enlarges in the epithelial cells around the ovum. The epithelial cells lining this antrum form the membrana granulosa. The fluid in the follicle is called the liquor folliculi. This fluid is believed to be secreted by the granulosa cells. The actively growing Graafian follicle is responsible for its own ovulation by secreting estradiol that causes the LH surge that results in ovulation and the development of the corpus luteum.^{3,6}

In the early stages of the maturation of the ovisac, or follicle, the oocyte is in a mass of epithelial cells, called the discus proligerus, attached to the granulosa layer of cells. The egg and its adjoining granulosa cells are called the cumulus oophorus. Between the cumulus cells and the oocyte proper is the corona radiata, a compact layer

of cells surrounding the zona pellucida, which extends cytoplasmic projections through the zona pellucida to the vitelline membrane to provide nutrients to the oocyte for its maintenance and growth.^{5,27} The cumulus may be located projecting into the follicular fluid anywhere on the circumference of the membrana granulosa.^{5,25} As the follicle approaches maturation and ovulation, the cumulus oophorus either separates from the membrana granulosa and floats free in the follicular fluid or more often it is only tenuously attached. The ascent of the follicles to the surface of the ovary coincides with the appearance of the thecal layers. The theca interna develops a wedge-like cone that precedes the follicle through the ovarian stroma to the surface. In all species of domestic animal, except the mare, ovulation can occur over the entire ovarian surface. In the mare ovulation occurs only in the ovulation fossa or concave ventral medial portion of the ovary that is not covered by a dense tunica albuginea and mesovarium.^{5,14,21,24,29}

Ovulation takes place by a thinning process, usually avascularization and rupture, with slight bleeding, of the outer portion of the follicle wall and peritoneum. The ovum with the enclosing cumulus cells are washed out in the gradually-released gelatinous follicular fluid and are caught by or pass into the fimbriated end and ampulla of the uterine tube, where fertilization takes place.⁸ In the cow, mare and other species the outer thin follicular wall that usually feels tense and firm during proestrus and early estrus becomes more flaccid and soft just prior to ovulation.^{5,6} In rare instances the ovum and its cumulus cells may be caught and retained in the collapsing walls of the Graafian follicle at the time of rupture. This may be a rare cause for failure of fertilization.

In domestic animals a circumscribed avascular area appears on the apex of the follicle that projects above the surface of the ovary.^{6,3,4} This thins out until a fine transparent membrane bulges above the surface. This is the basement membrane separating the granulosa and thecal layers of the follicle. This breaks and the follicular contents ooze from the follicle. Collapse of the follicle walls doesn't occur until after the cumulus has passed through the small stigma in the surface of the follicle. Ovulation may require a few seconds to several minutes or longer depending on the size of the stigma and the location of the cumulus in the follicle.

Intrafollicular pressure is not the cause for ovulation.^{6,4} The stigma is small and nearly round or oval. There is no sign of tearing of the follicle wall. As noted above just prior to ovulation the follicle becomes more flaccid and less tonic. Observed ovulations are not violent eruptions. Where the intrafollicular pressures have been measured there has been no increase in pressure

prior to ovulation. Recent work presented evidence to indicate that ovulation was probably brought about by the release of LH that releases histamine and possibly prostaglandin⁶ causing ovarian hyperemia. This hyperemia may stimulate the release of proteolytic enzymes, such as collagenase into the follicular fluid which may be responsible for the separation of the cumulus from the side of the follicle. Thus the proteolytic enzymes weaken the wall of the follicle and the stigma or avascular area develops and ovulation occurs at the superficial projecting area where the wall is not supported by the ovarian stroma.^{15,23}

After the follicle ruptures and the ovum is released a slight amount of bleeding may occur into the follicle. This is then called the corpus hemorrhagicum in the cow, ewe and sow and other species. In the mare a large blood clot, which can be palpated per rectum, and may feel like a follicle, fills the large lumen of the follicle. This bleeding occurs through the follicle walls and not at the site of rupture of the follicle. In the cow fibrin "tags" may develop on the ovary or fine adhesions between the ovary and the fimbria may occur following ovulation. This has no effect on fertility. It is possible that the enzyme reaction that weakens the follicle wall to produce ovulation acts for a longer period of time in the mare and therefore a greater amount of bleeding occurs through the follicle wall after ovulation.

Ovulation is largely under endocrine control. Under the stimulus of FSH from the anterior pituitary a number of vesicular follicles begin developing. As these follicles develop, an increasing amount of estradiol is produced by the theca interna and is absorbed into the circulation of the body as well as being present in the follicular fluid. In the body estradiol produces the typical changes in the tubular portion of the reproductive tract seen in proestrus and estrus. It also produces the characteristic symptoms and manifestations of estrus or heat by its action on the central nervous system. Except for the follicles that are to mature, usually only one in uniparous animals and a moderate number in the multiparous animals, there is a sudden wave of atresia that strikes many different size follicles a short time, about 12 to 24 hours or possibly more, before ovulation of the mature follicle. Atresia of the small Graafian follicles begins in the oocyte while in medium and large Graafian follicles atresia begins with degenerative changes in the granulosa and theca interna with the changes in the oocyte developing slightly later.^{6,25} Obliterative atresia occurs in small and medium-sized follicles but in large follicles cystic atresia occurs in which the antrum and follicle fluid are reduced only after complete degeneration of the follicle wall with fibrotic changes in the theca. Follicular atresia can occur

at any stage of growth, and degeneration of the oocyte may start at any stage of atresia.¹⁶ Cystic atresia may occasionally be associated with a degree of luteinization of the cystic follicle.

The cause for the atresia of the "second rank" follicles and the mechanism controlling the number of follicles allowed to mature and ovulate are not known.

Progesterone produced in the Graafian follicle before ovulation may play an important role in cattle in the release of LH and ovulation.^{6-9,11} More work is required in order to elucidate the nature of the exact mechanism of ovulation in animals. Release of LH by the anterior pituitary is necessary for and causes ovulation of the mature Graafian follicle. A large amount of LH is released from the bovine anterior pituitary gland usually within 1 to 5 hours after the onset of estrus by the stimulus of a rising estradiol blood level produced by the maturing follicle.^{5,11,13,26}

The corpus luteum which was already developing from the granulosa cells lining the Graafian follicle at the time of ovulation grows very rapidly following ovulation. The production of progesterone by the corpus luteum then suppresses LH and FSH production. If fertilization and pregnancy take place, the corpus luteum is maintained by the secretion of luteotropic hormone or LH from the anterior pituitary gland and the lack of release of prostaglandin from the endometrium caused by the influence of the conceptus. If pregnancy does not occur, then the corpus luteum degenerates and, with the decline in the production of progesterone late in the estrous cycle FSH and LH are again produced and a new wave of follicles begins to grow followed by the onset of proestrus. The approximate minimum time required for the development of the follicles and ovulation in domestic animals is 3 to 4 days, as revealed by work on sheep, and the manual removal of the corpus luteum in the cow.

In the cow a wave of follicular growth with an accumulation of small Graafian follicles, less than 5 mm in diameter occurred during the third and fourth days of the cycle resulting in a large follicle 9 to 18 mm in diameter at the 13th day. A second-wave of follicular growth occurred between the 12th to 14th day with the production of small follicles 5 to 8 mm in size resulting in a single large follicle, 12 to 16 mm, at 16 days that usually ovulates 4 or 5 days later.²⁵ A wave of atresia follows each growth wave leaving in most cows only one large follicle. Thus it apparently took 7 to 9 days from early follicle growth to ovulation in the cow. This diphasic growth wave of follicles has not been reported in other domestic animals.

Recent studies have shown a continuous growth and atresia of large follicles during the estrous cycle in the

cow with an increased rate of atresia, growth and replacement from day 13 to ovulation, especially after day 18.^{5,12,19,28,30} Small follicles decreased from day 3 to 18 and medium sized follicles were most numerous day 13 just after blood estrogen levels rose at mid cycle. These studies did not support the previous two-wave theory of Rajakoski.²⁵ The corpus luteum has an inhibitory action on large follicles on days 8 to 13 even though medium-sized follicles increased. Apparently the largest active follicle in unipara exerts an inhibiting intraovarian effect on smaller follicles.¹⁹ The ovulatory follicle in the cow varies from 10 to 20 mm. in diameter and secretes large amounts of estradiol at the time of onset of behavioral estrus that promotes the LH surge.²⁸ The latter hormone acting on the LH receptors in the granulosa cells induces ovulation of the follicle.

Even though nearly all the reproductive function can occur without nervous innervation of the lower portion of the body, there is definite evidence that ovulation, as well as other phases of the reproductive cycle, are influenced by the nervous system in the intact animal. Heifers, when bred by a vasectomized bull, ovulated an average of 7.7 hours after the end of estrus as compared to 9.9 hours when not bred.¹⁸ The ovulation of heifers was delayed 24 to 66 hours by the administration of massive doses of atropine at the onset of estrus; but when chorionic gonadotropin, or LH was administered shortly after the atropine, ovulation occurred about 10 hours earlier than normal.⁷ This indicated that atropine prevented the normal release of LH from the pituitary. The administration of gonadotropic hormone during early estrus shortened to 1.25 hours the normal time of 10.5 to 12.25 hours from the end of estrus to ovulation.¹⁷ Progesterone given in 5 to 15 mg doses intramuscularly at the onset of estrus reduced the average length of estrus 3.6 hours, the average time from the end of estrus to ovulation 5.4 hours, and the average time from the onset of estrus to ovulation by 9 hours.⁸ Atropine blocked the effect of progesterone and this blocking action took place in the hypothalamus.¹¹ The LH release mechanism is stimulated by the action of estrogen, and in certain species other external factors such as coitus in the queen, affecting the hypothalamus.

Ovulation is spontaneous in all animals except the rabbit, cat, and ferret. In these latter species one or repeated mountings or intromissions may be required to release LH from the pituitary and cause ovulation. Ovulation in these species may be caused by stimuli, such as gently manipulating a glass rod in the vagina simulating coitus or by the injection of luteinizing hormone. Ovulation usually occurs at a fairly constant time following the stimulus of coitus or the injection of LH at estrus. In the

rabbit it occurs about 10.5 hours later, and in the cat about 27 hours later. This stimulus in the rabbit is apparently emotional and can be produced by the excitement of being mounted by another doe. It can also be produced by coitus when the vagina and vulva are anesthetized.²

When 25 I.U. of LH was injected intravenously into isolated mature female rabbits, 50 percent of them ovulated between 10-1/2 and 10-3/4 hours later. This therapy can be given to queens to terminate estrus. These are other examples of the way in which peripheral and central nervous stimuli affect ovulation.

With the exception of the cow, ovulation usually occurs before the end of estrus in all domestic animals that ovulate spontaneously. The cow, due to its low threshold for estrogen, remains in estrus only a short period and then an "estrous block" of central nervous origin develops and the cow goes out of estrus even though additional amounts of estradiol are being produced.¹ The approximate time of ovulation for the various domestic animals is as follows.^{2,3,2,9,8,11}

Cow and ewe—about 24 to 30 hours after the onset of estrus. In the cow this is 10 to 14 hours after the end of estrus.

Sow—about 35 to 45 hours after the onset of estrus.

Mare—about 4 to 6 days after the onset of estrus.

Bitch—24 to 48 hours after the onset of estrus.

Queen—24 to 30 hours after onset of estrus and coitus.

The ovum of the bitch and probably the mare don't extrude the first polar body for several days after ovulation at which time fertilization can occur.^{3,6,8}

Superovulation—Discovery of the gonadotropic hormones, and interest and research in embryo transfer have resulted in experiments on various means of inducing superovulation, or the release of numerous ova from the ovaries of uniparous animals. (See Chapter 20.) This can be produced during late metestrus, diestrus, and early proestrus by daily subcutaneous injections of FSH for 3 to 6 days, followed by an intravenous injection of LH, or, if timed properly so that the last FSH injection comes just before estrus, the cow may ovulate the numerous artificially produced follicles by means of its own secretion of LH.^{6,2,5a,5b} (See Chapter XX.) Superovulation can be produced in cattle by injecting 2,500 to 3,000 I.U. of PMSG intramuscularly on the 16th day of the cycle or when the corpus luteum is manually removed. Five days later 2,000 I.U. HCG may be given intravenously to promote ovulation although it is not necessary as the female's own LH causes ovulation. In sheep and goats 1,000 to 1,500 I.U. PMSG injected on the 12th day and 16th day of the cycle, respectively, will induce

superovulation in these species. In sows and mares FSH injections to cause superovulation is not yet satisfactory or practical. PMSG is of no value for superovulation in mares and presently is not available in the U.S. In cattle about 15 percent of the superovulated ova were morphologically abnormal.

By using prostaglandin preparations superovulation to obtain embryos for transfer is facilitated. Presently PMSG or more commonly a purified FSH gonadotropic product is injected into the donor cow on day 8 to 12 of the estrous cycle. The gonadotropic hormone (FSH) is given twice daily at gradually reducing doses for 5 days.² On the third day after the initial injection of either PMSG or FSH, a luteolysing dose of prostaglandin is administered with estrus occurring several days later. In cows the desired number of embryos produced is about 8 to 10. There are great sources of variation in the response of cows to gonadotropins and the number of ova or embryos produced. These variations have been related to the variable potencies of the gonadotropic hormones employed and the different breeds and ages of cattle used as donors. Further study is indicated.^{1,2}

Because numerous corpora lutea form following superovulation the bovine ovary may be five to ten times normal size. Thus it is recommended not to inject FSH into animals 4 to 5 days prior to estrus if superovulation is to be avoided. A cow given PMSG, "Gonadin" was bred and conceived 6 days later but aborted sextuplets at 6 months of gestation.²⁰ After repeated injections of gonadotropic hormones cows may become refractory to them unless a proper "rest" period is provided. Since antihormones are produced when impure products are used, repeated injections of the proteinaceous gonadotropic hormones may result in fewer ova being ovulated.

Ova (Embryo) and Sperm Transport and Fertilization

Ova transport—As ovulation approaches there is a marked increase in the tonicity, edema and motility of the fimbriae of the uterine tubes in domestic animals; the fimbriae nearly clasp the ovary in order to receive the egg. These effects are under the endocrine control of estrogen during the estrous period. Following ovulation, the cumulus oophorus which was liberated from the mature Graafian follicle is transported from the surface of the ovary into the uterine tube. This transfer is effected by the direct action of the cilia of the fimbria and infundibulum on the cumulus as well as the currents of fluid created by the beating cilia flowing toward the ostium of the uterine tube. Essential to these immediate transport mechanisms are the contractions of the smooth

muscle of the mesovarium and regular contractions that change the position of the ovary with respect to the infundibulum and fimbria.^{3,6,9,22,25}

The rate of transport of the ova through the ampullary portion of the oviduct to the area of the ampullary-isthmic junction is quite rapid and is probably accomplished in a relative few minutes, 8 to 30.^{3,6,8} This transport is effected by peristaltic and antiperistaltic muscular contractions of the smooth muscle in the ampulla together with ciliary activity under the hormonal control of estrogens. The cilia in the rabbit uterine tube beat at a rate of 1500 per minute. The beat of the cilia towards the uterus creates currents in the tubal fluid and the contractions of the uterine tube keeps the ovum in constant motion which aids in egg and sperm contact and fertilization.^{6,22,25} Sperm penetration of the ovum and fertilization which requires several hours, occurs in the ampulla of the uterine tube. The physiological significance of the oviduct fluid which is secreted in greatest amounts during estrus is not well understood.²⁵ Most of this fluid passes into the peritoneal cavity. Adhesions and obstruction or ligation of the distal or fimbriated portions of the bovine uterine tube causes hydrosalpinx. Some fluid may pass through the isthmus into the uterus.

The ova or eggs of domestic animals at the time of ovulation are one of the largest cells in the body and vary from 120 to 185 microns or 0.12 to 0.185 mm in diameter not including the zona pellucida.^{6,1,23} In ungulates the ovum contains very little glycogen but large amounts of lipid material; whereas in rodents the reverse is true. These materials are necessary for energy production to produce protein biosynthesis in the ovum. Certain ova may be defective and have obvious structural abnormalities including: small or giant ova, oval or flattened ova, ova with a ruptured zona pellucida, ova with large polar bodies or vacuoles within the vitellus, ova with an abnormal cytoplasm, abnormal-shaped ova, atypical 2-blastomere ova and etc.²³ These abnormal or degenerated eggs may be due to improper maturation of the oocyte, genetic or environmental factors or failure of polar body extrusion. The incidence of abnormal ova varies between the breeds and strains and is greatest in older females.^{6,23}

The cumulus and corona cells around the zona pellucida of the ovum in most domestic animals only persist for a few hours or less after ovulation and fall away in the oviduct. In the bitch and queen the corona cells may persist for several days. The protoplasmic projections from these cells into the zona pellucida are withdrawn soon after ovulation due to contact with fibrinolytic enzymes in the oviduct fluid. The cumulus and corona cells die and separate from the ovum aided by the ciliary and

muscular activity of the oviduct. Inside the zona pellucida is the vitelline membrane or vitellus which is similar to the plasma membrane of somatic cells. The zona pellucida is a homogeneous semipermeable structure surrounding the ovum composed of conjugated protein capable of being dissolved by proteolytic enzymes such as trypsin and chymotrypsin. After fertilization the vitellus shrinks and a perivitelline space is formed between the zona pellucida and the vitelline membrane into which the polar bodies are extruded.

Most ova of domestic animals have ovulated when the second maturation division has reached metaphase and the first polar body has been extruded. In the bitch and probably the horse, ova are ovulated as a primary oocyte and mature in the oviduct. The fertile life of ovulated ova in domestic animals is relatively short, 6 to 24 hours or less except in the bitch where they may remain fertile in the uterine tube for 4 or more days due to their delayed maturity.^{3,6,8} In cattle inseminated 2 to 4 hours after ovulation both the conception rate and the percentage of normal embryos at 35 days were 75 percent.¹¹ When insemination took place 6 to 12 hours after ovulation the conception rate was 60 to 75 percent but only 30 percent of the embryos were normal at 35 days. Insemination after 12 hours following ovulation resulted in conception rates that were very low, and normal embryos were unusual. A high rate of fertilization in cows inseminated at 13 hours post-ovulation in cattle but no fertilization at 16 to 22 hours postovulation was reported.³³ The loss of fertility or viability is not rapid or sudden and aging eggs may be fertilized normally but produce embryos that die early in gestation. With further loss of viability of the ovum, fertilization may be abnormal or fail to occur. Under usual conditions of estrus and natural service in situations where a male is present with the females, spermatozoa will reach the site of fertilization in the oviduct before ovulation and the arrival of the ova. Under conditions of artificial insemination this orderly sequence of events may be altered and infertility result. Fertilization of "old" eggs in swine is associated with polyspermy and abnormal development.²⁹

In domestic animals the eggs or ova remain in the oviduct in the ampullary-isthmic area for 3 to 4 days before passing rapidly through the isthmus and the uterotubal junction into the uterus. In the sow the ova may pass into the uterus in 1-1/2 to 3 days possibly associated with multiple ovulation.³ After rapid transfer to the ampullary-isthmic junction, swine eggs remain there for about 30 to 45 hours and enter the uterus 30 to 60 hours after ovulation.⁴⁰ Ovine ova remain in the ampullary-isthmic junction for 50 to 60 hours following ovulation due to the strong antiperistaltic contractions in the isthmus.⁶ In

most domestic animals fertilized ova require 3 to 5 days to pass through the uterine tube into the uterus; but may require 6 to 8 days in the dog, 5 to 9 days in the cat, possibly 6 days in the mare² and 2 to 3 days in the sow.^{1,3,6,8} An accelerated rate of uterine tubal transport of ova has been reported in superovulation in the cow possibly due to elevated steroid levels.¹⁶ The normal transport of ova through the uterine tube can be severely disturbed by injections of estrogen, progesterone or other drugs and anesthetics. The stage of the estrous cycle, the species of animal and the dose levels of the above agents all produce varying effects on the isthmus and the rate of ova transfer to the uterus.²⁵ Depending upon the dose of estrogen and the species injected some ova may be trapped or blocked in the ampullary-isthmic portion of the uterine tube, "tubal locking"; while in others the ova are rapidly passed into the uterus and are expelled through the cervix into the vagina.²¹ The failure to demonstrate "tubal locking" in a recent experiment may have been due to the very low dose of estradiol injected.¹⁶ These effects appear to be due to the reaction of the isthmic portion of the uterine tube to the injected hormone or drug. It has been suggested that edema in the isthmic area might play a role in tubal regulation of the time of transport, but muscular effects by the gonadal hormones seem more logical from the evidence.⁸ Under ordinary conditions the fertilized ovum or developing zygote remains in the uterine tube until the corpus luteum is formed and the endometrium is under the influence of progesterone so a proper environment and nutrition is available upon entering the uterus. If the egg is not fertilized it fragments into many irregular cytoplasmic segments and disintegrates in the uterus under the influence of phagocytosis. In the mare unfertilized ova may be retained in the uterine tube for weeks or possibly months. This trapping phenomenon has been reviewed² but no satisfactory explanation has been proposed other than the possibility that the fertilized ova by its "hormonal" secretions controls its passage through the uterine tubes.

Sperm transport in the female—In the cow, ewe, bitch and queen the ejaculate at coitus is forcibly sprayed over the cervix and anterior vagina forming a "seminal pool" in the cranial portion of the vagina. In the bitch the large ejaculate, 7 to 20 ml., is carried into the uterus through the relaxed cervix by the muscular activity of the genital tract. In the mare and sow, as described earlier, the semen at coitus is largely placed into the uterus. There is no evidence that seminal fluid passes from the vagina into the uterus in the cow, sheep, queen, doe or man.³⁹

After ejaculation the spermatozoa in the seminal plasma migrate or diffuse from the plasma into the mucus of the

female genital tract where they may be protected, nourished and transported. In the cow as much as 150 ml. or more of cervical mucus may be obtained at estrum. Bovine cervical mucus contains mucoids (amino acids, sugar and sialic acid), glycogen, protein, enzymes, globulins, salt, urea and very small amounts of glucose. Vaginal and cervical mucus in the other domestic animals under the influence of estrogens also changes from a tough tenacious consistency in diestrus or anestrus to a more liquid, viscid, stringy mucus during proestrus and estrum. This permits and favors sperm cell migration. The velocity of sperm cells in bovine cervical mucus at estrum is 56 microns per second, (3 mm./minute) versus 132 microns per second in saline.⁴² The "fern test" of cervical mucus is positive when mucus from the cow or other animals in estrum is smeared on a slide and allowed to dry producing a fern-like aborization due to the high NaCl and water content of the mucus at this stage of the cycle. No specific substance harmful to spermatozoa has been recovered from normal cervical mucus. Leucocytic phagocytosis, bacterial endotoxins, and abnormal pH may play a role in preventing the penetration of sperm cells through cervical mucus. "Hostile" cervical mucus is a catchy term loosely used to describe certain conditions affecting the cervical mucus in women.

The passage or transport of spermatozoa from the vagina through the cervix and uterus and into the uterine tube is very rapid, less than 15 minutes, in all domestic animals and man. Sperm cells in the bitch are at the uterine entrance of the uterine tubes 25 seconds after ejaculation.² Spermatozoa have been found throughout the bitch's genital tract within 20 minutes after the onset of copulation. This transport time was 8 minutes in the ewe.³⁶ It was demonstrated that in the cow spermatozoa were transported from the cervix to the ovarian ends of the uterine tubes in less than 2 to 4 minutes.^{45,46} This occurred whether the spermatozoa were living or dead and followed either natural or artificial insemination. The interval from ejaculation to the presence of spermatozoa in the uterine tubes was reported to be somewhat longer in species other than the cow, one-half to several hours.³ Spermatozoa could also gain entrance to the uterine tubes in cows and sows during the luteal phase of the cycle.²⁰

Movement of the spermatozoa in the uterine lumen is due to strong contractions of the uterine wall augmented by the release of oxytocin at coitus or artificial insemination.⁴⁶ Fright and/or excitement might release epinephrine and interfere or inhibit temporarily the uterine contractions. There is no evidence that epinephrine release at coitus or soon after affects fertility. Prostaglandin, a substance from the seminal vesicles present in sheep, goats, possibly other animals, and human semen

is an oxytocic agent that can also stimulate the smooth muscle of the genital tract. Since the vaginal mucous membrane is permeable to prostaglandin it may also play a role in spermatozoan transport.⁴² The spermatozoa are thus transported largely in a fluid medium or mucus by capillary action in the cervix and by ciliary activity and contractions of the walls of the genital tract. The sperm cell's contribution to this transport up the female tract is a small one because of the relatively slow rate of movement for the long distance to be traversed. However, this motility of the spermatozoa is probably important at the natural barriers of the cervix, the utero-tubal junction, the isthmus of the oviduct and in the initial penetration of the sperm cell into the cumulus. Motility of the sperm cell is essential to fertility. Since dead sperm cells and inert particles will pass through the uterus and into the uterine tube, the motility may be most essential to traverse the cervix and penetrate the cumulus cells or zona.³⁶

Millions to billions of spermatozoa are usually ejaculated into the female genital tract of domestic animals at coitus. In the mare, bitch and sow most of these promptly enter the uterus. In the other species only about 10 or 100 million spermatozoa pass through the cervix into the uterus with more sperm cells being in the base of the horns than in the apex of the horns. Several hundred to less than a thousand spermatozoa gain access to the ampulla of the uterine tube, and only 10 to less than 100 would be in vicinity of the unfertilized ovum. Apparently the uterotubal junction and the isthmus have some controlling role in the numbers of spermatozoa that gain access to the uterine tube. In the rabbit after mating, and just before ovulation, the distribution of spermatozoa in the doe's genital tract were as follows: 20×10^6 sperm cells in the vagina, 12×10^6 in the caudal portions of the uterus, 50×10^4 in the apical portions of the uterus, 4×10^3 in the uterine tubes but only 500 spermatozoa in the ampulla of the uterine tube where the ova were fertilized.¹⁰ In sows the number of spermatozoa in the uterine tube is affected by the volume of semen entering the uterus as well as the concentration or numbers of spermatozoa.⁵ When 1 ml. of fresh or frozen semen containing millions of live spermatozoa was placed in mid-cervix in heifers, 4 hours later 469 and 191 spermatozoa were in the uterine tubes, and 1559 and 733 spermatozoa were in the uterus, respectively.³⁰ Four hours after insemination only 3 percent of the inseminated spermatozoa could be recovered.

A review of the literature, indicates that in mammals only a small proportion of spermatozoa ejaculated at coitus reach the distal end of the uterine tube.³² Some sperm cells may actually enter the peritoneal cavity.²⁵ Apparently natural barriers at the cervix and uterotubal junc-

tion limit the number of spermatozoa going to the site of fertilization. Rabbits inseminated with less than 20,000 to 100,000 spermatozoa per insemination failed to conceive.¹⁵ This number of spermatozoa varied with the extender and the degree of dilution. A 0.6 percent decline in conception rate in cattle with each million decline from 12,000,000 to 4,000,000 spermatozoa inseminated was reported.⁴⁷ Below the latter figure the decline in conception rate was very rapid, about 3.6 percent for each million decline in sperm cell numbers to about 1,500,000. Conception rates, when 12 to 14 million, 6 to 8 million, and 1 to 3 million actively motile bovine spermatozoa were inseminated were 67, 64 and 49 to 53 percent, respectively when based on 60 to 90 day nonreturns.

Thus a minimum number of motile spermatozoa is necessary for fertilization and conception. In sows and probably mares and bitches a minimum volume of ejaculate or artificially inseminated semen is also necessary for optimum conception rates.

In most domestic animals sperm cells can only retain their viability and fertility at a high level for about 24 to 48 hours in the female genital tract. The longest fertile period for spermatozoa in the female tract of most domestic animals is 48 to 72 hours.^{3,5,8} In the mare and the bitch spermatozoa may survive and be fertile for 5 to 6 days. Like aging ova, aging spermatozoa may be capable of fertilizing the ovum but this may result in embryonic deaths.²⁹ The most common result of aging spermatozoa whether they age in liquid semen at 5°C or in the female genital tract is failure of fertilization. The loss of fertilizing capacity of frozen semen, especially in liquid nitrogen, is very slow and gradual and extends over a number of years.

The vagina of the sow and ewe is not a favorable site for sperm cell survival and they lose their motility and die in 6 to 12 hours or less. The cervix with its viscous mucus of estrum is the most favorable site for the survival of spermatozoa in the cow and ewe. Sperm cells live in the cervix for 36 to 48 hours or possibly slightly longer and this site appeared to act as a sperm cell reservoir for spermatozoa in the cow, ewe and doe.^{35,36} Sperm cells retain their motility in the uterus and oviducts for about 24 hours. The uterus is not a highly favorable site for sperm cell survival because the presence of spermatozoa stimulate the invasion of leucocytes and the phagocytosis of spermatozoa. In swine it was shown that by 30 minutes after service the volume of seminal fluid in the uterus was greatly reduced and leucocytes were entering the lumen.³¹ Sperm cell survival in sows appeared to be longest in the mucous folds of the uterotubal junction. Ciliated cells in the apex of the uterine horns of sows were observed. By 8 hours postcoitus the

numbers of leucocytes were greater than the spermatozoa and by 27 hours after service only rarely were spermatozoa found in the sow's uterus. The uterotubal junction was a "sperm reservoir" in the sow.²⁵ The elimination of spermatozoa following their death in the female genital in the other domestic animals is by phagocytosis as in the sow.^{34,35} Possibly a few dead spermatozoa may be expelled through the dilated cervix.

Fertilization of the ovum occurs in the ampulla of the oviduct within one to two hours after ovulation if the spermatozoa are present in the oviduct. By this time the second reduction division of the ovum is in progress except in the bitch and probably the mare in which this division is delayed.⁶ Fertilization involves the penetration of the ovum by the spermatozoon, the activation of the ovum, the formation of the male and female pronuclei and the mingling of the maternal and paternal chromosomes to constitute the genome of the new zygote with a diploid number of chromosomes. A recent study reported evidence for species-specific sperm plasma membrane receptors for the zona pellucida. This sperm-egg interaction further assures their mutual attraction and the process of fertilization.^{3,41}

Capacitation of spermatozoa is the process that spermatozoa of all animals must undergo in the uterus or oviducts before achieving the capacity to fertilize ova. Capacitation time in sheep is 1-1/2 hours. Capacitation time in the other domestic animals is also about 1 to 6 hours.^{3,33} There is evidence that ejaculated bull, stallion and boar semen has a decapacitation factor that is lost in the female genital tract.^{3,6} In rabbits spermatozoa placed in the oviducts 2 hours before or after ovulation failed to result in conception. If they were placed in the oviduct 4 hours before, 6 percent of the ova were fertilized, and 6 hours before ovulation, 78 percent of the ova were fertilized.^{13,14} Spermatozoa can penetrate porcine ova within 3 hours of insemination.²⁷ Capacitation produces a change in the acrosome called the "acrosome reaction" with a release of lytic enzymes such as hyaluronidase. No changes occur in the sperm head proper in the uterus but a functional change in the sperm head may take place when the sperm cell contacts the granulosa cells of the cumulus. Thus capacitation may allow the "acrosomal or vesiculation reaction" to occur to permit the sperm cell to penetrate the granulosa cells and zona pellucida. This enzyme permits the sperm cell to penetrate the cumulus cell mass around the ovum by depolymerizing the hyaluronic acid-protein matrix of the cumulus. The cumulus cells including the corona radiata in most domestic animals break down and separate from the zona pellucida early. In the bitch and queen the corona cells may remain for some period of time. This early breakdown of the cumulus cells is caused by autolytic changes, ac-

tion of the bicarbonate ions in the oviduct, ciliary and muscular activity of the oviduct and hyaluronidase or possibly other enzymes if spermatozoa are present.

Before the sperm cell can penetrate the zona pellucida it loses the acrosome cap and plasma membrane exposing the perforatorium and inner acrosomal membrane which are responsible for the penetration through the zona pellucida.^{3,4,6,7} It is reported that a lytic enzyme such as trypsin together with hyaluronidase may permit the sperm cell to dissolve in oblique "tunnel" through the proteinaceous zona into the perivitelline space.⁴³ When the plasma membrane of sperm head and vitelline membrane are in contact, the two structures unite and the entire sperm cell passes into the cytoplasm of the egg. In certain sterile bulls, boars and dogs, the spermatozoa have defective or knobbed acrosomes. These animals are sterile because their spermatozoa cannot penetrate the ovum. Usually when the sperm cell contacts the vitelline membrane in most domestic species, maturation of the ovum by meiosis is resumed with the expulsion of the second polar body. The cause of this "activation" of the ovum is not known but it proceeds to pronucleus formation.

Two factors are apparently responsible for preventing, except on rare occasions, the penetration of more than one sperm cell into the ovum. The first is the relatively few spermatozoa in the oviduct at the time of fertilization. The second is when the first sperm cell contacts the vitelline membrane a rapid reaction takes place both in the zona pellucida and the vitelline membrane that blocks the further entrance of sperm cells.^{1,2} It is believed that this reaction is brought about by the release of a substance from the vitelline membrane or the cortical granules just beneath this membrane. It is not uncommon when examining fertilized eggs to see many sperm cells on or in the zona pellucida and in certain species in the perivitelline space.

After the male and female pronuclei form, the chromosomes in each pronuclei unite to form the zygote. This union of the two chromosome groups is called syngamy, at the conclusion of which fertilization is complete. The diploid or tetraploid zygote usually immediately divides into two blastomeres and the cleavage of the ovum progresses rapidly in the next few days to the blastula stage.^{44b} The approximate number of days from ovulation to the blastocyst stage of development is 6 in the horse, 7 to 8 in the cow, 6 to 7 in the ewe, 5 to 6 in the sow and 4 to 5 in the queen. The time of entry of the cleaving fertilized ova into the uterus in domestic animals is about 2 to 6 days after ovulation. This is usually shorter in swine and in superovulated cattle,^{1,2} longer in bitches, queens and mares. The passage of the ova through the isthmus of the uterine tube is rapid. The passage of the fertilized cleaving ovum into the uterus and the control

of this passage by the gonadal steroidal hormones acting on the muscular isthmus of the uterine tube has been described previously. Some interesting time relations in regard to fertilization in domestic animals have been reviewed.² Sperm cell penetration of the ovum begins about 3 hours after ovulation in ewes, pronuclei are formed 11 to 39 hours after ovulation in the cow and 3 to 9 hours after ovulation in the ewe. The fertilized egg divides into the two-cell stage about 24 hours after ovulation in the mare and 19 to 24 hours after ovulation in the ewe.

The most common abnormalities of fertilization are polygyny and polyspermy. Polygyny is incomplete maturation of the egg with a failure to expel the second polar body resulting in a triploid zygote. Polyspermy where more than one, usually two, sperm cells enter the egg is also characterized by triploidy or a 3N instead of a normal 2N chromosome complement in the zygote. Aging of the egg increases the incidence of these anomalies. Twenty percent or more of swine zygotes were polyspermic or digynic when the sow was bred more than

Table 17. The Reproductive Cycle of Domestic Animals*

Animal	Onset of Puberty	Average Recommended Age for First Service	Length of Estrous Cycle	Follicle Diameter (mm)	Length of Estrum	Time of Ovulation	Optimum Time for Service	Ovum Transport Time	Advisable Time to Breed After Parturition
Mare	10–24 m. (18 m.)	2–3 yr.	19–23 d. (21 d.)	35–55+	2.0–13 d (7.2±2.9 d) (5.7 d)	1–2 d. before the end of estrus	2–4 d. before end of estrus or the 2nd–3rd d. of estrus	4–6 d.	About 25–35 d. or 2nd estrus; about 9 d. or 1st estrus only if normal in every way
Cow	4–24 m. (6–18 m.)	14–22 m.	18–24 d. (21 d.)	10–20	12–28 h. (18 h.) (Temperate Zone)	10–15 h. after the end of estrus	Just before the middle of estrus to the end of estrus	3–4 d.	60–90 d.
Ewe	4–12 m. (first fall)	12–18 m.	14–20 d. (16.5 d.)	15–19	24–48 h. (30–36 h.)	12–24 h. before the end of estrus	18–24 h. after the onset of estrus	3–4 d.	Usually the following fall
Goat	4–12 m. (first fall)	12–18 m.	15–24 d. (20 d.)		30–60 h. (36–48 h.)	About the last day of estrus	24–36 h. after the onset of estrus	3–4 d.	Usually the following fall
Sow	5–8 m.	8–9 m.	18–24 d. (21 d.)	7–10	1–4 d. (2–3 d.)	30–40 h. after the onset of estrus	12–30 h. after the onset of estrus	2–3 d.	First estrus 4–9 d. after weaning pigs
Dog	6–12 m. (7–10 m.)	12–18 m.	1–3 cycles per year (1.6 cycles per year) aver. every 7 months	6–8	4–12 d. (9 d.)	1–2 d. after the onset of true estrus	2–3 d. after onset of true estrus or 10–14 d. after onset of estrous bleeding	6–8 d.	Usually the first estrus or 3–4 weeks after weaning pups
Cat	6–15 m. (8–10 m.)	12–18 m.	15–21 d. ¹		9–10 d. ¹ 4 d. ²	24–30 h. after coitus (27 h.) ²	— ²	4–8 d.	Usually the 1st estrus or 3–4 weeks after weaning kittens

*Numbers in parentheses are average figures. 1, 2, 3, 4, 5, 6, 11.

¹The cat has several cycles each breeding period. The latter occur usually 2 or 3 times a year if it is not bred.

²The cat does not ovulate spontaneously. If coitus occurs the cat goes out of estrus in about 4 days.

36 hours after the onset of estrus.^{37,38} Migration of the early zygote from one uterine horn to the other horn is fairly common in ewes, mares, bitches, sows and queens but rare in cows. Migration of the ova across the peritoneal cavity of domestic animals has not been reported.

The formation and development of the corpus luteum under the influence of LH results in the production of progesterone necessary for the preparation of the uterus and probably the rapid passage of the zygote through the isthmus into the uterus. Progesterone is also essential to the maintenance of pregnancy. Because of the effect of the blastocyst on the endometrium, the release of prostaglandin is inhibited and LH secretion maintains the corpus luteum. Otherwise in nonpregnant animals starting about 16 days in the cow and sow and about 10 to 12 days in the ewe and mare the corpus luteum would begin to involute resulting in another estrous period 4 to 5 days later. Placement of or spacing embryos in the uterus in multiparous animals occurs during this early embryonic period. The blastocyst elongates rapidly in the cow, ewe, and sow but remains spherical in the mare, bitch and queen. The uterine luminal fluid or "uterine milk" is rich in mucopolysaccharides, protein, free amino acids, salts like an ultrafiltrate of blood plasma supplemented by secretions of the uterine glands. The shedding of the zona pellucida is probably caused by intrinsic factors in the developing blastocyst.^{5,24,25} Normal gestation and zygote passage into the uterus is carefully synchronized. The early loss of fertilized eggs or embryos is usually not recognizable and is called infertility or sterility.

A thorough knowledge of the various physiologic reproductive phenomena of each domestic species is essential in order for the veterinarian to understand and intelligently treat the various causes of infertility and supervise artificial insemination, embryo transfer and reproductive health programs. The knowledge in this basic field is being rapidly advanced and as more information is obtained clinical application of this knowledge and treatment will be based increasingly on facts instead of empiricism.

The basic physiologic reproductive knowledge necessary for all veterinarians on the domestic species is given in Table 17. These are average or mean figures. Individual animal variations and differences are common but as a general guide this information is useful. A more complete discussion of the reproductive cycle, endocrine effects on the cycle and the reproductive physiology of the postpartum period and the reproductive physiology of the postpartum period and the reproductive physiology of the postpartum period will preface each of the following Chapters on female infertility in the various domestic species.

Chapter XIII

INFERTILITY IN THE COW

It has been estimated by Asdell that sterility and reproductive troubles in dairy cattle in the United States cost \$250,000,000 annually. In New York State these losses annually amount to \$20,000,000 when figured on the basis of data collected on the causes of culling from Dairy Herd Improvement Association herds. Culling of cows on the basis of sterility has increased from 1.1 percent to 2.5 percent in the last 15 years.³ Much of this rise may be accounted for by better recording. In Northeastern United States 12 to 19 percent of dairy cows culled from herds each year were culled because of infertility or sterility.^{104,140,160} The great economic importance of cattle infertility on a world wide basis has been considered.⁴⁵ Artificial insemination, increased productivity of cows, higher costs of raising and feeding cows, and better education of the farmer and veterinarian all have served to emphasize the importance of maintaining the fertility in dairy and beef herds and individual cows.

The control of brucellosis by vaccination and testing, and trichomoniasis by AI, and vibriosis with antibiotic-treated semen and vaccination of cows has greatly reduced the severe problem of contagious genital infections but has focused attention on other causes of abortion and infertility. The increased movement of purebred cattle between states and herds has occasionally resulted in the introduction of an infectious venereal disease that seriously affected the herd's fertility. The widespread use of hormones as aids or cures in treating certain sterility problems has been recognized. With larger herds and greater mechanization of farms, management problems of handling cattle, detecting estrus for artificial insemination, maintenance of records, and nutritional problems are becoming increasingly important. With more veterinarians taking an active interest in this field many farmers are coming to realize the value of the routine preventive health practices of pregnancy and routine genital examinations in maintaining good productive and reproductive levels in a herd.

A well-managed dairy herd should have 60 to 70 percent of the cows conceive on first service with an average of 1.3 to 1.7 services per conception. There should be less than 10 percent of the cows with reproductive "problems." The calving interval from one calving to the

next should be between 12 and 13 months. It has been reported that for every day a cow has failed to conceive beyond 90 to 100 days postpartum it is costing the farmer 1 to 2 dollars. Thus in a poorly-managed herd of 100 cows with a calving interval of over 13 months for every 30 days reduction in the calving interval the farmer would realize an increase in income of \$3,000 to \$6,000 in 1982 dollars.^{87,132} Even in high-producing cows it is necessary to maintain this 12 to 13 month calving interval because in the cow's lifetime there would be more peaks of high production and a greater total production of milk. Furthermore with longer calving intervals the cow is more likely to freshen at the time of year when prices for milk are the lowest and there is a greater chance for culling the cow for economic reasons. In beef herds the cow that fails to conceive during the breeding season is usually culled for economic reasons. Since 95 percent of the variation in calving intervals or breeding efficiency is due to nongenetic reasons, the importance of management and veterinary supervision of the reproductive activities in the herd is obvious.^{40,152}

There is no such thing as a normal infertile cow. Either there is a clinical or nonclinical pathologic cause or the animal has not been properly exposed to fertile semen during an estrous period. In the next section will be a discussion of the reproductive physiology of the bovine animal. This is essential to the understanding of the pathologic causes of infertility and for the devising of management practices that will promote a high level of fecundity.

Bovine Reproductive Physiology

The Bovine Estrous Cycle—The cow is polyestrous and comes in estrum throughout the year. The estrous cycle length in heifers is an average of 20 days with 85 percent of the heifers having cycles of 18 to 22 days. In cows the average length of the estrous cycle is 21 days and 84 percent of the cows have cycles of 18 to 24 days.² The individuality of the animal may affect the cycle length, but the season has no effect on cycle length. In beef cattle the average length of the estrous cycle is 20 days;

79 percent of the cattle have cycles of 17 to 23 days. It was reported that 83 percent of the heifers had estrous periods within the range of 10 to 21 hours in length while 93 percent of the cows fell within the range of 13 to 27 hours.² The average duration of estrus was about 18 hours.^{11,138} Ovulation is spontaneous in the cow and occurs an average of 10.5 to 15.5 hours, average 12 hours, after the end of estrus. This range of time may vary from 2 to 26 hours. Heifers tend to ovulate about 9 hours after the end of estrus. About 80 percent of the ovulations occur from 4 P.M. to 4 A.M.^{2,4}

In Zebu and crossbred Zebu cattle the average length of estrus is short, 4.7 to 7.4 hours, range 2 to 14 hours, respectively.^{1,32,109,113} Zebu cows tend to associate with the bull for a longer period with many of the cattle exhibiting estrus during the night and early morning hours.¹¹⁸ The average duration of estrus in European dairy or beef cattle in tropical countries and in southern states is shorter, 12 to 13 hours, than in the temperate zone.^{32,47,60} **Bos indicus**, Zebu or Indian cattle, or their crosses are more heat tolerant, and have a higher fertility in spring, summer and fall months in the countries near the equator.¹⁷ They tend to be less fertile in the winter months. They seldom come into estrus while nursing their young, possibly for nutritional reasons.³² Brahman cattle have calving intervals of 414 to 554 days.¹¹³ They seldom show heterosexual activity of mounting other cows. Brahman cattle had a lower LH peak at estrus, a smaller corpus luteum and lower progesterone values in diestrus than European cattle.¹¹³ Their gestation periods vary from 271 to 310 days, average 293 days.¹⁰⁹ European cattle, **Bos taurus** or cattle of the temperate zone are less adapted to hot climates.

Three to 6 percent of pregnant cows, especially the first trimester of pregnancy, exhibit signs of estrus and up to 85 percent of these cows were rebred during pregnancy^{49a} (see Chap. II, Pregnancy Diagnosis). In 5970 pregnancy examinations in cows, 59.2 percent were pregnant in the right horn and 40.8 percent in the left. Of 4290 heifers, 54.4 percent were pregnant in the right horn and 45.6 percent in the left horn.¹⁰³ Thus 55 to 60 percent of the ovulations and pregnancies occur in the right ovary and horn. Transuterine migration of the bovine embryo is very rare.

Manual removal of the corpus luteum, which is only possible in cattle, produced estrus in 3 to 5 days, the average time being 4.2 days.⁴ In over 300 Herefords in which the corpus luteum was expressed manually about equal numbers came into estrus on each day from 2 to 7 days.¹⁴ In the author's experience, most cattle show estrus the third day after removal of the corpus luteum and if external symptoms of estrus are not observed,

the animal should be inseminated or bred late on the third day or on the fourth day. Because of the occasional hemorrhages and secondary adhesions or rare deaths, this practice is presently seldom followed as equally satisfactory results can be obtained with a luteolysing dose of a prostaglandin with the onset of estrus occurring in the same time period as manual removal of the corpus luteum.

The symptoms of estrus in the cow are characterized by a great amount of homosexual behavior. Normal and abnormal estrous behavior patterns in cattle have been described.^{44,46,59}

The amount of sexual activity is generally related to the amount of estrogen present but in a few ovariectomized animals estrogen failed to produce symptoms of estrus possibly due to a lack of progesterone since the latter is synergistic with estrogens in producing signs of estrus.^{4,93} There are great differences in individuals in the intensity of estrous symptoms exhibited. Heifers usually exhibit more marked symptoms of estrus than do cows. When artificial insemination is practiced and a bull does not run with the herd, careful observation of cows by the owner or herdsman twice a day or more often at non-feeding periods is essential for the maintenance of a satisfactory breeding program. The onset of estrus was gradual over a period of several to 24 hours in 66 percent of the cows and heifers, and abrupt in 34 percent.¹¹⁵ Animals in the "coming in" stage of estrus were often restless, raised and twitched their tails, discharged some milky-colored mucus from the vulva and often associated with a larger or more aggressive cow. This "coming in" stage was more noticeable in heifers.

The cow in estrus is usually restless and often remains standing rather than lying down. The appetite, ruminations, and milk yield may be slightly decreased. Bellowing is frequent especially if the cow is separated from the herd. The cow in estrus will attempt to mount other cows and will stand to be mounted by others cows. This latter sign of standing to be mounted is the most significant and important sign to observe in the detection of estrus. This characteristic immobility or willingness to stand without moving for the male to mount and complete the copulatory act is the cardinal sign of estrus in all domestic animals, cow, mare, ewe, doe, sow, bitch and queen.

Although the vulva of the cow in estrus was sniffed by other cows, the cow in estrus was never observed to sniff the external genitals of the other cattle.¹¹⁵ The heterosexual and homosexual behavior of the cow in estrus was always more intense than that of its partners. The tail may be raised and there is often a long string of clear mucus hanging from the vulva or present on the

tail or buttocks. The vulva is usually somewhat congested, flaccid, edematous, and relaxed. The cow in a stanchion tends to hold her head high and has an alert, interested, even inquisitive, attitude. The cow may urinate frequently. Three to 6 percent of cows, with occasional reports as high as 14 to 18 percent of cows showed signs of estrus after conception.^{39,60,112} This occurred most often the first trimester of the gestation period over a range of 11 to 213 days with a mean of 63 days.

On vaginal examination the vaginal mucosa, especially the cranial portion, is congested and slight edematous. The large amounts of stringy mucus, 50 to 100 ml., present in the vagina at estrus comes from the vaginal and cervical mucous cells under the influence of estradiol.⁸⁸ At the time of estrus the viscosity of the mucus is lowest, and its flow elasticity greatest. When estrous mucus is smeared thinly on a slide and dried the high salt or NaCl content crystallizes into a fern or arborization pattern. The external os of the cervical canal is usually pink, congested, edematous, and slightly relaxed and open at the time of estrus. The cow in estrus seldom objects to and usually stands well for a vaginal examination. The vaginal speculum slips in easily due to the viscid mucus present in the vagina. Vaginal smears during proestrus and estrus show increased numbers of cornified cells, but variations between cows are so great that the vaginal smear in the cow cannot be regarded as a reliable indication of estrus. During diestrus the vagina is pale and dry and the mucus is scant and rather sticky. The speculum therefore passes with greater difficulty than during estrus.

On rectal examination during estrus and for 1 to 2 days before and afterwards, the uterus is usually erect, turgid, and somewhat edematous due to the estrogenic stimulation of the uterine muscle and tissues. This is most noticeable in heifers. Usually 1 to 5 smaller follicles start development but undergo atresia during estrus and after ovulation. On rectal palpation early in estrus the ovarian follicle is about 1 cm. in diameter or less, and smooth, convex, tense and slightly fluctuating due to the follicular fluid present. This fluid is amber in color. The maturing Graafian follicle before rupture is 10 to 20 mm, or 1 to 2 cm, in diameter. At the time of ovulation in the cow only a very slight amount of bleeding occurs at the rupture site.

The corpus luteum develops rapidly from the granulosa and theca cells of the collapsed follicle under the tropic influence of LH from the pituitary gland. By 48 hours after ovulation the corpus luteum is about 1.5 cm in diameter and slightly crepitant on palpation per rectum. By 7 to 8 days after ovulation the corpus luteum

has reached its maximum size of 2 to 2.5 cm. in diameter. The corpus luteum in the cow is irregular in shape, usually oval, and with a cone-like projection about 1/2 to 1 cm. above the surface of the ovary. The corpus luteum of estrus weighs from 4.1 to 7.4 grams and is nearly similar in size and weight to the corpus luteum of pregnancy.¹² The size of the corpus luteum based on manual palpation and observation on laparotomy at 7 to 8 days postestrus has no correlation with progesterone production or plasma progesterone levels.^{113c} The corpus luteum of pregnancy decreases in size just before parturition but may be palpable for many months after parturition as the corpus albicans, a small fibrous structure, on the ovary. The mature corpus luteum is brownish yellow to yellow orange in color, giving it the common name of "yellow body." In about 25 percent of the corpora lutea there is a small cavity about 0.4 cm. in diameter. In a few cases large cavities 1 cm or more in diameter, filled with an amber fluid may be present.^{4,12} These corpora lutea containing large cavities are spoken of as cystic corpora lutea. Cystic corpora lutea have not been observed in a cow in the last third or half of the gestation period.⁷⁹ Graafian follicles that failed to ovulate but became partially luteinized are called luteal cysts. These pathologic luteal cysts have a smooth convex surface due to the thick-walled fluid-filled follicle that failed to ovulate. While the cystic corpus luteum follows a normal ovulation and although it contains a variable amount of fluid in its center, lutein tissue protruding through the site of ovulation produces an irregular, raised area on the surface of the ovary.¹² Normal corpora lutea are irregular in outline and have a liver-like consistency. Cystic corpora lutea are similar to normal corpora lutea on palpation except they are usually larger, more spherical and fluctuate on pressure. The cystic corpora luteum is not considered to be pathological but the luteal cyst is pathological. The corpus luteum maintains its size until about 48 hours before estrus, after which time its size diminishes rapidly. Its color at this time of rapid involution is light orange to yellow. By 48 hours after estrus its size is about 1 cm. and by about 10 days after estrus 0.5 cm.¹² As it becomes older its color turns to dark orange and then brick red. This eventually becomes a small white fibrous area the size of a large pin head, the corpus albicans. On rectal palpation, when one ovary is definitely larger than the other the difference is usually due to the presence of a corpus luteum in that ovary. Cysts may also cause this discrepancy in size.

In cows, body temperatures taken deep in the vagina were lowest just before estrus, high on the day of estrus due to the cow's activity, low at the time of ovulation and high during the luteal phase of the cycle as in

women.¹⁷⁰ Determining body temperature changes, the glucose content, or the arborization or fern pattern of cervical mucus were not practical tests for indicating estrus or heat and the time to breed cattle.^{9,75,170} Direct visualization of the ovaries of cattle during the estrous cycle by endoscopic methods has been reported.^{8,92}

About 15 to 36 hours after ovulation, about 24 to 48 hours after estrus, or about 40 to 60 hours after the onset of estrus a discharge of blood and mucus from the vulva may be observed in many cows. This metrorrhagia from the edematous endometrium in the caruncular areas occurs due to a breakdown of congested capillaries. Although clinical evidence of bleeding occurs in only 80 percent of heifers all show the presence of red blood cells on examination of vaginal swabbings at this time.¹⁵⁹ Metrorrhagia in cattle was observed in about 75 percent of heifers, and 48 percent of cows.⁴ In any particular animal clinical bleeding may not be observed following every estrus.

It is a common belief amongst a few farmers that post-estrous bleeding following service is an indication that conception did not occur. In 100 heifers that were bred, 81 showed clinical prostestrous bleeding. Eighty-five percent of those that conceived bled, and of those that did not conceive, 74 percent bled. In another group of 100 cows, 61 bled and 69 percent of those that conceived bled, and of those failing to conceive, 39 percent showed metrorrhagia.¹⁴¹ The metrorrhagia that occurs in cattle is not similar to menstruation in primates, as it occurs at the end of the estrogenic phase of the cycle or early metestrus, following estrogen withdrawal. While in primates bleeding occurs at the end of the luteal phase of the cycle or the end of diestrus, following progesterone withdrawal.⁶⁵ Small perimetrial hemorrhages in the subserosa of heifers' uteri were commonly seen from estrus to the fourth day postestrus. Hemorrhages of this nature were not observed in pluriparous cows.¹⁵⁹

Optimal service time—Insemination of cattle between 8 to 24 hours, or especially 7 to 18 hours, before ovulation results in the highest rates of conception.¹⁴⁶ Ovulation should occur in heifers in the temperate zone about 22 to 36 hours after the onset of estrus. Conception rates were still better than 50 percent from service more than 24 hours before ovulation, if the cow was in estrus, to within 6 hours of ovulation. Conception rates drop rapidly in cows bred after ovulation or after 10 to 18 hours after the end of estrus.^{20,138,146} In other studies^{11,146} conception rates of cows inseminated about 10 hours after the onset of estrus was about 82 percent; at 20 hours after the onset of estrus or soon after going out of estrus 62 percent; by 30 hours after the onset of estrus or near the expected ovulation time, the concep-

tion rate was 28 percent. This rate dropped rapidly so that by 50 to 60 hours after the onset of estrus very few cows conceived. However, a conception rate of 20 to 30 percent was reported if cattle were inseminated while they were showing metrorrhagia and a bloody mucous discharge.^{7,85} Based on the above data, the best time for insemination is from just before the middle of estrus to 6 hours after estrus or from 6 to 24 hours after the onset of standing estrus.^{103b} (See repeat-breeding cows.) In 7,346 dairy herds in which 455,196 cows were artificially inseminated in one year the nonreturn rate of 66 percent was similar for cows serviced once a day at about the same hour, once a day either in the A.M. or P.M. or twice a day with cows observed in estrus in the A.M. serviced that P.M. or cows in estrus in the P.M. being serviced the next A.M. When the herd size was 20 to 50 cows, 51 to 100 cows, 101 to 150 cows and over 151 cows the nonreturn rates were 68, 66, 64 and 62 percent respectively. Cows in loose housing had a 64 percent nonreturn rate compared to 67 percent in tie or stanchion housing.^{103b}

Although the possibility of conception may be somewhat less in cows with shorter- or longer-than-normal cycles of 17 to 25 days, many of those cows do conceive when they are bred.¹⁴⁹

Intravaginal deposition of semen in artificial insemination gives poor conception rates because of the small numbers of spermatozoa deposited. The rectovaginal technique for introducing semen into the cervix was superior to the speculum technique with about 16 percent better conception rate.¹⁴⁹ Deposition of semen in the cranial cervical canal gave equally as good results as semen deposited in the uterine body or horns and the technique was simpler. Because the endometrium is easily injured, and infection and occasional abortion may result from intrauterine deposition of semen in pregnant cows, and since about 3.5 to 6 percent of pregnant cows show estrus, it has been recommended that cervical deposition be used instead of the uterine deposition of semen.¹⁴⁹

Hormones of the Estrous Cycle—The level of hormones in cattle, with the possible exception of LH, are low in comparison to other domestic animals. In recent years highly sophisticated assay techniques have been devised that have further delineated the hormonal control of the estrous cycle in cattle. The subject of hormone levels in the reproductive endocrine glands and the blood plasma at different stages of the estrous cycle and during pregnancy was reviewed.^{25,116,156} Follicle stimulating hormone (F.S.H.) plasma levels range from 300 to 550 ng/ml., with low values for 3 or 4 days after estrus and higher values at estrus coinciding with peak values of luteinizing hormone (LH). Luteinizing hormone (L.H.)

plasma levels range from 1-1/2 to 3 ng/ml. produced by frequent daily episodic fluctuations or pulses with a gradual rise to 4 or 5 ng/ml. just before the next estrus with a very high peak, the LH surge, of 11 to 15 ng/ml. early in estrus that lasts for only a few hours.

Progesterone levels in plasma average 5 to 7 ng/ml. (range 4 to 9 ng/ml.) during the midcycle from 6 to 19 or 20 days when two to three days before the next estrus regression or involution of the corpus luteum occurs rapidly under the influence of prostaglandins from the endometrium and possibly the corpus luteum and progesterone levels fall below 1 ng/ml. during estrus and then slowly rise to normal diestral levels by day 6. Following superovulation in the cow progesterone levels in the last milk rose from 8.2 ng/ml. at midcycle to 52.6 ng/ml. and correlated with the number of ovulations and embryos recovered.^{43a}

Estradiol levels in plasma average 2 to 7 pg/ml. from the day after estrus with a slight peak at midcycle to 2 or 3 days before the next estrus when the estradiol level rises and reaches a peak early in the next estrus of 10 to 20 pg/ml., after which it falls rapidly.

An excellent recent review of the physiology and endocrine control of the estrous cycle of domestic food-producing animals has been published.^{66b} The role of oxytocin in luteolysis is discussed in light of the recent observation that oxytocin is present in considerable concentration in the bovine corpus luteum where it is probably synthesized. Large quantities of arachidonic acid, a prostaglandin precursor, is also found in the corpus luteum as well as the uterine endometrium. Recent studies have shown that PGI_2 is luteotropic and $\text{PGF}_{2\alpha}$ is luteolytic. Thus a balance of these two prostaglandins may determine the functional state of the bovine corpus luteum. The presence and release of oxytocin from the bovine ovary during the estrogenic phase of the estrous cycle may be responsible for the greatly increased tone of the uterine musculature characteristic of estrus in the bovine species.

The blood plasma levels of certain reproductive hormones during the bovine estrous cycles are generally quite different from those during the gestation period when F.S.H. and L.H. are low, the latter about 1.0 ug/ml. Progesterone levels are about the same as during diestrus and decline to very low levels at parturition. Estrogen levels rise during late gestation to a peak at parturition of 3000 to 5000 pg/ml. total estrogen. The half-life of the progesterone in the blood in cattle was short, about 10 to 20 minutes, indicating the need during the estrous cycle and pregnancy for a continuous large supply.⁷⁶ Normal corpora lutea in pregnant heifers at 15 days after insemination contained an average of 270 mg. total pro-

gesterone and no pregnant heifers had less than 100 mg. which was the minimum necessary for embryo survival.¹³⁶

In ovariectomized cows conditioned with 0.2 to 0.4 mg of estradiol/1000 lbs, 1 to 4 mg of progesterone would produce maximal synergistic action with the production of typical estrum lasting 6 to 12 hours.⁹³ Both of these hormones necessary for typical expression of estrus are produced in the ovary during the preovulatory development of the follicle. The CL from the previous cycle contains measurable progesterone for several days after estrus.⁵⁴ Large doses of progesterone 30 to 60 mg. antagonized or prevented estrous behavior in estrogen-treated ovariectomized cattle.

Puberty and the onset of estrous cycles (See Chapter 12)—As discussed previously placing young heifers on a nutritious diet high in TDN from birth can hasten puberty and the onset of estrous cycles. This can also permit heifers to be bred successfully at a younger age if they are continued to be fed well during the first gestation period. Breeding heifers on the basis of body weight is therefore indicated, so that heifers can calve at about 2 years of age without serious calving problems. Crossbred heifers tend to show estrus a month or so earlier in life than the parent breeds. Depending on the level of nutritional intake, heifers first show estrus from 7 to 18 months or 28 to 72 weeks of age. In 53 Holstein heifers the time after birth at which first estrus occurred was more variable than the weight which averaged 42 weeks and 610 lbs., respectively.⁹⁶ During the prepuberal period most heifers had one or more follicles with a diameter of 0.5 to 2 cm. and showed evidence of increased follicular activity about 20 to 40 days before the first ovulation. Variable signs of estrus were observed at these times. At the first estrus 74 percent of the heifers exhibited "silent" estrus, or failed to show signs of estrus. This percentage dropped to 43 percent the second estrus and 21 percent the third estrus. Thereafter the estrous periods and signs were normal. Ovulation failed to occur in 13 percent of 53 heifers after the first estrus but thereafter failure of ovulation was rare. Nearly similar results were reported in 37 Holstein heifers in a later study.¹⁰¹ Heifers should be of sufficient age and weight to reach puberty prior to any hormonal treatment to induce or control estrous cycles if acceptable pregnancy rates are desired.^{132b}

The postpartum period and the onset of estrous cycles—A review of the literature on postpartum ovarian activity and uterine involution indicated the interval from parturition to first observed estrum varied from 30 to 76 days in dairy cattle and 40 to 48 days in beef cattle.^{98,99,100} The time required for uterine involution based on rectal palpations and clinical observations and mea-

measurements varied from 26 to 52 days in dairy cattle and 38 to 56 days in beef cattle. In general the interval from calving to first estrus was greater in cows with higher production, in cows nursing calves or being milked 4 times a day, in cows on a poor or low level of nutritive intake, and in older pluriparous cows with 4 or more parturitions.^{121,157} A longer postpartum interval to first estrus occurred in nursed dairy cows, anemic cows and in those being fed thyroprotein.

When Brahma-Hereford heifers were allowed to suckle their calves only once a day, starting at postpartum day 30, the postpartum interval to first estrus was 69 days average vs 168 days for control heifers that suckled their calves normally. These times were shortened to 32 and 124 days when the experiment was started at 21 days postpartum and the level of nutrition was increased.^{113b} This relationship of nursing and the delayed onset of estrous cycles after calving was further reported upon.¹⁶⁵

Involution of the uterus was prolonged in pluriparous cows when compared to primiparous cattle and also in abnormal parturitions characterized by dystocia, retained placenta, twinning, metritis, milk fever, displaced abomasum and other disease or stress factors. Ovariectomy and physiologic doses of estradiol had no effect on uterine involution but progesterone delayed uterine regression.⁹⁰ However others⁴³ reported that progesterone and estradiol somewhat shortened the intervals to ovulation and conception. Thus uterine involution proceeds normally even if reproductive cycles and estrus do not occur. Exogenous estrogens or progesterone, ovariectomy, or nursing calves have little or no effect on the rate of uterine involution.¹³³ Sloughing of caruncular tissue occurred between 7 and 14 days postpartum and by 30 days the surface epithelium over the caruncular areas were regenerated.¹⁵⁷ Normal cows usually develop a mature follicle that ovulates and is followed by the formation of a corpus luteum at 13 to 15 days after calving.^{89,98-100,157} The duration of the estrous cycle from the first ovulation to the second ovulation was 3 to 4 days shorter than the normal length cycles, 20 to 21 days, that followed thereafter. "Silent" estrus occurred in 77 percent of the first postpartum ovulations, 54 percent of the second and 36 percent of the third ovulations, and was more common in high-producing cows.⁹⁸⁻¹⁰⁰ Cystic corpora lutea and cystic follicles were fairly common and a failure of ovulation occurred occasionally in up to 10 percent of the cycles.²¹ Ninety percent of the first corpora lutea developing within 15 days after calving formed on the ovary opposite to the previously gravid horn; this percentage dropped to 60 percent in cows ovulating 15 to 20 days after parturition.⁸⁹ The corpus luteum of pregnancy had regressed at 4 days postpartum to 1×1.5 cm in size

and was usually not palpable after 14 days postpartum.

Uterine involution in normal cows is largely completed as indicated by the size of the uterus and the condition of the endometrium at about 30 days postpartum and since normal estrous cycles are usually occurring by 30 days after calving^{98-100,157} it is logical to ask whether it might not be feasible and practical to commence breeding a month before the generally previously recommended minimal time of 60 days postpartum.

In the early 1950's a number of studies conducted on early postpartum breeding of dairy cows indicated that breeding cows prior to 60 days resulted in conception rates below 50 percent, an increased number of services per conception and even prolonged the postpartum interval to conception with adverse effects on the subsequent pregnancy and parturition.^{74,125,142-146}

Subsequent studies on large numbers of cows showed that conception rates per service in cows bred 20 days or less postpartum average 18 percent, those bred 20 to 40 days averaged about 35 to 45 percent, from 40 to 60 days postpartum about 50 to 60 percent. A definite increase in number of services per conception occurred in cows bred prior to 50 days postpartum. These early bred cows had a shorter calving interval, often averaging 11 to 12 months, due to a reduction in days from calving to conception. There was no evidence that early postpartum breedings were associated with an increased incidence of delayed returns to estrus, infertility or subsequent abortions or retained placentas.^{15,42,57,106,131b,137a,161,162}

Since the optimum calving interval for maximum daily milk production in high-producing dairy herds is controversial and since for high milk production a dry period of 42 days or more is essential,⁴² a somewhat flexible management program is indicated based on the age and productivity of the individual cow, the ease of calving and the presence or absence of periparturient disease and the evaluation of the recovery or involution of the genital tract based on routine postpartum rectal examinations. Two and three-year-old cows had a 61 percent postpartum first service conception rate. Cows 4 years-old and older had only a 35 percent conception rate on first service postpartum. The occurrence of one or more postpartum diseases reduced the first service conception rate and milk production was negatively correlated with conception.^{137a} A desirable goal of a calving interval of 12 to 13 months in a high-producing herd translates into a postpartum "open" interval of 85 to 115 days, respectively, for all of the cows in a herd. Having many cows over or under these figures in order to arrive at a desirable average figure should be regarded as poor management. Further information on this important postpartum period will be discussed later in this chapter.

Conception rates for estrous cycles of less than 18 days in length were poor, about 34 percent, in cows not bred at the previous estrus.^{38,145} Increased calving intervals in dairy and beef cows often occur after they reached 5 years of age or after their fourth lactation period.

Physiologic utero-pituitary-ovarian relationships and the luteolytic mechanism controlling the estrous cycle—The corpus luteum, follicle, and the placenta are the only three transitory endocrine glands. The understanding of the mechanisms controlling the formation and involution of the corpus luteum is essential. The corpus luteum is present and active in the fertile cow for about 320 days a year. It only involutes long enough in the normal cow to permit a follicle to mature and ovulate in order to perpetuate the species. The presence of a functioning corpus luteum on the ovary is of much more significance than various stages of follicular development or atresia.

Although more work is required to explain certain aspects of the utero-pituitary-ovarian relationships, the major aspects of this relationship have been reviewed.^{50,51,133} It is generally accepted that LH which is the principal luteotropic hormone in the cow¹²⁸ is released from the anterior pituitary gland to produce ovulation; corpus luteum formation from the granulosa and thecal cells; corpus luteum persistence; and secretion of progesterone necessary for suppression of follicle growth, early embryonic growth, development and attachment, and for the maintenance of normal pregnancy. The presence of the embryo with its elongated trophoblast is necessary by about the 14th day of the cycle to prevent the involution of the corpus luteum which starts, in the absence of the embryo, about the 15th or 16th day of the cycle. The process causing the regression or involution of the corpus luteum of the estrous cycle to permit Graafian follicle development is called the luteolytic mechanism. This releases prostaglandin F_{2a} from the endometrium in the absence of the substance or hormone from a developing blastocyst.¹⁰ This mechanism of estrous cycle regulation is more complex than realized ten years ago and possibly involves a balance or interaction between ovarian steroids, gonadotropic hormones and the luteotropic action of prostacyclin early in the cycle⁹⁴ as well as other unknown influences. If conception has occurred the conceptus prevents the release of prostaglandin and the resulting involution of the corpus luteum and causes pregnancy to be maintained. In the cow the prostaglandin from the endometrium is carried to the ovary by the local utero-ovarian pathway.⁵² Many studies influencing and elucidating but not completely explaining, the luteolytic mechanism have been performed.^{52,116}

Thyroidectomized or parathyroidectomized cows were

fertile and could carry fetuses to term and rebreed. Low fertility associated with high environmental temperatures was not associated with depressed thyroxine secretion rates.¹⁶² There was no evidence that feeding iodinated casein caused infertility, even after 2 years of continuous feeding. The thyroxine secretion rate in dairy cattle was 67 percent higher than in beef cattle.¹⁰⁸ Adrenal function in relation to reproduction was reviewed in relation to ovarian inactivity, cystic ovaries and prolonged or shortened gestations.^{151,155}

Other endocrine effects—Typical signs of estrus can be produced both clinically and on vaginal and rectal examination in an ovariectomized heifer by the daily injection for 3 days of 0.10 mg. of estradiol or 0.25 mg. of stilbestrol.⁵ Thus it makes more understandable the reason why massive therapeutic doses of 4 mg of estradiol and 40 mg of stilbestrol, greatly exceeding the physiologic dose, can cause cystic ovaries.

Other associated endocrine phenomena related to the uterine luteolytic mechanism and uterine-pituitary-ovarian physiology include the following.⁴⁹⁻⁵¹ Exogenous estrogens, such as 5 mg estradiol valerate or injections of estradiol having a prolonged effect, given to cattle at midcycle caused early CL regression.^{18,166} This is probably due to an interference with LH release since concurrent injections of gonadotropins prevent the regression of the CL. Exogenous estrogen is luteolytic and levels of FSH and LH that promote increased estrogen secretion might also promote luteolysis.⁶⁸ Daily exogenous injections of 100 IU of oxytocin days 2 to 6 after estrus caused the failure of the corpus luteum to develop with an early return to estrus and a short cycle of 10 to 14 days.^{18,35,37} The author has observed this as a cause for repeated short cycles and infertility when the owner of a high-producing cow gave repeated daily injections of oxytocin to cause milk "let down." These short cycles are due to the release of prostaglandins from the uterine endometrium by the exogenous oxytocin and the subsequent luteolysis is produced by the released prostaglandins.^{94b} Adrenocorticotropin (ACTH) 100 units daily on days 2 through 8 of the cycle significantly reduced CL weight. The effect of ACTH on the adrenal gland to produce corticosteroids that can cause abortion as well as uterine involution is noteworthy.¹⁸ An injection of LH in an adjuvant at midcycle or daily injections of HCG starting at day 15 prolonged the life of the CL and increased estrous cycle length in cattle.^{164,167} Although these injections of HCG caused accessory corpora lutea to develop, it had no effect on embryo survival. Thus, as expressed by Short¹²⁷ the CL can be "murdered" by the local effect of the uterine luteolysin prostaglandin on the CL; it can be "starved to death" by the removal of the

tropic stimulus, LH, due to the systemic effect of prostaglandins and estrogens on the hypothalamus and pituitary gland; or the CL can die of "old age" since the CL in each species has a finite life span.

Synchronization of Estrous Cycles or Ovulation

Control—Estrus synchronization or control of the estrous cycle and ovulation whereby one to many heifers or cows in a beef or dairy herd could be brought into estrus at a specific time is highly desirable from a practical, economic standpoint to breed cows artificially to proven sires, to shorten the breeding season and cluster calvings, and to improve estrus detection. Manual removal of the corpus luteum per rectum was a common practice for producing estrus until recently. (See Section on Anestrus.) This practice frequently produced bleeding, adhesions and ovarian damage with occasional hemorrhage and deaths. The first endocrine products available and used for this purpose were stilbestrol and other estrogenic products. These products could produce signs of estrus within 24 hours after injection but since a physiologic estrus and ovulation did not occur conception rates were extremely low and occasionally cystic ovaries were produced. The gonadotropic hormones became available and results in inducing estrus were poor, the costs of the drug high, and occasionally superovulation or anaphylaxis was produced.

About 25 to 30 years ago progesterone and progestins became available that by injection or feeding would suppress the gonadotropic hormones and the estrous cycle for long periods of 20 to 25 days during which the corpus luteum would involute. When the progesterone or progestins were withdrawn estrous cycles with ovulations would occur within the next 2 to 6 days. However conception rates at this controlled estrus were too low, 15 percent below controls, to be of practical or economic value.⁶⁶ Many hundreds of experiments with many hormones, such as estradiol and gonadotropic or GnRH hormones in combination with progesterone have been performed to improve synchronization and fertility with equivocal or little success. The two most promising of these current experimental procedures for synchronizing estrus involve a short term exposure to progesterone of 7 to 9 days. One treatment consists of an estradiol injection at the time of implantation of a progestogen, (Syncromate-B) or norgestomet (Searle) under the skin of the ear of heifers or lactating cows that is removed 9 days later.^{66,80,131} This procedure has been combined with the administration of prostaglandins on day 7 or with removal of nursing calves for 48 to 60 hours. (Shang treatment.)^{26,78,131} The second treatment is to insert a progesterone releasing intravaginal device (PRID) followed by the injection of a luteolytic dose of prostaglan-

din the day before removal of the PRID on the seventh day.⁶⁶ This experimental treatment resulted in 76 percent of the heifers being in estrus within a 24 hour period. This degree of synchrony is important for AI. Conception rates were about 80 percent for both treated and control heifers in which estrus detection practices were excellent and heifers were bred 12 hours after estrus was observed. In another report 44 cyclic Holstein heifers were synchronized with a PRID and 10 mg estradiol benzoate. The PRID was removed 12 days later and 2 days thereafter 84 percent of the heifers were in estrus and bred by fixed AI 56 and 74 hours after PRID removal with a 63 percent conception rate.^{82b} Further studies are indicated. Currently only the former of these latter three treatments with steroid or progesterone components have been approved for use in the U.S.

Within the last 5 to 10 years many experimental trials have been conducted to control the estrous cycle with prostaglandins F_{2a} and its analogues.⁶⁶ When a luteolytic dose of prostaglandins is injected between days 5 and 16 of the estrous cycle, estrus and ovulation follows within 3 to 6 days. They are ineffective when given the first five days of the cycle.⁶⁶ Currently these products are approved for use in beef cattle, dairy heifers and dairy cows. Increased concentrations of PGF_{2a} or its metabolites can only be detected in the first milking after treatment.^{66,129} Many varied treatments or procedures have been used in synchronizing heifers and cows with the prostaglandins (Lutalyse, (PGF_{2a}) 20 to 35 mg. IM or 5 mg. intrauterine) or an analogue (Estrumate or closprostenol, 0.5 mg or 500 ug IM). Some protocols of these treatment procedures include:

(1) Heifers are observed carefully for 5 days and bred about 12 hours after estrus. On the fifth day the remainder of the heifers are given a single dose of prostaglandin and these are observed and bred similarly during the next 4 or more days. Conception rate for control heifers was 74 percent and for treated heifers was about 60 percent.⁶⁶ Other experiments have utilized breeding by bulls or timed inseminations, either once at 60 to 80 hours, or twice at 72 and 96 hours. If estrus occurs late on the second or early on the third day after the injection of prostaglandin earlier breeding than 72 hours is indicated. If a cow shows estrus the day after breeding at 72 hours she should be rebred to get the best conception rates. The best results were obtained when the heifers or cows were bred 12 hours after estrus was first observed.^{16,19,28,66,80} A recent report using 12.5 mg PGF_{2a} by this system was superior to (2) as more cows showed estrus, 65 vs 43 percent, respectively and the cost was lower. Breeding based on observed estrus was superior to timed insemination.^{32b}

(2) All heifers were injected with prostaglandin twice 11 days (10 to 12 days) apart to attempt to synchronize all heifers and then bred to bulls or with AI on observed estrus or at timed inseminations either single services at 60 to 80 hours, or double services at 60 to 72 and 80 to 96 hours.^{16,28,80}

(3) A variation of the treatments used in (1) or (2), especially for herds with many unobserved estrus periods, would be to rectally examine all heifers and cows every week and treat those that are nonpregnant with a mature corpus luteum and breed on both observed estrus and at a timed insemination unless they coincided within a few hours.^{123,124}

(4) Inject all heifers and breed on observed estrus. Those not in estrus after the first injection would be given a second injection in 10 to 12 days and bred at observed estrus or on a timed insemination.^{16,19,28,80}

(5) Many other variations and procedures can be used to assist or improve results including careful observation for estrus at frequent intervals, every 4 hours, from 2 to 5 days after injection, and the use Kamar or other heat detection devices. The use of GnRH or a small dose of estradiol to promote the LH surge after giving prostaglandins has not proven to be of value.⁶⁶

Recent studies on estrus synchronization have shown that 10 to 25 percent of beef cows and heifers were not detected in estrus within 5 days after PGF_{2a} administration due to failure of regression of the CL, or the CL regressed but estrus was not observed or estrus occurred 7 to 10 days after PGF_{2a} injection. PGF_{2a} was less effective in regressing the CL between days 4 and 9 of the cycle than later in the cycle.^{81b} It was also noted that the interval to estrus after PGF_{2a} treatment was affected by season, age of the female (shorter in heifers), breed and plasma progesterone level at treatment.^{81b} Estrus response following the first PGF_{2a} injections was low, 45 to 50 percent, in 6 beef breeds and the pregnancy rate after PGF_{2a} injections was poor, 20 to 35 percent, in the Brahman and Brahman-crossbreed cattle, compared to Angus, Hereford and Simmental cattle, 60 to 65 percent.^{148a} In two groups of dairy heifers injected with PGF_{2a} between 6 to 10 days and 11 to 16 days of the cycle response rate was 59.3 vs 95.6 percent respectively and the conception rate was 50 vs 74 percent respectively.^{158a} Prostaglandin injection had no adverse effect on fertility. In 2000 cows bred within 24 hours after the onset of induced and observed estrus, conception rate was 69 percent compared to 60 percent in untreated herdmates.^{91b} The interval from PGF injection to the onset of estrus is often too variable to result in high pregnancy rates with set-time inseminations. Prostaglandin injections can be highly beneficial in cycling dairy cows with unobserved

estrus to achieve conception in a minimum time period.^{96b}

It is important to realistically assess an owners managerial ability. The use of prostaglandins will not "cure" or alleviate infertility due to underfeeding, infectious venereal diseases, defective or poor semen, improper insemination practices, poor records, a lack of observation of estrus, a lack of, or improper identification of animals, and a lack of cattle handling facilities. If prostaglandins are given to pregnant cows or heifers especially under 150 days after gestation, they usually will abort. Thus the status of the cows and heifers in the herd, the degree of managerial ability and organization are vital to successful estrous synchronization. It is unfortunate that usually the herds deficient in this organization are the ones that request or expect a "one-shot" cure. If 70 percent of the properly synchronized estrus periods and ovulations are observed and the conception rate at that service is 60 percent there will only be 42 percent conceptions in the treated animals. A conception percentage above this level requires healthy cattle and excellent management as rates below this figure are commonly experienced in herds attempting estrus synchronization.

INFECTIOUS DISEASES CAUSING INFERTILITY IN COWS

The infectious reproductive diseases of cattle may be divided into the systemic diseases such as tuberculosis, which occasionally or rarely may affect the reproductive organs, and the more important venereal diseases which infect the genital tract such as: trichomoniasis, vibriosis, brucellosis, and possibly mycoplasmosis and ureaplasmosis. Granular venereal disease, infectious pustular vulvovaginitis due to the IBR-IPV virus and other miscellaneous infections may also affect the reproductive tract and fertility. It is significant that in trichomoniasis, vibriosis and brucellosis a local immunity develops in the genital tract and antibodies may be found in the vaginal mucus for variable, but not prolonged, periods. Any combination of these infectious diseases may occur simultaneously in an animal or herd. A recent review detailed our present knowledge of the reproductive tract, including the reproductive hormones, as a component of the secretory immune system.^{68b}

Trichomoniasis

Definition—Trichomoniasis is an insidious venereal disease of cattle characterized by infertility, early abortion, and pyometra and is caused by the protozoan, *Tritrichomonas fetus*, transmitted to cows by the chronically-infected bull.

Etiology—According to Morgan this disease was first described by Kunstler in France, in 1888, but Mazzanti of Italy in 1900 is generally credited with the discovery. Because of the widespread interest in the discovery in 1897 of Bang's disease, or contagious abortion, apparently little or no work was done on trichomoniasis until the 1920s and 1930s.⁵ In 1932 trichomoniasis was found

in Pennsylvania by Emmerson and since that time the disease has been found in nearly every state in the United States and has been worked on intensively by many investigators. Trichomoniasis has been reported in many countries throughout the world. In Wisconsin, where trichomoniasis was a problem 1,577 bovine uteri from a local packing plant for trichomonads were examined.⁵⁷ Of 997 pregnant uteri only 2 were positive. Of 580 non-pregnant uteri there were 100 cases of pyometra and 13 percent were positive for *Tritrichomonas fetus*. In 9 infected herds involving 800 cattle, it was conservatively estimated that the losses totalled \$200,000 due to loss of potential milk and calves and loss of value of the infected sires.⁷ In recent years trichomoniasis has been diagnosed in the U.S. more frequently in beef herds and less frequently in dairy herds probably due to the extensive use of artificial insemination in dairy cattle. Trichomoniasis is a major contributor to poor calf crops (50 percent) and prolonged calving seasons in beef herds.^{24a}

The results of a survey of 828 western range bulls in 34 herd associations for trichomoniasis showed 7.5 percent of the bulls and 26 percent of the associations were infected.⁴² In two other recent studies 7.8 and 7.3 percent of range beef bulls were infected with *T. fetus* in Oklahoma and Florida.^{6,68} The disease has also been described in range cattle in Australia.²⁵ Since 1940 over 10 A.I. Studs in the U.S.A. have experienced outbreaks of trichomoniasis in their bulls.^{12,32} Beef herds, dealers' herds, valuable purebred herds, and institution herds that frequently change or purchase bulls and cows, are those in which trichomoniasis is most likely to appear.

The causative agent of this disease, *Tritrichomonas fetus*, is a flagellated protozoa with a pyriform or pear-like body. Three small flagella are located at the cranial end of the trichomonad. An undulating membrane extends the length of the body and terminates in a single caudal flagellum. The organism varies from 10 to 25 microns in length and 5 to 10 microns in width. A red blood cell is 5 to 7 microns in diameter. It is about one-third larger than the head of a bovine sperm cell. In fresh preparations the organism is actively motile, exhibiting a jerky, twisting, irregular, spiral continuous rolling and erratic type of movement.^{1,52} Progressive rapid forward movement is seldom observed. *T. fetus* is rapidly killed by drying, by the presence of antiseptics, excessive heat and by other adverse conditions or environment. Once dead it quickly loses its shape, so that it is difficult to distinguish from cellular debris. A common type of vaginitis in women is caused by *T. vaginalis*, an organism distinctly different from *T. fetus*.

Recent studies have shown that it is highly probable that *Trichomonas suis* frequently found in the digestive

tract and nasal cavity of swine is similar to *T. fetus* based on morphology, clinical signs produced by injections of *T. suis* into the genital tract of heifers and on serologic tests.^{30,39,41,49-51} The fact that these two protozoa from different body sites in swine and cattle are apparently identical may well account for the spread of the disease from swine to cattle, especially beef cattle where the two species are often housed together.

In cattle, *T. fetus* is found only in the female genital tract, vagina, cervix, uterus, and uterine tubes, and on the penis and prepuce of the bull. In rare and unusual instances retrograde trichomonad infections of the seminal vesicles or epididymides may occur.^{12,16} The greatest concentration of organisms in the bull was found in the fornix, on the glans penis and adjacent prepuce.^{12,37}

Trichomoniasis is a venereal disease spread from animal to animal at the time of coitus or artificial insemination. Trichomoniasis may be spread from bull to bull in an AI stud at the time of semen collection or if bulls are allowed to run together and mount each other. Only rarely is it spread by other means such as by grooming animals that have a discharge from the vulva, or by the use of contaminated instruments, speculums or preputial or vaginal douching nozzles.¹² Placing many *T. fetus* organisms on the vulva of heifers failed to cause infection.²⁵ The transmission of trichomoniasis by artificial insemination was first reported in 1939.³³ By means of 7 inseminations, the disease was produced in 6 out of 9 uninfected females, and thus demonstrated that trichomoniasis could be spread by artificial insemination with fresh undiluted semen from an infected bull.^{7,12} Semen from an infected bull was diluted 1 to 25 to 1 to 80 times in an egg-yolk-citrate buffer with sulfanilamide.⁶⁶ Of 600 cows inseminated by semen from the infected bull 5 showed early abortion and 1 developed pyometra. Trichomonads were present in 7 out of 28 ejaculates collected from infected bulls. Storage of the liquid infected semen in the usual manner, and the addition of antibiotics and extenders apparently had little or no inhibitory effects on the organisms.⁴⁴ In 1953 examination of 168 bulls in 5 artificial insemination associations found 23 infected.¹³ The rate of transmission of infection by artificial insemination was estimated at less than 1 percent. This would not be serious in artificially inseminated cows and the percentage of conceptions on first service of infected bulls would not be noticeably affected.⁴⁶⁻⁴⁸ On the other hand in some herds bred artificially, the incidence of infection was as high as 20 percent.⁶³ The transmission rate might be serious, however, if the infected cows were bred to the herd sire and the disease thereby transmitted. The low incidence of infection from artificial insemination is due to the methods of

collection, storing, and dilution of the liquid semen. Only by the recovery of the organism in occasional isolated abortions or pyometra cases can trichomoniasis be traced to infected bulls used in artificial insemination. A high infection rate in nonimmune heifers when bred artificially with infected semen was reported even though the semen was extended 1 to 40.⁶⁶ A great difference between infected bulls in the ability of their semen to transmit infection when used for artificial insemination was noted. This may be due to the great difference in the number of organisms present in the sheaths of different bulls.¹² The previous evidence was reviewed and confirmed the fact that *T. fetus* could survive in frozen and thawed extended bull semen even though glycerol was toxic to *T. fetus*. In glycerol-egg yolk-citrate extender *T. fetus* did not survive freezing and thawing; while in glycerol-egg-yolk phosphate or glycerol-milk extenders some organisms did survive. Thus bulls used in AI service should be free of trichomoniasis or spread of the disease might rarely occur.⁴⁵

In natural service the transmission rate of the disease is about 80 percent. In 24 susceptible females bred to an infected bull, only 28 natural breedings were necessary to produce infection in all the females.^{7,9,12} After natural service to an infected bull 23 of 26 heifers became infected but the conception rate was 45 percent.⁶⁵ Of twenty heifers bred to an infected bull, 19 became infected after one service. From 15 to 50 days postservice organisms were found in all 8 slaughtered heifers in the vagina and cervix, in the uterus in three-quarters of the heifers and in the uterine tubes in one half of the heifers.⁵⁹ No gross or microscopic lesions were present in these heifers. In 12 heifers slaughtered between 60 and 100 days postservice, 7 had acute or chronic lesions in many areas of the genital tract, 2 of these had impending abortions and 1 had pyometra. The other 5 heifers of the 12 had no microscopic lesions and in only one of these was *T. fetus* recovered from the cervix and vagina.⁵⁹ In another transmission trial a noninfected bull bred an infected cow and then bred nonexposed cows within 20 minutes; 25 percent of the latter became infected. If the time between services was extended to 3 to 24 hours none became infected and all conceived. Thus noninfected bulls may passively transmit infection during mating but the rate of transmission is low.²⁵ Bulls were also quite susceptible to infection with 4 of 9 bulls becoming infected after the first service to an infected cow. However, 2 of 9 bulls proved highly resistant and could not be infected after 6 services to infected females. Young bulls with less well-developed mucosal crypts and folds in the prepuce are much more resistant to experimental infections than are older bulls. Bulls under four years of age are

seldom found naturally infected and are difficult to infect experimentally.² Exceptions to this observation may be due to breed or individual differences in susceptibility as a few 2 year-old infected bulls have been reported.^{1,52} Bulls, unlike cows, do not seem to be able to develop immunity, even after 2 or 3 infections. If given sexual rest for a period of time cows will usually develop an immunity and rid themselves of the infection; whereas once a bull becomes infected the infection is permanent and only occasionally does spontaneous recovery occur. Cows may readily be infected experimentally by the introduction of *T. fetus* into the vagina or uterus. Although bulls are less susceptible to artificial infection of the prepuce, they more readily contract trichomoniasis after natural service to an infected cow. Except in sporadic cases due to artificial insemination the disease usually appears in a herd as an insidious venereal enzootic infection.

Signs—Being insidious in nature, trichomoniasis is often well-established in a herd before the symptoms reach proportions sufficiently alarming so that a veterinarian is called. The breeding records of any herd affected with sterility should be carefully studied. The possibility of the presence of this disease can often be surmised on the basis of good breeding records. Often the original source of the infection can be traced to a certain bull or non-pregnant cow added to the herd. Purebred herds that sell breeding stock should be extremely cautious in accepting "returned" infertile animals back into their herd after they have been exposed to cattle in other herds.^{24a} Infertility frequently starts after such additions. Once the disease has been diagnosed, herd records are also of value in planning a control program. After the cows have been exposed by coitus to a trichomonad-infected bull the following signs may be observed:

(1) Trichomoniasis will fail to become established in a small number of cows or heifers either because of the small numbers of trichomonads introduced or because of the natural resistance of the female. Conception and a normal gestation period will follow. Approximately 5 to 20 percent of the cows or heifers may fall in this category. Normal gestation and parturition may result in spite of the infection.^{57,65} Trichomonads have been isolated on rare occasions throughout a gestation period terminating in a normal parturition.

(2) When *T. fetus* becomes established after coitus there is no reaction nor any clinical lesions or discharge for the first 3 or 4 days. However, by 4 to 9 days the presence of a moderate vulvovaginitis and cervicitis may be observed on clinical examination. Discharges from the genitals are absent or very scanty during most infections unless pyometra occurs and then a mucopurulent

exudate is usually discharged irregularly. Under field conditions these symptoms in most cattle would usually pass unnoticed.¹² The above symptoms are so slight as to be of little significance and other infections of a non-specific type may produce similar symptoms. In rare instances a more severe and chronic type of vaginitis may develop in the cranial portion of the vagina in cows with trichomoniasis. This is characterized by a rough, rasp-like corrugated vaginal mucosa. Some clinicians indicate that this lesion when observed is nearly pathognomic for the disease. Trichomonads may be found in the vaginal exudate, which is usually watery, clear, or cloudy, often containing whitish-yellow flakes of pus. The presence of trichomonads in a cyst of Gartner's duct 11 weeks after the apparent recovery of the cow from trichomoniasis was reported.¹⁵ In general, clinical symptoms are absent or mild and usually pass unnoticed by the herdsman.

The acutely or chronically-infected bull shows no gross lesions.

(3) The most common symptom of trichomoniasis is infertility, characterized by the necessity for many services per conception and by the frequent occurrence of a prolonged period between estrual periods after breeding. One herd of 50 cows during the height of the infection had an average of 5.15 services per conception over a 2-year period. Prior to the development of the disease the conception rate had been a normal 1.82 services per conception.^{7,9,10,12} Some cows must be bred 6 to 8 times before conception occurs. *T. fetus* produces a mild inflammation of the uterine tubal epithelium, endometrium, cervical and vaginal mucous membranes, and affects the developing embryo and fetus. There is no evidence to show that it may interfere with fertilization of the ova. Nearly 40 percent of infected cows after breeding showed shorter- or longer-than-normal inter-estrual periods during the time they were infected.¹² The longer interval between estrums were most commonly noted. Most of the trichomonad abortions or resorptions are caused by the early death of the embryo and fetus from 15 to 80 days of gestation rather than the less common and often observable abortions occurring after three months of gestation. In early embryonic deaths the embryos usually macerate and are absorbed in the uterus or are expelled unnoticed. Occasionally pyometra may result from a macerating embryo and the accompanying endometritis. If cows are infected at one service to an infected bull and fail to conceive, a subsequent service to a clean bull, either naturally or artificially, will not result in a safe conception until the cow develops an immunity and eliminates the organism. Thus infertility produced by the original infected bull persists even though subsequent breedings are to a noninfected bull. Tricho-

moniasis is actually characterized mainly by infertility and only occasionally by observable abortions and pyometra.

(4) Abortions due to *T. fetus* usually occur between 1 and 16 weeks of pregnancy.⁵⁷ Abortions occurring after 5 months of pregnancy are very rare. If an exposed cow has conceived and carried a normal fetus for 6 months, abortion due to trichomoniasis will probably not occur. Most fetuses aborted before 90 days are not observed. Those aborted the third to fifth month of gestation are usually slightly macerated and autolyzed and are expelled with the fetal membranes around the fetus along with a variable amount of dark, reddish-brown exudate. Occasionally on routine rectal examinations in infected herds these dead fetuses may be diagnosed. Retained placenta is very seldom observed following a trichomonad abortion. The number of observed abortions will vary in an outbreak, depending upon the severity of the infection, the closeness with which the cows are observed, and whether the outbreak is during the summer pasture season or during the winter months when the cows are stabled. Occasionally a mucopurulent reddish-brown discharge may precede an abortion. In a careful study of 50 infected cows, only 2 abortions were recognized and 5 cows developed pyometra.^{7,9,10,12} In 5 herds studied in Maryland involving 300 beef and dairy cattle, only 1 abortion and 1 pyometra were observed. In an outbreak involving about 20 cattle which the author was able to study and follow closely, 1 cow aborted a recognizable fetus and 1 had pyometra. An outbreak in a herd of 75 animals was cited^{21,22} in which 9 observed abortions and 7 unobserved abortions occurred in cows previously diagnosed pregnant. No cases of pyometra were noted. More often the history in an outbreak of trichomoniasis is that the herdsman believed a cow safely pregnant and then 60 to 90 days or more after service, estrus is again exhibited.

(5) Pyometra may be present in 0 to 10 percent of the cows in an outbreak of trichomoniasis. Trichomonad pyometra is postcoital or postservice and not postpartum. When death of the developing embryo or early fetus occurs and abortion or maceration and absorption do not occur, pyometra develops. The corpus luteum in the ovary persists and the cervix may remain tightly closed and sealed with no discharge of pus. More often, however, the cervical seal breaks down and a slight amount of pus escapes into the vagina and is discharged occasionally from the vulva. Since estrus does not occur with pyometra this condition may pass unnoticed for up to 8 or 9 months unless a vaginal discharge is observed or a diagnosis is made on rectal examination. The amount of pus in the uterus varies from about 60 to 8000 ml. with

an average of 1500 ml.⁵⁸ The pus in trichomonad pyometra has a characteristic thin, yellow-grey, watery, flocculent consistency, often containing yellow flakes of pus and shreds of fetal membranes and tissues; in rare cases small fetal bones may be present. The pus has been described as having a "potato soup" color and consistency. Odor may be absent or rather sweetish, but is not fetid. No evidence of perimetritis or other uterine lesions are present. If on rectal examination a diagnosis of pyometra cannot be made positively, another examination 1 or 2 months later is indicated. Usually trichomonads may be recovered in pure culture from this pus. In examining 20 cases of trichomonad pyometra trichomonads were found in every case in numbers from 320 to 3,520 million per ml. with an average of 1552 million per ml.⁵⁸

Diagnosis—The history of the introduction of a new infected animal into a herd followed by a gradually increasing problem of infertility characterized by failure of conception after frequent services, prolonged periods after service before the next estrual period including cows apparently conceiving but coming into estrus several months later, and the occurrence of occasional early abortions and pyometra are characteristic symptoms of this disease. In recently infected herds all cows and heifers are susceptible. In more chronically infected herds most cows have an acquired immunity, while virgin heifers are susceptible. These symptoms are also quite characteristic of vibriosis due to *Campylobacter fetus venerealis*. Some bulls are infected with both vibriosis and trichomoniasis. The positive diagnosis of trichomoniasis, as in vibriosis, requires the finding of the organism in one or more infected animals or a diagnosis based on immunologic reactions due to the local immunity developed in the genital tract.

Diagnosis in the bull consists of checking the natural breeding records and finding which older bulls are probably chronically infected and checking the preputial smegma of these particular animals carefully, and if necessary repeatedly, by the swab, the pipette, or the douche method. These older bulls are of great diagnostic value for detecting the presence of *T. fetus* infection in a herd.² After natural service the numbers of organisms on the penis and sheath are reduced. Following a period of sexual rest for 5 to 10 days to allow the numbers of organisms to increase, the bull is confined in a stall, chute or stanchion. A sideline on the bull is often helpful in restraining the animal in a stall. To avoid fecal or other contamination from the preputial hairs, they are clipped and the preputial orifice is thoroughly washed with soap and water, rinsed, and wiped dry. After its head is fastened and its tail pushed up and forward as restraint, the

abdomen is stroked and then the sample is taken from the prepuce. This sampling procedure can be hazardous to the operator because all range bulls and most dairy bulls resent this sampling and will kick violently unless they are accustomed to being handled and groomed. The use of a bull electroejaculator may be helpful in diverting the bull's attention and getting him to stand quietly.^{56b}

For direct examination of the preputial smegma for the presence of *T. fetus*, the swab, the pipette or the douche method may be used. In the swab technique, a sterile cotton swab or one made with one-half of a 4 × 4 gauze pad soaked in a physiological saline or lactated Ringer's solution is introduced into the sheath on a 36 to 40 inch wire or long narrow forceps, or wrapped around the bristles of a small brush on the end of a long wire. The sheath is swabbed in a back-and-forth circular motion in the region of the fornix and glans penis where most of the trichomonads are located. The swab is then removed and placed in a small amount of physiological saline solution. This may be examined at once on the farm or later in the laboratory. The pipette technique^{1,2,10,12} consists of introducing a 24-inch sterile, Bartlett, plastic preputial or plastic Al pipette with attached bulb or syringe from which the air has been expelled. In the average adult bull which has not been used for service in several days, 1 to 10 ml. or more of smegma and fluid may be removed by aspiration from the sheath by a back-and-forth gentle scraping motion of the end of the pipette in the region of the glans penis. This is flushed into a vial containing 5 ml. of physiological saline, lactated Ringer's solution or Kupferberg broth⁴⁸ refrigerated and examined later in the laboratory. The douche technique consists of introducing 200 to 250 ml. of sterile physiological saline into the sheath and closing the external orifice with the fingers to prevent the loss of the saline solution.^{17,29,37} The solution is vigorously massaged back and forth in the sheath for several minutes and allowed to run back out of the sheath into a broad-mouthed beaker and poured back into a bottle for laboratory examination. Occasionally this procedure will stimulate the bull to urinate and require the douching to be repeated.

Since the *T. fetus* organisms often occur in the infected bull in small numbers they must be located in fresh samples in which the organism is alive and motile or cultured to increase the number of organisms. The combination of the pipette technique with culturing is about 95 percent accurate.¹ Samples must therefore be handled properly after collection, by avoiding extremes of temperature, contact with harmful chemicals, and evaporation. It is highly desirable to examine samples or culture them within a few hours of collection. If an immediate examination is not possible the samples may be kept in

a cool place such as a refrigerator or shipped to a laboratory under refrigeration to control bacterial growth, and examined within 24 to 48 hours. Ordinary freezing at 32° F. will destroy trichomonads. Pipette samples should be allowed to settle for several hours or centrifuged for 10 minutes at 2000 R.P.M. After most of the supernatant fluid is poured off, the superficial layer and the sediment where the organisms are concentrated are mixed. This material is dropped on a glass slide to make a thin pool that is examined under low power with a reduced amount of light. A cover glass should not be used; 3 slides must be carefully examined before the sample is considered negative. A similar technique is used in examining swabs. In the douche technique, the 250 ml. of saline solution and preputial washings are centrifuged for 10 minutes at 2000 R.P.M. at the laboratory. [If a large centrifuge is not available allow the preputial washings to settle for one-half hour and draw off 15 ml. of the sediment and centrifuge the latter. Take a small amount from the bottom of the tube and examine on a warm slide under subdued light for the presence of trichomoniasis.^{24a}] After the supernatant fluid is decanted, the remaining material is centrifuged in a like manner in a 15 ml. centrifuge tube. The supernatant fluid is poured off and the sediment is mixed with 0.5 to 1 ml. of the remaining fluid and examined. The pipette method was superior to the swab technique, and the douche technique superior to both.²⁹ In the field where a laboratory was not available the swab and pipette methods were most practical. Using the pipette technique a positive test was recorded on 42 to 85 percent of the samples from known infected bulls.¹³ Two infected bulls were considered atypical inasmuch as only 8.5 to 19.5 percent of the preputial samples from them were positive. Of 23 infected bulls of 168 bulls examined, 15 were diagnosed on the first sampling, 6 on the second and 2 on the third sampling. In rare instances positive bulls may not be found until the fifth sampling with the pipette; for this reason these workers recommended that at least 6 negative samples at weekly intervals be considered as a minimal diagnostic routine under practical conditions. The use of the more cumbersome douche technique might reduce the numbers of preputial samples required. The direct swabbing or scrubbing of the exposed glans penis with gauge sponges in saline solution appeared promising in detecting infected bulls when the numbers of trichomonads present were low. The penis was exposed manually after tranquilization of the bull. Semen examinations for trichomonads are not feasible since sperm motility interferes with the examination.

By the use of modified Plastringe or Diamond's or other media containing nutrients and antibiotics, prepu-

tial smegma material can be layered on culture media and incubated for 3 to 5 days and examined.^{1,3,35,43,48a}

This method utilizes the collection techniques outlined above and the modified douche technique for obtaining a sample of smegma. The smegma or mucus for culture when placed on top of the media allows the motile anaerobic *Trichomonads* to migrate to the bottom of the culture tube while the contaminating bacteria remain at the top of the tube. The inoculated tube is incubated at 38° C and the fluid at the bottom of the tube is pipetted out and examined in 24 and 48 hours for trichomonads. Culture techniques save a great deal of time when compared to the direct microscopic examination by a skilled person. It is also a more accurate technique.

Diagnosis in the cow may be accomplished by examination of the aborted fetal membranes, the mouth cavity of the fetus, the fetal fluids, the stomach contents of the fetus, or the exudate in the uterus for *T. fetus*. Following abortion the organisms usually disappear within 48 hours. In cows with postcoital pyometra the exudate should always be examined for trichomonads. *T. fetus* are often found in such great numbers that dilution is necessary in order to observe them clearly. In cows bred artificially, early abortion and pyometra are about the only conditions in which trichomonads might be found or suspected. The early occurrence of vaginal immunity to the organism is responsible for the disappearance of trichomonads from the vagina. The organism which is motile traverses the cervix into the uterus where it remains and produces an endometritis that lasts for one to several months. During this time organisms may be found periodically in the vagina. Vaginal samples from suspected females should be examined during the early vaginal phase of the infection, which lasts for about 5 weeks after the coitus that produced the initial infection. Thereafter the presence of vaginal infection may occasionally be observed about 3 to 7 days before estrum.³⁸ This pattern occurs only in previously uninfected animals. Consequently in selecting females to culture it is best to select if possible virgin heifers bred the first time to a supposedly infected or suspect bull. Sample the vaginal mucus with a 14- to 16-inch-long, plastic pipette in a manner similar to the examination of the bull. These samplings should be made 12 to 19 days after the infecting service and then 3 to 7 days prior to each subsequent estrum. In one trial only 7 of 36 cows bred to infected bulls had positive cervical-vaginal mucus cultures about 90 to 100 days after service. Seven of the 36 cows, 2 percent, aborted but only 3 of these, or 8 percent of the 36 cows had positive cultures.³ Finding the trichomonad organisms in cows cannot be done as regularly nor as easily as in bulls so the cow is less fre-

quently employed for routine diagnostic purposes.^{2,3}

It may be desirable to check certain bulls further and for this purpose 2 or more virgin heifers may be bred naturally and vaginal samples taken regularly from 12 to 19 days later. If no positive recoveries of the organism are made, the bull may tentatively be considered free of the infection. Vaginal exudate, if present, should be taken from any suspected cow and especially from cows exhibiting a rough, rasplike corrugated vagina and examined for *T. fetus*.

The living *Tritrichomonas fetus* can be readily identified under the microscope by its characteristic size, shape, undulating membrane, and jerky, erratic motion and continuous rolling.⁵² *T. fetus* in live culture seldom if ever ceases to move, whereas other protozoa occasionally stop moving. Other protozoa, such as: *T. ruminatum*, *Entrichomastix ruminatum*, *Bodo fetus* and others, may also be observed, especially in contaminated samples containing feces.⁵⁷ Their size and motion however, differs from that of *T. fetus* and they have no undulating membrane. These other forms of protozoa are more likely to be observed if samples are held for 18 to 48 hours at room temperature before examination or if samples are taken from the cranial portion of the prepuce.

In pregnancies that terminate in abortions at 90 to 150 days or in pyometra, *T. fetus* may survive for 4 to 5 months in the genital tract of a cow. In most cows however the infection may persist for only a few weeks, 4 to 5, in the vagina and for up to about 60 to 90 days, 2 to 3 months, in the uterus before local immunity results in spontaneous recovery. Infected bulls may remain as carriers of *T. fetus* but no lesions or inflammation of the sheath or penis is produced in either acutely or chronically infected males.

A vaginal mucus agglutination test has been described.⁴⁹⁻⁵¹ Since agglutinating antibodies are developed locally in both the vagina and uterus this has been used as a herd test for *T. fetus* infection. It is not satisfactory for testing individual animals. The antibodies appear as early as 18 to 21 days after infection but reach a high level by 40 days. No systemic antibodies with blood titers were ever observed. In northern Ireland this test was used as a herd screening test to locate those herds that were infected.

Prognosis—The prognosis is usually good if the owner follows a carefully planned control program. In the individual cow the prognosis is good because the non-pregnant cow tends to develop an immunity which although temporary, eliminates the infection in about 3 to 6 months. However the immunity produced is relatively short-lived and reinfection may occur.^{1,2} In certain cases

of uterine infection in pregnant cows, or of pyometra, the infection may survive in the uterus for much longer periods or until abortion or parturition occurs or the pyometra is cured. Occasionally secondary invading organisms such as *C. pyogenes* may produce a more severe pyometra and sterility. Cows very rarely, if ever, carry *T. fetus* infection in their uterus through an entire gestation period. In some longstanding cases of infertility due to pyometra or chronic endometritis, conception may fail to occur and the cow is sold for economic reasons. The prognosis for bulls is more guarded. Since older bulls are usually permanently infected and only very rarely recover spontaneously they usually are sold for slaughter unless they are valuable and treatment is decided upon. Any bull not worth more than 3 times his salvage value should be slaughtered. If the bull is valuable then treatment and posttreatment testing involving a period of about 3 to 4 months is indicated. Treatment and the many post-treatment test samples required are expensive. Fortunately treatment is highly effective.⁶³

Herd treatment—The various possible programs that can be used to eliminate the infection should be carefully explained to the herdsman and the owner. The veterinarian can usually outline a practical plan or procedure for the control of trichomoniasis in the herd. There is no satisfactory or successful method to immunize cows artificially against trichomoniasis.

The most practical and easy method to control and eliminate trichomoniasis in a dairy herd is stop all natural service and breed all cows having normal genital tracts by artificial insemination to disease-free bulls for a period of about one to two years before resorting again to natural service by bulls proven free of *T. fetus*, or by virgin bulls. Cows with pyometra should be treated and cows that abort or have an embryonic resorption should not be rebred for 1 or 2 months after the uterus involutes to its normal state. If artificial insemination is utilized for all cows, this author sees no benefit from requiring that all cows have 3 normal length cycles prior to re-breeding to ensure that most cows will have freed themselves of the infection. This may promote a higher rate of conception on first service but the loss of production would be excessive by such a delay in service on many cows in the herd that may be nearly recovered or have recovered from *T. fetus* infection. However the owner should be warned that an increased number of services will be necessary, especially on cows that had been recently infected and have not developed an immunity. Infected bulls should be sold or, if valuable enough, should be treated. Breeding infected bulls to supposedly immune cows may result in fairly satisfactory conception rates but the infection will continue in the herd. Im-

munity to trichomoniasis lasts only a short period of months. Even cows that have conceived and had a normal gestation period and parturition should not be bred back by natural service within 90 days of calving, since cows may rarely carry the infection through the gestation period. Infected and noninfected cows may be housed or pastured together with practically no danger of spread of the disease since trichomoniasis is rarely spread except by venereal contact. This above practical artificial insemination procedure will work well for most dairy and a few beef herds, if no bulls are kept and if close veterinary supervision and good management are available.

Another control method that is rather difficult to carry out is to divide the herd of female cattle into two groups

(1) the clean nonexposed cows and heifers including virgin unbred heifers, pregnant or open heifers or cows that have never been bred by a known trichomonad-infected bull or a bull suspected of being infected and nonpregnant cows that have recently calved after a normal gestation period and have not had a service by an infected or suspect bull. Any cow or heifer where the breeding history is not definitely known should be placed in the second "infected" group.

(2) the infected or possibly infected cows or heifers include those pregnant or nonpregnant animals that have had coitus with an infected or suspect bull and have not had a normal gestation period following that service.

In Group 1 the noninfected cows and heifers may be bred by a noninfected or virgin bull or by artificial insemination. In Group 2 the "infected" or "suspect" nonpregnant females should be given 60 to 90 days, or 3 normal estrous cycles, sexual rest before being rebred to cheap noninfected "sacrifice" bulls which can be slaughtered at the end of the breeding season. All pregnant and nonpregnant cows should be examined at monthly or bi-monthly intervals until they are pregnant 6 months or more, or are sold as infertile. Females with pyometra, abortions or metritis should be treated before breeding or sold for slaughter. After calving these cows should not be rebred for a period of 60 to 90 days and then they may be bred naturally to a noninfected bull. This latter method has been employed successfully in a number of beef herds where the "infected" and "noninfected" herds can be kept some distance apart with no danger of contact or mixing of animals between the two herds. In a few beef herds the disease was eradicated by breeding virgin bulls to virgin heifers and keeping these animals together and separate from the infected herd for a number of years until the infected herd could be eliminated or replaced. Accurate breeding records, carefully identified cows and bulls, good fences and intelligent man-

agement is necessary to eliminate this disease by methods other than by selling all bulls and going into an artificial breeding program for all the females in the herd.

Individual treatment—The treatment of most infected cows is not necessary, inasmuch as these animals if given sexual rest will overcome the infection. Cases of pyometra and abortion and secondary metritis must be treated and handled as described later in this chapter. Many veterinarians feel that with treatment, recovery may be more rapid and complete. To satisfy the owner that something is being done for these heifers or cows, many of which have been bred repeatedly, treatment is often undertaken. These treatments which are of questionable value may include douching of the vagina and possibly the uterus with 2 to 3 ml. of Lugol's solution in 100 ml. of water, 4 to 5 percent sodium perborate solution, 1 to 3 percent chlorine solution, or 1 percent acriflavine solution, once or at several intervals a week or 10 days apart. Various antiseptic treatments of the genital tract of the infected cow were useless in elimination of the organisms, which can be done only by the development of immunity.⁶⁵ Some veterinarians will sample and culture the cervical and vaginal mucus or uterine exudate in pyometra. If infection is present they will treat the cows orally or parenterally with drugs recommended for the treatment of bulls.

Treatment for bulls has received much attention in the last 30 years. For the first 20 years a number of different techniques and drugs were used to affect a cure mainly by local treatment of the prepuce and penis, often at repeated intervals that was very time-consuming and expensive. These treatments of "Bovoflavin Ointment," acriflavine ointment and hydrogen peroxide and others used locally and sodium iodide intravenously or their combination has been described.⁶⁰ These treatments are presently seldom used because of the difficulty or dangers in their application and the not uncommon failures in the cure of the *T. fetus* infection.

Presently the treatment of choice is the oral administration of 50 mg/kg or 25 mg/lb of body weight of dimetridazole (1,2-dimethyl-5 nitroimidazole) (Rhodia Inc. N.Y.C. or Emtryl, Salisbury Laboratories, Charles City, Iowa). This drug is used for the treatment of blackhead in turkeys and like the following drug is not approved in cattle.^{1,24,52,54-56} Another similar drug metronidazole (1-B-hydroxyethyl-2-methyl-5-nitroimidazole (Searle, Chicago, Ill.) is used for treating *T. vaginalis* in humans.^{1,34} The dose of this latter drug was 10 to 75 mg/kg of body weight intravenously every 12 hours for 3 injections or once daily for 2 days. Dimetridazole can also be given intravenously in a 10 to 20 percent sulfuric acid solution at a dose level of 10 mg/kg of body weight daily for 5 days or 50 to 100 mg/kg of body weight at

a single injection. Because of severe side-effects of dyspnea, ataxia, recumbency and weakness from intravenous therapy the oral therapy is preferred. Dimetridazole is usually administered by boluses, drench or by stomach tube. When mixed with feed it may be unpalatable so it may not be completely consumed. Since bulls on a high concentrate ration may develop rumen stasis, a ration high in roughage should be fed before and during treatment. Following therapy a designation of a cure should be based on 3 consecutive negative cultures over a period of six weeks starting 45 to 60 days after treatment.⁵² The possibility of strains of *T. fetus* developing resistance to dimetridazole has been reported.⁵⁵ Dimetridazole has been used at the dose level of 25 mg/lb daily for 5 days orally to treat over 100 bulls with trichomoniasis with 90 to 95 percent success in eliminating the infection.^{24a} It is doubtful that any commercial company will for economic reasons go to the expense of obtaining official approval of dimetridazole for the treatment of trichomoniasis in bulls and cows. Preliminary evidence indicates the drug may be present in milk from treated cows for a period of 4 to 6 days.^{24a,b}

Treatment of bulls without eradication of *Trichomonas fetus* in the herd is useless, since bulls which have recovered are susceptible to reinfection. Careful observation and repeated checking of the bulls after treatment is necessary. This is the most important aspect of the treatment of bulls for trichomoniasis. For 3 months after treatment with Bovoflavin Ointment negative preputial samples even if collected twice a week have little significance. Furthermore, test matings with susceptible females were not reliable during this period. Coitus with 2 or more virgin heifers might be allowed at intervals during this posttreatment period and vaginal mucus samples should be examined and cultured frequently between 12 and 19 days after coitus. If still negative the bull can be restored to service but careful observations should be made on females bred to him.

Further studies on cure rates and the required testing protocol to be followed in assessing the posttreatment status of bulls after the use of the nitroimidazole drugs is indicated.

Prevention—Preventing the introduction of trichomoniasis into a herd is of vital interest to an owner and his veterinarian. The precautions should include: knowledge of the reproductive efficiency in the herd of origin of any stock purchases; thorough examination of newly-purchased suspect bulls with a pipette to obtain preputial samples for culture, at least 3 to 6 times at weekly intervals; repeated examinations 12 to 19 days after coitus of the vaginal mucus of the first 3 or 4 cows and heifers bred to these bulls; and prohibition of coitus for newly-

purchased nonvirgin, nonpregnant heifers and nonpregnant cows that have had coitus since their last calving, to prevent the introduction of trichomoniasis by females. These animals should be bred by artificial insemination. All recently acquired cows that are pregnant should be withheld from coitus for 90 days after calving and allowed to pass at least 2 heat periods before being bred naturally.¹²

In artificial breeding centers the need for a careful examination and history on the bulls before purchase, and proper and frequent examination, 3 to 6 negative preputial examinations at weekly intervals, of all service-age bulls as they enter the stud and periodically thereafter is essential to prevent the possible introduction and spread of this infection into many herds. Owners should be careful of their source of semen for artificial insemination in their herds especially if a herd sire is also maintained.

VIBRIOSIS

Definition—Vibriosis or venereal campylobacteriosis is a venereal disease of cattle caused by *Campylobacter fetus venerealis* spread at the time of coitus or at the time of artificial insemination with improperly handled and treated semen, and characterized by infertility with an increased number of services per conception. Early embryonic deaths are common and abortions from 4 to 7 months of gestation are occasionally observed. The cow develops an immunity to the infection and will have a subsequent normal gestation period but may remain a carrier for many months. The older bull remains a chronic carrier of infection. Although the name of the organism has been changed from *Vibrio* to *Campylobacter* the disease will continue to be called Vibriosis.²⁴

Etiology—Vibriosis was first described in 1910 and 1913 in sheep and cattle. During the period of 1918 to 1923 a number of reports were made on the causative agent, pathogenesis, and other factors associated with this disease^{68,69,70} and the organism called *Vibrio fetus* now called *C. fetus*. This organism may appear as motile, or nonmotile, gram-negative, short, comma-shaped rods, or as double spiral-shaped filaments. It grows slowly, scantily, and with difficulty on most laboratory media. All laboratory animals except guinea pigs appear refractory to infection but the organism may be pathogenic for chick embryos. *C. fetus*, is pathogenic for man in which it causes an undulating fever, placental infection and abortion.^{25,26} There is a close genetic relationship between certain ovine, bovine and human vibrios

so human vibriosis might be acquired by contact with animals.

Within the past 25 years the various pathogenic vibrio have been isolated and studied.^{8,18,19,24,50,80} (See Table 18.) *C. fetus venerealis* is a serologically homogenous strain and both Type I and Subtype I (or Type II)^{27-29,50} are similar in antigenicity and pathogenicity. *C. fetus intestinalis* is also pathogenic in that it is a common cause of abortion in sheep and causes sporadic abortions in cattle. *C. fetus intestinalis* only rarely produces infertility.¹⁹ It can survive for a period of time in the gut of animals but does not persist in the genital tract of cows. There are 3 serotypes of *C. fetus intestinalis*; A and B are found in the intestine of sheep and cattle while C, including *C. fetus jejuni*, are found in the intestines of mammals and birds. This latter serotype C causes abortion in sheep and enteritis in dogs and man.²⁴ *C. bubulus* also found in the genital tract does not produce disease and²⁴ does not persist in the genital tract of cows. *C. bubulus* is a nonpathogenic vibrio that is commonly found in fecal material and in the cranial portion of the prepuce of bulls.

C. fetus venerealis is an obligate parasite found only in the female genital tract and its contents, fetus and placenta, and in the prepuce of the bull. *C. fetus venerealis* localizes in the anterior vagina and cervix and usually invades the uterus about 7 days after natural service to an infected bull. The infection remains in the uterus and oviducts for a number of weeks to 3 months producing a moderate endometritis and salpingitis.^{24,64} This results in infertility and early embryonic or fetal deaths. When an immunity develops the infection is eliminated. However, the infection may remain in the cervix and vagina for 8 to 18 months or more. Rarely a cow may carry the infection through a normal gestation period.^{19,22,53,58,59} Vulvar exposure of susceptible heifers with *C. fetus* failed to produce infection so spread of the disease by contact is unlikely.⁴⁷ Young bulls under 4 or 5 years of age are difficult to infect. They may carry the organism from cow to cow during the breeding season but rapidly become free of infection when isolated from infected cows.

In bulls over 5 years of age vibriosis may become a chronic infection in the prepuce and persist for years. The numbers of vibrio organisms in the sheaths of infected bulls varies greatly. Most of the organisms are present in the deeper portions of the sheath around the glans penis and fornix but no lesions are produced.^{21,28,63,77} Thus the carrier female as well as the carrier bull are responsible for maintaining the infection in the herd from year to year. Under certain circumstances bulls may develop immunity. The immunity or resistance in cows is not a strong one but is sufficient in most cases to permit conception and a normal gestation even if the organisms survive in the tract for several days or weeks.^{31,32,34,35}

C. fetus venerealis from the prepuce contaminates the semen as the organism has never been found in the deeper portions of the male reproductive tract. Special media, techniques and experience are required for the laboratory recovery of *C. fetus venerealis* from mucus from the vagina, cervix and uterus of cows and especially the contaminated mucus of the bull's prepuce. The Campylobacter organism is highly susceptible to light, drying and other adverse influences. It cannot live in the alimentary tract of the cow.⁸

Vibriosis is a venereal disease of cattle spread by the chronically-infected bull to susceptible cows by either natural or artificial service. The initial studies on this disease were done in the early 1950s.^{41,45,46,71,75} *C. fetus venerealis* was probably the most important cause of infertility in beef cattle in the western range states until preventive vaccines were commercially available.^{28,29,36,79} It may still produce significant infertility and losses in range beef herds. Until the advent of the widespread use of artificial insemination with antibiotic treated semen it was also a very common cause of infertility in dairy herds in the U.S.A.

Vibriosis has been reported widespread in nearly every state in the United States, in Australia, South Africa, Sweden, England, Holland, Canada, and other countries in the world. The presence of *C. fetus* in the semen can be explained in the same manner as the presence of

Table 18. Cultural Characteristics of the Common Campylobacter Organisms

Vibrios	Catalase	H ₂ S Production	Tolerance to 3.5% NaCl	Tolerance to 1% glycine	Fluorescent Antibody Reaction*
<i>C. fetus venerealis</i> (Type I & Subtype I)	+	—	—	—	+++
<i>C. fetus intestinalis</i>	+	+	—	+	(+)
<i>C. bubulus</i>	—	+++	+	+	—

*Conguate prepared from *C. fetus venerealis* (Obtainable from Armour-Baldwin Lab.).

trichomonads in the semen, namely by contamination of the artificial vagina at the time of service. **C. fetus** infections were found in 25 of 45 herds investigated in the region of Beltsville, Maryland.^{20,21} A 38 percent incidence of vibriosis infection in beef herds in California was reported based on the mucus agglutination test.³⁹ These herds had histories that were suspicious of vibriosis. Sixty percent of the 105 herds in Sweden studied by means of the mucus agglutination test were, or showed evidence of having been, infected with vibriosis.⁶ Thus vibriosis is probably much more widespread and common than is trichomoniasis and for this reason is of greater economic importance. Although abortion has been produced in a few animals by the intravenous injection of the organism, introduction of organisms into the animal's body by any means other than the genital tract of the female or the prepuce of the male has not resulted in infection. It is probable that natural infection of the cow except by coitus or artificial insemination is rare. Occasionally the infection might be spread from cow to cow by improperly cleaned instruments or insanitary procedures used in the treatment of the genital tract of cows. Infection except by coitus or insemination rarely if ever occurs even when infected and noninfected animals run together.^{21,41,46} In artificial insemination studs there is definite evidence of the intrastud spread of infection. Of 143 bulls in an artificial breeding stud 56 percent were infected; the percentage of infected animals was the same for 39 bulls that had never had a natural service as it was for 104 bulls that had previously been in natural service.³⁸ It was felt that contact and spread of infection between clean and infected bulls occurred on teaser bulls or steers at the time of semen collection or in pens where a number of bulls ran together and mounted each other. Over 20 percent of all bulls used artificially in Denmark were infected with **C. fetus**.^{60,61} The incidence of infection in susceptible cows is high following coitus with infected bulls. For example, of 30 virgin heifers bred with infected fresh semen at a dilution rate of 1 to 4 with extender without antibiotics, 26 heifers developed vibriosis.³⁸ Prior to the addition, of antibiotics to semen, artificial insemination was probably a major factor in the spread of this disease.⁶⁰ It is significant that in one large AI organization that conception rates based on 60 to 90 day nonreturns rose from 52 percent in May of 1948 to 74 percent in September of 1949 after the addition of antibiotics to the semen. No other changes or treatments were made in the semen collection, processing, or insemination. Since the advent of the regular and proper addition of antibiotics to semen the incidence of the disease is practically limited to herds using natural service. As with trichomoniasis the disease

is more prevalent in dealer's herds, valuable purebred herds, and institution herds, where there is a higher incidence of purchase and sale of cows and bulls. Virgin heifers and virgin bulls are free of the infection.

Signs—Vibriosis like trichomoniasis, is insidious in the manner in which it enters a herd. The condition may not be recognized for several months or more, until signs of infertility with failure of conception occur in a large number of cows. Herd infections have been described in the following manner.^{6,10b,21,41} **The acute type** of infertility problem is seen when the infection is first introduced by an infected bull into a susceptible herd. The drop in conception rate is marked, occasionally to less than 10 percent and the infertility may last for 2 to 6 months or more. Within this time the cows usually develop immunity with the production of antibodies of the IgA class that persist for months in the vagina. While the IgG antibodies are found in the uterus and rid that organ of infection in the convalescent phase of the disease,^{13,24} a cell mediated immunity may also be involved.¹³ Conception will follow breeding to either an infected or noninfected bull. Prior to the development of this immunity, breeding to a noninfected bull or with noninfected semen does not correct the infertility as the **C. fetus** organisms are present in the female from the original infecting service. **The chronic or subacute type** of infertility in a herd may be characterized by a history of an acute fertility problem in the past. Only a vague or intermittent infertility is present in the cows or in newly-purchased cows but a considerable amount of infertility may be present in the heifers after being bred to older infected bulls. This may not occur until the second breeding period if it is a practice to breed the virgin heifers in a herd to a virgin noninfected bull. In some herds the infertility may be limited to the portion of a herd served by a single bull, or it may involve all cows bred naturally, while cows being bred artificially with antibiotic-treated semen conceive normally. Examination of the bull and its semen usually reveals no abnormalities or lesions or explanation for the infertility. Abortions may occur in both the acutely or chronically affected herds but are more frequent in the acute outbreaks. Some virgin heifers have a natural immunity or develop it promptly and conceive within 2 months. Others conceive promptly but remain carriers of the organism for months. While others remain infected for months, have many services, or abort.^{58,59}

The specific signs of vibriosis in cattle may be listed as follows:

(1) Vibriosis may fail to become established in a susceptible animal after coitus with an infected bull, either due to natural resistance or because the numbers of or-

ganisms were too small to cause infection. Conception and normal gestation may occur. Occasionally the infection fails to establish itself rapidly in the uterus and cause the early death of the young embryo. Gestation therefore may continue for a number of months and then terminate in 3 to 7 months in abortion. The number of susceptible animals bred to an infected bull that fail to become infected are small, probably less than 5 to 25 percent. Thirty heifers that were artificially infected at the time of insemination; 7 conceived on first service and in 24 the infection became established.³⁸

(2) Endometritis and occasionally salpingitis has been described in *C. fetus* infection of the genital tract of cows and heifers.^{41,46,75} No vaginitis or cervicitis or other lesions were noted.^{28,53} A slight mucopurulent exudate may be present in the vagina. This may occasionally be noted as a discharge from the vulva and probably comes from the uterus or is due to other secondary infections. The infection or inflammation produced by *C. fetus* is mild in its effect on the mucosa. The estrual mucus may be cloudy and increased in amount in recently-infected heifers. The cervix may be reddened and postmortem gross and histologic examination of the uterus and endometrial biopsy may reveal an exudate and a slight to moderate degree of endometritis. By 30 days after inoculation of the cervix a subacute diffuse muco-purulent endometritis with a periglandular lymphocytic infiltration was present. The pathogenesis of *C. fetus* infection in cattle has been described.¹⁴ As the cow develops immunity and overcomes the infection, the estrual mucus becomes clear before pregnancy is established. In most recently infected animals the symptoms of endometritis pass unnoticed by the average owner or herdsman or are not detectable clinically. If cows are examined for failure of conception or infertility no specific signs of vibriosis can be observed. Rectal examination of the uterus is of no value in the diagnosis of an endometritis since the inflammation is so mild no obvious uterine changes are produced. No physical symptoms or lesions have been observed in the recently-infected bull. Most infertile *C. fetus*-infected cattle conceive before the endometritis and the organisms have completely disappeared.^{13,28,30}

(3) Infertility or failure of conception lasting for a period of 2 to 6 months, and in some herds 12 months, in susceptible cows or heifers bred naturally to an infected bull or bred artificially with fresh or frozen semen to which no antibiotic has been added is the most common symptom of vibriosis. Before 1950, it was thought that *C. fetus* was characterized principally by abortion; since 1950, however, infertility due apparently to the early death of the embryo caused by the *C. fetus* organism has been shown to result in the greatest economic loss. This

symptom of infertility and failure of conception, as in trichomoniasis, is the most constant and severe condition encountered with vibriosis. This has been demonstrated by field observations.^{21,41} In experimentally infected animals 19 artificially infected heifers required from 1 to 16 services, with an average of 5, per recognizable pregnancy.⁴⁵ In a similar experiment 20 heifers were infected.⁴¹ They required an average of 5.1 services per conception compared with an average of 1.3 to 1.6 services per conception for control heifers bred to uninfected bulls. A herd using 5 bulls, 1 of which was infected with *C. fetus* was described.^{20,21} The cows bred to the 4 noninfected bulls conceived with an average of 1.1 to 1.8 services per conception with 2.5 to 32 as the average number of days lost from first service to pregnancy. Of 18 cows bred to the infected bull, 5 failed to develop any infection and all 5 conceived on first service while the other 13 became infected and were bred an average of 3 services per conception with an average loss of 89 days from first service to pregnancy. Vibriosis in a range beef herd may be suspected when many cows continue to come into estrum in the latter part of the breeding season. The calving season is prolonged with a significant number of calves produced early followed by a period when relatively few calves are dropped and then late in the calving season more calves are born.^{28,36,79}

Pregnancy rates as low as 20 to 70 percent may be seen in some beef herds at the end of the breeding season. In other chronically-infected herds the pregnancy rates may be 60 to 85 percent with a poor conception rate in the virgin heifers. If routine vaccination of all breeding stock is practiced the pregnancy rate is usually from 80 to 95 percent.^{28,36,79} In an extensive field experiment it was reported that cows inseminated with semen from *C. fetus*-infected bulls had a much greater embryonic mortality rate and much lower nonreturn rate than with noninfected semen or with semen containing streptomycin.^{28,36,78} Cows bred with semen from infected bulls to which no antibiotic was added had a 42.7 percent conception rate compared to a 62.3 percent conception rate from similarly diluted semen from apparently noninfected bulls.

(4) Long estrous cycles ranging from 27 to 53 days with an average of 32 days are experienced by many recently infected cows and heifers.⁴⁶ Prolonged irregular estrous cycles of 25 to 60 days and even to 100 days are common following the first service of a susceptible female to an infected bull.^{6,21,41,75} This delayed or long interval may occur following any service in infected cows. Long cycles may be explained on the basis that fertilization takes place, the fertilized embryo may survive for 12 to 14 days or longer and is then killed or destroyed

by the *C. fetus* organisms, early embryonic death. If the fertilized ovum is destroyed prior to 14 days after fertilization then estrus will probably occur at the regular cycle length. Fertilization is apparently not affected by *C. fetus* infection.²⁰⁻²²

(5) Abortion was formerly considered the principal symptom of the disease. A 4 to 20 percent abortion rate of recognizable fetuses with an average of 12 percent in a herd was reported.⁵⁹ After reviewing the literature it was found that 3.4 to 29 percent of aborted fetuses from brucella-free cows were found positive on culture for *C. fetus*.⁶² An incidence of 8.6 percent of 1302 aborted fetuses were reported as positive for the presence of *C. fetus* in England.⁴¹ In both of these series a fairly large group of fetuses were so contaminated that recovery of pathogenic bacteria such as *C. fetus* was impossible. Of the 112 fetuses found positive in the latter study, 1 aborted embryo was recovered at 38 days, 1 at two months, 1 at two and one-half months, 5 at three months, 8 at four months, 30 at five months, 39 at six months, 15 at seven months, 3 at eight months, and 9 unknown. In a report on 198 aborted fetuses, the number of fetuses and the time of abortion was: 9 from one to two months of gestation, 14 from two to three months, 17 from three to four months, 29 from four to five months, 52 from five to six months, 36 from six to seven months, 26 from seven to eight months, 12 from eight to nine months, and 3 expelled dead at term. This was based on bacteriologic evidence in about 50 percent of the cases and on uncertain serologic evidence in the rest. Thus the greatest incidence of observed abortion is from 4 to 7 months of gestation. It is highly probable, according to our present knowledge, that abortions prior to 4 months are more common but are not observed and are considered as infertility or failure to conceive. Usually there is some indication of impending abortion after the fourth or fifth month of gestation by the presence of a vulvar discharge and slight edema of the vulva. Some enlargement of the udder may occur. In early abortions the placenta is usually expelled with the fetus. In late abortions retention of the fetal membranes may occur. Pyometra is rarely observed in *C. fetus* infection in cattle. The lesions in abortions at middle or late gestation are mainly in the fetal membranes, the fetus suffering secondarily because of interference with its circulation. The lesions resemble those of *Brucella* abortion. The intercotyledonary spaces are filled with a thick, purulent, viscid material. The cotyledons may be greyish white in color with much cheesy exudate between the maternal caruncle and the fetal cotyledon. The membranes may be thickened and edematous and the amniotic fluid turbid due to fetal diarrhea. *C. fetus* organisms may be found

in the placenta. The aborted fetus usually shows autolytic changes of subcutaneous edema; thin, bloody fluid in the body cavities; and a thick, yellow, flocculent, turbid material in the stomach that usually contains many *C. fetus* organisms. The stomach content of normal fetuses is clear, semi-liquid, and mucoid in nature.

Lack of libido in bulls—Infected bulls pasture-bred on susceptible cows copulate frequently. Because of the excessive sexual load occasioned by many of the cows returning to estrus, the bull may lose weight and libido.

Diagnosis—On the basis of the herd history or symptoms, a careful review of the breeding records, and a careful physical examination of the individual animals in the herd, including the bull, to be certain that no seminal pathology is present, a tentative diagnosis of vibriosis or trichomoniasis might be made. Since in most areas vibriosis is more common than is trichomoniasis as a cause for herd infertility and failure of conception, vibriosis is usually the diagnosis; but trichomoniasis should be suspected until sufficient tests have been made to make certain of the diagnosis.

Pyometra is rare in vibriosis but is occasionally observed in trichomoniasis. Abortions in trichomoniasis usually occur within the first four months and seldom after the fifth month of gestation while in vibriosis abortions in the fifth through eighth months are common. It is possible to find both vibriosis and trichomoniasis in a bull, a cow, or a herd. Herds with infertility due to sterile or infertile bulls with defective semen or infertility due to a lack of energy intake, especially in beef herds, may simulate the signs of vibriosis and a careful differential diagnosis is imperative.

Since vibriosis, similar to trichomoniasis, is not a systemic disease, antibodies are rarely found in the blood serum. Thus blood or serologic tests for diagnosing vibriosis are seldom used as reliable results cannot be obtained.

Since the infection in the female genital tract produces a local immunity, the agglutination test on vaginal mucus is useful for diagnosing the presence of vibriosis in a herd. Tests on vaginal mucus for the presence of antibodies to *C. fetus* was first described in 1949.^{71,75} This test was improved and made highly reliable for diagnostic purposes.^{6,39,46} The vaginal mucus from a cow or heifer infected with *C. fetus* gives a positive agglutination reaction approximately 30 to 80 days following the infecting service. This reaction persists in most cows for about 7 months or a range of 4 to 23 months. The mucus should not be taken from cows that have recently calved or for 3 to 4 days after estrus, as these cows may have metestrial blood in the mucus. Samples taken at these times may give false positive reactions. The excessive

amounts of mucus from cows in estrus should not be used for this agglutination test as false negative results may be obtained because the antibody level is diluted. In infected heifers only 21 percent of the vaginal mucus samples taken during estrus gave an agglutination reaction while 91 percent of samples taken agglutinated from about 4 to 5 days after estrus to 1 to 2 days before estrus.⁴¹ The agglutination test at the proper time on samples obtained from about 10 heifers which had been bred for the first time at least 2 months, but not over 9 months previously, should establish or disprove a diagnosis of vibriosis in a herd. The vaginal mucus agglutination test is most useful in dairy herds where the stage of the estrous cycle of open cows is usually known and confinement of cows in stanchions is often possible.

The tampon method of collecting vaginal mucus samples was perfected.⁷³ The technique of collecting vaginal mucus samples consists of holding the cow's tail to one side and washing the vulva and adjacent parts with soap and water. The vulvar lips are held open, and the vulva rinsed with clean water; a plastic 12 inch speculum containing both a tampon made of a gauze pad with a 16 inch string attached and the placement rod is inserted into the vagina. The speculum should be pushed as far forward as possible, and then the rod pushed forward, moving the tampon out of the speculum and into the cranial part of the vagina. To prevent air from entering the vagina and ballooning it, the thumb should be held over the end of the speculum while it is being withdrawn. The free end of the string is tucked between the vulvar lips to prevent its being soiled by feces. The tampon is left in the vagina at least 20 minutes to absorb an adequate sample of mucus. To remove the tampon wash the cow's vulva again, grasp the string and pull out the tampon and place it and the string in a plastic sample bottle. Samples should be kept in a refrigerator until mailed or taken to the laboratory. Inasmuch as no preservatives are added to the samples, they should not be sent through the mail over weekends or holidays to avoid spoilage. The necessary equipment may be supplied by the laboratory or made by the veterinarian. The use of a human vaginal tampon introduced into the cow's vagina with a plastic insemination pipette and transported in 4 ounce plastic bottles available in supermarkets has been described.³⁹ The laboratory should be sent an unused tampon and bottle for weighing. This is necessary to ascertain the amount of mucus present in each sample for dilution purposes. Care should be taken that infection is not spread from cow to cow. Separate equipment is necessary for each animal. Only certain vibrio antigens were suitable for the vaginal mucus agglutination test. Those that give too many false positive reactions when tested on virgin heifers

should be discarded.⁶ Any titer is significant but 1:25 is considered suspicious and 1:50 or more is positive.^{38,39} The number of positives in a representative sampling would vary, but one positive animal is probably sufficient to establish the presence of the infection in a herd.

Cultures of vaginal, cervical or uterine mucus taken at estrus from heifers and cows by pipette have been described.⁷⁵ Culturing of cervical mucus was the preferred method of diagnosing vibriosis in range beef herds as the animals only needed to be handled once and samples could be taken at any stage of the estrous cycle or even during pregnancy.^{28,23} Artificial insemination pipettes attached to 2-1/2 ml plastic syringes to produce a vacuum were adapted to collect cervical mucus samples.^{10b,28,30,33} The pipettes were passed through a sterile plastic or glass speculum to avoid contamination in the vestibular area. The pipettes were sealed with polybulbs and shipped to the laboratory in dry ice; freezing the pipettes in liquid nitrogen was not satisfactory because of breakage. The efficiency of recovering *C. fetus* from frozen vaginal or cervical mucus samples in the laboratory drops about 20 percent after 2 days in dry ice.¹⁰ This technique must be performed carefully and samples taken promptly to a laboratory for culture. In 88 samples of mucus from artificially- or naturally-infected heifers, vibrios were recovered in about 26 percent of the samples.⁴⁷ In another study 83.1 percent of the samples of mucus recovered from infected heifers at the time of estrus were positive on culture while only 26.5 percent of samples collected at other phases of the cycle were positive.⁴¹ Positive cultures were obtained from vaginal mucus samples taken by a specially-designed instrument, from animals recently bred, repeatedly bred, after calving, and after conception. A total of 429 vaginal mucus samples were collected and 26 percent were positive for *C. fetus*.²¹ Positive isolations from vaginal mucus were made as early as 11 days and as late as 224 days after conception. Positive cultures were obtained from 8 cows 21 to 196 days after calving. In a total of 114 vaginal mucus samples from 71 known virgin heifers none was positive for *C. fetus*. On routine examination of *C. fetus*-infected cows or heifers *C. fetus* was recovered from vaginal mucus in 76 percent of the cattle for only 40 days; in 12 percent the organism was found for 2 to 6 months; and in the remaining 12 percent for 7 to 12 months.²¹ About 50 percent of heifers were positive on culture one week after exposure to *C. fetus*.³³ From 3 to 9 weeks after breeding large numbers of vibrio were present in the samples. During the first 3 months after exposure nearly all open heifers, 80 to 90 percent, were positive so at this time random samples from 6 to 10 open heifers in a herd would be adequate for a diagnosis.

In cattle exposed 6 months previously only 20 percent were positive so 20 samples of mucus should be taken from open heifers or cows at this stage of the infection. Samples taken at the time of calving gave poor results. A biopsy instrument to recover the organism from the uterus of infected cows or heifers was described.⁷⁵

Culture of *C. fetus* from semen and preputial smegma—Although the other diagnostic tests are very useful, the isolation of *C. fetus* is the only unequivocal test. When cervicovaginal mucus can't be cultured promptly after collection the F.A. test is the best.³ Cultures of *C. fetus* can usually be recovered by a well-equipped laboratory with trained personnel. In culturing 306 ejaculates taken in as sanitary a manner as possible from 81 infected bulls vibrio were recovered in 20 percent of the samples.³⁸ In 307 samples on another trial *C. fetus* was recovered 20 percent of the time, or once in 5 ejaculates.²¹ The culturing of preputial smegma samples taken in the same manner as for recovering trichomonads was described.^{67,82} This procedure was more accurate than the culturing of semen samples. Special techniques were necessary because of bacterial contaminants in the prepuce. A fluorescent antibody screening test was developed to use on preputial and vaginal mucus samples; a positive test required confirmatory vibrio cultures, since certain *C. fetus intestinalis* strains and occasional *C. fecalis* strains fluoresced.^{80,82}

Another rather cumbersome technique used to detect *C. fetus* in bulls is to breed them to 2 or more virgin heifers and obtain vaginal mucus for culture from the fifteenth to the thirtieth day.²¹ After inseminating 1 ml. of undiluted semen into the cervical canal of 2 or more virgin heifers during estrum, samples were taken from the uterus 4 days after service and once a week thereafter, regardless of the phase of the cycle. In 8 heifers bred in this manner to known infected bulls 32 of 35 uterine biopsy samples were positive for *C. fetus*, while only 15 of 35 vaginal mucus samples taken at various times in the estrous cycle were positive on culture.^{1,2} This technique resulted in a positive diagnosis 14 days after breeding the heifer. Later, as a means of diagnosing vibriosis in a bull it was recommended to take 3 ejaculates from a bull in the same vagina, and douche the prepuce with saline solution. The semen and saline douche fluid were mixed and centrifuged. One ml. of sediment was inseminated into the cervix of a heifer in estrum and the heifer was cultured as described previously.^{60,61}

Procedures have been developed so veterinary practitioners can collect vaginal mucus, semen or preputial samples in the field in a proper manner and have them reach the laboratory in satisfactory condition for culture. More laboratories are being equipped with facilities and

personnel for performing this culturing technique. The fluorescent antibody technique aids greatly in the diagnosis of vibriosis by detecting *C. fetus* in cervical mucus cultures.⁴³

Aborted fetuses should always be cultured as this is one of the easier methods of diagnosing the presence of *C. fetus* in a herd. Immediately following abortion the fetus and possibly the fetal membranes if clean and not heavily contaminated should be taken to the laboratory for culture. The stomach contents and lungs are the organs in the large fetus from which *C. fetus* may most commonly be cultured. In small fetuses the amniotic fluid may be cultured. Some workers have reported finding the organism on direct smear or by fluorescent antibody techniques or culture of the stomach contents or exudate on the fresh cotyledons of the placenta.²⁴ If the fetus is small and cannot be taken immediately to the laboratory in the fresh state, it may be frozen, packed in dry ice, and sent by special delivery. If the fetus is large, the esophagus, duodenum and trachea may be carefully ligated and the stomach and lungs removed and handled as above. Ten to 39 ml. of stomach fluid from the aborted fetus may be removed in an aseptic manner and placed in a sterile vial. This may be frozen and shipped. If the fetus lives for even a short time, usually the stomach contents are contaminated by many bacteria. It is often possible in abortions caused by *C. fetus* to obtain pure cultures of this organism from the stomach contents of the fetus. The finding of the organism is a certain diagnosis that *C. fetus* is present in the herd. A differential diagnosis should be made between *C. fetus venerealis* and *C. fetus intestinalis* in cases of bovine abortion.

Prognosis—In vibriosis the prognosis in the cow is usually favorable as the infertility ordinarily is temporary in nature and after a period of 3 to 6 months most infected cows develop immunity to the infection and conceive. The greatest loss is economic and is due to the delay in conception. Most cows if they abort conceive after a suitable period of sexual rest unless a secondary infection produces permanent damage. Old bulls remain chronically or permanently infected unless isolated and treated. In many young bulls the infection is transient and disappears when they are removed from service.

Treatment—Our present knowledge is adequate to largely control vibriosis in beef herds and to eradicate the disease in dairy herds. Basically, the control methods are the same as in trichomoniasis. Genital contact between infected and noninfected animals should be prevented. Presently systemic vaccination with bacterins is highly effective in controlling infertility due to vibriosis in cattle.^{5,10a,b,28,40}

In a dairy herd the best and easiest way to control

vibriosis is to breed only artificially with semen from noninfected bulls; or with semen from infected bulls, that has been diluted or extended at least 1 to 25 with extender to which 500 to 1000 units of penicillin and 50 to 1000 micrograms of streptomycin or other effective antibiotics for each ml. of extender have been added. This extended semen should be held at refrigerator temperature for at least 6 hours before use. The semen should be collected, diluted, cooled, and held according to methods outlined in the chapter on artificial insemination, to assure maximum sperm survival. The handling of infected semen in this manner will, by the time of insemination, destroy any vibrio organisms present.⁵⁴ Vibrio-infected semen diluted 1 to 4 with extender without antibiotics resulted in 26, or 86.6 percent of 30 heifers becoming infected with vibriosis after insemination.^{38,45} When the infected semen was similarly diluted 1 to 25 with an extender without antibiotics and used to inseminate 29 heifers only 4, or 13.8 percent, became infected. This indicated the value of dilution in reducing the incidence of infection. In 94 heifers inseminated with infected semen diluted 1 to 25 with extender to which 500 units of penicillin, 500 micrograms of streptomycin and 3 mg of sulfanilamide per ml. had been added, then stored for 6 hours, none developed vibriosis. *C. fetus* was not isolated from 99 "repeat breeding" cows and heifers and cows from 7 herds that had been artificially inseminated with antibiotic treated semen from known infected bulls.^{21,22} Streptomycin alone was as effective as combinations of streptomycin and penicillin and sulfanilamide in controlling the spread of *C. fetus* in the semen.⁷⁸ The author has never recovered a fetus positive for *C. fetus* from an aborting cow that had been bred only artificially with antibiotic-treated semen. However the use of antibiotics in semen was considered an uncertain method of controlling vibriosis. The author knows that on the basis of the above data and his experience this method is highly effective but agrees that it is a thin line of defense against the disease. Bulls used for artificial insemination should be free of vibriosis to be certain that they cannot accidentally spread *C. fetus* in the semen.

The control of *C. fetus* in frozen semen is more difficult than in the extended liquid semen because the glycerol interferes with the effect of the antibiotics on the organism. Evidence was presented to show that frozen semen from vibrio-infected bulls extended with egg-yolk-citrate buffer with penicillin and streptomycin added in the proportions of 500 to 1000 units and 500 to 1000 ug respectively, did not produce vibriosis or infertility when used for the insemination of virgin heifers.⁴⁴ Although ampules of recently frozen semen may contain

viable vibrios holding frozen semen for several weeks resulted in their destruction. This has been confirmed over the past 20 years as very few cases of vibriosis have been reported in cattle bred with properly treated frozen semen. Two heifers were reported to have been infected with frozen semen stored for a year in an antibiotic and glycerol extender.⁵¹ Such occurrences are probably rare. The addition of 500 units of polymyxin B sulphate, 500 units of penicillin and 1000 ug of dihydrostreptomycin per ml. of extended frozen semen also was an effective means for the control of vibriosis.⁷² Recent studies have shown the importance of the antibiotic treatment of raw semen before it is extended and frozen and to evaluate the efficacy of antibiotic treatment procedures with each extender and processing technique used by the AI industry to prevent the spread of *C. fetus* in semen. Antibiotic treatment of *C. fetus*-infected semen extended in 3 common extenders did not eliminate the organism in one of them.^{36b}

In controlling vibriosis in a herd, artificial breeding to a noninfected bull, or to an infected or suspect bull after proper dilution and treatment of the semen with antibiotic and storage before use, should probably be continued for at least 2 to 3 years, in light of work indicating that vibrio will survive in the cow for only a short time in 75 percent of the animals, for longer periods of 2 to 12 months or more in another 24 percent of the infected females, and in a few cows for as long as 196 days after the termination of a normal pregnancy initiated by infected semen. Further work is necessary on this aspect of the disease. A total insemination program for most beef herds is impossible to accomplish so other control methods, particularly vaccination are necessary.

Some veterinarians advocate a period of 3 month's sexual rest for the acutely infected herd, after which breeding can be resumed with the infected bull or by artificial insemination inasmuch as within this time the cows have probably developed a satisfactory degree of immunity or resistance to the infection. The value of a 3-month rest period is questionable except to conserve the bull, as some females recover more promptly than others and if these were withheld from service the economic loss would be unnecessarily increased. Following natural infection a good immunity to vibriosis is produced that lasts from one to three years.^{2,8,31} The virgin heifers may be bred to young virgin bulls, which should continue to be used on them for the second pregnancy and thereafter. The infected bulls may be mated to the infected, immune cows and this program continued until the infected herd is eliminated. This procedure is difficult to follow over a period of years without an accident that would allow the infection to spread by venereal con-

tact from the infected cows or bulls to the vibrio-free herd.

In beef herds where artificial insemination is impractical and the maintenance of two herds, a clean one and an infected one, is not possible, vaccination each year with a commercially-available adjuvant bacterin of all animals of breeding age a few months before the breeding season is indicated. Vaccination with a proven highly antigenic bacterin at either one or two intervals provides a good level of immunity even in virgin heifers bred to infected bulls.^{5,11,12,23,35-36,40,43,52,57} Although *C. fetus* organisms may occasionally be found in the genital tract of vaccinated heifers soon after service to infected bulls, conception occurs promptly and the organisms disappear rapidly in most animals due to the presence of antibodies of the IgG variety.¹³ But a vaccinated animal may be a short-time carrier of the infection and infect a susceptible bull that serves her. This resistance produced by vaccination is usually sufficient to overcome the carrier state in cows¹³ and possibly bulls.^{5,11,40} Conception rates of 90 percent are common in vibrio-positive beef herds following vaccination. Commercial adjuvanted vaccines (Vibrin, Norden Lab, Bo-Vibrio, Armour-Baldwin Lab. and Tri-vib, Fort Dodge Lab.) with either one to three strains of *V. fetus venerealis* and others, some combined with leptospiral vaccines appear equally effective in cattle herds in producing immunity and controlling the disease in the U.S. when given once a year. Vaccination of heifers 6 months or more before the breeding season may result in some loss of immunity by the time of service to an infected bull. Even though a good degree of immunity is present a year or more after vaccination, yearly vaccination 10 to 14 days before the breeding season is recommended.⁴ It is advised in order to maintain a high level of immunity and better conception rates. Vaccinal immunity and convalescent immunity decreased from 1 to 4 years after vaccination or exposure.^{10a,b,31} So an annual single vaccination of all cows in infected herds 30 to 120 days before breeding is usually recommended.

Systemic vaccination with an adjuvant bacterin produces sufficient IgG to protect the cow or heifer against uterine infection even though antibodies in the blood are low.^{13,24} Thus by means of either artificial insemination with properly controlled vibrio-free semen, separation of the herd into vibrio-free and vibrio-infected groups with proper isolation and control, by yearly vaccination with a bacterin of all breeding females or by a combination of these methods vibriosis as a cause of infertility in a herd can be controlled.

Treatment of individual cows by the intrauterine infusion of about one gram of streptomycin together with

penicillin in an aqueous or oily base has proven quite effective in controlled studies in eliminating the vibrio organism from the female genital tract. Elimination is most efficient if given within 24 hours after service to an infected bull.^{1,15,49,74} Practitioners evaluating such treatments should realize that within a few weeks after the initial infection and endometritis most cows are developing immunity and recovering from the disease. Treatment of infected cows, unless it closely follows the infective service, is in reality being given to convalescent animals. Thus antibiotic infusions of infected cows are of limited or uncertain value.

The treatment of bulls for vibriosis—Most young infected bulls have only a transient short-term infection and then spontaneously recover in a few weeks or months if the organism is not reintroduced into the prepuce. Twenty-two young bulls were repeatedly exposed preputially to *C. fetus*. They became long-term carriers between 40 and 70 months, 3 and 5-1/2 years, of age. Four of these bulls developed a temporary carrier state of 4 to 29 days prior to the long-term carrier state. The use of young bulls to limit spread of *C. fetus* is of dubious value. Vaccination of bulls is a better preventive measure.^{10b,15b} Bulls over 5 years of age may remain permanently infected although occasionally even old bulls will spontaneously recover from the disease.¹⁰ Bulls do not develop a long-lasting or permanent immunity to the infection. However effective vaccines incorporating large amounts of antigens and adjuvants have been developed in Belgium and Australia that will apparently produce sufficient immunity to terminate natural and prevent new infection in bulls.^{5,11,12} With immunized bulls temporary or passive contamination of the penis and sheath after breeding an infected heifer is not an important or significant factor in the spread of genital infection of *C. fetus*.^{12a} Only 1 of 47 susceptible heifers bred by a vaccinated bull shortly after service with an infected heifer developed an infection with *C. fetus*.

Although bulls are usually vaccinated with bacterins in the U.S., it should be noted the *C. fetus* lives commensally in the crypts and on the surface of the epithelium of the prepuce without producing any inflammation. Therefore it is difficult to envision circulating IgG diffusing into the prepuce and eliminating the organism unless there is enough "inflammation or trauma" produced at repeated copulations. Large repeated doses of vaccine might prevent or cure infection in bulls.^{10b,40} Further studies in the U.S. with available vaccines are needed.⁴⁰ If bulls are cured with antibiotics or vaccines they may readily be reinfected. There is little value to eliminating infection in a bull if he is to remain in natural service in infected herds. In an AI stud it is highly de-

sirable to eliminate vibriosis from all bulls even though the addition of antibiotics to the semen has proven quite effective in controlling vibriosis. Swedish and Danish AI studs have eliminated vibriosis and this was accomplished in a large AI stud in the U.S.A.⁴² Prior to treatment of bulls rigid control measures on the movement of bulls and hygienic measures in the collection of semen were instituted. All bulls in the stud were tested semi-annually by culturing and immunofluorescence of preputial smegma samples. Each new bull entering the stud was tested similarly during the isolation period of several months. All bulls infected with *C. fetus venerealis* were treated with 5 gm. of dihydrostreptomycin sulfate in 10 ml. of a 50% aqueous solution infused in the preputial cavity and massaged thoroughly through the skin of the sheath for 5 minutes while the preputial orifice was closed. This was repeated daily for 5 treatments. At the time of the first and third treatments two subcutaneous injections of 22 mg/kg of body weight of dihydrostreptomycin were given.⁴² Repeated tests of preputial mucus were conducted at biweekly intervals after treatment. Test breeding of virgin heifers to treated bulls followed by repeated cultures of the cervical mucus of the heifers could be done to determine if the treated bulls had eliminated the infection. This technique is more costly than the direct sampling of the preputial smegma. Treatment produced mild focal reddening and ulcerations of the penile mucosa that healed promptly. Other antibiotics in the treatment of vibriosis in the bull have been tried because of fear of producing streptomycin-resistant vibrio organisms, since streptomycin is also used to control the organism in semen. These antibiotics, tylosin and furacin have not proven as effective as streptomycin in the treatment of infected bulls.

BRUCELLOSIS

Brucella abortus infection has been discussed previously under the section on abortion, (See Chapter V) as that is the principal characteristic of the disease. However, evidence indicates that *Brucella* infection of the uterus plays a definite role in infertility even though infertility and endometritis did not occur in the recently infected nonpregnant animal.¹⁷ The role of the bull in the transmission of brucellosis is minor but interesting. According to early field observations, the bull was gen-

erally supposed, to be one of the more important factors in the spread of the disease. But the transmission of brucellosis from infected bulls to susceptible cows by natural service has not been demonstrated in controlled experiments. Infected bulls when bred naturally to heifers in estrum rarely spread the disease even when the prepuce had been artificially contaminated with *Brucella* organisms prior to service.^{54,55,75} However, it has been demonstrated that susceptible cows artificially inseminated into the uterus with infected semen from a positive *Brucella*-infected bull would develop brucellosis.^{16,54,55} Most infected bulls harboring foci of infection in the genital tract discharge *Brucella* organisms intermittently in the semen, but one bull had viable organisms in 80 consecutive ejaculations over a period of 18 months.⁵⁵ The uterine infection produced in heifers by intrauterine insemination of infected semen resulted in impaired fertility; only 1 susceptible heifer conceived on the first service out of 12 inseminated; 8 of the 12 susceptible animals became infected; only 2 infected animals conceived, and 1 of these aborted at 104 days of gestation. Each animal was inseminated an average of 3.5 times. The infertility was temporary, lasting 3 to 12 months. These results were interesting when compared with 12 other susceptible heifers bred artificially to the same bull but with the semen being inseminated into the external os of the cervix; 9 of 12 animals conceived on the first service.^{31a} From these experiments *Brucella abortus* should be included with *C. fetus* and *T. fetus* as an agent that can and will produce infertility or temporary sterility when introduced into the bovine uterus. Under natural conditions *B. abortus*, not being motile, cannot invade the uterus from its vaginal deposition as can *C. fetus* and *T. fetus*. This is a further reason for inseminating cows by placing semen into the cervical canal rather than into the uterus.

Intrauterine insemination may introduce other pathogenic bacteria that may cause failure of conception, endometritis, and temporary sterility especially if insemination is done late in the estrous period or in metestrus when the genital tract is under the influence of progesterone. Following abortion due to *Br. abortus*, a sexual rest period of 90 days or more and possibly several uterine treatments may be necessary to aid involution and recovery of the endometrium necessary for conception. Aborting animals should be isolated, as ingestion of infective material and discharges from the genital tract is the most common means of spreading brucellosis.

Further evidence of the adverse effect of *brucella* infection of the uterus was a report²⁰ that sterility was 4 times more frequent in suspects and 8 times more frequent in *Brucella* reactors than in negative animals. *Brucella*-positive cows averaged 2.8 services per conception

following normal calvings and 3.6 services per conception following abortions.⁶¹ Other evidence of this type was cited.⁶⁵ A more severe endometritis was present in infertile *Brucella* positive cows than in infertile *Brucella*-negative cows.¹⁸ These many reports serve to emphasize strongly the role of ***Brucella abortus*** in causing infertility in a herd, and the necessity of controlling this disease to prevent severe economic losses due to reproductive failure and abortion.

GRANULAR (NODULAR) VENEREAL DISEASE (GRANULAR VULVITIS) AND MYCOPLASMA, UREAPLASMA AND HEMOPHILUS INFECTIONS

According to Williams this disease was first described in Switzerland by Isepponi in 1887 as a cause for infertility and abortion.⁸² Since that time there has been much debate on whether or not the disease is an important cause of infertility. Most workers agree at present that there is no evidence linking this disease with abortion. Williams stated: "It may be said to be a lesion without a known cause and regarding the effect of which there is scant knowledge." No disease of the reproductive system of cattle has been so unproductive of conclusive results on research as has granular venereal disease. Only in the area of histopathology is there any agreement on the nature of this disease. The lesions and the mucopurulent vulvar discharge often following service, are readily noted by both farmers and veterinarians. Therefore granular venereal disease or granular vulvitis has frequently been incriminated as a cause for infertility in cattle. The term granular vaginitis used to designate this disease is a misnomer as the papules or granules are largely limited to the vulvar mucosa and are only sporadically found in the vagina.⁴⁵

The disease is seen most commonly in heifers during the breeding period for their first and second pregnancies. The condition has been noted occasionally in calves as young as 11 days of age and in heifers prior to puberty. It is less acute and severe in middle-aged and older cows. It is observed most commonly in postpartum heifers and cows especially following natural service and less commonly as pregnancy progresses toward term. It is rarely observed at the time of parturition. Granular venereal disease is seen in practically any herd at any time of year with an incidence varying from 10 to 90 percent of the cows or heifers. Occasional acute herd outbreaks are observed that spread rapidly through the herd and even affect prepubertal heifers. This may be due to the vulvar sniffing which is common in cattle. This may carry the organism from the nose of one animal to the vulva

of the other.^{13,23-26,51} Since the mycoplasma and *Hemophilus* organisms are commonly found in the respiratory as well as the lower genital tract spread of infection is favored by this behavior. The lesions differ greatly in severity between heifers and cows in a herd. In general the disease occurs more commonly and more severely in young cows or heifers being bred naturally by the bull than in those being artificially inseminated. The lesions of this condition may be observed on the penis and prepuce. The lesions are present more commonly in bulls serving cows naturally than in bulls in an artificial insemination stud that ejaculate into an artificial vagina. The disease in bulls should be called **granular venereal disease** or **granular balanoposthitis**.

The mode of spread of the disease is not known, but apparently if it is due to an infectious agent, it is spread rapidly and easily. This is difficult to prove, inasmuch as isolated control heifers may develop the condition. This condition in cows more properly should be called a granular vulvitis. In the acute stage in cows these nodules are reddened and highly inflamed, causing a mucopurulent type of discharge that may mat and hang from the vulvar tuft of hairs. If these cattle are bred by a bull, or if a speculum is passed, the granules or nodules are likely to bleed. The cow or heifer in this acute stage exhibits some pain when the vulvar lips are handled and may exhibit irritation and pain when urinating, as well as by not standing quietly to be bred. In these acute severe cases there are many nodules, usually appearing confluent and tending to be in ridges or rows on the top of the folds of mucous membrane. The vulva may be slightly swollen. Occasionally discrete, 2 to 5 mm, white inclusion cysts containing an exudate may be observed in the dorsal commissure or lateral walls of the vulva.^{23,25,45} Bulls with acute severe lesions may occasionally refuse to copulate or will be slow to breed. Coitus tends to aggravate the lesions especially in heifers with a small vulva that are bred to a large bull. In mild and chronic cases of granular venereal disease the lesions are few in number and are usually found around the lower half of the vulva and around the clitoris. The chronic nodules are pale yellow in color and no exudate or inflammation of the mucosa is apparent. Following breeding the granules that were pale before breeding ordinarily become congested and reddened. Thus chronic lesions may become acute. But chronic lesions are much more common especially in cows the last half of the gestation period.

These nodules or granules histologically are lymph follicles, lymphoid accumulations, or hyperplastic lymphoid elements beneath the mucosa and therefore the disease may be a normal response to various insults. It is interesting to note that similar lesions have been de-

scribed in the dog.¹ In the male dog a follicular balanoposthitis with hypertrophied lymph follicles may occur. In the bitch similar lymph follicles in the vulva were described. These lesions are common in the genital tract of sheep, goats and swine, but in a mild form.^{1,45,82}

These granular or papular hypertrophied lymphoid lesions in the mucous membrane are similar to those observed beneath the third eyelid in follicular conjunctivitis in dogs and in follicular pharyngitis in horses. These latter two conditions are usually ascribed to and associated with bacterial or possibly viral infections.

The cause of granular venereal disease has been ascribed in many reports over many years as due to *Streptococcus vaginitidis*, a hemophilus-like pleomorphic rod, a virus and other organisms, mycoplasma, *C. pyogenes*, *Staphylococci*, and *E. coli*, and most recently ureaplasmas or T.-mycoplasmas and *Hemophilus somnus*.^{1,2,22,23a,b,26b,43,51,69}

Mycoplasmas or ureaplasmas are very small bacteria that lack a cell wall. They are commonly found in the upper respiratory tract and lungs and the vagina and vulva of cattle and also humans.^{1,13,21,23a,b,26b,31b,50,51,62,73} They are generally susceptible to the tetracycline antibiotics.²³ Mycoplasmas and ureaplasmas vary greatly from non-pathogenic to pathogenic strains. Some authors, indicate they may be part of the normal flora of the vagina and vulva and prepuce and penis. They are seldom found in the uterus and oviducts.^{13,21,62,73} Pathogenic ureaplasmas were inoculated into the uterus or cervix of 23 virgin heifers, 16 of 19 heifers developed granular venereal disease lesions in about 4 days from which the organism could be isolated for 13 to 41 days. Clinical cases of the disease persisted for several months. However the ureaplasma could only be isolated from the uterus or uterine tubes for 1 to 7 days. Only a short-lived endometritis and salpingitis were produced.^{25,26} When heifers were bred naturally to a bull infected with *Mycoplasma agalactiae* var *bovis* the IgA levels in the vagina rose to high levels while the IgG levels in the noninfected uteri remained low. Thus this reaction resembles that seen in vibriosis. The evidence indicates that IgA provides protection for the animal in the superficial areas such as the vagina and the nasal cavity and the IgG provides protection for the deeper organs of the body such as the uterus and lungs.²¹ One study showed that pathogenic ureaplasma (T. mycoplasma) could cause cessation of ciliary activity, ciliary collapse and sloughing and finally disorganization of epithelial tissues with necrosis and desquamation⁷³ which might explain the underlying cause of infertility when these organisms affect the ciliary activity of cells in the cervix, uterus and oviducts of upper genital tract of cows.

These studies, though quite convincing,^{23-26,71} require further confirmation as others have doubted whether a specific agent is the cause of bovine granular venereal disease.^{45,70}

The incubation period for the development of the acute stage of granular venereal disease is short, 2 to 5 days, after exposure or breeding with the formation of nodules or papules in the vulva and around the clitoris that are red and inflamed and result in a mucopurulent discharge. The acute phase gradually recedes over the next 2 to 3 months unless reinfection occurs. But this latter response is much less severe than the initial reaction.^{25,26} Others have reported a 2 to 3 week incubation period with an increase in severity and number of granules developing, through the eighth week.²² The lesions of granular venereal disease consist of small elevated papules or granules found mainly on the vulvar mucosa just inside the vulvar lips most commonly in the region around the clitoris. (See Figure 105.) In more severe cases the granules may extend up the lateral walls of the vulva to the dorsal commissure. Diagnosis is based on the clinical signs and lesions of granular venereal disease.

In the 1950's about 10 percent of 2530 cows were found affected with granular venereal disease.⁷⁶ The fertility of affected animals was 6 percent lower than that of the other 90 percent. Of 4616 cows being bred by artificial insemination; 49 percent had no evidence of granular venereal disease; 44 percent, or 2,065 had mild symptoms; and 7 percent, or 289 cows, had severe lesions.⁷⁶ The conception rates on first service in each group were 68.9 percent, 65.7 percent, and 58.1 percent, respectively. Therefore the difference in rates was significant. Whether *C. fetus* was present and influencing these results was not reported. A temporary infertility was as-

Figure 105. Granular Venereal Disease in a Heifer—Note the concentration of lymphoid follicles around the clitoris.

sociated with granular venereal disease.²²

Canadian researchers^{23,26,50,51,62} have isolated ureaplasma (T. strains of mycoplasma). **Mycoplasma bovinegenitalium** and **Hemophilus somnus** from clinical cases of granular venereal disease. Ureaplasmas were isolated from 100 percent of acute granular vulvitis cases, from 74 percent of chronic cases and from 23.5 percent of normal herd mates.²³ Recent advances in laboratory culture methods, special transport media,⁵¹ refrigeration and rapid transport to the laboratory are necessary to isolate these organisms.

These organisms are commonly found in the external genital organs, vulva and prepuce, and respiratory tract of cattle. Mycoplasma which encompass many species of achleoplasma, including **A. laidlawii**, and **M. bovinegenitalium** and **M. (agalactiae) bovis** and the ureaplasmas of which there are many species, are found on serosal or mucosal surfaces of the urogenital and respiratory tracts, mammary gland, joints and eyes. **Hemophilus somnus** is a Gram negative coccobacillus that causes septicemia, pneumonia, thromboembolic meningo-encephalitis, probably the calf diphtheria syndrome in feedlot or young cattle, and arthritis.⁵¹ These organisms may be found in both normal and diseased animals. Further studies are indicated to differentiate the pathogenic and non-pathogenic species of these organisms by serologic or other methods and to better understand their role in abortions, granular venereal disease (vulvitis and balanoposthitis), endometritis, toxic metritis, salpingitis and seminovesiculitis in cattle and other animals. It should be further noted that mycoplasmas and ureaplasmas also cause infertility, abortion and urethritis in humans.^{31b,40}

The prognosis is usually fair to good in granular venereal disease but in acute cases it may be 2 to 4 weeks or more before the acute signs subside. As far as completely curing the condition in cows and bulls the prognosis is guarded, as sometimes several months or more are required. Granular venereal disease may remain chronic, or acute lesions may recur. In longstanding cases in bulls, the lymphoid enlargements may become fibrotic. If a high incidence of early embryonic deaths occur with this disease one should suspect a combined infection with **C. fetus** and/or **T. fetus**.

Mycoplasma bovinegenitalium, ureaplasmas and **Hemophilus somnus** were isolated from acute cases of granular vulvitis or granular venereal disease in cattle associated with a purulent discharge, endometritis and infertility. This acute form of the disease was seen most commonly with intensive management, over-crowded, unsanitary free-stall barns, and heavily fed, stressed dairy cows and heifers in the winter.^{23-26,51} First service conception rates dropped from over 50 percent to 30 percent during the acute phase of the disease and returned to 50

percent after intensive therapy with postbreeding infusions of 1 gm of tetracycline or oxytetracycline into the uterus, cervix and vagina and using a sheathed or protected insemination pipette for AI or intrauterine infusions to reduce the numbers of pathogenic organisms carried from the vulva into the cervix and uterus. Since bulls carry these organisms in their prepuce and occasionally in their seminal vesicles, semen used for AI should contain levels of antibiotics to eliminate these organisms and prevent their spread. Minocycline HCL is effective in the control of mycoplasma and ureaplasma in the extended semen and lincomycin and spectinomycin controls mycoplasma. **H. somnus** is readily eliminated by a variety of antibiotics. Tetracyclines cannot be used in extended semen because of their harmful effect on spermatozoa. Granular vulvitis, endometritis and salpingitis have been produced experimentally by the introduction of certain of these three organisms, especially the ureaplasma, into the vulva, cervix and uterus. Based on early studies recovery from uterine infections and endometritis may be quite prompt.

The treatments for granular venereal disease are so many and varied that the author believes this condition fits into the category with other conditions treated with a similar wide variety of therapy in which probably any treatment within reason or no treatment at all would be equally successful. The older more commonly used treatments in affected cows and bulls are locally applied antibiotics and antiseptics but their value is questionable. When conception rates were greatly reduced, due to ureaplasma infections 1 gm of tetracycline in solution infused into the uterus cervix and vagina 24 hours after service gave encouraging results.^{23,26b} Treating the granular lesions in the vulva with irritating or cauterizing drugs appears to clinically result in the most rapid improvement in acute cases of granular vulvitis. They should not be used in bulls. These include 1 to 2 percent acriflavine ointment, straight Lugol's solution, or 4 to 5 percent silver nitrate solution repeated as needed every 7 to 10 days.

Since this condition tends to improve with time and since copulation aggravates the condition, breeding is stopped in the severe cases, especially in bulls, for several weeks or longer. The owners are advised to breed their affected cows and heifers by AI possibly using a small plastic speculum or tube to guide and protect the AI pipette so that it does not contact the vulvar mucosa.^{23,26b,51} This seems to cause no exacerbation of symptoms. If they cannot be bred artificially, a period of sexual rest for 2 to 4 weeks is advised in the severe cases. A killed vaccine is currently available for immunizing against **H. somnus** but its value in genital infections needs study.

In recent years investigations have resulted in ad-

vancing our knowledge of the mycoplasmas, ureaplasmas and Hemophilus organisms. The pleuropneumonia like organism (PPLO) now called **Mycoplasma bovis** is only mildly pathogenic in the female genital tract and is frequently isolated from the tract. **Mycoplasma bovis** was isolated from cattle in several herds suffering from infertility and occasional abortions.^{23a,28,51} In some cases ovarian adhesions and cervicitis were present; in others a mucopurulent discharge was noted several days after coitus. The organism was found in semen. Varying degrees of endometritis, salpingitis and adhesions between the fimbria and peritoneum was produced in 7 of 8 heifers receiving an intrauterine inoculation of a suspension of mycoplasma (**M. agal. bovis**) recovered from a case of bovine mastitis.³⁶ The doses used were considered to be excessive. This condition, produced experimentally, has not yet been described as a clinical entity. The **M. bovis** organism which is quite pathogenic for the female genital tract is seldom found there. The common occurrence of mycoplasma and ureaplasma in the prepuce of bulls and in the semen has been described under infertility in the male.^{1,2} It is questionable if many of the isolated mycoplasma spp. are pathogenic as heifers inseminated with infected semen samples did not become infertile. Only one group of isolates produced inflammatory changes in the endometrium. A study of many strains of mycoplasma by morphological, cultural and serologic means as an aid to separating pathogenic and saprophytic organisms has been conducted.^{1,2,5,6} Similar studies are needed with the ureaplasmas and **H. somnus**. Many mycoplasma cultures are a mixture of several strains, 166 pure strains were recovered by cloning, characterization and serologic techniques and 13 serotypes were found not including the bovine T. strains or ureaplasmas. Serotype B or **Mycoplasma bovis** caused vulvovaginitis, epididymitis, seminovesiculitis, arthritis and rarely mastitis.^{1,2,5,6,25,26} Serotype F or **Mycoplasma agalactiae var bovis** caused mastitis, endometritis, salpingitis, salpingo-peritonitis and abortion.⁴⁰ This type of organism was cultured from semen from a bull that when bred to heifers apparently produced conception but the animals came back into estrum in about 4 weeks and thereafter were infertile.⁶³

Acholeplasma (M.) laidlawii was recovered from the oviducts in 52 or 71 percent of 73 repeat breeders,⁴¹ while only 42 or 24 percent of 179 cows slaughtered for other reasons were infected. Lesions were found in 117 infected uterine tubes. Many workers^{1,5,23} consider this **Mycoplasma** nonpathogenic. It is possible that the early workers in studying this PPLO or mycoplasmal organism were actually dealing with vibriosis and recovered these rather ubiquitous mycoplasmas. This PPLO organ-

ism was found in semen in 94 percent of the bulls.³ Freezing of mycoplasma in semen had no adverse effect on the organisms,³⁹ and they were quite resistant to antibiotics commonly used in semen extenders.²³

Hemophilus spp. was reported to cause an outbreak of vaginitis and cervicitis in a herd of dairy cattle,¹² It was characterized by a copious, purulent, yellowish-white discharge from the vulva and a hyperemia of the vagina and cervix lasting for 2 to 3 months. The disease could be spread by coitus and resembled viral vaginitis described previously. The vulva was not affected. A hemophilus-like organism was described as a cause of granular vulvitis.²² **Hemophilus somnus** has been isolated from cases of granular venereal disease.^{25,26}

In a review of the role of the Mycoplasmas in diseases of bovine reproduction it was reported that mycoplasmas have been isolated from the genital tracts of cattle, humans, horses, dogs, pigs, goats and cattle.^{1,2} Those organisms associated with lower genital tract infections of granular vulvitis were **M. bovis**, **M. bovis**, ureaplasmas (**T. mycoplasmas**) and **A. laidlawii**. Those organisms associated with the upper genital tract infections of endometritis and salpingitis are **M. bovis**, **M. bovis**, **M. agalactiae bovis**, ureaplasmas and **H. somnus**. In bulls **M. bovis** and ureaplasmas and occasionally **M. agal. bovis** can cause seminovesiculitis and possibly orchitis and epididymitis and be present in semen.^{1,23-26,51}

Many more studies will be needed on mycoplasmas, ureaplasmas and Hemophilus organisms commonly found in the lower reproductive tract, vulva and prepuce and upper respiratory tract to determine the pathogenic and nonpathogenic serotypes and the mechanisms whereby they gain access to the upper reproductive tract, uterus, uterine tube, seminal vesicles and testes. These further studies are necessary to clarify the presently very confusing literature and clinical disease picture. With the rapid advances in microbiology and immunology in recent years the isolation of these organisms and the delineation of their importance, pathogenesis, epidemiology and therapeutic control measures should be forthcoming.

Other Bacterial Infections

Leptospirosis due to **L. pomona** has not been shown to be the cause of infertility or early death of fertilized embryos; although abortions, especially the latter half of the gestation period, are common. Statements that **L. hardjo** and **L. mini-szwajizak** have been associated with infertility in enzootically infected herds have appeared recently in the literature, a careful perusal of the articles

cited^{34b,36a} do not support this observation. Infertility associated with abortions, secondary retained placentas, and metritis and delayed conception are characteristic sequelae of any abortifacient disease including leptospirosis. Leptospiral organisms have not been shown to be a cause of early embryonic deaths or conception failure.

Streptococcal infection characterized by cervicitis was described in 1932 as a common cause for infertility in cows. This organism was frequently recovered from inflamed genital tracts of cows failing to conceive but it is unlikely that it was responsible for enzootic outbreaks of infertility. The author observed one herd of dairy cattle with much infertility characterized by a mucopurulent discharge from the vulva in some animals and early embryonic deaths with long intervals between services. On culture of the vagina of the cows at necropsy a pure infection of *Streptococcus dysgalactiae* was isolated. Endometritis was present. Sanitary conditions in the herd were marginal; all cows calved in the same calving stall. The bull may have spread the infection at the time of coitus.

Corynebacterium pyogenes has been described as a cause for failure of conception, for a persistent mucopurulent discharge from the vulva and even occasionally for permanent sterility.^{37,38} Apparently it gains entrance to the genital tract at the time of parturition or when a retained placenta is present. This organism causes a chronic postpuerperal metritis, endometritis, salpingitis, or pyometra with delayed involution of the uterus. This invasive organism may be difficult to cure and the prognosis should be guarded^{35b} (See Endometritis).

C. pyogenes infection of the postpartum genital tract is occurring with increasing frequency as the herds of cattle get larger and close confinement, "zero pasture," and overuse of a few calving stalls that are not properly "sterilized" between cows. In affected herds nearly 90 percent or more of cows calving in the infected environment or in those calving stalls become infected and develop a copious, yellow, mucopurulent discharge that lasts for 2 to 6 months resulting in great delays in conception even though eventually the infection is overcome and the cows conceive. Retained placenta and calf scours are also commonly observed in these same herds due to the unsanitary conditions. Since the infection obviously occurs at or soon after calving, having the cows calve in a different clean environment away from the contaminated facilities or at pasture often results in a prompt and dramatic reduction in clinical cases of vaginitis, cervicitis and metritis. Enough properly designed calving stalls that can be thoroughly disinfected or sterilized between calvings and/or moved, if portable, to a clean location are necessary for large free stall dairy herds.

A vulvovaginitis due to *C. pyogenes* occurring one to four days following coitus has been described.¹⁴ These infections persisted for 7 to 14 days but often recurred at a subsequent breeding to the same bull. Similar *C. pyogenes* organisms were cultured from the vagina of affected cows and the prepuce of the bull. An acute vulvovaginitis was reported due to *E. coli* toxins introduced by coitus with an infected bull.¹⁴ Signs developed within 4 to 6 hours of service and lasted for only several days.

Other low grade infections found in the genital tract of sterile or infertile cows or cows exhibiting a mucopurulent exudate include:

*Micrococci	
*Diphtheroids	
* <i>Pseudomonas aeruginosa</i>	
* <i>E. coli</i>	
Bacilli	
Staphylococci, albus and aureus	
*Enterococci and others	
Actinomyces	Yeast
Neisseria	Mycobacteria
Flavobacterium	Salmonella
Sarcina	Alkaligenes
Proteus	Gaffkya
Molds	Chromobacteria

*The organisms most commonly found.

These infections have been described as being found in the genital tract and uterus of cows that fail to conceive.^{4,27,35a,c,38,52} These ubiquitous organisms recovered from the bovine genital tract were mainly saprophytic strains in normal cows but in infertile cows the strains were primarily pathogenic.^{35a,c} Undoubtedly they may gain access to the tract at the time of parturition or breeding and if the conditions are favorable they establish themselves at least temporarily and possibly cause varying degrees of inflammation of the uterus, cervix, vagina, vulva, and oviduct possibly resulting in infertility. Twelve heifers artificially inseminated with semen from bulls with semino-vesiculitis due to *Ps. aeruginosa* developed varying degrees of metritis, cervicitis and vaginitis and the organism could be recovered in 4 of 8 heifers 44 days postservice.³² The discussion of the diagnosis and treatment of these nonspecific infections will be made later in this Chapter. (See Endometritis.) Cases of infertility due to these various wound-infection type of organisms are usually sporadic and not associated with an enzootic type of infertility. The organisms mentioned above, including streptococci, *C. pyogenes* and PPLO or mycoplasmas are ubiquitous and will occur in some cows despite proper management. Their treatment is largely

symptomatic. The same organisms are frequently present in bull semen but apparently seldom pass beyond the vagina and cervix to establish themselves in the uterus. *Pseudomonas*, coliforms, and staphylococci are more common in bulls' semen than in the genital tract of cows, probably due to contamination of the semen with organisms common in the sheath.

A condition similar to an enzootic venereal disease in naturally-bred cattle occurred in some artificially inseminated herds, with 15 percent or more of the cattle showing varying degrees of infertility even when neighboring herds of the same breed served by the same technician have less than 5 percent "repeat breeders."³¹ This condition may occur after 2 to 3 years of artificial insemination and no *C. fetus* or *T. fetus* are isolated from the cows. These workers were unable to isolate the causative organism or determine its mode of spread. Other researchers have found similar perplexing problems.¹⁷ In the future, therefore, possibly other organisms including viruses may be found as causes of "enzootic" infertility.

Necrotic vulvitis of feedlot heifers has been well-described. The cause is unknown. It has been observed in lots where hogs are present and injuries and vulvitis have been blamed on them. It may occur following rectal examination. Anovulvitis may be observed secondary to a diarrhea where an irritant is apparently present in the fecal material. Body temperatures may be slightly elevated for a few days but healing occurs in two weeks. Infertility in affected heifers has not been reported. It has been suggested that an allergic factor may be involved.

Actinomycosis—Two cases of actinomycosis of the bovine genital tract, characterized by large swellings that proved to be multiple sclerotic abscesses with extensive pelvic adhesions were described.⁸² One of these cases developed following a retained placenta. Actinomycosis is difficult to differentiate from tuberculosis but the swellings in the latter are more nodular. Due to the extensive lesions the prognosis was poor and both cases were cultured and diagnosed after slaughter.

Tuberculosis—Tuberculosis of the genital tract of the cow has not been observed the last 50 years in the Ambulatory Clinic of the New York State Veterinary College. With the almost complete eradication of this disease in the United States the opportunities for observing it in this country are very rare. However, in other countries where tuberculosis is still prevalent the infection may involve the female genital tract and produce sterility and abortion. Tubercular lesions of the vulva, vagina, cervix, uterus, oviducts, and ovary have been reported.^{11,82} (See Figure 106.) The disease usually affects the uterus and oviducts producing characteristic nodular swellings, enlargements and adhesions between the uterus,

Figure 106. Genital Bovine Tuberculosis—involving the ovaries and mesometrium.

(Courtesy of F. Megale.)

oviduct, ovary, surrounding broad ligaments, rectum, and other organs and tissues. The genital discharge from these lesions is usually non-fetid. In most cases the uterine involvement is bilateral, a fact which may differentiate the condition from other infectious or pathologic lesions of the uterus. Bovine tuberculosis due to *Mycobacterium bovis* is by far the most common type affecting the uterus and causing sterility and abortion. Occasionally the avian type may be found.^{29,68} This type is characterized by small abscesses about 0.25 inch in diameter, involving the endometrium. The avian type of tuberculosis is not readily diagnosed per rectum because of the lack of enlargement of the uterus or oviducts and the fact that adhesions do not develop. The tuberculin test may fail to detect animals severely affected with bovine tuberculosis. Avian tuberculin may be of assistance in diagnosing the avian form, although it is usually diagnosed on postmortem examination. Culture of the genital discharges together with the presence of characteristic nodular swellings and adhesions aids in the diagnosis of this disease. Severely affected animals are usually hopelessly sterile and should be slaughtered. In milder infections conception may occur, but abortion or retained placenta may result. Infection of the genital tract of the cow may result in the spread of tubercular infection to the penis and prepuce of the bull at coitus.

INFECTIOUS VIRAL DISEASES CAUSING BOVINE INFERTILITY

Infectious Pustular Vulvovaginitis (IBR-IPV)
(Vesicular Venereal Disease, Coital Vesicular
Exanthema, Infectious Balanoposthitis, Genital
Cowpox, or Blaschenausschlag)

This viral disease has been described previously with IBR-IPV abortion (See Chapter V) since the two diseases are caused by the same herpes viral agent. Infectious pustular vulvovaginitis (IPV) is described as a non-vesicular viral disease characterized by papules, pustules, but no vesicles, that rapidly coalesce to form a diphtheritic membrane that detaches leaving ulcers in the mucosa of the vulva, vestibule and vagina especially over the areas of the lymphoid follicles.^{33,46} Intracellular inclusion bodies can be found in affected cells in the mucosa of the genital tract. The cows exhibit an elevated temperature for several days early in the course of the disease. Edema, pain on urination, and a yellowish serous to purulent discharge from the vulva is characteristic of the disease. The ulcers, diphtheritic membranes and severity of the infection differentiates I.P.V. from granular venereal disease. The disease may spread rapidly through the herd and even affect unbred heifers. The respiratory and abortion forms of the disease rarely accompany the genital form. However rare outbreaks have been reported where simultaneous infections with the upper respiratory, genital and conjunctival forms of IBR-IPV, but no abortions, occurred.⁴⁹ Abortions in pregnant cows commonly occur after the respiratory disease but are only rarely observed following the genital form of the disease.

The cause for this is not completely understood. (See IBR-IPV Abortion, Chapter V.) Natural service by the bull may spread the disease as this virus may produce a balanoposthitis, but other means of spread such as by switching tails of cows confined in stanchions or grooming may also spread the disease from one cow's rear parts to the next. The farm dog licking the genital discharges on the vulvas of affected cows and then normal cows may transmit the disease. The IBR-IPV virus may be transmitted by artificial insemination in liquid or frozen semen and cause an endometritis and a temporary short-lived infertility.^{47,66,72}

Although this disease is rather common in Europe and Australia it is observed only occasionally in the United States. Even though IBR, the respiratory form of the disease, is common in New York State only 1 to 3 outbreaks of IPV are reported each year. A similar observation was made in California.⁷⁴ Two outbreaks occurred

in the same herd 4 years apart.⁶⁹ Similar reoccurrences of the disease in the same herds have been reported in Europe. In one study⁶⁶ when bulls harboring preputial infections of IBR-IPV were bred naturally to susceptible heifers lesions of infectious pustular vulvitis resulted but conception rates were normal. However if IBR virus was infused into the uterus after breeding infectious pustular vulvovaginitis developed and the conception rate was low, 40 percent. An increased number of services per conception was required due to the endometritis and salpingitis produced. About 30 percent of the estrous cycles were shortened due to the endometritis.⁶⁶

The onset of the disease is rapid and within 3 to 6 days involves 60 to 90 percent of a herd; the incubation period is short, usually 48 to 72 hours. Similar lesions occur on the penis and prepuce of affected bulls. Affected bulls may refuse coitus. Although infectious pustular vulvovaginitis interferes with breeding until the lesions heal, this form of the disease is not known to result in sterility, infertility, or abortion.

The prognosis is generally favorable, as healing occurs in about 2 to 4 weeks. Occasionally severely affected bulls may develop adhesions between the penis and prepuce, or a stenosis of the prepuce may occur, possibly due to secondary infections. Scarring or adhesions of the vulva or vagina have not been reported.

Treatment is usually unnecessary and oftentimes is difficult to administer because of the problem of restraining the affected cattle due to the painful vulvar lesions. However, some authors recommend douching with mild antiseptics. Regular douching of the sheath of the affected bull with oily preparations might be indicated to distend the sheath and prevent adhesions. Breeding should cease for 3 to 4 weeks or until the affected animals recover. Because of its highly transmissible nature, this disease should be reported to the State Veterinarian. Veterinarians, inseminators, and others working in these herds should be careful not to carry and spread the infection. Vaccination with IBR vaccine is not indicated once the disease has appeared.

When IBR-IPV virus was present in semen used for intrauterine insemination of heifers it produced a necrotizing endometritis, short estrous cycles of 11 to 15 days in length, many cystic corpora lutea and only 1 of 12 heifers conceived.^{47,66} A number of practitioners have reported that low rates of conception occurred in heifers bred within one month of subcutaneous or intramuscular vaccination with an attenuated IBR vaccine. This has not been observed with the intranasal vaccines.

Specific Bovine Venereal Epididymitis and Vaginitis or "Epivag" is a chronic disease of cattle, transmitted by coitus and found only in East, South and Cen-

tral Africa. The cause is apparently a virus.⁵⁸ Vaginitis in cattle in South Africa may also be due to a viral agent similar to the IBR-IPV virus.^{30,56} The disease is characterized by a severe mucopurulent vaginal discharge in females, permanent adhesions of the Fallopian tubes, and by a hardening and swelling of the epididymis in the bull. This disease has been well-described.^{42,71,77}

Etiology—European cattle are very susceptible to the infection whereas Zebu cattle are resistant to the disease, at least, clinical symptoms are not exhibited. The disease has been transmitted experimentally by genital swabs from cow to cow or by placing minced infected epididymal tissue in the vagina. The material was bacteriologically sterile and no protozoa were found. The disease in the natural state is transmitted only by coitus. Preliminary attempts to produce the disease by filtrates of the material have failed. The disease is the most important cause of bovine sterility and infertility in Kenya.

In herds having breeding trouble 42 percent had this disease and in these herds 34 percent of the bulls became permanently sterile. The disease may remain latent in a herd for some time.⁷

Symptoms—The incubation period is 2 to 8 days. During the active stage of the infection there is an odorless, mucoid vaginal exudate, egg-white in consistency but opaque and yellow in color. The discharge from the vulva mats the hair on the tail and buttocks, forming dull, grey, yellow flakes as it dries. Speculum examination reveals diffusely reddened areas in the cranial portion of the vagina but there are no ulcers, vesicles, or granular lesions. A diagnosis of this disease in a herd is easy but in individual animals may be difficult. The acute infective stage may last for 2 weeks to 9 months. Estrous cycles are normal, but service is rarely followed by conception. In grade herds most cows and heifers recover eventually but 15 to 25 percent are permanently sterile due to unilateral or usually bilateral involvement of the uterine tubes with adhesions, hydrosalpinx, or ovarian and bursal adhesions.

In the bull a balano-posthitis may occur but it is mild and frequently not observed. The characteristic lesion in the bull is an enlargement and hardening of the epididymis that is usually bilateral. Although the entire epididymis is involved, the tail is involved most severely and may resemble a billiard ball in size and hardness. Occasionally an orchitis of a temporary nature may precede this epididymal enlargement and testicular degeneration and atrophy may occur. Bulls can be infected by intraurethral injection. The lesions in bulls take 3 to 6 months to develop and sexual desire remains normal. In advanced cases there are adhesions between the scrotum and the epididymis. On postmortem examination dry ad-

hesive areas of peritonitis or pleuritis may be found. The vesicular glands of bulls usually become enlarged and firm and changes may take place in the vas deferens.⁷

Treatment—The disease can easily be controlled by artificial insemination using noninfected bulls. In time it will spontaneously disappear from the females. More work is required on the determination of the etiologic agent, the length of time cows remain infected, and the practical methods of control when artificial insemination is not possible.

Miscellaneous Viral Infections of the Bovine Female Genital Tract

Contagious Anterior Vagino-Cervicitis in cattle has been described in South Africa as resembling the disease just described. However no permanent lesions are produced in the cow and no lesions are observed in the bull. The cause is not known.

An involvement of the uterus causing sterility as a sequela to lumpy skin disease of cattle in South Africa has also been described.^{77,79}

A catarrhal vaginitis and cervicitis clinically similar to "epivag" in cows was described in 4 herds in California.^{48,59} Affected cattle had a profuse nonodorous yellow mucoid discharge from the vulva. The cervix and vagina of the diseased cows was hyperemic and edematous but no pustules were present as in IPV. No other portions of the genital tract were involved. Although the disease appeared to spread following coitus, the bulls showed no clinical signs of the infection. The course of the disease lasted from 7 days to 3 months. Fertility was lowered and conception often was delayed several months. A few cows conceived during the clinical stages of the disease. The cause of this vagino-cervicitis was an entero-virus culturally different from the virus of "epivag." Sterility did not occur in this disease. Antibiotic treatments were of no value and immunity was short-lived.

Viral infertility in cattle has been characterized by a vaginitis, edematous endometritis, a mucopurulent genital discharge, abortions at 2 to 8 months of gestation with edematous fetal membranes, and by a temporary infertility in bulls.⁶⁰ The incubation period was 3 to 10 days. The disease could be spread to susceptible cattle by coitus and intravaginal, but not the intravenous injection of filtered genital mucus from infected cattle. It was reported that the virus, and possibly more than one was present, could be passed through eggs.

Transmissible viral fibropapillomas may occasionally be observed on the vulva and perineal region of heifers and the prepuce and penis of young bulls. The growths may be single or multiple. These tumors might be transmitted by coitus. The tumors in heifers are similar to the common skin wart and usually regress spontaneously in 2 to 6 months. This process may possibly be hastened by the use of wart vaccine. This condition does not cause infertility in heifers. The fibropapillomas may be removed surgically.³⁴

Bovine Virus Diarrhea (BVD)-Mucosal Disease (MD) virus is widespread in cattle. It has been incriminated in early embryonic deaths⁸ in cattle as well as in abortion, maceration, fetal mummification, congenital cerebellar disease and cataracts and other ocular defects. Seronegative cows for BVD-MD when bred naturally to a bull with semen containing the BVD-MD virus or given an interuterine injection of the virus after a natural service, all seroconverted within a few weeks but had a markedly reduced conception rate until this conversion occurred.^{57,81} No effect was observed in seropositive cows. Thus because most cows in the population are seropositive and BVD-MD virus is only rarely excreted in the semen, this virus is probably not a major cause of conception failure or repeat breeding.⁸¹

It has been demonstrated that BVD-MD virus may remain for weeks in the uterus and oviducts of cows. It has also been shown that BVD-MD virus causes no consistent lesions in the genital tract and no abnormalities of the estrous cycle occur as in IBR-IPV. But evidence has been presented that the BVD-MD virus may inhibit the normal development of preimplantation bovine embryos⁸⁻¹⁰ Further studies on the effect of BVD virus on developing embryos as a possible cause of repeat breeding is indicated.

Parainfluenza-3 virus infection given either intramuscularly or infused into the uterus after breeding had no effect on the breeding efficiency of infected susceptible heifers compared to control heifers not infected.¹⁹

HORMONAL DISTURBANCES RESULTING IN INFERTILITY

Most hormonal disturbances causing infertility or sterility in cows and other animals are secondary to basic nutritional, hereditary and stress or work factors. Occasionally hormonal disturbances may be due to the ingestion or injection of exogenous steroids or other hormones. Hormonal diseases may include cystic ovaries, failure of estrum (anestrus) and repeat breeders due to failure of ovulation, failure of fertilization and early embryonic deaths. The widespread indiscriminate use of many hormones on an empirical basis by veterinarians 25 to 30 years ago has been followed in recent years by a much more selective and knowledgeable employment of the various hormones for their specific action in certain limited and carefully diagnosed infertility conditions. The use of assays for determining the plasma or milk progesterone levels further assists these diagnoses.

Cystic Ovaries

Cystic ovaries in dairy cattle is one of the most common conditions causing infertility, 6 to 19 percent,^{39b} that the veterinarian is called upon to treat. Twelve to 14 percent of all problem breeder cows have cystic ovaries.⁴⁹ A recent abattoir survey in England of 8071 bovine female genital tracts revealed that 10 percent had abnormalities. The most common abnormality was cystic ovaries with an incidence of 3.8 percent.³ In 5083 lactations over a 60 year period the percentages of dairy cows with cystic ovaries was 1.0, 3.1, 3.3, 4.0 and 5.2 for Brown Swiss, Ayrshire, Jersey, Guernsey and Holstein breeds, respectively.³⁰ In Holsteins the incidence of cystic ovaries for cows having twins was 12.7 percent compared to 4.9 percent for cows having single births. Cows with metritis had an incidence of 10.4 percent cystic ovaries compared to 5.1 percent of cows without metritis.³⁰ The more often the cow was treated for milk fever, the higher the likelihood that cystic ovaries would develop, 20 percent vs. 4 percent for cows with no milk fever. In 375 calving intervals in a Holstein herd cystic ovaries occurred in 11.2 percent. Seventy percent of the cysts occurred from 16 to 45 days after calving and 69 percent of these cows recovered without treatment and became pregnant prior to 300 days. Twenty-nine percent recovered in less than 30 days.³⁰ In 1599 Holstein lactations cystic ovaries occurred in 14.5 percent with the highest rate of occurrence 3.5 percent, or about 25% of cows with cystic ovaries, between 31 and 45 days postpartum. A second peak occurred in infertile cows after

Figure 107. Cysts of the Bovine Ovary.

120 days.²¹ Thus in dairy herds cystic ovaries occur in 10 to 20 percent of problem breeders.³⁵ This latter review indicated that 10 to 40 percent of all dairy cows will develop cysts once in their lifetime and 35 to 45 percent of cows having one episode will have the condition repeated during their lifetime. Cystic ovaries occurred most frequently the second to fifth lactation.^{30,35,62} Since 60 percent of cows developing ovarian cysts before the first postpartum ovulation and 20 percent thereafter spontaneously reestablished estrous cycling,^{39b} the above estimates of the incidence of ovarian cysts are low. Thus cystic ovarian disease prolongs the postpartum interval to first estrus in 10 to 30 percent of dairy cows and is a serious cause of infertility.

Cystic ovaries in cattle are characterized by follicular cysts or cystic degeneration of the Graafian follicle, luteal or luteinized cysts, and cystic corpora lutea. Follic-

ular and luteal cysts are anovulatory cysts while the cystic corpus luteum is an ovulatory cyst. The basic cause for these cystic conditions appears to be a failure of the hypophysis to release sufficient amounts of luteinizing hormone, LH, to produce ovulation and proper luteinization of the corpus luteum. (See Figures 107 through 111.)

Follicular cysts are anovulatory follicles that persist on the ovary for 10 days and often much longer, have a diameter greater than 2.5 cm. and are characterized by either nymphomania or continuous or frequent estrus, or by anestrus. Luteal cysts are anovulatory follicles over 2.5 cm. in diameter that are partially luteinized and persist for a prolonged period and are usually characterized by anestrus. Follicular cysts and luteal cysts may be hard to differentiate clinically as there is great variation in the amount of luteal tissue in anovulatory cysts. The former may be multiple on both ovaries while the latter are more often single. The follicular cyst is thinner-walled and the wall is more tense and distended than the softer thicker-walled luteal cyst. The follicular and luteal cysts have a smooth convex surface since ovulation does not occur. The luteal cyst wall is thicker due to the presence of a lining of luteal tissue. The fluid in the luteal cyst is usually more amber or darker yellow or brown in color than the pale yellow clear fluid in the follicular cyst.⁷⁰ Follicular cysts are probably more common than are luteal cysts. Thirty percent of 1191 cystic ovaries contained luteal cysts,⁸⁰ (See Figures 107 through 111). Other workers have reported an incidence of 15 and 65 percent luteal cysts based on clinical examination and plasma progesterone assays.^{19,61}

Cystic corpora lutea follow a normal ovulation but contain a fluid-filled central cavity 7 to 10 mm. or more

in diameter. Cystic corpora lutea on rectal palpation feel similar to large, swollen normal corpora lutea as they have a projecting crown of luteal tissue that protrudes through the site of ovulation. Cystic corpora lutea often have a slightly fluctuating, soft consistency. This may be the most common of the cystic conditions affecting the bovine ovary with a possible incidence two and a half times greater than cystic follicles. Thirty seven cystic corpora lutea and 14 follicular cysts were found in 204 nonpregnant cows at slaughter.⁴⁷ In 357 estrous cycles followed by rectal examinations the incidence of normal corpora lutea, cystic corpora lutea and follicular cysts were 62.4, 25.2 and 12.3 percent.⁵⁴ The incidence of cystic corpora lutea was 34 to 41 percent in cycling

cows.^{20,29} The total progesterone in cystic corpora lutea was about 110 ug at 7 days of the cycle compared to about 180 ug in normal corpora lutea of the same age. About 100 to 150 ug of progesterone is needed in the corpus luteum to permit normal embryo development.⁶⁸ By 11 days of the cycle the cystic corpora lutea averaged 223 ug and the normal corpora lutea 295 ug of total progesterone.

Cows with cystic corpora lutea have normal estrous cycles and if conception occurs there is usually sufficient luteal tissue and progesterone to maintain pregnancy.²⁹ Small central cysts less than 7 mm. in apparently normal corpora lutea are common and may be found in up to 30 percent of corpora lutea.²⁶ These central cysts are lined by a layer of connective tissue, they become smaller late in the estrous cycle as the corpus luteum regresses and are seldom found in pregnant cows' corpora lutea after the fourth or fifth month of gestation.^{26,47} For practical purposes most cystic corpora lutea are not pathological; ovulation was normal; they do not influence cycle length;^{47,54} they may follow a slightly longer than normal estrous period;⁴⁷ and most cows with cystic C.L. usually maintain the pregnancy to term. However, they may be caused by mild faulty release of L.H. hormone and thus be caused by the same basic deficiencies producing follicular cysts and luteal cysts.^{26,47,67}

Since cystic corpora lutea have a questionable pathologic significance the term cystic ovaries will be applied only to the common follicular cysts and less common luteal cysts. Further detailed clinical, histological and endocrinological studies are needed to more accurately assess the incidence of each type of cyst since recent reports have indicated the incidence of luteal cysts to range from 15 to 70 percent and follicular cysts from 30 to 85 percent.^{19,35,61,80}

Etiology—Cystic ovaries is principally a disease of all breeds of dairy cows although occasionally beef cattle are affected. While the author has observed the disease most often in Holstein cattle, it must be pointed out this is the major breed in New York State. The disease is more common in closely-confined, stabled animals during the winter months of December, January and February, than during the summer and fall months.^{32,54,62} The latter authors reported 44 and 48 percent of their cases of cystic ovaries occurring during these three months. However in New York State there is a concerted effort to have cows calve in the fall of the year. Cystic ovaries affects cows of all ages from puberty to senility but is most commonly observed following the second to the fifth parturition,^{24,30} or from 4-1/2 to 10 years of age.³² In 295 cases studied by the author⁶² 41, or 13.9 percent, occurred in cattle from 1 to 3 years of age; and only 3

Figure 111. A Bovine Cystic Corpus Luteum.

(Courtesy K. McEntee.)

of these were virgin heifers; 160 or, 54.2 percent, occurred between 4 and 6 years of age; 74, or 25.1 percent, between 7 and 9 years of age; and 20, or 6.8 percent, over 10 years of age. In a study of 64 cystic cows in a herd of 341 head over a period of 10 years the number of cows that developed cystic ovaries in any given service period after the first period was fairly constant.¹² Certain cows may have repeated attacks of cystic ovaries during a service period or during different service periods. Of 433 cows studied 53 suffered repeated attacks.²⁴ In 341 cows 64 cows had cystic ovaries; of these, 12 were affected at 2 service periods, 4 at 3 service periods, and 2 at 4 service periods.¹² Thirty-five to 45 percent of cows with cystic ovaries had repeated attacks within a service period.³²

The occurrence of cystic ovaries is closely associated with stress in the periparturient period. Twin births, retained placenta, metritis and milk fever were associated with an increased incidence of cystic ovaries.^{30,54,55} The high incidence of the occurrence of cystic ovaries between 15 and 45 days postpartum coincides with peak levels of milk production and the onset of estrous cycles.^{21,78} ACTH, 200 IU given intramuscularly near estrus prevented the LH surge and estrus in 5 of 6 Holstein heifers.⁶⁹ ACTH, 300 IU given daily during the follicular phase, from about day 16 of the estrous cycle caused ovarian cysts in nonlactating Holstein cows.⁴³ Thus stress-induced ovulation failure may be a cause of spontaneous follicular or luteal cysts. It is seen more commonly in the higher producing cows. Affected cows have a higher quantitative milk yield than do normal cows. On the basis of the average milk yield in the herd, 45 percent of the nymphomaniac cows were excellent producers, 48 percent fair producers and only 7 percent poor producers.^{12,24} The occurrence of nymphomania was not associated with the level or percentage of butter fat produced. There were 1280 service periods, 341 of which were in virgin heifers, during which the animals were not milked; 457 records were made during the time the cows were in the milking herd and milked twice daily, and 105 records on animals started on test but returned to the milking herd before conception; and there were 359 service periods of cows on official test being milked 3 or 4 times a day.¹² In these 4 categories the incidence of nymphomania or cystic ovaries was 3.4 percent, 6.8 percent, 8.5 percent and 10.6 percent, respectively. The increased incidence of cystic ovaries in test cows might be explained either on higher production, increased feeding, more frequent daily milking, or all three factors.¹

Many workers believe that increased feeding especially of rations high in protein stimulate lactation and the development of cystic ovaries. This fact could not

be confirmed but the evidence was suggestive.⁵⁷ The time of onset of cystic ovaries in cattle is usually from 1 to 4 months after calving, with a peak around 15 to 45 days.^{21,45,54,78} This is the time when milk production is usually the highest. This condition may occasionally occur following repeated services as late as 4 to 9 months after calving.^{21,61} Nymphomania or cystic ovaries occurred even in heifers that were withheld from service for a number of years.¹⁷

In 312 cases of nymphomania or cystic ovaries observed by the author there appeared to be a seasonal incidence of the disease; 151 cases, or 48.4 percent, occurred during the months of December, January and February. During these same months in comparable years the N.Y. State Artificial Breeders Cooperative inseminated only 35.7 percent of over 325,000 cattle bred those years. High feeding levels causing increased milk production, coupled with lack of exercise and sunlight might be contributing factors to the cystic condition during the winter months.^{54,62}

There is evidence to show that nymphomania or cystic ovaries is hereditary. This conclusion has long been held by clinicians. A hereditary predisposition to nymphomania existed in the Swedish Highland breed.²⁴ In 331 Swedish Red cattle affected with nymphomania, 26 percent of their dams had nymphomania, 41 percent were normal, and in the remainder this information was not known. In the Friesian breed 102 cows had nymphomania and of these 21 percent of their dams had nymphomania, 45 percent were normal, and in the remainder no information was obtained.²⁴ Of 245 daughters out of 144 dams 43 dams had been cystic; they produced 82 daughters, of which 26.8 percent developed nymphomania.¹² The remaining 101 dams had never been cystic; they produced 163 daughters, of which only 9.2 percent developed cystic ovaries. In their data there was no evidence of an heritability of cystic ovaries from cows staying in the herd for less than 4 service periods. They therefore eliminated those cows and recorded only those that remained in the herd for 4 service periods or more. Dams with cystic ovaries had 27 daughters, of which 48.1 percent had cystic ovaries whereas noncystic dams had 46 daughters, of which only 21.7 percent had cystic ovaries. Nearly all cows that suffered from a recurrent development of cystic ovaries had a genetic predisposition to the disease.³² Because of this factual evidence and the many observations by most practicing veterinarians of cystic ovaries in succeeding generations of a cow family, there is every reason to assume the existence of a hereditary predisposition to cystic ovaries and nymphomania. In recent years, with the increased use of artificial insemination and the increased level of pro-

ductivity in our purebred and commercial dairy herds, the incidence of this condition is increasing. In a few herds the problem of cystic ovaries became so severe that the owner became discouraged and the herd was dispersed.³¹ In the Ambulatory Clinic of the N.Y. State Veterinary College the incidence of cystic ovaries rose from 333 cases between 1948 to 1953, to 1530 cases between 1963 and 1968—or over a 100 percent increase for each 5 year period in an area where cow numbers declined slightly from 1943 to 1968. Some of this increase may be due to the farmer becoming educated, recognizing the symptoms and calling for treatment: or preventive herd health practices including routine postpartum examinations of the genital organs may result in earlier diagnosis and treatment with fewer cases of spontaneous recoveries occurring.⁷⁸ It may be because treatment is usually successful in maintaining the cow in the herd so that the condition may recur subsequent years; or it may be due to widespread use of bulls by artificial insemination that transmit this inherited predisposition toward cystic ovaries along with high milk production.

Further study should be made of the heritability of this condition. A significant sire line effect on the incidence of cystic ovaries in a large purebred Holstein herd was noted.⁵⁰ In a recent report of 2,112 calvings over a 7-year period by 649 cows in one dairy herd 17 percent of the cows produced at least one daughter that had cystic ovaries. Two bulls sired 17.6 percent of these affected daughters significantly more than was expected since they sired only 11.6 percent of all the daughters in the herd.^{42b} In Sweden where AI bulls siring daughters having a higher than normal incidence of cystic ovaries were culled the frequency of cystic ovaries declined from 10.8 percent in 1954 to 5.1 percent in 1961.⁴ Also the two abnormalities of ovulation, cystic ovaries and twinning, are closely associated and both are probably hereditary. The relationship was discussed in Chapter IV. AI studs in the United States should heed with concern and action the above evidence.

The actual mechanism leading to the development of cystic ovaries is not completely understood. The discovery that injections of gonadotropic substances rich in L.H. had a highly specific and curative effect on this condition, definitely indicated that the disease was probably due to a deficiency of LH hormone normally released prior to the time of ovulation.¹³ The delta cells of the anterior pituitary that produce gonadotropic hormones degranulate or release their hormone shortly after the onset of estrus in normal cows. In cows that fail to ovulate this degranulation fails to occur, or may occur later, or may not occur as completely as in normal animals.^{37,48} Pituitary gland gonadotropin content at estrus and four

days after normal estrus and ovulation was 3.0 to 9.1 ug while in cows with follicular cysts, the pituitary glands contained 6.1 to 15.1 ug of gonadotropin at estrus and 4 days later.²⁰ Thus in cystic ovaries the normal release of LH failed. The failure of the release mechanism or an actual deficiency of luteinizing hormone from the anterior pituitary gland prevents normal ovulation and development of the corpus luteum. Since in cows with cystic ovaries plasma levels of estradiol, progesterone, FSH and LH and testosterone were the same as found in the various stages of normal estrous cycle, evidence would indicate that the cause of cystic ovarian disease is due to an abnormal time sequence of hormonal changes rather than differences in the concentration of the hormones between cystic and normal cows.¹⁹

In a series of 5 cases treated by the author⁶² one dose of LH was given to each cow after a normal estrous cycle and estrum followed by continuous symptoms of nymphomania, 2, 5, 5, 6, and 7 days and the presence of cystic follicles. These cows conceived to the insemination or natural service on the first day of estrum preceding the development of the nymphomaniac symptoms. This probably indicates that enough L.H. was present to cause ovulation but not enough to cause normal luteinization of the follicle with the result that a number of other follicles matured, failed to ovulate and became cystic. The injected luteinizing hormone caused a rapid luteinization soon enough so that normal attachment and development of the fertilized ovum took place. If treatment had not been given, the fertilized ovum probably would have perished and a well-established case of nymphomania or cystic ovaries would have developed. Others have recorded similar cases of cystic ovaries treated within 10 days after insemination and fertilization in which pregnancy occurred from that service.

Cystic ovaries in cattle can be produced by the injections of estrogens, especially in the latter third of the estrous cycle.²³ Intramuscular injections into cycling cows of doses greater than 4 mg. of estradiol or 40 mg. of stilbestrol may result in cystic ovaries. Prolonged or high doses of estrogens have been reported^{15,16,47} as causing cystic ovaries. Androgens could also cause this disease. Thus exogenous injection of steroids and possibly other hormones can interfere with the normal release of L.H. and produce cystic ovaries. Cystic ovaries were produced experimentally^{58a} by the injection of 5 mg estradiol benzoate on day 16 of the bovine estrous cycle or the injection of bovine LH antiserum before the onset of estrus. The former injection caused premature release of LH and resulted in smaller cysts, 2 to 3 cm., than the latter treatment, 5 to 6 cm. cysts. In both types of cysts the plasma estrogen levels were elevated. Thus cystic

ovaries may be due to premature release of LH or an insufficiency of LH at the time of ovulation.

A hyperestrogenic syndrome in unrelated dairy cattle in Israel characterized by cystic ovaries, udder development in calves, increased incidence of estrus during early pregnancy, estrogenic changes in the genital organs, infertility, and abortions caused by feeding large amounts of alfalfa hay with a high estrogenic content was described.² Estrogens might also be present in higher than normal amounts in red clover, pea ensilage and mold on hay and silage.¹ If a herd experiences more than a 30 percent incidence of cystic ovaries and hereditary factors are not the cause, estrogens in the feed should be suspected.^{5,8,38}

The pituitary gland and especially the adrenal gland were larger in cows with cystic ovaries than in normal cows. Certain cows with cystic ovaries exhibited a masculine behavior and appearance and had increased levels of 17-ketosteroids from the adrenal gland in the urine.²⁴ This syndrome was called "adrenal virilism." However, the bovine adrenal gland is a poor source of androgens.⁶⁷ Many long-time nonlactating sterile cows develop a steer-like appearance.

The steroid content of ovarian cysts was studied and the previous literature was reviewed.⁶⁷ Although estradiol-17B was the major steroid in normal ovarian follicles, the concentration of this steroid was significantly lower in follicular cysts, 50 to 75 ug. vs 20 to 30 ug. per 100 ml. of fluid, respectively. Histologically the steroid producing granulosa cells in the follicular cysts were undergoing atresia. Some cyst fluid samples contained large amounts of progesterone and these cysts on histologic examination showed atretic or luteinizing changes. Other steroids such as estrone and androstenedione were also found in the cyst fluids. The absolute concentrations and relative amounts of various steroids found differed greatly both between animals and within the same animal. There was no correlation between the size of the cyst and the hormone content. The cyst itself was not the primary defect in ovarian disease.⁶⁷ Cysts were degenerating structures both histologically and endocrinologically. In normal follicles growth and endocrine activity accompanied each other while in cysts follicular growth continued but endocrine activity declined. Neither the concentrations or the total amount of estradiol indicated the cysts produced increased amounts of estrogen. However, estrogens were produced in cystic ovaries for a longer period of time and more continuously than estrogens in a normal cycling cow.

It was impossible to correlate the behavior exhibited by cystic cows with the steroids present in the cysts. This behavioral pattern was complicated since both proges-

terone and testosterone can potentiate estrogens in bringing a cow into estrus. Progesterone in large doses can inhibit estrus in an estrogen-primed animal. Cows tend to become refractory to even high doses of estrogen and fail to show signs of estrus. Furthermore the frequency of the development of new follicles and hormonally active cysts will affect the behavior of the cystic cow.⁶⁷

In 23 cows with cystic ovaries, 21 had estradiol plasma levels higher than those recorded during the preovulatory surge of estrogen in normal cows, 25 to 100 pg/ml. While 11 cows had plasma levels of progesterone over 1.5 ng/ml, commonly seen in normal cows in diestrus. The presence of progesterone in these cows did influence the estradiol levels.⁶⁴ Eight cows with ovarian cysts were studied over 30 days and LH plasma concentrations were different within and among the cows. Only one cow had a mean progesterone level above 1.0 ng/ml, but concentrations greater than this were observed in at least one of the samples in the other 7 cows during this period. With the development of new cysts, older cystic structures regressed in 6 of the cows but no spontaneous recoveries occurred during this period in the 8 cows.³⁹ The presence or absence of behavioral estrus, nymphomania or anestrus could not be associated with the endocrine levels in the blood plasma.⁶⁴ The concentrations of estradiol, progesterone and testosterone from non-luteinized vs luteinized bovine ovarian cysts were 81.9 vs 3.5, 163.7 vs 563.4, and 4.4 vs 2.1 ng/ml, respectively.^{32b} The concentrations of estradiol, progesterone and testosterone in normal follicular fluid and ovarian cyst fluid about 10 days after treatment with 100 ug GnRH causing luteinization of the outer cells of the theca interna^{10b} were 55.7 vs 3.9, 181.9 vs 766.0 and 5.7 vs 3.0 ng/ml., respectively.^{32b}

Thus physical changes in cystic structures together with the development of new cysts in the ovaries, variations in the hormonal content of the ovarian cystic fluid⁶⁷ and changes and variations in the level of estradiol, progesterone and LH in the blood plasma of cows with cystic ovaries indicate that the condition of ovarian cysts is not a stable or static but a changing one. Follicular cysts may become luteal cysts. Older luteal or follicular cysts may involute and disappear when new follicles and new cysts develop.³⁹

Some older authors and veterinarians indicated that cystic ovaries were associated with or even due to uterine infections. The uterus was examined histologically and bacteriologically in 62 cows with cystic ovaries and evidence of an endometritis was found in only 4 cases. Infection of the uterus is seldom seen associated with cystic ovaries. Of the author's cases of cystic ovaries or nymphomania, 72 cows conceived promptly within 60

Figure 112. A Chronic Cystic Ovary Associated with a Unilateral Mucometra.

Courtesy K. McEntee.

days of treatment without treatment of the uterus. A few cases of infection were encountered.

Signs—Cystic ovaries develop in cattle most commonly from 15 to 45 days postpartum.^{21,45,54,78} but may occur quite commonly up to 120 days or more. Behavioral signs are variable for several reasons as discussed under the etiology but for general purposes cows can be divided into two groups, nymphomaniac and anestrus cattle. The cows with nymphomania exhibit frequent, irregular, prolonged, or continuous signs of estrum. These cows are often nervous, restless, and bellow frequently. Only very rarely does a nymphomaniac cow become vicious. These cows may occasionally accept the riding of another cow, or coitus by the bull at any time. Most nymphomaniac cows frequently attempt to ride other cows but often refuse to stand to be ridden. Nymphomaniac cows may be as sexually aggressive as a bull in seeking out and attempting to mount a cow approaching or in estrum. The homosexual and heterosexual characteristics of cattle are aggravated during this disease. The affected cows because of their actions are often spoken of as “bullers.” These cows, especially if on pasture are likely to lose weight during the disease because of constantly moving about, attempting to mount, and stirring up the other cows. The cows with the cystic ovaries that show anestrus are not observed in estrum for long periods of

time, several months or more. In this group of cows the symptoms of estrum, if they are present, are very mild and infrequent. The owner of these cows, if they have been bred, may believe them to be pregnant. Others, about 15 to 20 percent, have had a normal estrum or two and then failed to show estrum thereafter even though they were not bred. Some of these cows may at times act as if they might be in estrum but refuse to stand for the bull or for other cows to mount them. Some cows with cystic ovaries may show anestrus initially and then exhibit nymphomania later or conversely some nymphomaniac cows may continue to have cystic ovaries but after a varying period of time exhibit anestrus.

The incidence of cows with cystic ovaries exhibiting nymphomania or anestrus varies and is strongly influenced by the postpartum interval at which the condition is diagnosed per rectum. More cystic follicles developed from 0 to 30 days than from 31 to 60 days postpartum. About 85 percent of the cows, that developed follicular cysts prior to 60 days exhibited anestrus.^{45,55} A study of 187 cows with cystic ovaries in which many were examined in the early postpartum period of 30 to 60 days reported a 62.5 percent incidence of anestrus.⁹ A study of 265 cases of cystic ovaries examined only at the request of the owner from about 80 to 150 days after calving reported the incidence of anestrus to be 26.4 percent.⁶² Thus as the number days following calving at which the cystic ovarian condition is diagnosed increase the incidence of nymphomania also increases.

A constant and prominent sign of cystic ovaries is the relaxation of the sacrosciatic ligament, most noticeable at its caudal border.²⁴ In cows showing nearly constant estrum 78 percent of the cows had highly relaxed ligaments, 10 percent moderately relaxed and 6 percent slightly relaxed ligaments. In cows with frequent heats, 50 percent had highly relaxed 42 percent moderately relaxed and 5 percent slightly relaxed ligaments. In a few cases because of the relaxing effect of estrogens on the pelvic ligaments constant mounting and being mounted may lead to dislocation of the hips and to pelvic fractures. The pelvic ligaments of anestrus cows were highly relaxed in about 40 percent of the cows, moderately relaxed in 30 percent, slightly relaxed in 12 percent and normal in 18 percent of the cows. The genital organs are usually slightly edematous and atonic. The vulva is often increased in size, and relaxed and swollen. Prolapse of the vagina and symptoms of pneumovagina may occur especially in nymphomaniac cows. An increased amount of mucus may be present and appear as a discharge at the vulva. This mucus is thicker, more tenacious, and more opaque than the mucus of estrum. The mucus is whitish grey in color, giving it the appearance of a mu-

copurulent discharge. However there are usually few leucocytes in the mucus. The external os of the cervix is usually large, dilated, and relaxed.

On rectal examination the relaxation of the pelvic ligaments is very noticeable on palpation. The cervix, especially the external os, is usually large, and the uterus is also enlarged, and its walls are thickened and flaccid. In long-standing cases of cystic ovaries the uterus may be atrophied, small and flaccid. On palpation of the uterus it seldom develops tonicity or becomes erect or turgid as usually occurs in a normal uterus especially at or near estrum. One or 2 to 4 cysts varying in size from 2 to 7 cm. in diameter are felt on one or both ovaries. These cysts are usually peripheral in location, thin-walled and burst readily with pressure applied by the fingers. At times it may be difficult to differentiate between a cyst and a normal follicle. Cysts persist for 10 days up to several months or longer. No luteal tissue or corpus luteum is usually palpable in the ovaries of cows with follicular cysts. Even cystic corpora lutea are not present. Occasionally a thick-walled, rather fluctuating, luteal or luteinized cyst may be found. These are often associated with anestrus cows. Occasionally a large atretic follicle together with a normal corpus luteum may be found in a pregnant cow the first trimester of gestation. This does not affect the pregnancy. Usually the cyst is larger than 2 or 2.5 cm. in diameter whereas the normal follicle is smaller. The cyst is usually thicker-walled than is the follicle. The uterus of a cow with cystic ovaries is usually flaccid, whereas the uterus during estrum is erect and tonic. The mucus of estrum is much clearer and more stringy than that in the cow with cystic ovaries. Occasionally cows 40 to 90 days pregnant may have a good-sized follicle and a normal corpus luteum. A cyst larger than 8 to 10 cm. in diameter may indicate the presence of a granulosa cell tumor.

The size and number of ovarian cysts were similar for both nymphomaniac and anestrus cows.^{24,62} The incidence of ovarian cysts in 433 cows was as follows: both ovaries cystic 50 percent, right ovary cystic 31 percent, and left ovary cystic 19 percent.²⁴ The author in a total of 352 cases found the incidence to be 43.8 percent, 33.2, and 23 percent, respectively. On postmortem examination of the genital organs of 6286 Swedish Highland cows an incidence of 14.8 percent cystic ovarian degeneration was found, 6 percent involved only the right ovary, and 5.5 percent involved both ovaries. Thus in nymphomania, as in the incidence of left- and right-horn pregnancies, the fact that the right ovary of cows is slightly more active or functional than the left is further illustrated.

Gross examination of cystic ovaries revealed the fact that multiple cysts were more common than were single

cysts and the large single cysts frequently showed evidence that they had been formed by the union of several cysts.²⁴ The lining of the cyst was smooth and basal portions occasionally had a thin circumscribed area of yellowish lutein tissue. Some lutein tissue has been observed in many ovarian cysts by the author and his associates. The cystic fluid was clear and slightly yellow or amber in color. In large cysts the ovarian tissue was atrophied. On histologic section the granulosa layer of cells and ovum are often missing, but scanty portions of granulosa cells could be found in the basal portions of the cyst and in some cases these appeared luteinized. The theca interna was likely to be flocculent and edematous and show degenerative changes. Some hyaline changes in the theca interna were occasionally observed. The degenerative changes were more marked in the peripheral portions of the cyst.²⁴

The gross appearance of the uterine tube was normal in most cases.²⁴ Sometimes the uterine tube was thickened and some yellow fluid could be squeezed out after incising it. Microscopically this was composed of epithelial cells and debris. In cows with cystic ovaries the ovarian bursa or ventricle was larger than normal and the mesometrium was more relaxed. In nymphomaniac cows the uterus and cervix usually were large, edematous, and flaccid. The cervical canal was dilated and relaxed, permitting a finger or pencil to pass through. The endometrium was smooth, moist, semi-transparent, and edematous. In a few cases cystic enlargement of the endometrial glands was noticed as pinhead rounded elevations with transparent capsules. Usually the uterus was empty but the endometrium was covered with thin mucus. Occasionally as much as 100 ml. of mucus was found in the uterus. The vagina, clitoris and vulva were swollen. Microscopically the greatest changes are found in the uterine mucosa. These changes, especially in nymphomaniac cows, were characterized by marked hyperplasia of the mucosa and cystic dilation of the endometrial glands. In some cases cystic dilation was so marked that the endometrium developed a typical Swiss-cheese appearance on histologic section. (See Figure 113.) In some anestrus cystic cows with a small uterus the mucosa showed slight atrophic changes and hyperplasia and cystic dilation of uterine glands. These hyperplastic and cystic changes in the endometrium are characteristic of changes produced by long-continued action of estrogens from the cystic ovaries.

In long-standing cases of nymphomania the relaxation of the pelvic ligaments produces a tipping of the pelvis and an elevation of the tail head that is made more pronounced by the relaxed sacroscopic ligaments. This elevated tail head is sometimes called the "sterility hump"

Figure 113. Cystic Endometrial Glands Caused by Cystic Ovaries.
Courtesy K. McEntee.

because it tends to persist after recovery. (See Figure 114.) Associated with the elevation of the tail head is the elevation of the ischial tuberosities and a ventral dropping of the lumbosacral articulation. This tipping of the pelvis may result in an unsteady gait and a predisposition to injury. These changes in the pelvic ligaments are associated with prolonged low level estrogenic stimuli and probably not due to excessively high estrogen levels in the blood plasma.¹⁹

Figure 114. A "Sterility Hump" in a Cow Associated with Chronic Cystic Ovaries and Relaxed Pelvic Ligaments.

Figure 115. A Steer-like Appearance of a Cow with Chronic Cystic Ovaries and Infertility Lasting for Three Years.

Hydrometra or mucometra may develop following a long-standing condition of cystic ovaries. (See Figure 112.) Cows with cystic ovaries observed by the author and his associates were initially treated apparently successfully and bred. The owners believed them to be pregnant but after 6 to 8 months the normal signs of pregnancy did not develop. Rectal examination revealed mucometra and cystic ovaries. A marked atrophy of the uterine wall or myometrium had occurred with severe cystic dilation of the endometrial glands resulting in mucometra with the uteri containing 100 to 1000 ml. of watery mucus. (See Figure 113.) On rectal examination in some cases the uterine wall was found to be so thin that it was difficult to palpate. Hydro- or mucometra may affect only one uterine horn or a portion of one horn. The ovaries were usually larger than normal but the cysts were multiple, small (1 to 2 cm. in diameter), and thick-walled. The cysts were extremely difficult or impossible to rupture by manual pressure. This same condition occurred in 3 heifers that developed chronic cystic ovaries out of 25 heifers that were withheld from breeding for 4 to 5 years.¹⁷ The cervical canal in these cases is usually closed by an accumulation of mucus and debris. In one case in which treatment was instituted by the author to relieve the mucometra by drawing off the mucus, infection was established and pyometra resulted. In another cow with 100 ml. of mucus in the uterus, 20,000 I.U. of chorionic gonadotropin was injected intravenously and luteinization of the cysts and expulsion of the mucus from the uterus resulted. Most cases however fail to respond to treatment. The marked similarity of this condition in cattle to cystic degeneration of the uterine wall in horses, and to hyperplasia of the endometrium with cystic di-

lation of the endometrial glands, hydrometra, and, in some cases, secondary pyometra in dogs is evident. The endometrial changes are probably produced in the three species by the gonadal steroids, estrogen and/or progesterone.

In rare cases of chronic cystic ovaries and anestrus the cervix may become greatly enlarged to 5 to 6 inches in diameter and filled with a tenacious mucus, mucocervix. The uterus in these cases is flaccid but not distended with mucus. The cause and prognosis are similar to mucometra.

The effect of cystic ovaries on milk production is variable. Some authors report a drop in milk production in nymphomaniac cows. Others report good milk production until treatment is given, at which time there is a drop in production. In a careful study of 74 cows it was demonstrated that the cystic condition was apparently responsible for increased production.³⁶ The longer the cows were cystic the greater the production of milk. Cows with anestrus produced more milk than nymphomaniac cows. This indicated that the low levels of estrogen from the cystic ovaries probably stimulated milk production.

Prognosis—The earlier that cystic ovaries are diagnosed and treated, the better is the prognosis. In a series of 229 cases diagnosed and treated by the author within 6 months of parturition 79 percent conceived after 1 treatment, 10.7 percent had to be retreated, and 10 percent were sold because they were sterile, poor producers, or for other reasons. In 46 cows diagnosed and treated between 6 and 12 months after calving, although 78.3 percent recovered, only 58.7 percent conceived after one treatment and were retained in the herd, 8.7 percent were retreated, and 32.6 percent were sold. Many were sold because it was not economical to maintain them as non-lactating cows for many months in commercial herds. There was no essential difference between the rate of recovery and conception rates between cows showing nymphomaniac symptoms and cows showing anestrus. In 124 cases of nymphomaniac cows treated within 60 days of the onset of symptoms 78.2 percent conceived and 21.8 percent were sold. In anestrus cows, symptoms in many cases were lacking or unnoticed for an undetermined period of time. Of 46 cows, many of which had not been observed in estrus since calving, treated within 120 days of the onset of anestrus, 76.1 percent conceived and 23.8 percent were sold. The size or number of the cysts bore no relation to the symptoms shown or to the rate of recovery. In some cases two or more treatments may be necessary to effect a cure. Recovery is not assured until the affected cows are safely pregnant. About 20 to 30 percent or more of cows with cystic ovaries if they conceive will develop cystic ovaries again at

subsequent service periods. Another factor to be considered seriously in the prognosis is the possible furthering of this cystic problem to the future detriment of dairy breeds inasmuch as there is a definite hereditary predisposition to cystic ovaries and twinning. Cows having two or more episodes of cystic ovaries were hereditarily predisposed toward the disease.^{32a} Bulls with an increased incidence of daughters with cystic ovaries should be slaughtered.^{4,32a}

The prognosis in cases of severe cystic degeneration of the endometrium and atrophy of the uterine wall in hydrometra or mucometra is poor. Most cows with mucometra or rare cases of mucocervix should be sold since only a very few cases respond to treatment. Spontaneous recovery from cystic ovaries frequently occurs. About 50 percent of the cases of cystic ovaries occurring within 45 days of calving recovered spontaneously before 60 days postpartum. In 42 cows with cystic ovaries, 30 of which developed between 15 and 45 days postpartum, 69 percent recovered without treatment and became pregnant before 300 days postpartum.⁷⁸ In 34 cows treated for nymphomania about 15 percent were sold as sterile and the remainder required about 3 services per conception after treatment; about 40 percent of the cows conceived on first service.⁷³ A lowered conception rate associated with early embryonic deaths following recovery from cystic ovaries was also noted.⁵⁰

Treatment—Rational treatment should have as its aim the development of a functional normal corpus luteum either by spontaneous recovery or rupture of the cysts, repeatedly if necessary, administration of GnRH or luteinizing hormone (LH) or preventing the continuous release of luteinizing hormone from the pituitary gland by the administration of progestational compounds. The bovine corpus luteum is formed mainly from the granulosa and thecal cells.⁶⁷ Since these cells are the first cells to degenerate in the cystic follicle, treatment to be successful should be undertaken soon after cyst formation or when newer young cysts are forming on the already cystic ovary containing follicular or luteal cysts.

The earliest reported treatment for cystic ovaries consisted of repeated manual removal or rupture of the cysts at 6- to 10-day intervals until a normal cycle and corpus luteum developed. This frequent manual massage and trauma to the ovary is not desirable if it can be avoided; moreover, repeated visits by a veterinarian for the massage of the cow's ovaries is costly. In a series of 188 cases reviewed by the author in which cystic ovaries were treated by manual removal of cysts, a recovery rate of 37.2 percent was reported.^{14,51,62} Of 24 cases of cystic ovaries occurring in a herd of 150 cows, 8, or 37.5 percent, conceived twins after treatment.¹⁴ Of 11 animals

bred within 35 days after removal of the last cyst, 6, or 54.5 percent, conceived twins; only 3, or 24 percent, of 13 animals bred after 35 days following rupture of the last cyst had twins. Because of this high twinning rate following treatment it was then recommended that breeding be deferred until the second normal estrum unless the ovaries were palpated to determine the presence of 1 or 2 ripe follicles, and the cow then bred or not bred accordingly. In cows having ovarian cysts centrally located, or thick-walled so that manual rupture was not possible, the treatment required tapping the cyst with a needle or ovarian scalpel through the vaginal wall. Stoll's cyst aspirator⁷⁰ works well in these cases. Two hundred forty two cows with cystic ovaries were treated by manual rupture of the cysts. Three-quarters of these cases were treated within three months of parturition. Cows with the shortest time interval from parturition to treatment recovered significantly more quickly; 45.7 percent or 107 cases, recovered after one treatment.⁶⁵ These results complement the observation that single ovarian follicular cysts occurring before 45 to 60 days after calving have a 50 percent spontaneous recovery rate and the observations of many veterinarians that manual removal of these early postpartum cysts is often successful in restoring a normal sexual cycle.⁵⁴ Many veterinarians may manually remove cysts prior to 50 days but do not treat with LH or GnRH until 50 to 60 days or more postpartum. A trial on the comparative efficacy and costs of spontaneous recovery of early ovarian cysts, manual rupture of these cysts which usually is easily accomplished, and treatment with GnRH or HCG should be conducted on cows in which ovarian cysts are diagnosed prior to 60 days postpartum. Spaying will correct nymphomania but removing only one ovary if it is affected with cysts is useless, since the remaining ovary will promptly develop cysts. Affected nymphomaniac cows should be kept isolated from the herd so that they do not annoy or injure themselves or other cattle by excessive mounting.

Although a number of authors had suggested the possible value of LH in treating bovine cystic ovaries and the successful treatment of a few cases with LH ("Antuitrin S") in 1943 was reported,⁸ it was not until 1944 that successful results in the treatment of many cows with cystic ovaries, both follicular and luteal cysts, using unfractionated sheep pituitary extracts intravenously was published.¹³ This report demonstrated the value of LH in curing the disease. Of 81 cows with nymphomania or cystic ovaries treated, 88 percent recovered and had a normal corpus luteum in 31 days. Of 53 cows bred after a single injection of the pituitary extract, 36 conceived. After retreatment of 16 animals 6 more became preg-

nant. Thus a total of 68 percent conceived. These workers reported that it was not necessary to rupture cysts prior to treatment. Since then a number of reports on the treatment of cystic ovaries have recorded the successful use of pituitary extracts rich in LH, or chorionic gonadotropin HCG.⁶²

Injections of human chorionic gonadotropin (HCG) 5000 I.U. intravenously and 10,000 I.U. intramuscularly resulted in a higher incidence of conceptions than 2500 I.U. intravenously, 78.4 percent, 81.6 percent, and 73.7 percent conceptions, respectively.⁶² Another study reported 68 percent recoveries from cystic ovaries in Guernseys and 78 percent recoveries in Holsteins by the administration of 5000 I.U. chorionic gonadotropin intravenously.⁹ Due to the cost of the product it is more economical to treat most cows with 2500 to 5000 I.U. of chorionic gonadotropin intravenously than the 10,000 I.U. dose intravenously or intramuscularly. Intramuscular injections of 1000 to 5000 units of chorionic gonadotropin in 14 cows resulted in a slightly lower conception rate of 64.3 percent.⁶² No difference was observed from year to year in the efficacy of the pituitary or chorionic gonadotropin products rich in L.H. A comparative study reported on the treatment of 278 cows with cystic ovaries with the intravenous injection of 10 RU "Vetrophin," a sheep pituitary gonadotropin, 65 cows with 5 R.U. "Vetrophin" intravenously, and 38 cows with 5000 and 10,000 IU HCG intramuscularly. Recovery and conceptions after one treatment were 65.5, 69, 78, and 71 percent, respectively, for these treatments. Thus large doses of HCG improved results only slightly.

Only one case of anaphylaxis has been observed by the author. A moderately-affected case, occurred after the administration of 5000 I.U. of human chorionic gonadotropin intravenously. No reaction has been observed or reported with the use of the sheep pituitary product, "Vetrophin."

Of 185 cows in which cysts were removed by manual pressure through the rectum at the time of treatment with either pituitary LH, or chorionic gonadotropin, 156, or 84.3 percent, recovered; 29 or 15.7 percent, did not recover. 133, or 71.9 percent, conceived; 20 or 10.8 percent, were retreated; and 32 or 17.3 percent, were sold. Of 103 cases in which the cysts were not ruptured at the time of treatment with LH, 87, or 84.5 percent, recovered; 16, or 15.5 percent, did not recover; 79 or 76.7 percent, conceived; 11, or 10.7 percent, were retreated; and 13, or 12.6 percent, were sold. No benefit resulted from removal of cysts at the time of treatment with an L.H.-rich product.^{61,62} Since trauma to and adhesions of the ovary may be produced by manual removal of cysts this practice is unnecessary and contraindicated. After

injections of LH the cysts luteinize and developing follicles may ovulate and luteinize⁷⁹ and symptoms of nymphomania cease in 3 to 6 days in affected cows that recover. Although most of the unruptured cysts luteinize, the cystic fluid may remain until a few days before the next normal estrus when the luteal tissue and the cystic fluid recede and disappear rather rapidly. A normal estrus will occur in most cows from 15 to 30 days after treatment, with most cows exhibiting estrus 20 to 25 days after treatment.

Within the last 10 years rapid advances in the study of the peptide releasing factors from the hypothalamus has resulted in the synthesis of the decapeptide gonadotropic releasing hormone (GnRH) or luteinizing hormone releasing hormone or factor (LH-RH or LH-RF) or the commercial product "Cystorelin."* This decapeptide when injected in any manner usually intramuscularly into cattle causes a dose related increase in plasma concentrations of luteinizing hormone (LH) from the anterior pituitary gland. Although doses of GnRH in Europe are higher, 0.5 to 1.5 mg., the dose used in the U.S. is 100 ug. (50 ug/ml) in 2 ml. For long existing cases, relapses, or slightly better response on initial treatments larger doses of GnRH may be used.³⁵ This product is currently cheaper in price than 5000 to 10,000 I.U. of human chorionic gonadotropin. GnRH is non-toxic even in large doses and produces no side effects or anaphylactic reactions. Refractoriness to the GnRH does not develop in cows as occurs after repeated injections of human chorionic gonadotropin (HCG), a foreign protein.

In the normal cow the rising level of estradiol early in estrus in the absence of progesterone from the corpus luteum results in the preovulatory surge of LH in cows with a serum level of 40 to 50 ng/ml that is believed to induce proteolytic enzyme synthesis in the Graafian follicle that weakens its wall resulting in ovulation. Immediately after, or even slightly before, ovulation LH induces luteinization or a conversion of the steroidogenic activity of the granulosa and theca cells from estradiol to progesterone synthesis and within 5 to 6 days the mature corpus luteum is formed that secretes progesterone to regulate the estrous cycle and, if the fertilized ovum is present, to maintain pregnancy. Progesterone has a negative feedback on the hypothalamus and the pituitary on LH release.³⁹ Cystic ovaries in cows, as indicated earlier, are due to a failure of the normal release of LH and GnRH necessary to cause ovulation and luteinization of the ovulated follicle.

Recent reports indicated the treatment of cystic ovaries with 100 ug GnRH IM caused luteinization of the cystic structures without ovulation.^{39b} Larger doses of GnRH, 0.5 to 1.5 mg or 750 to 10,000 IU HCG given IM caused ovulation of 1 to 3 cystic or mature follicles followed by the formation of corpora lutea.^{39b,71b} About 40 percent of ova recovered from these cows, following AI within 24 hours after treatment, were fertilized. Ovulation occurred about 27 hours after treatment.^{71b} Thus GnRH and HCG may induce ovulation and CL formation besides luteinizing the cystic structures. Like HCG therapy, manual rupture of the ovarian cysts is not necessary or recommended. Within 9 to 13 days after GnRH or HCG treatment the increased amount of lutein tissue produced in the cystic structures is producing a plasma level of progesterone that is similar to that in the estrous cycle in about 80 percent of the treated cows.⁴¹ The onset of estrus after treatment may range from 9 to 30 days depending on the ovarian and endocrine status of the cow.^{10,39} In the 20 percent of cows failing to respond to treatment by the re-establishment of the estrous cycle the cause may be due to the cystic structures being unable to respond to LH release because of degeneration of the granulosa and theca interna layers.^{40,41} Other causes might include: unobserved estrus, the hypothalamus and/or pituitary may not be responsive in releasing LH due to elevated estradiol concentrations,⁴¹ or high ACTH and cortisol levels may be present that suppress estrus.^{43,69}

The success or response to treatment of cystic ovaries with GnRH is about the same as with human chorionic gonadotropin (HCG).^{10,35} In 225 dairy cows with cystic ovaries treated one to three times with 100 ug of GnRH at less than 30 to more than 90 days postpartum that clinically recovered with a normal estrous cycle was 76 percent, 78 percent and 66 percent for the three treatments, respectively. The conception rate on first service after treatment was 49 percent and 83 percent of the cows eventually became pregnant at an average interval of 87 days from treatment to conception.⁷⁸ In a controlled study 114 dairy cows with cystic ovaries were divided into four equal groups and given 0 ug, 50 ug, 100 ug and 250 ug of GnRH as an intramuscular injection.^{9a} Recovery rates based on the development of a normal estrous cycle or conception were 21 percent, 64 percent, 82 percent and 77 percent. The mean days from parturition to treatment for these four groups was 63, 111, 89, and 94 days, respectively. Most cows came into estrus 18 to 23 days after treatment with GnRH, the range of days was 8 to 35.^{10,39} Other reports on the treatment of cystic ovaries with GnRH have been cited with essentially similar responses.^{25,35} In one study there was no difference in response to 10,000 I.U. of chorionic gonadotropin (HCG)

*Abbott Laboratories, Chicago, Ill.

and 250 ug GnRH.⁶¹ However early diagnosis and treatment increased the chance of recovery as pregnancy rates within 90 days postpartum for groups treated within 59 days, 60 to 120 days, 121 to 180 days and over 180 days were 48, 39, 51 and 26 percent.⁶¹ Since the incidence of recoveries are similar for GnRH and HCG, the advantages of the former are its cheaper cost and the evidence that refractoriness on repeated doses, due to the production of antibodies against a foreign protein, does not occur. If a normal estrous cycle has not occurred within 23 days of GnRH treatment, the cow should be reexamined and possibly treated again. This may be necessary in about 20 percent of the cows.

In all carefully controlled studies on bovine cystic ovaries spontaneous recoveries are reported. These are most commonly observed early in the postpartum period. About 50 percent of cows developing cystic ovaries within 45 days postpartum recovered spontaneously before 60 days postpartum.⁵⁵ In the two studies^{9a,78} 21 and 29 percent of spontaneous recoveries occurred in cows with cystic ovaries diagnosed between less than 30 to more than 110 days postpartum. Thus early postpartum examinations⁷⁷ 15 to 45 or 60 days, together with early treatment of ovarian cysts will improve the rate of recoveries. The decision for the best time to examine cows to possibly treat by rupture of cysts formed soon after calving, or treat the cows with GnRH or HCG will vary with the prevalence of cysts in the herd and the frequency and cost of the examinations.⁷⁷

The combination of GnRH or LH (HCG) and prostaglandins recently have been shown to have certain advantages in the treatment of cystic ovaries.^{10,19,35,40} Treatment of cystic ovaries with GnRH or LH (HCG) results in about 80 percent of the cows developing luteinized cysts or CL by 9 to 13 days after the injection followed by estrus 18 to 23 days (range 9 to 35 days) after the injection. If a luteolyte dose of PGF_{2a} is given 9 to 14 days after treatment with GnRH most cows will exhibit normal estrus 3 days later or 12 days after the injection of GnRH. This treatment aids in helping to synchronize estrus and shortening the time from GnRH injection to conception by 7 to 10 days in many cows.^{10,40}

The second regimen is based on the facts that HCG or GnRH will effectively cure luteal cysts as well as follicular cysts by providing or releasing LH. From 15 to 75 percent of the cystic structures on the bovine ovary are luteal cysts as determined by palpation, abattoir studied and plasma progesterone levels.^{10,19,35,61,80} The proposed and apparently successful therapy for cows with cystic ovaries consists of injecting a luteolysing dose of prostaglandin which should involute all lutein tissue in the cystic ovarian structures, followed by a dose of GnRH or HCG 3 or 4 days after the injection of PGF_{2a}. If estrus

is observed at this time, breeding is indicated. The time to the next estrus can be shortened by a second injection of PGF_{2a} 9 to 14 days after the dose of GnRH or LH. These modifications of the usual treatment with GnRH or LH may prove valuable in the treatment of cystic ovaries in certain cows despite the increased cost. Further studies are indicated.

Many cystic ovaries in dairy cows develop between 15 and 60 days postpartum when milk production is at peak levels. Recent studies have shown that plasma and pituitary levels of LH are low at parturition and increase from 8 to 30 days later.^{60b} However the pituitary is responsive to treatment with GnRH by day 14 postpartum and the resultant LH surge will cause subsequent ovulation, corpus luteum formation and the onset of estrous cycles. Fertility increased as the number of estrous cycles prior to 60 days postpartum increased.^{60b} Although more studies are indicated reports have shown that when 204 Holstein cows were given 200 ug of GnRH intramuscularly between days 8 and 23 postpartum the incidence of follicular cysts was reduced from 15.2 to 5.7 percent.^{9b} However the interval to first insemination, interval to conception and inseminations per conception did not differ from controls also bred for the first time between 80 and 90 days postpartum. In another study 100 or 250 ug. of GnRH were given to 335 dairy cows in two herds from 13 to 15 days postpartum.^{66b} In this trial the incidence of ovarian cysts in treated and control cows was similar, about 15 to 25 percent. However in one herd given the larger dose of GnRH and insemination of cows begun at 50 days postpartum the treated cows had a shorter calving to conception interval, 81 vs 96 days, a better overall conception rate, 75 vs 56 percent and a lower number of services per conception, 1.23 vs 1.74, than the controls.

If the cow has calved 50 days or more before the treatment of cystic ovaries and if no definite pathology of the genital tract is present requiring further rest or treatment, the author and others have recommended that the cow be bred the first estrus after the injection of luteinizing hormone. No observable increase in twinning or delayed conception has been caused by this practice. The practice of breeding promptly is indicated because if cows are pregnant cystic ovaries cannot recur! If cows are allowed to have two or three estrous cycles after therapy for cysts relapses are more likely to occur at each ovulatory period. In the early treatment of certain cases some veterinarians remove cysts manually without injecting LH and if there is no response they treat with LH on a return trip. In the end this procedure may be more costly to the farmer than if the veterinarian administers LH on the initial call.

If a case of cystic ovaries fails to respond to an in-

jection of LH or GnRH and a second call is made a larger dose is indicated. The author also recommends a possible change of products from a gonadotropic hormone from pituitary LH to chorionic gonadotropin, or vice versa. In 12 cases retreated with the same product 3 to 4 weeks after the first unsuccessful treatment, 5, or 41.7 percent of the animals recovered and conceived. In 31 cases of cystic ovaries in which a different product from a different source was used for the second treatment 26, or 83.9 percent, recovered and 67.7 percent of the cows conceived.⁶² Since gonadotropic hormones are protein in nature and originate from a species of animal other than the bovine species, antibodies develop from the first injection, and neutralize some or much of the same hormone when reinjected. When repeated injections of gonadotropin were used to superovulate cows the animals rapidly developed a refractoriness or inability to respond to the hormone that persisted for months. Other more recent studies have confirmed the development of antihormones against the injected gonadotropin such as HCG and PMSG. The more refined the gonadotropin the less antigenic it was in causing antihormones.

The injection of small doses, 500 to 2000 I.U. of HCG or 0.5 to 5.0 R.U. "Vetrophin" directly into the ovarian cyst by means of a fine needle inserted through the vaginal wall or ischiorectal fossa while the other hand of the operator in the cow's rectum manipulated the cystic ovary has been reported upon.^{62,75} Although the cost of the hormones used by this technique was less, the results were about the same as other modes of administration of LH. The site of the injection by-passed the body fluids to act directly on the ovarian structures to produce luteal tissue thus avoiding possible neutralization of the LH by antihormones in repeatedly treated cows. This procedure has not proved to be popular or commonly performed.

Under the influence of estrogens, early in estrus LH is released from the pituitary gland. Since progesterone and similar products suppress the release and favor the storage of gonadotropin by the pituitary gland probably by acting upon the hypothalamus to prevent the release of GnRH, these products have received attention in the treatment of cystic ovaries.³⁶ Researchers treated 100 cows that developed cystic ovaries and remained in estrus for a few days after service with 750 to 1500 mg of Repositol progesterone intramuscularly.⁷ The nymphomaniac signs terminated in most of these cows within 36 to 72 hours and 67 of the cows conceived.

Ninety-eight cows with cystic ovaries were given 109 treatments of either 50 or 100 mg. of progesterone in oil daily subcutaneously for 14 days. The cysts were not ruptured.³⁶ Normal estrous cycles and estrus resulted in 60 percent of the cows; 48.7 percent and 52.5 percent

of the cows treated with 50 and 100 mg. of progesterone, respectively, conceived. Of 30 untreated control animals with cystic ovaries only 13.3 percent conceived. The average interval from treatment to conception was about 45 days with about 2+ services per conception. Presently progesterone therapy for the treatment of cystic ovaries is seldom used.

In a discussion of the treatment of cystic ovaries in cattle the author would be remiss if he did not again call attention of his readers to the fact that this condition is frequently due to an inherited weak hormonal constitution. The repeated successful treatment of affected cows simply increases the length of time these cows remain in the herd and increases the numbers of their daughters who also have an inherited predisposition for this disease. In many cases the veterinarian would be doing the farmer and the breed a favor by declining to treat certain cows and to recommend their slaughter. Herds with a high incidence of cystic ovaries should be bred to bulls from lines free of cystic ovaries or by bulls shown to have daughters with a very low incidence of the disease.

Failure of Ovulation or Delayed Ovulation due to a failure or delay in LH release from the anterior pituitary gland and not associated with cystic ovaries may occasionally be a cause of infertility in cows and heifers. This is probably a minor cause for infertility since only 3 out of 104 repeat-breeding cows failed to ovulate.⁷¹ Failure of ovulation occurred in only 3 percent of 247 cows examined.¹¹ This low incidence of failure of ovulation is further supported by other studies.^{6,71} Ovulation failure occurred in 13 percent of heifers on their first standing estrus and in 2 percent on their second estrus.⁵³ Thus present evidence would indicate that failure of ovulation and atresia of the follicle with an absence of cystic follicles is an uncommon cause of infertility in the cow. It appears to be more common in the ewe and mare at the beginning or transitional phase of the breeding season. In a careful study of 58 cows 69 percent had ovulated by the day after estrum and 65 percent of those bred conceived. The other 31 percent of cows had ovulated by the second day after estrum and of those that were bred only 36 percent conceived.²⁸ However in a study of 118 Friesian and 161 Afrikaner cows and heifers over a 4-year period including a total of 536 estrous periods, defective ovulations occurred in 140; 47 cases or 34 percent ended in anovulation and 93 cases or 66 percent had delayed ovulation. Forty-one of the 47 anovulatory follicles regressed, 4 became follicular cysts and 2 luteal cysts. In delayed ovulation the delay was less than 48 hours in 85 percent of the cases. In 2 cases ovulation occurred 7 and 9 days after the cessation of estrus and both cows conceived to inseminations performed the day

before ovulation.⁷⁴ These authors recommended that if the follicle had not ovulated by 24 hours after service the cow should be inseminated again. In 51 cows reinseminated 24 hours after the first insemination 32 conceived while none of the 18 cows that had failed to ovulate within 24 hours of service conceived. They reported that only one of 17 cows inseminated after ovulation conceived and only one of 36 cows conceived when the follicle was manually ruptured at the time of insemination. They indicated that the two main causes for defective ovulation were nutritional deficiencies, especially during the winter months, and an hereditary predisposition characteristic of certain infertile cow families in both dairy and beef breeds. Because some reports indicated that anovulation or delayed ovulation are rare and other reports indicated they were common, more work is necessary on the incidence and importance of defective ovulation as a cause of lowered fertility. In light of the latter study it should be noted that if cows are bred early in their estrous period, which usually lasts 18 hours, range 6 to 30 hours, ovulation, which usually occurs 8 to 16 hours after the end of estrus, may not have occurred by the end of the 24 hour period after breeding in the normal cow. Thus breeding in the second half of the estrous period is most desirable. Delayed ovulation may result in aging of the sperm and ova and also a lowered rate of fertilization and a higher embryonic death rate. (See Repeat Breeders.)

Suspected failure of ovulation, or delayed ovulation may possibly be diagnosed by the palpation of a mature follicle on the ovary more than 24 to 48 hours after the end of estrus, especially if bloody mucus is in the vagina. The use of GnRH at breeding to assure ovulation only produced a very moderate increase in conception rates. Thus the cost benefit ratio may mitigate the regular use of GnRH. However in selected or problem cows where large follicles with delayed ovulation is suspected on the basis of repeated examinations of the ovary it may be used at breeding or six hours before or after breeding.^{25a} Routine doses of GnRH in estrus synchronization also has not proven advantageous. It should be noted that HCG (LH) has proven superior to GnRH in the ovulation of the donor cow for embryo transfer. There is little evidence that failure of ovulation or delayed ovulation is often repeated at consecutive estrus. If anovulation or delayed ovulation was diagnosed, rebreeding and the injection of LH or GnRH may be indicated since these hormones hasten and promote ovulation in the cow. In these cases it might be advisable to rebreed the cow again 24 hours after the first service so fresh viable sperm cells would be available when the ovum was released. More work is needed to assess the importance of delayed ovu-

lation and failure of ovulation without cystic follicles and to improve the diagnosis and treatment of these conditions.

Infertility Associated with Multiple Ovulations in Cattle

In a study of 294 ovulations at which breeding occurred, 252 were single ovulations and 42 multiple ovulations, as determined by rectal examination. The incidence of multiple ovulations was 14.3 percent. The conception rate in single ovulations was 57.5 percent, and in multiple ovulations 28.6 percent.⁴² Of these latter conceptions represented by 12 cows only 3 resulted in twin births. In a previous study in this same herd the incidence of multiple ovulations was 13.1 percent and the incidence of twinning was 1.92 percent. (See Discussion of Twinning in Unipara in Chapter IV, and Superovulation in Chapter XX.) Multiple ovulation is probably due to the release of increased amounts of FSH. Heredity and cystic ovaries may be associated or predisposing factors. Thus multiple ovulations resulted in infertility either due to defective ova incapable of fertilization or growth or because multiple ovulation may be a manifestation of an endocrine disturbance reflected in an abnormal transport of ova or failure of the proper attachment of the embryo. When twin or multiple ovulations occur from one bovine ovary and the fertilized ova develop in the horn corresponding to that ovary, a higher rate of embryonic death results than where twin ova are released from each ovary and each embryo develops in a separate horn, bicornual twins. This low survival rate in multiple ovulations and conceptions maybe a fortunate occurrence, as the harmful effects of twinning in cattle are well known. The above study may explain the occasional cases in which although on early pregnancy examination two corpora lutea are found, and twinning is therefore suspected, only a single birth occurs.⁴² The situation as detailed above is very similar to twinning in mares in which there appears to be a "mechanism" in the uterus that eliminates one of the twin embryos. (See Twinning in the Mare.)

FAILURE OF ESTRUM, OR ANESTRUM

Failure of estrum, or anestrus, in cattle is the principal symptom of many conditions that may affect the estrous cycle (see Physiology of Reproduction). It is the most common single cause for infertility in cattle. In many instances where owners or herdsmen are negligent in observing their cows closely, anestrus is reported to the veterinarians when actually the condition does not exist. Anestrus in cows is observed most commonly either after parturition as postpartum or preservice anestrus, or following service as postservice anestrus, when conception does not occur. In heifers it is frequently observed as a herd problem especially during periods of lowered nutritive intake. Because failure of estrum is due to multiple causes often not directly related to the endocrine system, a complete history should be obtained, a careful clinical examination of the genital tract and ovaries per rectum and vagina by a speculum should be made, and a physical examination of the cow might be necessary so that an accurate differential diagnosis is possible. If more than several animals are affected it may be a herd problem involving management and/or nutrition in which case a careful herd survey and examination of all cows and their breeding records is indicated.

Unless this is done the veterinarian has permitted the owner or farmer to make the diagnosis, and treatment will be equally unreliable and erroneous. If a hormone is injected on this empirical basis neither the farmer, the animal, or the veterinarian is likely to be benefited. Following this essential examination, the cows or heifers that fail to show estrum may be divided into two classes, cows with a functional corpus luteum, and cows without a functional corpus luteum.

Cows that are found on rectal examination to have a normal functional corpus luteum present in one of the ovaries. Since cystic corpora lutea have a normal function, these are included in this class. In this class are cows or heifers that are pregnant, those with a persistent corpus luteum due to uterine pathology and those that are ovulating and cycling regularly but are not recognized as exhibiting estrum either because it is "weak" or "silent" or because the owner has failed to observe it. Normal cows have a functional corpus luteum in their ovary 85 percent of the time.

1. Anestrus due to pregnancy—All veterinarians performing regular rectal examination on cows have had many cases in which the owner has requested treatment for a heifer or cow that fails to show estrum, only to find on examination that the animal is already pregnant. The history or the owner's records can often be very misleading. This finding has occurred even in well-man-

aged herds where accurate records are kept. This serves to emphasize the importance of a careful rectal examination, including the palpation of both uterine horns to their apices, preceding treatment of any anestrus cow. It is extremely embarrassing to remove a corpus luteum or to inject an estrogen or prostaglandin to bring a cow into estrum at the request of an owner, and have the cow abort a 40- to 120-day fetus a few days later. Usually when the veterinarian tells the owner the approximate age of the conceptus the owner can recall when or how conception occurred. Only rarely is the owner at a complete loss to know how the conception occurred. If the cow's genital tract feels normal and healthy and there is a possibility of the cow having been serviced within the last 30 days, it is advisable to examine the cow two to six weeks later to determine if conception occurred before any treatment is given. Thus some cases with so-called anestrus may be pregnant and the corpus luteum, if palpable, may be the corpus luteum of pregnancy. One of the most common causes for prolonged anestrus is pregnancy. However, some pregnant cows may exhibit occasional signs of estrum, especially the first three months of gestation.⁹⁴

In 228 lactating cows which had milk progesterone levels determined twice a week for 120 days postpartum, 34 or 15 percent of the cows were inseminated when the progesterone levels were high.⁸⁶ Of these 34 cows 20 or 59 percent were probably pregnant from a prior service. Of these 20 cows inseminated when pregnant 8 or 40 percent aborted. Therefore all inseminations after the first should only deposit semen into the cervix and not into the uterus or a trained inseminator or veterinarian should decide whether to inseminate the cow or not.⁸⁶

2. Anestrus due to a retained or persistent corpus luteum—The retained or persistent corpus luteum is invariably observed in association with some uterine pathology such as: pyometra, fetal maceration, mucometra, mummified fetus and other disease states causing endometrial damage and inability to produce prostaglandins. Retained or persistent corpora lutea rarely occur in cows in the presence of a normal nonpregnant uterus.¹⁰²⁻¹⁰⁴ There is no evidence that cystic corpora lutea tend to persist longer than normal corpora lutea. The corpus luteum of pregnancy is nearly completely involuted by 7 days postpartum and it never persists.^{62,63} The most commonly observed "retained" corpus luteum occurs following breeding and conception and then 10 to 90 days later the embryo or fetus dies, is macerated, and absorbed or expelled, and the cow previously thought to be, or even diagnosed as pregnant, comes back into estrum or is examined and found not pregnant. This condition is spoken of as early embryonic or fetal death and

may be due to infectious, hormonal, genetic, physical or traumatic causes. Luteal cysts, as described under cystic ovaries, may persist for a long period and cause anestrus by secreting progesterone resulting in plasma concentrations similar to those occurring in diestrus.

(a) **Retained or persistent corpus luteum associated with gross uterine pathology.** Retained, imbedded, or persistent corpora lutea are associated with pre-service or postservice pyometra, fetal maceration, mummified fetus and rare cases of mucometra.⁷² A few heifers have been observed that failed to show estrus and on examination had functional corpora lutea and a normal uterus. When these corpora lutea were removed the heifer came into estrus and another corpus luteum developed. (See Figure 117.) This CL also persisted for months and the heifer remained anestrus. The histopathological findings in these heifers after slaughter revealed an absence of endometrial glands and in one heifer a lack of caruncles. In heifers or cows with a uterus unicornis if the corpus luteum develops on the ovary corresponding to the missing horn, a long period of anestrus may result if there is not sufficient normal endometrium or endometrial glands in the cystic apex of the defective horn to exert a luteolytic effect on the CL on that side. (See Figure 116.) This may result in a persistent corpus luteum without a pregnancy occurring. Cases of anestrus associated with uterine pathology and

Figure 116. Anestrus Associated with Segmental Aplasia of the Bovine Uterus, Mucometra, Mucocervix and a Retained C. L.

Figure 117. Congenital Absence of Endometrial Glands in a Heifer with Anestrus and a Retained C. L.

a functional corpus luteum, as well as pregnancy, are probably caused by the failure of the release of prostaglandin from the endometrium or endometrial glands.³⁶ As described previously a prolonged persistence of the CL can also be produced by hysterectomy. In these pathological cases rectal examination of the uterus will usually reveal the cause of the failure of estrus. In most of these conditions that exist for several months or more the corpus luteum becomes more centrally located in the ovary and may be more difficult to palpate. These conditions have been described already or will be described later under pathologic conditions affecting the uterus. Manual removal of the retained or imbedded corpora lutea in these cases is usually difficult and requires more pressure than do corpora lutea that have been present a shorter length of time. Injection of a luteolytic dose of prostaglandin will in most cases involute the CL, evacuate the uterus and reestablish the estrous cycle. Without a routine pregnancy examination these conditions are likely not to be diagnosed until 6 to 8 months after breeding because the cow is believed safely pregnant. In most pyometra cases secondary to retained placenta and a postpartum metritis the condition is usually characterized by a mucopurulent vaginal discharge and a failure of estrus following calving. Most cases of mucometra are characterized by chronic follicular or luteal cysts and anestrus and an absence of a normal corpus luteum. When

mucometra is associated with slight or moderate anatomic defects of the genital tract, the estrous cycle is regular and normal developing, mature, and regressing corpora lutea are present. Mucometra with a persistent corpus luteum might rarely follow early embryonic death. Occasionally these conditions may recover spontaneously but most would exist for months without estrum unless diagnosed and treated. In diagnosing and treating cases of retained corpora lutea an accurate breeding history is often helpful.

(b) **"Retained" corpus luteum associated with early embryonic or fetal death**—This condition is actually not a true "retained" corpus luteum but is a corpus luteum of a pregnancy that terminated early and was not recognized as an abortion. If because of infection or defective development, the embryo dies early, before the middle of the cycle, then estrum occurs at its usual interval; but when the embryo succumbs later, the onset of the next estrum is delayed. In many of these early embryonic deaths under 90 to 120 days, the fetus or embryo is so small it may not be seen when it is aborted, or it may remain and macerate in the uterus and further delay the onset of estrum until the trophoblast dies and is resorbed by the uterus. In this condition the so-called "retained or persistent" corpus luteum and anestrus always follow a breeding after which conception and pregnancy are not diagnosed or recognized. If early embryonic deaths are suspected as a herd or individual cow's problem, examining the uterus and ovaries and/or determining the concentration of progesterone in the milk or plasma 21 to 23 days after service may aid the diagnosis. (See Pregnancy Examinations.) The cow usually comes in estrum spontaneously after the embryo or fetus is expelled or resorbed. The condition has been commonly observed in trichomoniasis, vibriosis and trauma to the early embryo by rough manipulation of the uterus. Defective sperm or ova may result in an imperfect zygote that succumbs 15 to 90 days or more after conception and produces a similar condition of a delayed estrum following breeding. This condition of early embryonic deaths has been studied by workers associated with artificial insemination and is described under repeat breeder cows.

There is a marked difference between the percentage of cows actually pregnant and the percentage of cows apparently pregnant on nonreturns at 28 to 35 days after artificial insemination and at 60 to 90 days after insemination. This discrepancy is in part due to early death of the embryo or fetus and largely due to failure to observe estrum after an infertile service. The condition has been erroneously described clinically as "persistence or retention" of the corpus luteum.

The following comparison has been given between reported nonreturns on 4,286 cows after first insemination and actual pregnancy diagnosis by rectal examination.¹⁰

Number of Days After First Insemination	Reported Non-Return Percentages	Actual Percentage of Cows Pregnant	Percentage Difference
30-60	67.8	52.9	14.9
60-90	58.4	52.9	5.5
90-120	55.7	52.9	2.8

Thus a decline of 23.2 percent from cows supposedly pregnant at 30 to 60 days to cows actually pregnant at 90 to 120 days after the first service was reported. The figures reported may be a little higher than present figures because antibiotics were not added to the semen and vibriosis was not being controlled before 1949. On data based on about 44,000 cows in 1954 the difference between cows apparently pregnant according to 28 to 35 day nonreturns, and actual pregnancies at more than 180 days was about 16 percent and the difference between cows apparently pregnant at 60 to 90 days, as based on nonreturns, and actual pregnancies at more than 180 days was 6 percent.²⁹ By employing nonreturns to service, estrus and cyclic milk progesterone patterns, the embryonic mortality rate between 28 and 75 days after breeding was an estimated 7.2 to 12.5 percent. Failure to detect estrus following an unsuccessful insemination was the major reason for the 22.9 percent delayed returns to estrus.⁵⁰ In a study of Israeli-Friesian cattle an 8.5 percent embryonic mortality was reported between 20 and 50 days postservice.⁷⁶ Thus this postservice anestrus which occurs in 40 to 60 percent of cows in a herd¹⁰³ is comprised of both a smaller component of early embryonic death and a larger component of failure to observe subsequent estrus periods.⁹⁴ In a fertility study of nearly 10,000 Holstein cows in 125 herds in Northeastern U.S., in 1975,^{82a} the apparent incidence of unobserved postservice anestrus was greater than preservice anestrus confirming the reports by Zemjanis.¹⁰³ The average postpartum day for the first service was 87 days for 8800 cows when 60 days was the desired time. The interval from first to second service for 4300 cows was 41 days and for second the third service for 2000 cows was 40 days.

Following service many cows, 40 to 50 percent, fail to conceive; subsequently they come back in estrum after a period usually longer than the normal estrous cycle. In some instances this may be due to early embryonic death and this delayed onset of estrum or period of anestrus may be diagnosed as "persistence" or "retention" of the

corpus luteum because the cows are not known to have been pregnant, have not had a history of estrus or abortion, and have a corpus luteum on one ovary. About 18 percent of cows bred naturally or artificially returned to service within 28 days while about 25 percent returned to service after 28 days.⁸³ On careful clinical examination at weekly intervals on 426 cows in 22 herds this investigator found 332 that failed to come into estrus within 28 days of service; 234 of these were diagnosed pregnant and of those 12 aborted, 3 abortions were observed and 9 were not observed. About 48 percent of return services to artificial insemination in Kentucky occurred after a prolonged interval of 25 days or more.⁶⁷ In the experiment station herd of cattle, of 1347 cycles following service 44.8 percent were prolonged; while of 2429 cycles not following service only 26.8 percent were prolonged. Breeding cows soon after calving was not a cause for delayed returns to estrus; on the contrary there was a tendency for the cows to come back into estrus in less than 18 days when bred at 5 weeks or less after parturition.⁶⁷ The study noted that 11.5 percent of the cycle lengths were 27 to 33 days for repeat services as compared to 3.3 percent of the cycles not following service. Thus early embryonic deaths after service may be the cause of so-called "retained" corpora lutea.

(3) **Anestrus due to subestrus, "weak" or "silent" estrus**, occurs fairly often, according to many veterinarians on the basis of clinical observations. The cow may not show estrus for 30 to 120 days or longer after calving even though closely observed by a competent herdsman; but on rectal examination during this period the cow shows evidence of having ovulated by the presence of a normal corpus luteum; or occasionally the cow may be in estrus or have just ovulated, as based on the typical changes in the genital tract or ovary and by the presence of estrual mucus or metestrual bleeding.

Subestrus, weak estrus, or silent estrus, occurs more frequently between calving and 60 days than it does 60 days or more after parturition. In 286 ovulations 78 or 27.3 percent were silent.⁴⁷ The incidence of "silent" estrus during the first 60 days after calving was 44.3 percent of 140 ovulations, but only 11.0 percent of 146 ovulations were "silent" during the period of 60 to 308 days. Of cows examined that had not come into estrus within 28 days of breeding and were not pregnant, 31 or 28.2 percent exhibited "silent" estrus or subestrus.⁸³ Ovulation in all cows occurred at an average of 25.4 days earlier than the first postpartum estrus and 68 percent of the cows showed at least one "quiet" ovulation or "silent" estrus before the first clinically apparent estrus.²² Older cows, over 5 years of age, tended to show longer intervals between parturition and estrus than did

the younger cows. A high incidence of "silent" estrous cycles, when behavioral signs of standing estrus were not observed, were reported during the postpartum period in the cow.^{56,62,63} Seventy-seven percent of the cows at the first estrus after parturition, 55 percent at the second estrus, and 35 percent at the third estrus exhibited "silent" estrus. By 90 days after parturition over 93 percent of the cows had shown visible signs of estrus. Seventy-four percent of 53 heifers that reached puberty exhibited "silent" estrus at the time of their first ovulation, 43 percent at the time of the second estrus or ovulation and 21 percent at the time of the third estrus.⁶⁰ About 10 percent of the ovulations during the service period were "silent."^{90,91} These periods were observed in 16.5 percent of the cows. From these reports it is evident that "silent" estrus is probably a common cause of anestrus and loss of time in rebreeding animals. This condition is clinically characterized by failure of estrus. These animals when turned out twice a day and closely observed for 20 to 30 minutes and teased by a bull will fail to show standing estrus even though they are ovulating. In some cases occasional, mild signs of estrus might be shown. Of 20 cows bred artificially during "silent" estrus 65 percent conceived.⁹¹ The time of insemination was based on repeated rectal examinations of the ovaries and palpation of the maturing follicle. Recent studies have shown that these former reports may be incorrect if cows are observed continuously 24 hours a day or by closed circuit television.^{48,94} In this latter study although the time of first, second and third ovulations after calving were similar to the above or 19.5, 44.4 and 63.7 days, respectively, an observed estrus was detected in 50 percent, 94 percent and 100 percent of the respective three ovulations. Thus "silent" estrus, a term used by the former authors, possibly should have been "unobserved or undetected" estrus. The former is more acceptable to the herdsman! More postpartum silent estrous periods occurred in nursed cows than in cows milked twice a day. The interval from calving to first estrus was 30 days longer in nursed cows than in milked cows; the interval from the formation of the first CL to the first estrus was 30 days in nursed cows and 17 days in milked cows. The interval from calving to the first CL was 53 days in nursed cows and 36 days in milked cows.⁹⁷

The physiologic basis for the failure of typical symptoms of estrus to accompany ovulation is not known but a lack of sufficient secretion of estradiol by the mature and secondary follicles or due to a need for a higher threshold of estrogen in the central nervous system of certain individuals at certain times to produce the nervous symptoms characteristic of estrus and acceptance of the bull is questionable since all ovulating cows have

an increased concentration of estradiol in their plasma during estrus. Progesterone can potentiate the action of estrogens in bringing a cow into estrus.⁷⁷ Standing estrus may require a regressing CL still producing some progesterone to result in good signs of estrus. A recent study showed hormone levels in plasma at the onset of estrus had no effect on intensity of estrus or on conception rate. Estrous activity was greater in the morning than in the evening, in the winter than in the summer and in barn-housed cattle than those in free-stalls or on pasture. Conception rates were similar in cows bred at the time estrus detection and 12 hours later.^{25b} Certain breeds of cattle have a hereditary predisposition for "weak" estrus whereas other breeds exhibit more marked estrous symptoms.⁵² In this country the author has observed that the Guernsey and Holstein breeds are more apt to have a predisposition toward "weak" heats than is the Jersey breed.¹⁹ Certain sire lines in a herd of Holstein cows exhibited a significantly higher incidence of silent heats or quiet ovulations than others indicating that a genetic variation affects this condition.⁵¹ Cows in advanced age, arthritic cows, cows with footrot, untrimmed feet or other painful diseases may not show good signs of estrus. They may refuse to mount, or to stand to be mounted, and separate themselves from the rest of the herd. Cows on slippery concrete floors, especially during the winter months, may not exhibit signs of estrus by standing to be mounted or by mounting. Placing cows in a dirt-floored lot or area greatly facilitates estrus detection.

(4) **Anestrus due to unobserved estrus** is, on clinical examination impossible to differentiate from "silent" estrus, subestrus, or "weak" estrus. Estrous periods are usually about 18 hours in length but in some cattle, especially heifers, estrus may be only 8 to 12 hours long. In tropical countries and the southern states the length of the heat periods in the English and dairy breeds is shortened to 12 to 13 hours and in Zebu cattle estrus lasts only 5 to 8 hours. A study of Canadian cows by continuous monitoring with a television camera showed the duration of "standing" estrus to be 7.5 to 10.1 hours depending on the number of cows in estrus at the same time. About 70 percent of cows exhibited signs of estrus from 6 PM to 6 AM or during the night hours.⁴⁸ Since most cows are observed in estrus several or more hours after the onset of estrus and since the highest conception rate occurs near the middle or toward the end of estrus, it is recommended to breed cows soon after they are observed in estrus rather than 12 to 24 hours later. If a cow is still in estrus 12 hours after service she should be rebred.²⁸ During the middle of the day, especially in hot climates or when cows are eating are poor times to observe cows for estrus. When environmental temperatures

were maintained at 75 to 95° F it was shown that the duration of the estrous period was 11 hours compared to 20 hours in heifers maintained at atmospheric temperatures of 62 to 65° F.^{34,89} Under the former stress condition the intensity of estrous signs were also reduced so that the incidence of anestrus was 30 percent when signs of estrus were watched for twice a day. In the other groups without heat stress the incidence of anestrus was only 7 to 8 percent (See Bovine Reproductive Physiology). These short periods could be missed especially if the animals were turned out of the stanchions or watched only once a day. This problem and "weak" estrus are difficulties which must be overcome in educating farmers to artificial insemination. If an owner or herdsman does not watch his cows carefully at least 20 to 30 minutes 2 to 4 times a day in a yard where the cows are free to move about, many heat periods will not be observed. In the northern latitudes artificial lighting early in the morning and late at night is necessary to adequately observe cows for estrus. Cows exhibiting "weak" estrus or subestrus are fertile but often because of poor timing of the insemination, conception rates are lower. The owner or herdsman should be acquainted with the estrous symptoms of each cow, so that if certain cows show mild or slight symptoms these can be watched for and recognized. In general the larger the herd or the greater the number of cows per man, the greater the incidence of anestrus. Due to laziness, ignorance, neglect, carelessness or inability to set priorities, some farmers cannot use artificial insemination service because they fail to observe and detect estrus in many of their cows. After trying artificial insemination these farmers usually resort to the earlier method of allowing a bull to run with the herd.

Anestrus due to unobserved estrus was reported in 39 percent of 5848 reproductive cycles in dairy cows, 11 percent were in preservice cycles and 28 percent were in postservice cycles.^{101,104} These cases were called functional anestrus and 90 percent of all anestrus cycles were in this category. Only 10 percent of the anestrus cycles were due to pathological or organic causes. Twenty percent of postservice anestrus cows were not pregnant even though the herdsman assumed them to be pregnant. The economic importance and monetary loss due to unobserved estrus was calculated to be 30 and 42 production days for preservice and postservice anestrus, respectively. If this loss was valued at \$.50 or \$1.00 per day, the annual loss for each dairy herd for the 13 dairies comprising the 2600 cattle in the study was \$750 or \$1500, respectively.

Herds in which continuous observation, 24 hours a day, was maintained 90 to 95 percent of the cows were observed in estrus within a 24 day period.^{48,94} Only 4 to

10 percent of the cows were anestrous without detectable abnormalities. In the average fairly well-managed herd only 40 to 60 percent of the estrous periods are noted. With the advent of larger herds and fewer caretakers per herd the incidence of anestrous due to unobserved estrus continues to rise and has become the greatest single cause for infertility in large dairy herds being bred artificially.

The prognosis in cases of failure of estrus or anestrum cows found to have a normal functional corpus luteum on repeated rectal examinations depends upon the cause. In anestrum due to a persistent corpus luteum caused by some uterine pathology the prognosis is good in fetal mummification and early embryonic deaths. While in pyometra the prognosis is fair to good and in late fetal maceration, mucometra or a congenital absence of uterine glands in the endometrium the prognosis is guarded to poor. The longer the condition, such as pyometra, has existed the poorer the prognosis for the future breeding life of the cow. Conception following early embryonic deaths may be delayed, especially in diseases such as vibriosis. In "weak," "silent" or unobserved estrus the prognosis is usually fair to good as close observation reduces the incidence of anestrum due to this cause.

Treatment of failure of estrus or anestrum in cows should be based on a careful differential diagnosis, often requiring careful recordings of repeated rectal examinations.

The treatment of retained or persistent corpora lutea due to uterine pathology such as pyometra, mucometra, mummified or macerated fetuses will be described later in this text. These conditions often respond to the injection of 40 to 100 mg of stilbestrol or 4 to 10 mg of estradiol, repeated in 2 to 4 days if necessary for several injections or prostaglandins to cause an involution of the retained corpus luteum, the evacuation of the uterus, and the reestablishment of the estrous cycle. In a few cases manual removal of the corpus luteum, as described below, may be indicated but the dangers associated with this treatment, especially in pyometra, greatly limit this mode of therapy. The use of prostaglandin F_{2a} (Lutalyse), 20 to 35 mg, or cloprostenol (Estrumate), a prostaglandin analogue, 250 to 500 μ g, intramuscularly are preferred treatments over estradiol preparations such as estradiol cypionate, and possibly estradiol valerate, to cause luteolysis of the corpus luteum, evacuation of the uterus and produce normal estrous cycles. Luteal cysts causing anestrum and elevated progesterone levels in blood plasma may be treated with GnRH, HCG or prostaglandins as described under cystic ovaries, usually with excellent results.

Treatment of persistence of the corpus luteum due to long-standing pyometra and fetal maceration with the

presence of bones in the uterus may occasionally result in the restoration of the estrous cycle but conception usually fails to occur due to the chronic uterine damage caused by the infectious process. In some instances a laparohysterotomy may be necessary to remove the bones from the uterus. In the rare cases of heifers with a congenital lack of endometrial glands causing the persistence of the corpus luteum, no treatment is possible. It might be desirable to take an endometrial biopsy or recover the uterus at slaughter so the diagnosis may be confirmed by histopathological methods.

Treatment of anestrum due to early embryonic death is usually not necessary since the embryo or fetus and its membranes are expelled, or macerated and resorbed. The corpus luteum of that pregnancy involutes and estrous cycles are reestablished. If the latter course is followed it may require two to six weeks following the death of the zygote before estrus occurs. Detection of anestrum due to early or late embryonic deaths, and post-service anestrum due to "silent," "weak" or unobserved estrus requires an early accurate pregnancy diagnosis between 35 to 45 days of pregnancy and possibly a second examination in certain cows or herds with vibriosis, trichomoniasis or a high incidence of fetal mummification at 80 to 150 days or more days of gestation. As previously mentioned, examination of the genital tract and ovaries for the presence of a corpus luteum and a lack of estrus or high progesterone levels 21 to 23 days after service can provide an early presumptive diagnosis of pregnancy and an early indication of embryonic death. Because anestrum of pregnancy is expected after service many owners fail to realize the importance of early pregnancy diagnosis to reduce the serious losses incurred due to post-service anestrum in cows failing to conceive or affected with early embryonic deaths.^{102,104}

Treatment of failure of estrus or anestrum, in the common instances of "weak" or subestrum, "silent" estrus or unobserved estrus, often requires careful, accurately recorded examinations of the genital tract of affected cows, careful assessment of herd management practices, and diplomatic education and instructions for the herdsman and cattlemen. Cows or heifers with a preservice or postparturient anestrum should be examined at 50 to 60 days postpartum or at 15 to 18 months of age, respectively, if they have not exhibited estrus by that time. A variety of treatment regimens, some already suggested under the prior discussion of the etiology of anestrum, have been used. These include:

(a) Improved management practices—Owners and herdsman often need to be trained in how to observe cows for estrus. If services per conception are low (1.2) and the average number of days open are high (150) on

a herd basis, estrus detection would only be 25 percent. While another herd with 2.5 services per conception, 115 days open would have an excellent estrus detection rate of 80 percent and etc.^{9b} The signs and degrees of external manifestations of proestrus, estrus and postestrus should be thoroughly understood.^{3a,94} Cows to be observed for estrus should be grouped or turned out together and watched carefully for 20 to 60 or more minutes twice or more times per day especially during periods of activity such as before and after milking and during the early morning, evening and night hours. Observing cows during the feeding period is not satisfactory. Observing cows on pasture is better than in barnyards.⁹⁴

Signs of estrus in order of their importance or significance include:⁹⁴

- (a) Standing immobile to be mounted—This is the most important single sign and observed in 79 percent of cows in estrus. Standing heat was observed in 4.5 percent of cows not in estrus and in 7.3 percent of standing heats were seen in pregnant cows.
- (b) Mounting other cows repeatedly, exhibiting both homosexual and heterosexual activity.
- (c) Ruffled, scraped or rubbed rump and tailhead. These signs are misleading as they persist for 4 to 6 days.
- (d) Group activity of sexually active cows is important especially at night. It includes cows in estrus or proestrus and nymphomaniacs. These cows often stand close together within a few feet of each other. Moving animals and driving helps the owner observe signs of estrus. Don't isolate cows in estrus from a herd as they are excellent heat detectors.
- (e) Restlessness—if on pasture cows interrupt grazing and roam around, increased activity, can use pedometers on legs but they are often lost.⁹³ If tied, cows often remain standing rather than lie down. By using pedometers it was determined that cows in free stalls and in comfort stalls were 4 and 2.75 times respectively more active during estrus than when not in estrus.^{47b}
- (f) Vulva swollen, edematous, relaxed—This is seen in only a few cows and is unreliable.
- (g) Stringy mucus hanging from vulva especially after mounting or lying down. This useful but seen infrequently.
- (h) Sniffing and licking of vulva, flehmen reaction, also chin resting and rubbing cow on rump.
- (i) Tail raising and switching, frequent urination and bellowing is also seen in cows in diestrus.

Thus these are all signs of estrus but each alone, except possibly (a) are not highly dependable.^{3a,94} Each farm must select procedures and the men to observe, record

and get cows bred early in the postpartum period so calving intervals of 12 to 13 months are realized. Competent, accurate recognition of all or a high percentage of estrous periods in cows from the time of first desired breeding until after they are diagnosed pregnant is essential to a satisfactory herd reproductive program. Careful records of these observations on properly and easily identified cows should be made before, during and after the breeding period. The use of heat expectancy charts are very helpful if records of previous estrous periods are accurately recorded. The use of teaser or "gomer" animals will be discussed. Some owners are incapable of properly observing cows for estrus or unwilling to spend the time to do so properly. In this instance breeding bull(s) should be run with the herd as an economically viable artificial insemination program is impossible to accomplish. In stanchion barns it is desirable to turn cows out of the barn twice or three times a day even in the winter months and observe the cows carefully. In a stanchion barn the tails and buttocks of the cows should be carefully observed daily to detect bleeding or a clear mucous discharge. In a dark barn a flashlight might prove helpful in this examination. As an aid in stimulating closer observation of cows for estrus some owners offer incentive payments to hired men or herdsman detecting cows in estrus and conceiving to a service at that estrus. The economic importance of a conscientious, observant herdsman or owner cannot be overestimated in maintaining a good conception rate and a short interval between calvings in a herd.

Heat Detection Aids or Treatment for Anestrus that may be used to supplement, not replace, careful, frequent visual observation of the herd include many techniques or practices.

(a) Cattlemen have used a cheap, plastic heat detecting device* that is glued to the top of the sacrum of postpartum cows due to be bred and of cows after breeding to assist in detecting estrous periods. When a cow in estrus is mounted by another cow or teaser bull the normally white plastic device turns red due to the release of a dye due to pressure on the device by the brisket of the mounting animal.¹⁷ These detectors may be helpful to farmers or ranchers with cattle on pasture. Cows should be examined twice a day. If a detector is only partially red that cow is often not in estrus. An Australian study on pastured cattle indicated that Kamar detectors were 90 percent effective in detecting estrus vs. 56 percent by observation alone. One drawback was that about 25 percent of them may be lost or rubbed off by mounting.

*Heat-mount Detectors by Kamar Inc., Earl D. Smith, Box 26, Steamboat Springs, Colo., 80447.

These cows were usually in estrus. Some farmers use a colored tape around the tail as well as a Kamar detector.⁹⁴ Other farmers will use a colored marking chalk or a water-soluble latex paste on the tailhead as an aid to detect estrus. Another alternative to a Kamar detector or chalk applied to the tailhead is to apply a green water-soluble plastic paint with a roller from the first sacral to the fourth coccygeal vertebrae from calving to confirmed pregnancy. In one large herd this aid increased the detection of estrus before postpartum day 60 from about 62 to 95 percent.^{94b} Conversely a study in Northeastern U.S. indicated that visual observation was 93 to 97 percent accurate in detecting estrus in dairy cows compared with the 82 to 88 percent accuracy of Kamar heat detectors.⁷⁰

(b) Teaser or "gomer" bulls, nymphomaniac cows, or cull or ovariectomized cows injected with repeated, large doses of testosterone have been used to aid in detecting cows in estrus. If bulls are only vasectomized they may spread venereal diseases in the herd. Also such teaser bulls are seldom kept beyond one year and must be replaced and there are problems when bulls are allowed to run with the herd.⁹⁴

In large, artificially-inseminated dairy or beef herds in which the detection of cows in estrus is difficult, one or more vasectomized young bulls may be allowed to run with the herd. These bulls, if used properly, are very efficient in detecting cows in estrus. Young disease-free bulls can be vasectomized in the standing position under epidural and local anesthesia or they may be cast, tied, and rolled on their backs and vasectomized under local anesthesia. Using careful clean surgical technique the operator makes separate incisions through the skin and the tunics investing each spermatic cord. The hard cord-like vas deferens is separated from the plexus of coiled veins and arteries. Two ligatures are placed on each vas about 2 inches apart and 1 inch of the vas is removed. The skin incisions are closed and antibiotics are administered for 4 to 5 days. Semen should be collected once a week for 3 weeks. By this time practically no spermatozoa are in the ejaculate and those that are present are dead.

Several cases have been reported where apparently properly vasectomized bulls regained their ability to fertilize cows. In humans sperm granulomas following vasectomy were common and 5 of 432 vasectomy cases recanalized.⁷³ The cut ends of the vas deferens should be fulgurized by electrocautery and the sheath of the vas deferens should be ligated or closed over the cut end of the distal portion of the vas to prevent spontaneous recanalization. It might also be advisable for the operator to place the removed sections of the vasa deferentia into

a 10 percent formalin solution and send them to a laboratory for histological confirmation of the removed tissue to prevent possible errors and lawsuits.

Other methods of preparing teaser or "gomer" bulls have been described. Epididymectomy by incising the bottom of the scrotum separating the tail of the epididymis from the testis, ligating the body of the epididymis and the vas deferens with nylon and removing the tail of the epididymis was recommended.^{65,95} This technique is probably better than the injection of a sclerosing agent into the tail of the epididymis,¹⁴ or the crushing of the tail of the epididymis with a Burdizzo emasculatome. These above methods do not prevent normal intromission and the possible spread of venereal diseases such as vibriosis and trichomoniasis. However teaser bulls prepared by the above methods retain a stronger sexual desire and drive than teaser bulls prepared by various operations on the penis and sheath that prevent normal intromission.

Operations on the penis and sheath to prevent conception include: (1) cutting the penis midway between the anus and scrotum and suturing it to the skin;⁸⁴ (2) placing three or four stainless steel or nylon sutures into the dorsal part of the penis cranial to the scrotum and suturing the penis to the abdominal wall;^{33,80} (3) making a small ventral incision in the skin and prepuce two to three inches behind the preputial office, suturing the skin and preputial membrane and inserting a 3/8 inch plastic urine drain for five days, followed by the dissecting apart of the skin and preputial membrane at the preputial orifice and suturing the inside membrane and outside skin to make a blind pouch to contain the penis;⁸⁰ (4) and incising of the skin around the preputial orifice and suturing the orifice so it is directed laterally instead of cranially, so the penis on erection is also protruded laterally. These operations and their modifications should be performed under good anesthesia and in an aseptic manner for best results. A male pseudohermaphrodite, a nymphomaniac cow or a cow or steer treated repeatedly with testosterone⁴⁹ may also be used as a teaser animal if it has sufficient sex drive. These latter animals have not been highly successful as estrus detectors.³⁰ (See Chap. XIX, Artificial Insemination.)

Bulls selected as "teaser" or "gomer" animals should have a strong, vigorous sex drive. If possible it may be desirable to turn these bulls out with the herd only for short periods in the morning and evening and then to alternate bulls to maintain their sex drive. A New Zealand company* has marketed a marking device for bulls

*Chin-Ball Mating Device, Frank Paviour Ltd., Mahana Rd. TeRapa, Hamilton New Zealand.

consisting of a small square stainless steel unit containing an exposed freely rotating steel ball that is fastened securely under the jaw by a special halter. The marker material comes in a variety of colors and is placed in the steel unit where it will store indefinitely. When the bull mounts a cow the marking material is rubbed in streaks down her back. These marks will last for 2 weeks but can be washed off with a detergent. One filling of the steel container is sufficient to mark 75 to 80 cows. These chin-ball markers must be kept filled with ink to be effective. Occasionally a bull on pasture with a herd will select a "harem" of cows and ignore the other cows. It was reported that smearing the brisket and inside of the legs with titanium oxide and grease was more effective than the chin-ball marker.⁹⁴ Some ranchers will have a bull in a pen near water, in a corral near salt or feed, or run their cows across a fence from yearling bulls. In these instances cows in estrus will gravitate toward the male animals and be easier to pick up.

(c) Drawing a milk sample from cows at the time of breeding and submitting it, with others, to a laboratory for **progesterone assay** is a simple and highly effective practice to determine the efficiency of a herdsman in detecting cows in estrus. It is also helpful in problem cows, if samples are taken 2 or 3 times a week for 3 weeks, to tell when the cow is in estrus or whether she is cycling. Milk samples taken at insemination and 21 to 24 days later from over 400 dairy cows in Northeastern U.S. showed that only 5.5 percent were inseminated at the wrong time, that is, when progesterone levels were elevated.⁷⁰ High progesterone levels were found in only 2.9 percent of cows in standing estrus, 2.6 percent riding other cows, 3.6 percent with roughened tailhead and 4.5 to 7.1 percent of cows that were unusually active, bawling or with clear or bloody mucus on the vulva. The Kamar heat detectors were not as accurate as visual observation. High progesterone levels at insemination were recorded in 12.4 percent of cows with full red Kamars and 18.3 percent with part red Kamars.⁷⁰ Besides the above uses for progesterone determination on milk, it will help monitor possible embryonic deaths, determine nonpregnant cows with good accuracy (90+ percent) but not pregnant cows (80 percent) 21 to 23 days after service.³² This test for progesterone because of time required for laboratory testing is not satisfactory for determining the time of insemination.

(d) The **electronic probe measurements** of electrical resistance of vaginal mucus reveals low resistance at estrus and correlated well with low milk progesterone concentrations, visual observations of estrus and positive Kamar heat detectors.^{32,42} This improved probe is inserted into the vagina every second or third day and re-

sistance readings of the dorsal and ventral vaginal mucus are recorded. The instrument is cleaned and disinfected between cows and cows must be confined for examination. Conception rates after insemination were similar where estrus was detected by visual examination and where estrus was detected by the probe when the cows were not seen in estrus.

(e) Other tests on bovine cervical mucus such as crystallization pattern or "ferming," glucose content, viscosity and pH either require laboratory tests, are laborious or not practical.^{30,94} Temperature monitoring to detect estrus is not yet practical.⁷⁴ In the cow body temperatures tend to decline slightly but noticeable with the involution of the corpora luteum and increase slightly during estrus because of increased activity. Good breeding records, the careful maintenance of a heat expectancy chart for each cow, and frequent examination of "problem" cows by a veterinarian who can predict the approximate time estrus are practices to follow in many "anestrous" cycling cows and can be helpful in controlling this common infertility problem. Rectal palpation of the genital tract and ovaries of a number of anestrous cows in a herd can readily diagnose "inactive" or non-functional ovaries without corpora lutea due to a low plane of nutrition, debility, a negative energy balance, failure to achieve puberty or a lack of estrous cycling.

(f) Frequent rectal, and if necessary vaginal, examinations of the genital tract by a veterinarian will determine the proper time to inseminate cycling cows with "weak," "silent" or unobserved estrus. The technique for predicting the time of estrus which is based on the physiologic and anatomical changes occurring in the genital tract of the cow during the estrous cycles have been described.^{46,59,85,102,104}

During proestrus, days 17 to 20 of the cycle, follicular growth is occurring and culminates in the mature Graafian follicle.⁶⁹ The corpus luteum is regressing in size, protrudes less above the surface of the ovary and becomes more firm in consistency. The uterus is developing increased tonus. On vaginal examination the last two days of proestrus the vaginal and cervical mucosa are becoming more pink, congested and edematous. The cervix becomes more relaxed and initially a cloudy and then a clear stringy mucus characteristic of estrus comes from it and collects in the anterior vagina. The cow will be in estrus within 1 to 3 days.

During estrus, day 0 or 1 of the cycle, the cow is receptive to the bull, stands to be mounted, and the changes described as occurring during proestrus are more prominent. The vulva is often edematous and relaxed. The corpus luteum is small and firm and the follicle is nearly mature, 1 to 1.5 cm. in diameter. This is the most easily

diagnosed stage of the cycle. The cow should be bred. If the cow exhibits "silent" estrus rebreeding the following day may be indicated if ovulation has not occurred.

During early postestrus or metestrus, day 1 or 2, the follicle may be soft and fluctuating and easily ruptures on pressure. This should be avoided. In most cases ovulation has occurred and the site feels like a crater-like depression 1 to 1-1/2 cm. in diameter in one of the ovaries. The uterus is less tonic but more edematous and thick-walled. The corpus luteum of the previous cycle is difficult to detect. Metrorrhagia may be observed by the presence of bloody mucus at the vulvar lips, on the tail or buttocks or by vaginal examination. This discharge may also be observed through day 3 of the cycle. A few atretic follicles may be present.

During late postestrus or metestrus, days 3 to 6 of the cycle the soft small, developing corpus luteum may be palpated and is growing rapidly, 1-1/2 to 2+ cm. in diameter, and is fairly soft in consistency. The uterus decreasingly lacks tone and loses its edema.

During diestrus, days 7 through 16 or 17, the longest stage of the cycle, the corpus luteum is mature, large and liver-like in consistency. The uterus is quiescent but not atonic. During this period some growth of small follicles occurs and results in one or more palpable follicles at 10 to 12 days that become atretic and regress by the end of this period. During this period the vaginal and cervical mucosa is rather pale and dry. The mucus is usually scant and sticky.

With practice a veterinarian can develop his skills to predict the occurrence of estrus with a high degree of accuracy. The efficacy of this method was excellent. Repeated examinations at 2 to 3 day intervals may be necessary. Sixty-nine percent of the cows examined showed estrus within 23 days.¹⁰⁴ The rate of conception on the first estrus was 10 percent better than that following removal of the corpus luteum, 55.7 percent vs 45.7 percent, respectively. Because of the dangers associated with enucleation of the corpus luteum, estrus prediction and prostaglandin injection are the methods of choice for handling anestrus due to "weak," "silent," or unobserved estrus in cycling cows. Thus rectal palpation can readily determine if the cow is cycling, and the approximate stage of the cycle. Laparoscopic examination of the bovine ovaries has been described.

(g) The removal of the corpus luteum by manual pressure through the rectal wall was formerly, 1920 through 1960, frequently employed in the treatment of anestrus in cattle when a functional corpus luteum was present. This method consists of grasping the ovary in a fold of the rectal wall between the fingers and first knuckle of

the thumb and pressing over the proximal end of the corpus luteum and enucleating it from the ovary. Care should be used so as not to rupture the rectal wall. The best time to remove the corpus luteum was during the middle of diestrus.³ Earlier removal of the soft C.L. may result in incomplete removal, and in proestrus the difficulty of removal increases. Some advocate squeezing through the tougher vaginal wall but this is usually not necessary since most corpora lutea are not centrally located and covered by a heavy capsule as occurs in long-standing retained corpora lutea.

Although removal of the corpus luteum formerly was a common form of therapy it should seldom be used and then probably as a last resort because of the possible dangers from its practice. Manual removal of the corpus luteum in cows with pyometra or other uterine infections is dangerous due to adhesions and ovaritis that may follow. In a removal of the corpus luteum the cow should not be pregnant or abortion will usually occur. After the corpus luteum is removed it should be dropped into the abdominal cavity and not into the ovarian bursa, where it may cause extensive adhesions. Adhesions of the ovary and, especially the fimbriated portion of the oviduct on the medial free border of the ovarian ventricle frequently follow rough manipulations even though bleeding may not be severe. Ovarian adhesions due to rough manipulation of the ovary was a common cause of permanent sterility.^{25,57,58} After removal of the corpus luteum excessive bleeding may take place from the ovary and cause a large hematoma around the ovary, permanent adhesions, and sterility. Fatal bleeding from the site of an enucleated corpus luteum has occasionally been reported. The incidence of fatal hemorrhage has been reported to be 1:1000 to 1:9000 removals of the corpus luteum.⁸⁷ The author has not been so fortunate as in his experience fatalities occurred at a rate of 1 to 300 to 500 enucleations. The method of expression of the corpus luteum had no influence on the fatalities. Removal of the corpus luteum can result in a loss of as much as 7 liters of blood into the peritoneal cavity.^{58,59} The removal of an embedded corpus luteum resulted in a loss of one liter of blood. In 22 to 25 cases in which the corpus luteum of the estrous cycle was removed, bleeding of one to three liters of blood was reported. In some cases the cow will temporarily develop a rapid pulse, tympany, and anorexia after removal of a corpus luteum. The manual ovarian treatment for anestrus was discontinued in experiments because the percent of conceptions showed no improvement over the controls, and furthermore removal of the corpus luteum produced permanent damage in a number of cases. Manual compression of the ovary for at least 5 minutes after removal of a corpus

luteum was recommended as a means of controlling bleeding. It is doubtful that epinephrine or other drugs administered parenterally will effectively prevent bleeding and the former drug may even be contraindicated. Many workers have reported that removal of the corpus luteum seldom results in any permanent trauma or adhesions; their observations were, however, only clinical. Because of these observations the author does not recommend removal of the corpus luteum in cows except in rare selected cases or only as a last resort. Properly used estrogen or preferably prostaglandin therapy will result in the involution of the corpus luteum without the dangers present in manual removal. Enucleation of the corpus luteum was followed by the same pattern of hormone secretion as that following the administration of a luteolytic dose of various prostaglandins, namely a sharp decline in plasma progesterone levels and a rise in LH levels.^{72a} Because manual removal of the corpus luteum is possible only in the cow of our domestic animals, this is not a sufficient reason to employ this mode of treatment in the bovine species. In cows of lesser value or in cows in which the production of milk is more important than the value of their offspring, the amount of damage or risk may not be great enough to prohibit the enucleation procedure.

The following reports from the literature summarize the results of manual removal of the corpus luteum. (See Table 19). From this table it appears that removal of the corpus luteum usually results in observable estrum in about 50 to 80 percent of the cases within 2 to 7 days, with conceptions in 25 to 70 percent of those cows bred on

the induced first estrum. In the author's experience removal of the corpus luteum from normal cows will result in about 50 percent conceptions at the next service a few days later. Most cows show estrum the third or fourth day after removal of the corpus luteum. A number of workers reported that the induced estrum frequently was "silent," or unobserved, and the animal should be watched closely for signs of estrum. Possibly this condition of "silent" estrum was the reason for the diagnosis and removal of the "retained" corpus luteum. If estrum is not observed the cow may be bred three to four days after the manual removal of the corpus luteum if conception is desired. If the cow shows estrum on the fifth day she should be rebred. Nearly 50 percent of normal cows thus treated will conceive. If the cow has a normal genital tract and is in anestrus due to "silent," or unobserved heat, removal of the corpus luteum should result in a higher rate of conception on the first estrum than if the retained corpus luteum was due to an embryonic death caused by vibriosis or some other infection in which a mild endometritis may be present. These same factors would also influence the conception rate obtained after the use of hormones.

(h) Hormonal therapy for anestrus—Estrogens have been shown to cause regression of the corpus luteum.^{20,29} The effect of estrogens on the corpus luteum is not so marked in hysterectomized heifers as in intact heifers so there is probably an interreaction with the luteolytic mechanisms in the endometrium or endometrial glands. Estrogens probably induce regression by also decreasing the level of circulating LH.²⁰ Five mg. of estradiol val-

Table 19. Summary of Selected Reports of the Manual Removal of the Corpus Luteum in Nonpregnant Cows

Author	Number of cows	Cows observed in estrum		Days estrum occurred	Conceptions
		No.	Percent		
Wright ⁹⁹	51	36	70	1 to 5	18, or 50% of those in estrum
Hofstad ⁴⁴	332	203	61.1	2 to 9	59, or 29.1% of those in estrum
Stalfors ⁸¹	105			3 to 10	38, or 35.6% of the total treated
Hancock ³⁹	70	35	50	2 to 7	10, or 28.5% of those in estrum
Lindley ⁵⁵	54	27	50		13, or 24.1%
Gibbons ³⁵	155	98	64.9	1 to 15	51, or 52.1%, on first service
Teige and Jakobsen	2746		62.5	1 to 7	49.7 to 58.7%

erate given as a single dose intramuscularly on the third or fourth to eighth or ninth day of the estrous cycle caused luteal regression in 17 to 20 heifers with 15 showing estrum before day 17 of the cycle.⁹⁶ Seven of 10 heifers injected on days 15 or 16 of the cycle developed large cystic ovaries and many developed signs of nymphomania. Other forms of estrogen caused a similar regression of the corpus luteum. The author has confirmed the effects of 5 to 10 mg. of estradiol valerate in inducing regression of the corpus luteum. Estradiol cyclopentylpropionate (ECP) as a single intramuscular dose to cause luteolysis has not proven to be as effective as estradiol valerate or the prostaglandins.^{75a} He has also produced luteal regression with 40 to 100 mg. of diethylstilbestrol but this tends to require a second or third injection at 48 hour intervals. One or possibly two injections of 3 to 10 mg. of estradiol at three day intervals or estrone, 5 to 15 mg., in a similar manner also will induce luteal regression either during metestrus or diestrus or in cases of retained corpora lutea associated with pyometra, mummified fetus or mucometra. In pyometra high and prolonged doses of estrogens such as 100 mg. of repositol stilbestrol may result in abnormal motility or peristalsis of the oviduct resulting in the introduction of infectious organisms from the uterus to the area of the ovarian bursa or fimbria of the oviduct causing ovaritis and adhesions even in cases where no ovarian manipulations were made. Cystic ovaries may occasionally follow estrogenic therapy. These occur most commonly when estrogens are given in late diestrus or in proestrus. They are rare in cases of retained corpora lutea. Large doses of greater than 4 mg. of estradiol and 40 mg. of stilbestrol are more apt to result in cystic ovaries than are smaller doses of estrogens.

Most earlier studies on the use of estrogens for the treatment of anestrus were uncontrolled and empirical. Factors that were not considered in most studies were the cause for the failure of estrus or the type of anestrus; the high rate of spontaneous recoveries and conceptions in cows with normal estrous cycles and genital tracts but having "silent," "weak" or unobserved estrous periods; the time following treatment that estrus and conception occurred, and whether normal ovulation occurred at that estrus or whether the signs of estrus that immediately followed the injection were due to the estrogenic hormone. Even spayed cows will exhibit estrus after an injection of an estrogen! Estrogenic hormones do not produce ovulation except low doses in late proestrus or very early estrus that simulate the rise in blood concentrations due to production of estrogens from the Graafian follicle causing the LH surge. The use of low doses of estrogens or estrogens and progesterone a day or two before an

expected estrus to improve the external signs of estrus has not proven of value and may lower the conception rate. Although estrogens have been widely used in the past in an empirical and haphazard manner for the treatment of anestrus, reports indicate that this type of therapy is of no, or questionable, value and may actually reduce the conception rate compared to heat prediction, removal of the corpus luteum or injection of a luteolytic dose of prostaglandin.

Although **prostaglandins** either **Lutalyse** (PGF_{2a}) 20 to 30 mg., or **Estrumate**, cloprostenol (a prostaglandin analogue) 250 to 500 ug or others are commonly used to produce luteolysis or involution of a functional or mature corpus luteum from day 6 to day 16 of the estrous cycle, or a persistent C.L. associated with uterine pathology such as pyometra or mummified fetus or for a luteal cyst. The use of such products in lactating cows have now been approved in the U.S. Fortunately the prostaglandins are shortlived and are rapidly broken down so the drug or its metabolites are only present at very low levels in the milk by the second milking. An adequate dose of prostaglandin or its analogue will act rapidly in involuting the C.L., causing a rapid cessation of progesterone production. The onset of the next estrus, as with the manual removal of the corpus luteum, occurs within 3 to 5 days, range 2 to 7 days. Giving two doses of prostaglandin or its analogue 10 to 12 days apart will cause nearly all healthy, cycling cows to come into estrum within 3 to 5 days. As mentioned earlier in this Chapter treated cows may be artificially inseminated when estrum is detected or by breeding twice AI at 72 and 90 hours or once about 80 hours after the injection. (See Estrus Synchronization.) If routine rectal examinations are performed by a veterinarian in cows during the postpartum period and anestrus due to unobserved estrus in cycling cows is a problem, selected animals may be treated during diestrus. Estrus is thus synchronized so artificial insemination and early conception is possible.^{75c} (See Estrus Synchronization with Prostaglandins.) A more desirable procedure than this is to establish an effective breeding program including careful observations and properly timed breeding of cows rather than relying on hormones for the detection of estrus. Repeated treatments of prostaglandins in a cow have not been shown to be contraindicated as is manual removal of the corpus luteum. Administration of prostaglandins prior to day 6 after estrus or in cows with follicular cysts or with "inactive" ovaries due to debility will be ineffective in establishing a normal estrous cycle.

Estrus synchronization by using progesterone, progestogens, estradiol valerate, prostaglandins F_{2a}, cloprostenol (a prostaglandin analogue) or a combination of

these drugs as described earlier in this chapter may aid in the detection of estrum in a similar manner as removal of the corpus luteum. With estrous synchronization good management is still necessary to detect estrus for proper timing of artificial insemination. Conception rates immediately following estrous synchronization are usually lower than normal if progesterone or progestogens have been employed unless the hormone can be removed from the body promptly (See Estrus Synchronization).

Since so-called "anestrous" cows with normal uteri and corpora lutea on the ovaries are probably cycling regularly most or all treated or untreated cows will show an observable normal estrus within 30 days. This probably accounts for the many early reports of successful treatments for anestrus in cattle. At present it appears that most types of anestrus except possibly underfeeding and gross pathology of the uterus, cervix, or ovaries are self-limiting and that recovery is usually spontaneous. For this reason the author firmly believes that hormone treatment or removal of the corpus luteum for correction of most cases of anestrus is of secondary importance to an accurate diagnosis. During the past 25 years the author has seldom relied on endocrine therapy to relieve anestrus which is a symptom most commonly associated with unobserved estrus. Hormones are used to correct uterine pathology associated with a persistent corpus luteum and for treating luteal and follicular cysts causing anestrus.

Anestrus cows with small or inactive ovaries with no functional corpus luteum palpable per rectum. These cows together with pregnant cows and cows with retained corpora lutea associated with uterine pathology are non-cycling cows. These non-cycling dairy cows comprise about 10 percent of all anestrous cows.¹⁰⁴ In beef cattle herds on range this percentage may be larger due to nutritive deficiencies especially in postpartum heifers.

(1) Due to "silent" or subestrus, or due to unobserved estrus, cycling cows may during the period of one to two days before, during, and one to three days after estrus, have only a small corpus luteum that might lead one on a single rapid examination to a diagnosis of anestrus due to failure of ovarian activity or nonfunctional ovaries. Careful examination usually reveals the uterus to be tonic and erect, a condition not seen in true anestrus or failure of the estrous cycle. If the ovaries are examined before ovulation the mature follicle and the regressing firm C.L. may be palpated, or if soon after ovulation the site of ovulation or a slight crepitation characteristic of an early developing corpus luteum may be felt. The corpus luteum of the previous estrous cycle is usually palpable but small. A vaginal examination with

a speculum and light is often essential since the presence of hyperemia, relaxation of the cervix, and typical vaginal mucus of estrus is indicative of estrus; and the presence of blood in the vaginal mucus indicates that ovulation occurred one to two days previously. It is not unusual in examining a number of normal, well-nourished cows that have a history of failure of estrus to find one or more of these cows approaching, in, or just over, estrus. This fact may be missed by a hasty examination especially if a speculum examination of the vagina is omitted. Cows in proestrus, estrus or very early metestrus should be bred. Cows in metestrus after ovulation has occurred should be noted on the heat expectancy chart and watched closely 18 to 20 days later.

Cows in anestrus due to a failure of the estrous cycle caused by nutritive deficiencies or debility from other causes; cows with cystic ovaries; and occasionally cows with such miscellaneous conditions including freemartinism, hypoplasia of the ovaries, ovarian tumors, and pituitary disturbances comprise this group of cows.

(2) Anestrus secondary to debility or marked loss in weight. Any severe and chronic adverse or stress conditions that affect the animal's body will produce an effect on the reproductive system, usually by causing a cessation of the estrous cycle and anestrus if the animal is not pregnant; or in more severely debilitating conditions, possibly causing abortion if the animal is pregnant. Reproduction is a "luxury" function of the body. If "stress" due to any cause is severe enough, estrous cycles and reproduction cease. The adverse debilitating conditions that suppress or stop the estrous cycle and produce anestrus are:

(a) A low plane of nutrition due to a lack of sufficient intake of carbohydrates, proteins, and other elements necessary to maintain body weight may cause a failure or delay in the onset of puberty or the onset of the estrous cycle following parturition. Energy deficiency or negative energy balance is common in high-producing cows the first 20 days after calving. Ovulation and luteinization occurred about 10 days after the energy balance was returning to a positive balance. To prevent longer calving intervals in high-producing cows, feeding of large amounts of energy is essential early in the first third of lactation.^{23b} Cows exhibiting estrus before 30 days postpartum were more fertile with fewer services per conception, 2.29, than cows with no heats in this period, 2.63.^{89c} (See Nutritional Causes for Infertility.) This condition is seen most often in heifers maintained on poor hay or on poor pasture or range. The incidence of "winter sterility" in England characterized by anestrus varied from 5 percent around Cambridge to 50 percent in the Yorkshire Mountains, where cattle were kept in cold,

dark barns and fed poor hay.³⁸ Heifers fed on a high level of nutritive intake reached puberty and developed estrum at an average of 9 to 10 months of age, whereas heifers fed on a lower nutritive level did not reach puberty and estrum until 16 months or more of age.^{13,78} These latter heifers were maintained at optimum environmental conditions except for the level of feeding. The various nutritive factors that adversely affect the estrous cycle may also include severe nutritive deficiencies of phosphorus, cobalt, iron, copper and possibly other trace elements. When these substances are lacking, anorexia and debility, with impairment or suppression of the secretion of the gonadotrophic hormones by the pituitary, may develop. It is well known in humans that starvation causes amenorrhea and a cessation of the menstrual cycle before other body disturbances appear. In rats a loss of 15 percent in body weight may stop the estrous cycle. This was illustrated in cows during an experiment on the effects of a sodium chloride deficiency.¹ When this common element was withheld for long periods the effects became very evident after calving. Lactation caused rapid loss of weight because the appetite was poor. Milk secretion declined and ceased. The cows became cachectic and failed to show estrum. On examination the ovaries were found to be small and inactive; an occasional small 1 cm. follicle was palpated. Estrum did not return until salt was supplied and the appetite, nutritive state, and body condition improved.

Most practicing veterinarians have observed anestrus on farms where cows and heifers are thin and poorly fed. In a survey of 1533 cows in 28 herds in New York State, carotene, vitamin A, calcium, phosphorus, and iodine deficiencies did not contribute to sterility.⁴⁰ Inasmuch as reduced hemoglobin, below 9 gm. per 100 ml. of blood, was noted in all anestrus cows, cobalt and copper deficiencies may have been a factor. In heifers or cows that are in a fair state of nutrition but are exhibiting anestrus, the condition may be due to a simple phosphorus deficiency, or a phosphorus and a protein or carbohydrate deficiencies. A herd of dairy cattle deficient in phosphorus intake was described but anestrus was not observed in the deficient cattle in this herd.⁶¹ Blood levels below 3 mgm. percent usually indicate a phosphorus deficiency.^{61,92} Failure of estrum with non-functional, inactive or "smooth" ovaries is observed most often during the winter months in the northern part of the country in cows on poor and inadequate amounts of feed. In the southern and western part of the country where the animals are on pasture most of the year the condition is observed most commonly during the dry, late summer pasture season when available feed is greatly reduced. It may also be observed under drouth conditions. A de-

lay in the occurrence of estrus after parturition especially in range beef heifers on a low level of TDN or energy intake prior to or after parturition has been reported.^{4,13,21,97,98} This was also associated with a lower conception rate after estrus occurred. Heavy lactation, with or without ketosis, will often result in the rapid loss in body weight and if this is extreme, cessation of the estrous cycle will occur. If the loss in weight after calving is more gradual, an estrus or two may occur before anestrus develops. In lactating cows showing anestrus of nutritional origin, milk production is usually lowered. Anestrus due to low nutritive intake is usually characterized by the fact that a large number of cows or heifers on a farm show the same symptoms. Examination of 4 or 5 animals that fail to show estrus will usually reveal small, atrophic, inactive ovaries. (See Figure 117.) No corpora lutea are palpable. The uterus is usually small, lacks tone, and is doughy and flaccid. On vaginal examination the mucosa of the vagina and cervix is pale and dry. Repeated examinations reveal no change in the reproductive organs. The affected animals are usually thin and have rough hair coats and dry feces.

(b) Chronic or debilitating diseases, by causing a decreased appetite, may result in failure of estrus due to a marked reduction of body weight. Examples of these diseases or conditions include severe mange, lymphocytoma, severe chronic traumatic gastritis, chronic severe pneumonia, Johnes disease, actinomycosis that interferes with eating, either severe external or internal parasitisms, including liver fluke infection,^{33a} severe suppurative processes such as suppurative arthritis secondary to foot rot with a secondary severe debility, advanced tuberculosis, hyperkeratosis, anaplasmosis, and other similar diseases and conditions. If the cow recovers from the disease or its effects are alleviated and appetite and body condition returns, the estrous cycles will be reestablished.

(c) Senility or old age with loss of teeth and inability to masticate properly, especially in older lactating cows, is a cause of loss of weight, debility, and anestrus or failure of estrus. In extremely old cows, 16 years and older, anestrus may rarely be associated with a severe reduction in the number of oocytes in the ovary as in menopausal women.

(d) Seasonal influences—especially environmental temperatures, sunlight, and exercise apparently play a lesser role than does nutrition on the estrous cycle and estrus. Failure of estrus or anestrus in cattle has often been observed in cows and heifers closely confined in dark stables and allowed little or no exercise. This may be compounded by a lack of observation and a lack of proper care and nutrition. In the northern part of the

country where cows are confined during the winter months, even though the cow is polyestrous the best conception rates occur in May, June, and July whereas the poorest breeding months are December, January, and February. This is undoubtedly a reflection of the amount of sunlight and its effect on the pituitary as well as the feeding levels, amount of exercise, type of feed available and closeness of observation for estrus. During the cold winter months additional nutritive energy is required by animals to maintain body temperature and in heifers an added requirement is necessary for growth.

Excessive heat stress over long periods of time may cause anestrus, a shortening in duration and intensity of estrus and an increase in incidence of "silent" heats.^{89a,b} Five of 6 two-year-old heifers developed anestrus and cessation of the estrous cycle after being kept for 5 weeks at a temperature of 90° F and 60 percent humidity. Besides these effects on the estrus cycle and periods, excessive heat and humidity greatly lowers conception rates and production in dairy cows in tropical climates during the summer months. The use of shade, evaporative cooling and partial air-conditioning greatly reduces or alleviates these adverse effects of heat stress.^{89b}

(3) Cystic ovaries, as reported previously, are characterized externally by failure of estrus or anestrus in about 25 to 75 percent of the cases. On rectal examination one or more follicular or luteal cysts are found. The uterus is usually doughy and flaccid and may be atrophied. The mucus in the vagina is tenacious, and varying degrees of edema of the vulva and relaxation of the pelvic ligaments occur due to prolonged estradiol concentrations in the blood plasma. Treatment consists of injecting luteinizing hormone (LH) or GnRH or prostaglandins for luteal cysts. Some cases of mucometra are associated with cystic ovaries and long-standing anestrus. This condition might be confused with pregnancy unless a careful examination is made. Another rare condition the author considers as also associated with prolonged cystic ovaries and anestrus is characterized by a greatly enlarged and dilated cervix filled with copious amounts of tenacious, tough mucus similar to the mucus of a cervical seal of pregnancy. This latter condition may also have mucometra along with the cervical lesion.

(4) Miscellaneous conditions characterized by anestrus or failure of normal estrus with no corpus luteum are generally uncommon and sporadic in the United States. These may include occasional cases of:

(a) Non-functional or "smooth" ovaries may occasionally be observed in apparently well-nourished older cattle in good condition the first 2 to 4 months after parturition when the level of lactation is high. Cows stressed at the period of calving by the occurrence of a

disease process such as retained placenta, dystocia, milk fever, ketosis, mastitis, twins and other debilitating diseases had a delayed onset of the estrous cycle of an average of 34 days compared to 15 days for cows with a normal parturition. Seven percent of the cows and 3.99 percent of the estrous cycles studied were characterized by a varying period of anestrus with "smooth" or non-functioning ovaries.⁹¹ The uterus is flaccid and lacks tone. Spontaneous recovery usually occurs. This condition is probably due to a reduced level of nutrition associated with a definite loss in weight. When production and energy intake are equalized, the estrous cycle will occur.

(b) Freemartinism may be a rare cause of anestrus in heifers purchased from unknown sources or raised by farmers who did not know that 90 percent of heifers born cotwin to bulls are sterile. These freemartins are usually steer-like in appearance. They have a small vulva with a coarse tuft of hair and a prominent clitoris. On rectal examination the uterus and ovaries usually cannot be palpated except as thin or small remnants of the normal structures. Vaginal examination will reveal an undeveloped vagina cranial to the vestibule.

(c) Congenital bilateral hypoplasia of the ovaries is rarely observed in the United States. Several related cattle were described with a complete absence of gonads.²⁷ In rare instances, heifers may have a fairly normal but small infantile genital tract but very hypoplastic, small, flattened, slightly corrugated ovaries the size of a bean or smaller 0.5 to 2 cm. long and 0.25 to 0.5 cm. in diameter. (See Figure 118.) These hypoplastic ovaries may be observed either unilaterally or bilaterally. Heifers unilaterally affected or those with partial hypoplasia of an ovary usually have normal estrous cycles. Small, inactive, immature ovaries 0.5 to 1.5 cm. in diameter; especially in prepubertal heifers, may erroneously be diagnosed as hypoplastic ovaries. Heifers should be in good physical condition with no obvious cause for the small inactive ovaries and be old enough to have estrous cycles before a diagnosis of congenital hypoplasia should be considered. In a few of these congenital or hereditary cases of hypoplasia, the uterus and oviducts on one or both sides may also be hypoplastic. In the United States congenital, or possible hereditary, bilateral total hypoplasia of the ovaries is rare and sporadic. In Sweden, widespread hereditary ovarian and testicular hypoplasia were formerly present in the Swedish Highland breed of cattle.^{26,53} Inbreeding has been associated with the development of this defect as with other hereditary anomalies of development.

(d) Tumors of the ovary are rarely noted as a cause of anestrus or failure of estrus. In the cow the most common tumor is the granulosa cell tumor that may cause

Figure 118. Bilateral Total Hypoplasia of the Ovaries in a 3-year-old Holstein.

occasional symptoms of either nymphomania or anestrus. The early stages of these tumors usually pass unnoticed and by the time clinical symptoms of pelvic relaxation, edema of the vulva, and others are evident, rectal examination will reveal the nature of the condition by the presence of an abnormally large ovary, 7.5 cm. or more in diameter, usually pulled forward and downward in the abdominal cavity. The ovarian artery to the diseased ovary is usually enlarged. Removal of the diseased ovary may be indicated in some cases. Several authors have reported finding granulosa cell tumors in related cattle. Rarely chronic tumors, abscesses and cysts in the ventral area of the brain affect the pituitary gland by causing pressure atrophy and a deficiency of gonadotropic hormones, thus producing cessation of the estrous cycle and atrophy of the gonads. Large and prolonged doses of the gonadal hormones, estrogens, progesterone

and testosterone, whether taken orally or by injection will suppress the release of gonadotropic hormones and result in smooth, inactive, nonfunctioning, atrophied ovaries. Anestrus due to this cause is also rare in cattle.

Treatment of anestrus in cows that have no palpable functional corpora lutea and in which the plasma progesterone levels are continuously low, or occasionally high as in luteal cysts, will vary with the clinical findings. Anestrous cows with cystic ovaries containing follicular or luteal cysts should be treated in ways described under cystic ovaries. Heifers or cows with freemartin genital tracts, bilateral total ovarian hypoplasia, which should not be confused with infantilism or failure to reach puberty, very rare absence of the gonads, ovarian tumors, or rare lesions of the pituitary gland or the hypothalamus should be slaughtered as treatment is not indicated or successful. Removal of one ovary affected with an ovarian tumor, especially a granulosa cell tumor, may rarely restore fertility to the heifer or the cow. In the case of unilateral ovarian hypoplasia the strong possibility that the condition is genetic in nature should be seriously considered. If ovarian atrophy or cystic ovaries are due to exogenous estrogens, or possibly progesterone, testosterone or progestagens, these should be removed from the diet or the ration changed or injections of the same should be stopped. It may take from a week to several months or more before the estrous cycle is reestablished.

Treatment of anestrus due to debility, cachexia or a lack of TDN (energy), protein, or other minerals should follow a careful clinical examination and diagnosis often requiring an analysis of the feed. If the cause is due to chronic debilitating diseases these must be corrected or alleviated so the female returns to a good condition with near normal body weight. Additional levels of TDN and other nutrients need to be fed to these animals. Therapy may require a number of months. In senile animals the prognosis is poor but occasionally pelleted, easily digested feed may be helpful.

Treatment of anestrus due to a low level of nutrition is obviously corrected by greatly increasing the nutritive levels. Since many farmers refuse to recognize they are underfeeding and mismanaging their stock, particularly heifers, this is a difficult or impossible problem to correct in some herds. Frequently nature corrects it in the spring when the animals are turned out to pasture where the feed is excellent and unlimited; the weather is warmer; the days longer; and exercise is plentiful. Occasionally a farmer or owner can be persuaded to accept your diagnosis and suggested treatment on a trial basis by taking several anestrous heifers with small functionless ovaries and placing them in the barn with the milking cows and

feeding them as if they were cows producing 50 lbs of milk a day. In 3 to 6 weeks these heifers usually come into estrus while their less fortunate companions—fed less and on a poor quality feed and usually kept in a colder and less favorable environment—remain anestrus. This same problem may be observed in certain areas of the country and in certain beef herds where there are deficiencies of either one or more minerals such as phosphorus, cobalt, iodine, copper, salt, iron, and others, and/or of total digestible nutrients. Often nutritional deficiencies producing cessation of the estrous cycle are multiple. In some high producing old cows that are very thin and poor and are persistent milkers, it may be advisable to stop lactation to enable them to gain enough body reserves so that estrous cycles will begin again. Good pasture is desirable. Estrus will not occur in these debilitated animals until they receive feed over and above the requirements for maintaining life and are in a positive energy balance. In heifers or cows in a fair to good nutritive state but failing to show estrus because of a phosphorus deficiency, steamed bonemeal or dicalcium phosphate should be fed free choice. Complex mineral supplements or specific mineral supplements may be necessary, free choice or incorporated into the salt or feed in anestrus, mineral-deficient cows with a low blood hemoglobin level.

In range beef heifers and cows the delay in the onset of puberty or estrus after calving, especially in nursing two-year-olds and the lowered conception rates have been described.^{13,79,97,98} These studies have demonstrated the importance of feeding proper supplemental levels of nutrients, especially energy and phosphorus to heifers and two-year-old cows after calving. The value of vitamins for the treatment of anestrus in range cattle is questionable.

Miscellaneous Infertility Conditions Possibly Associated with Hormonal Disturbances

Hormonal therapy for cows that are cycling regularly but fail to conceive has been used empirically in the past by many veterinarians. If the therapy has not been coupled to a careful diagnosis of the etiology of the repeat-breeder cow which is difficult, results are usually unsatisfactory or conception occurs despite the treatment. The use of luteinizing hormone (HCG) or GnRH to promote ovulation has been described but failure of ovulation or delayed ovulation only occurs occasionally. HCG may also be used about the third or fourth day after estrus to promote the growth and increase the size and

Figure 119. A "Smooth," Inactive Ovary Seen Bilaterally in Debilitated or Thin Heifers and Cows and Causing Anestrus.

progesterone production of the corpus luteum but its value has not been evaluated in controlled studies. Veterinarians have also suggested the use of repositol progesterone, 500 mg. a few days after breeding⁷¹ but controlled studies are also lacking. The use of small doses of estrogen or GnRH early in estrus to promote the release of LH and ovulation has not proven to be of value except possibly in a few special cases in cows in which early embryonic deaths apparently occur. F.S.H. is not indicated in cycling infertile cows or in non-cycling cows. Thyroid therapy in the form of iodinated casein (**Pro-tamone**) 1 gm. per 100 lbs. body weight orally daily, 5,000 to 15,000 mg. triiodothyronine (**Cytomel**, Smith Kline and French) in pellet form subcutaneously or 2 to 5 grains of thyroid orally daily has been used for anestrus. It has also been used empirically for infertile cows or heifers, especially those that are obese or have become steer-like in appearance. Thyroid preparations should not be used in thin cattle in which anestrus is due to a lack of T.D.N. or energy intake. A possible abnormal steroid metabolism in inbred Jersey cattle characterized by delayed puberty, a short estrus, irregular cycles, failure of conception and decreased secretion rate of sex steroid and cortisol has been described.²⁴ Controlled studies in infertile cattle with the above hormones is probably indicated to prove or disprove their value. It is unlikely they will be proven to be of value unless better diag-

nostic tests are developed so that the use of hormones becomes based on scientific, sound information.

Infertility Due to Nutritional Causes

During the past 30 years a great mass of knowledge has accumulated about the effects on animals of various nutrients and their deficiencies. Since much of the early

work was done on the rat and on laboratory animals, some nutritional fallacies have developed in so far as they pertain to domestic animals. The effect of nutrition on reproduction, sterility, and infertility has not been discussed but the relation of nutrition or nutritive deficiencies to abortion and anestrus has been reviewed in Chapters VIII and XIII. Excellent reviews on this field have been published.^{1,20,25,30,31,37,41–44} Only a few nutrients have a direct effect on fertility. Some infertility conditions blamed on nutrition may in reality be due to other related or nonrelated causes. Most field cases of reduced fertility or of sterility of nutritional origin are usually due to multiple deficiencies. Underfeeding may be accompanied by poor quality of feed and by deficiencies of protein, phosphorus and vitamin A. A protein deficiency is usually accompanied by a phosphorus deficiency, and a vitamin A deficiency by a protein and phosphorus deficiency. Sometimes reduced fertility believed to be of nutritional origin may be caused by the amount of light, environmental temperature, amount or type of work, or some other environmental influence. More work is required in this field as much of our present data is based on poorly controlled experiments and too few observations. It has been found that nutritional data accumulated on one species of animal does not always apply to other species. Symptoms of a certain deficiency in one species may differ from those in another species. At one time or another claims have been made that every known food factor is indispensable for normal reproduction.⁴¹ In so far as reproductive performance is based on the general health of the animal this may be true. Malnutrition leads to lowered vitality and lessened resistance to disease but proof of such effects on the reproductive system are few and all too often not conclusive. If disease is complicating the malnutrition then corrective efforts must be directed at both conditions. Lactation, however, places a heavy drain on an animal already deficient especially in certain minerals and in the general level of feeding. Specific deficiencies seldom cause specific lesions in the reproductive system. Infertility or sterility due to nutritional causes is usually characterized by a cessation of the estrous cycle and only under certain conditions is it characterized by a failure of conception or early embryonic death. Reproduction is a “luxury” function of the body. When body functions and needs are severely compromised, reproduction usually is the first system affected and if adverse influences are continued, reproductive functions cease.

Underfeeding, inanition, or starvation has been shown to delay sexual maturity in heifers^{30,37,44} and to inhibit estrous cycles in mammals of all ages. When dairy heifers were fed various levels of TDN from birth to first

calving equivalent to 62, 100 and 146 percent of the upper level of Morrison's Feeding Standard, the average age at the onset of puberty was 88, 49, and 40 weeks. The body size at the time of puberty was the same for all feeding levels. When the energy intake in the adult animal is low, follicles fail to develop to maturity and follicular atresia results, along with a loss of sexual desire, anestrus and cessation of the estrous cycle. Restricted food intake may have an effect on the early embryo but starvation after this period does not necessarily interrupt gestation but may cause stillbirth or birth of small, weak young.³¹ It is nearly impossible to conduct an experiment on a single food deficiency without encountering a partial inanition in animals. Under-feeding or inanition is seen in cattle most commonly during the winter months when they are confined and/or the quality and quantity of the feed is limited or reduced. In older cattle irregular estrous periods and anestrus are manifested as a result of underfeeding. Inanition reduced the secretion of gonadotropic hormones and other hormones by the anterior pituitary although the gonadotropic levels in the pituitary were normal.^{31,37} The fact that the ovaries remain responsive to stimulation by gonadotropes during under-feeding does not mean that normal estrous cycles and pregnancy could be maintained by administration of hormones, since undernutrition probably exerts a direct effect on the reproductive tract although the major effect is on the endocrine glands.

It has been shown in primiparous beef heifers that energy intake levels before and especially after calving and during lactation have a marked effect on the occurrence of postpartum estrus and conception rates.⁵⁷ In beef heifers fed high TDN, 9 lbs. and low TDN, 4.5 lbs. daily before calving and then high TDN, 16 lbs., and low TDN, 8 lbs. daily after calving the conception rate for 20 heifers in each group was High-High 95 percent, High-Low 77 percent, Low-High 95 percent and Low-Low 20 percent. The percentage of cows cycling by 60 days postpartum was 80, 81, 45 and 17 respectively in the four feeding groups. Thus it is more important that cows suckling calves receive more energy than pregnant animals.^{56,58} The birth weight of calves from cows on the low energy ration during pregnancy was 10 lbs. lower on the average than the weight of calves from cows on the high energy ration, 67 lbs. vs 78 lbs. Beef heifers should be fed to gain one pound a day from weaning through the breeding season.⁵⁷ Heifers of the English breeds of cattle should weigh 650 lbs. at the start of the breeding season. Beef cattle should be in good condition at calving and should be fed to gain 0.5 to 0.75 lbs. per day after calving until the end of the breeding season to avoid low reproductive performance. In a herd of 327

beef cattle free of infectious causes for infertility the conception rate dropped from 87 percent to 41 percent, 28 percent in lactating and 76 percent in nonlactating cows, under drouth conditions.⁹ Injections of vitamins A, D, and E during the breeding season failed to improve the conception rate. A higher incidence of dystocia in heifers was reported on a below normal energy intake during the gestation period.⁴⁴ Retarded early growth in cattle due to a low plane of nutrition was associated with a prolongation of the life span.⁴³

Evidence indicates that animals come into estrum and conceive most readily when their body weight is rising due to an increased plane of nutrition and conversely a low pregnancy rate occurs in beef and dairy cattle losing weight during the breeding season.^{12,13,21,23,30,36b,57} In 179 Ayrshire cows on 3 farms that were weighed every 4 weeks and serviced not less than 56 days postpartum, 98 cows whose body weight increased after calving had a 77.6 percent conception rate on first service while 81 cows whose body weight decreased had a 16 percent conception rate on first service.²³ There was no correlation between conception rate and milk yield. New Zealand studies showed that cows gaining weight had similar conception rates to those that lost only a modest amount of weight after calving.³⁴ It was also noted in Israel that a positive energy balance if achieved fairly promptly after calving resulted in an improved conception rate.²¹ They suggested that weighing cows at intervals after calving might be helpful in determining the need for increased energy intake and in determining the time for insemination. (See Anestrus.) The dairy and beef herd infertility syndrome associated with a negative energy balance and loss of weight was described^{12,30} to include: (1) low first service nonreturn rates; these are seldom below 30 percent, (2) spontaneous recovery but many cows are not pregnant by the third month after the first service, (3) affected cows lose an excessive amount of body weight, 5 to 10 percent, between calving and first service; such a loss is often not obvious, and (4) low blood glucose, hypoglycemia, is frequently observed in infertile cows at the time of the first service. The estrous cycle length was increased from normal to 34 days when cows were given insulin daily from day 17, but not day 18, through day 20 of the cycle.²⁹ In 11 cows mated 0 to 2 days after the last dose of insulin only 2 or 18 percent were pregnant at 8 weeks, and of 16 cows given insulin, 400 units daily the first four days after mating only 6 or 38 percent were pregnant at 8 weeks. While 15 of 20, or 75 percent, of the control cows were pregnant. Thus it is possible that a hypoglycemia at estrus and shortly after service may exert a harmful effect on conception. This effect may be brought

about by a lowering of the glucose or glycogen levels in the mucosa of the genital tract resulting in a lack of energy for spermatozoa and embryos. Further study of these interesting observations are needed. Reproduction in Herefords was more severely affected by low levels of TDN intake after calving than in Angus cattle.¹³ Weight gain in yearling heifers during the prebreeding period caused by "flushing" or feeding high energy rations was more important in its effect on age at puberty than was the gain during the wintering period.⁷ Thus it appears important that feeding practices in dairy and beef herds be such that, despite the stress and energy requirements of lactation, cows to be bred should be in a positive energy balance and gaining weight as soon after calving as is possible to realize the best breeding results.

Obesity due to overfeeding has been considered by many practicing veterinarians to be a cause of infertility in cattle. This is observed particularly in the beef breeds and has often been reported to affect valuable show cattle. Early references indicated erroneously that in these overly-fat animals the ovaries are small and estrus may fail to occur.^{1,56} Obese, over-conditioned dairy cows are prone to the "fat cow syndrome" at calving (see post parturient diseases). The diseases associated with this syndrome have an adverse effect on fertility and often greatly prolong the period from calving to conception.^{36b} Obesity and sterility might arise from the same cause such as hypothyroidism or from a pituitary lesion. Fat deposits in the ovaries and ovarian bursae were suspected of interfering with normal ovulation and transport of ovum to the oviduct. Recent nutritional research has not confirmed the observation in cows that obesity and infertility are associated. Reid stated, "It is as logical to assume that sterility is the cause of high condition as it is to assume the reverse."⁴³ In a rather large controlled experiment animals kept on a high plane of nutrition their entire life had fewer calves and a higher percentage of culling due to infertility than did the animals fed at normal and low levels of nutrition.³⁸ Swedish data, New Zealand reports, and experiments at Cornell,⁴⁴ indicated that heavy feeding hastened the onset of puberty, caused a slight increase in number of services per conception if heifers were withheld from breeding for a number of months after reaching puberty; and resulted in lower milk yields and a shorter life. Cattle reared on a high plane of nutrition had more breeding difficulties later in life and thus had a shorter productive life than cattle reared on a low energy intake.⁴³ A high level of grain feeding of up to 4790 kg per lactation over a period of years in dairy cows had no significant effect on conception rate.⁶ Fat heifers and cows with large deposits of perivaginal fat may have more difficulties at parturition. The problem of the effects of overfeeding on reproduction in cat-

tle is not settled and more controlled experiments are needed and indicated.

Protein deficiencies of either quality or quantity under the usual conditions of management of cattle are not common. Although the quality and quantity of protein might be important for reproductive functions, deficient amounts are seldom encountered except in severe inanition or underfeeding when vitamin A and phosphorus deficiencies are often complicating factors. The effect of a low level intake of protein on reproduction may be to reduce the total intake of feed, resulting in a delay in estrus.⁵⁶ The high content of phosphorus rather than protein may explain why cottonseed meal is a better supplement for beef cattle in the Southwest than is grain during the winter months.²⁴ Pelleted alfalfa fed at a rate of 2 to 5 lbs. daily per animal is an excellent protein supplement. The level of energy intake is more important for reproduction than is protein.

Vitamin deficiencies in cattle are mainly limited to vitamin A. Deficiencies of the other vitamins are not likely to cause reproductive failure.

Vitamin A deficiency adversely affects reproduction in most species. The effects occur during the latter half of gestation and are characterized by abortion or by the birth of weak or dead calves (See Abortion, Chapter V). It seems remarkable but it is nevertheless true that vitamin A deficient animals have normal estrous cycles, ovulate and conceive, and early fetal development occurs even though epithelial and other tissue changes have developed. Infertility in cattle and other domestic animals has not been associated with vitamin A deficiency or with a deficiency of the other vitamins.

In the mid to late 1970's many articles were published in Europe on the beneficial effects of beta-carotene on bovine fertility. Beta-carotene and vitamin A are deficient in corn silage.^{10,20} Supplementing such diets with 200,000 IU vitamin A and 300 mg. beta-carotene per head per day reduced the time from calving to conception, reduced the incidence of ovarian cysts and reduced embryonic deaths, early abortions and disease prone calves.^{20,27} The bovine CL contains beta-carotene but no vitamin A. The former can be converted into vitamin A. Evidence would indicate that vitamin A provided by good hay, especially alfalfa, and pasture should provide the vitamin needs for reproduction.¹⁹ The present requirement for vitamin A in dairy cattle is 3,400 IU or 8.5 mg of carotene/100 lbs. of body weight.¹⁰ Experiments are now being conducted to determine whether greatly increased amounts of beta-carotene are needed for reproductive efficiency. Recent reports do not support the early claims for beta-carotene supplementation.^{58b}

Vitamin A requirements during pregnancy are higher than in the nonpregnant animal and higher for the female

than the male animal. Vitamin A deficiencies are characterized by changes in the epithelial tissues, such as keratinization and degeneration of the placenta. Fetal death, abortion, dystocia, retained placenta, and septic metritis are likely to result. Vitamin A deficiency has been described in cattle grazing dry, bleached pastures and grain fields where possibly protein, phosphorus, and carbohydrate intake were also deficient. When green feed became available, night blindness, lacrimation, anorexia, diarrhea, loss of condition and other general symptoms of vitamin A deficiency, as well as abortions and stillbirths, ceased. The liver has the ability to store considerable amounts of vitamin A for some time; therefore symptoms of vitamin A deficiency take months to develop. Good timothy hay has a much lower content of vitamin A than does alfalfa hay. Under most conditions where roughage is of average quality, vitamin A deficiency is very unlikely to occur and even then the reproductive effects are not those causing infertility in the cow.

Vitamin B or B-complex deficiencies have been demonstrated in animals as producing the same inhibitory effects on reproduction as reduced food intake or starvation. This is not unexpected, as deficiencies of B vitamins are usually accompanied by a reduced appetite. By virtue of ruminal synthesis of these B-complex vitamins, cows are in no danger of suffering from vitamin B deficiencies. One of the B-complex vitamins, vitamin B₁₂, requires cobalt in its synthesis; cattle in cobalt-deficient areas may develop severe inanition due to lack of sufficient intake of feed occasioned by a cobalt and B₁₂ deficiency and a lack of appetite.

Vitamin C deficiency does not occur in cattle; only man, monkeys, and guinea pigs manifest symptoms of vitamin C deficiency, or scurvy, and even in these species no reproductive disturbances are produced when severe scurvy is present.

Vitamin D deficiency probably seldom occurs, due to the presence of vitamin D in roughage of almost any quality. If the animal gains access to sunlight or green pasture, adequate amounts are available. An uncomplicated vitamin D deficiency does not interfere with reproduction in mammals.³¹

Vitamin E deficiency, like vitamin A deficiency, does not affect the estrous cycle or ovarian function. In deficient rats pregnancy is interrupted after midterm by resorption of the fetuses. In the male rats vitamin E deficiency irreparably damages the seminiferous epithelium giving rise to its early name—the “antisterility” vitamin. In herbivorous animals it is doubtful that a need for vitamin E for reproductive purposes is greater than the quantity liberally present in the natural feed. Cows can reproduce on a vitamin E deficient diet. Heifers and bulls

receiving vitamin-E-deficient diets were fertile.¹⁵ In the past, extravagant claims have been made for the use and value of vitamin E supplementation of rations in the treatment of all types of reproductive disorders in cows and bulls. These claims and reports, largely commercially-developed and exploited, were uncontrolled. The use of wheat germ oil in cases where spontaneous recoveries of infertility are known to be high resulted in a great number of apparent “cures” with this product. Reports on more carefully controlled data and experiments using wheat germ oil or sprouted oats showed no difference in results between the treated and the control groups of cattle. At the present time vitamin E therapy for infertility cannot be recommended since it is of no known value.

Mineral deficiencies causing infertility in cattle are limited mainly to phosphorus and occasional trace minerals. Trace minerals in cattle nutrition have been reviewed.⁵

Phosphorus deficiency usually tends to occur when diets low in protein are fed, under range conditions when the grass is dry and dead, in areas where the soil is deficient in phosphorus, and in borderline phosphorus-deficient areas when the cows are lactating and are not fed sufficient protein or mineral supplements to maintain the necessary body levels of phosphorus. Until clinical symptoms of the deficiency, such as inanition, poor hair coat, and depraved and decreased appetite are evident, reproduction usually does not suffer. In some phosphorus-deficient areas cows had calves only every 2 years, and heifers failed to show estrus until over 2 years of age. The condition was most severe in the late winter and spring after a dry summer and fall. Some cows would have one or two periods of estrus after calving and then if they failed to conceive would not show estrus until the end of the lactation period. “Silent” or irregular estrus periods may occur in heifers. Thus the usual symptoms of phosphorus deficiency are delayed onset of puberty in heifers, and failure of estrus in cows. The relationship between phosphorus deficiency and infertility in dairy cattle was reviewed.³⁶ With proper phosphorus supplementation the number of services required for conception declined from 3.7 to 1.3 in dairy heifers suffering from a phosphorus deficiency. The Ca:P ratio, especially excess Ca to P., could influence fertility but this was not confirmed.^{17,18,26}

The phosphorus requirement for reproduction is about 10 to 12 gm. daily except during lactation when an additional amount is required.¹ Blood levels of phosphorus below 4 mg. per 100 ml of blood serum usually indicate a phosphorus deficiency; normal values are 4 to 8 mg. per 100 ml. Phosphorus levels are much lower in timothy hay than in legumes. In states where phosphorus

deficiency is common, the feeding of mineral supplements or cotton seed meal has resulted in marked improvement or increases in the yearly percentage of calves born. Mineral supplements to supply phosphorus include dicalcium phosphate or bone meal and these should be available free-choice together with trace mineralized salt for all cattle. Adding 1 percent sodium tripolyphosphate or monosodium phosphate to the grain ration will also increase the phosphorus intake.³⁶ **Calcium deficiency** does not cause reproductive failure in cattle.

Other trace element deficiencies, that may affect reproduction indirectly, are: **Manganese**—In cattle there are few reports of naturally-occurring manganese deficiencies. It appears nearly impossible to devise an otherwise normal ration for cattle that is deficient in manganese.^{42,43} However, reduced conception rates and anestrus in cattle deficient in manganese that was corrected by manganese supplementation was reported.^{30,45,54}

Cobalt deficiency in certain areas may cause a lack of appetite, depraved appetite, inanition, secondary failure of estrus, and delayed onset of puberty in cattle. Low hemoglobin values were observed in many anestrus animals. Cobalt is necessary for normal bacterial growth in the rumen. It is concerned in the production of vitamin B₁₂, which is an important factor in maintaining the appetite. In cobalt-deficient soils, legumes usually contain sufficient cobalt; but timothy hay produced on these soils is deficient in cobalt. **Copper and iron** deficiencies in some areas of the United States result in, or are complicated by, anemia, debility, lack of appetite, and consequently a reduced intake of feed. As with cobalt deficiency a secondary inanition, a failure of estrus, and a delayed onset of puberty may occur. The apparent association of anemia with hemoglobin values below 10 gms, especially in the range of 8.0 to 8.5 gms, per 100 ml of blood, and anestrus, delayed postpartum breeding and possibly repeat breeding have been reported upon in dairy cattle.^{2,52} In some cases this anemia has been related to low iron or copper levels in the forage. In certain areas such as some locations in Florida, a high molybdenum content in the feed results in severe scouring and loss of condition when copper is not added as a supplement in the feed. This loss of condition may be reflected in failure of estrus in cows or in the delayed onset of puberty in heifers. Copper-deficient cattle in New Zealand, England, South Africa and Australia,^{3,11,50,53} have marked general effects of lowered body health, loss of condition, slow growth and rough hair coat with secondary reproductive symptoms of failure of estrus, delayed conception, and infertility.

Iodine deficiency especially in the northern and north-

western parts of the United States may cause the birth of weak, premature or dead calves affected with goiter. Iodine is not known to affect reproductive processes. However, a lack of iodine can depress thyroid function.³¹ Hypo- or hyperthyroidism may reduce the secretion of gonadotropic hormones by the pituitary. An increase in conception rate was reported on first service and reduced irregular breeding intervals in herds in Finland receiving supplementary iodine compared to control herds.³³ In iodine-deficient areas iodine is usually provided in the salt. Severe salt deficiency over a long period of time, especially during lactation, will result in severe loss of body weight and anestrus.⁴⁶ **Zinc and selenium** has been shown to be closely associated with reproduction in laboratory and other animals but deficiencies in the large domestic animals have not been described.

Treatment of cattle with nutritional deficiencies is essentially one of prevention. In most deficiency areas these deficiencies are known and should be provided for by supplementing the ration. In most areas where cattle raising is profitable, deficiencies are usually uncommon in cattle fed near-normal or balanced rations. Usually general inanition, debility, and other symptoms are evident before reproductive symptoms develop. In most herds expensive mineral supplements are not necessary. Mineral supplements are added to the grain ration at a usual rate of 1 to 1.5 percent for dairy cattle. In certain mineral-deficient areas and in heavily lactating cows additional amounts or specific mineral supplementation such as magnesium may be necessary. A suitable mineral supplement for dairy areas in the northeast and middlewest consists of 86 lbs. of steamed bone meal or dicalcium phosphate, 12 lbs. of anhydrous ferrous sulfate, and 1.4 lbs. of copper sulfate and 1 ounce of cobalt sulphate or cobalt chloride. This can be fed free choice or added in small amounts, 1 ounce daily, to the grain ration.² If rock phosphate is used it should be carefully defluorinated to prevent possible fluorine poisoning. Chronic subclinical fluorine poisoning induced by feeding 5 to 12 ppm flourine in the drinking water caused anestrus, reduced conception rates and a drop in the pregnancy rate.⁵¹ In some cases subcutaneous injections of 1 to 6 mg. of vitamin B₁₂, 10 ml of iron dextran or 300 mg of copper glycinate may be given as needed if feed supplements are difficult to provide. There are few nutritional factors other than underfeeding that have been shown to have a widespread serious influence on reproductive functions. Trace elements had little if any effect on repeat breeding cows.⁸ Additional work, adequately planned and controlled, might profitably be applied to this problem of nutrition and fertility.

Miscellaneous nutritive, reproductive problems, especially infertility, may be associated with the consumption of excess estrogens from pasture plants especially during lush growing season. High estrogenic content of red clover, of alfalfa, subterranean clover and of ladino clover and other phytoestrogens have been reported upon.^{4,14,20,22,49,59} Infertility in cattle consuming such forage has been reported in isolated areas. Heavy kale feeding caused a reduced conception rate and prolonged intervals between estrous periods after service.^{32,39,40} No estrogens were found in kale but evidence of a goiterogenic factor was noted. Blood copper and hemoglobin were lower in kale-fed cows.³² Estrogenic mycotoxins or fungal metabolites may be a cause of infertility in cattle as they are in swine (See Chap. XVI) but evidence for this in the veterinary literature is scanty.^{8b,45b}

Congenital or Hereditary Causes of Infertility in Cows

Congenital or hereditary causes of sterility or infertility may be divided into those produced by definite anatomical defects of the reproductive organs, cytogenetic defects and those hereditary forms of infertility that are obscure, possibly due to multiple factors and difficult to assess. Because of the rapid advances in recent years in the control and elimination of many infectious venereal causes of infertility the genetic causes of infertility are assuming greater importance. Excellent reviews of this subject have been made.^{15,18,26,36,53,72} Many breed associations and artificial insemination centers have programs for monitoring and controlling undesirable genetic traits.³⁶

Hereditary or Congenital Anatomic Defects of the Reproductive Tract

Hereditary defects are usually due to single gene effects. Certain genes adversely affect both cows and bulls whereas others are sex-limited in their effect. In some females because of the severity of the abnormalities, sterility is manifested at the time of their first service period; while in other cows, in which the defect is less severe, it may not be detected until late in life.

Hypoplasia of the ovaries and testes has been well described.^{9,10,32-35,55-57} This defect is conditioned by a single recessive autosomal gene with incomplete penetration. This gene affects both cows and bulls in equal proportions. The affected ovary may be partially or totally hypoplastic. Depending on the severity of the hypoplasia and whether the condition is unilateral or bilateral, infertility or sterility will result. (See Figure 118.) In the latter instance the affected heifer is anestrus. The origin of this condition in the polled Swedish Highland breed of cattle traced back to two bulls born about 1900. Through extensive use of these bulls and of their offspring because of the high-butter-fat production of these

individuals, the condition was spread widely. In cows with hypoplastic ovaries, 87.1 percent were left-sided, 4.3 percent were right-sided and 9.6 percent involved both ovaries. This condition can be recognized in the affected Swedish Highland heifers by rectal examination as early as 9 months of age. The incidence of partial or transitional hypoplasia occurred in about the same percentage as the total hypoplasia of the ovaries or testes. These intermediate conditions can be evaluated only by repeated rectal examinations of the ovaries over a period of time or at the time of slaughter. The hypoplastic ovary undergoes incomplete development and a part or the whole ovary lacks a normal number or complement of primordial follicles. Both ovaries of normal heifers contained a total of 50,700 primordial follicles, range 6,800 to 100,000. Both ovaries, in affected heifers in which one ovary was totally or partially hypoplastic averaged 19,000 to 23,000 primordial follicles.⁵⁷ In affected heifers with bilateral hypoplasia there were fewer than 500 primordial follicles in partially affected ovaries and no follicles were present in the heifers with totally hypoplastic ovaries. In heifers the hypoplastic ovary is so small that it may be difficult to locate. It is a thin, narrow, structure of firm consistency, or in severe cases only a cord-like thickening in the cranial border of the ovarian ligament. The ovary has a shriveled or shrunken appearance affecting the entire ovary in total hypoplasia (See Figure 118) or usually the medial half or two-thirds of the ovary in partial hypoplasia. In other cases one-half of the ovary feels slightly raised and firm like a pea. In other cases the ovary of an adult cow may feel like a kidney bean with the surface smooth and stretched. If the surface of the ovary is rough due to luteal scars the ovary can be considered functional. In one-sided hypoplasia the tubular portion of the genital tract develops normally. In bilateral total hypoplasia the genital tract remains very small and infantile; estrum does not occur and there is no development of the secondary sex characteristics due to a lack of estrogens. In bilateral total hypoplasia the heifer is like a steer with long legs, a narrow pelvis, a poorly developed udder with small teats, and a small, firm uterus. In bulls similar hypoplastic changes affect the testes. Swedish Highland cattle that were totally white or had nearly completely white ears included in their number all cows with hypoplastic ovaries.⁵⁵ Those with black or red ears were not affected. Thus the degree of white color was associated with hypoplasia.

Through efforts of the Swedish government, the breed association, owners, and veterinarians, a campaign to control this condition has been established by culling affected animals. The incidence of this condition has dropped from 17.5 percent of the cattle in the Swedish

Highland breed in 1936 to 9.4 percent in 1948. In 1952 based on the examination of the genital organs from 6286 Swedish Highland cattle the incidence of hypoplasia of the left ovary was found to be 6.6 percent, right ovary 0.5 percent, and of both ovaries 0.09 percent; a partial hypoplasia of the left ovary of 3.3 percent, of the right ovary 1.1 percent, and of both ovaries 1.6 percent; or an incidence of total hypoplasia of 7.2 percent and partial hypoplasia of 6.0 percent. The incidence of this condition was severe enough in certain areas of Sweden that it resulted in a great increase in the incidence of right horn pregnancies which in 1939 was reported to be about 74 percent.³⁰ At the rate of decline in the incidence of the defect observed between 1936 and 1952, it would take more than a century to reduce it to less than 0.5 percent—a striking demonstration of the insidiousness and seriousness of some hereditary defects! The incidence of gonadal hypoplasia in cattle in Sweden had leveled off and remained about the same from 1954 to 1964.⁵⁸

Hypoplasia of the gonads is not known to occur in any hereditary pattern nor in any particular breed in the United States. The condition was described in 59 of 2935 Cows or heifers.⁶⁶ An incidence of 1.9 percent ovarian hypoplasia was reported in over 20,000 cows examined in Minnesota.⁷³ Several cases in closely-related Shorthorn cattle were described.¹⁷ Many other veterinarians including the author have observed occasional cases of unilateral or bilateral, total, partial or transitional hypoplasia in cows. The rare cows with bilateral total hypoplastic ovaries are sold as sterile but the danger of breeding the unilaterally or partially affected cattle should be seriously considered, and slaughter probably advised. In ovarian hypoplasia treatment with hormones is useless. The condition of hypoplasia should be differentiated from nonfunctional or atrophic ovaries in cows and small, inactive ovaries in heifers associated with a delayed onset of puberty due to inarition or underfeeding.

A gonadless condition or lack of one or both gonads has been described in cattle.^{14,33} The latter reported one case of a uterus unicornis in which only one ovary was present. The condition of a complete failure of development of gonads occurred in 3 heifers from the same dam sired by different bulls. The dam was inbred. The cow had 2 normal daughters; one was a twin and the other a full sister of 2 of the gonadless daughters.¹⁴ This was probably an inherited autosomal dominant.¹⁸ These gonadless heifers appeared normal until breeding age, but no estrum occurred and normal udder development was lacking. The genital tracts of these heifers were juvenile and undeveloped. Another case of a gonadless heifer, not related to the previous ones, was cited in which mucometra was present.¹³

Developmental defects in the tubular portions of the bovine reproductive tract—Most of these defects are probably hereditary in origin although some cases may be congenital. **Segmental aplasia of the Mullerian or paramesonephric ducts** and especially an **imperforate hymen** have been called “white heifer disease” because of the association of these genetic defects with white coat color. Reviews of these conditions reported that the Mullerian ducts fuse and develop in the bovine embryo when it is 5 to 15 cm. long or is 35 to 120 days of age.^{19,69} The author has grouped these conditions together because the defects as described in England, in Minnesota, and in New York State are very similar.^{2,14,65} “White heifer disease” was so named because it occurs most commonly in white heifers of the Shorthorn breed. This condition is considered to be caused by a single, recessive, sex-limited gene with linkage to the gene for white color.⁶⁵ Besides occurring commonly in about 10 percent of white Shorthorns, it has also been described in roan and red Shorthorns, Angus, Holsteins, Jerseys, Guernseys, Ayrshires and other breeds of cattle. The condition called arrested development of the Mullerian ducts occurred in a Holstein herd due to inbreeding a valuable sire upon his own daughters.¹⁴ Of 23 female offspring that were raised to breeding age, 12, or 56 percent, were sterile and 10 were of either low fertility or normal fertility. On the basis of this report, the condition was definitely due to a single, autosomal, recessive gene causing a sex-linked sterility due to inbreeding to a sire homozygous for this gene.²⁰

No single lesion is descriptive of this condition and a wide variety of anatomical defects may be noted. (See Figures 120–128.) For ease of description the author will generally follow Spriggs’ classification.⁶⁵ Segmental aplasia of uterine tubes is very rare. Two cases were reported in 2230 organs examined in Sweden.⁵⁸ The author has only observed two cases in his entire experience. Rarely a parovarian cyst may obstruct an oviduct.

The most severely affected cattle with segmental aplasia of the paramesonephric ducts are sterile due to the bilateral nature of the defects. These may be characterized by a hymenal constriction; absence of either the cranial part of the vagina, the cervix, or the uterine body, including part of the horns; and a cystic dilation of the uterine horns due to a narrow band of aplasia or a defect near the uterine body. (See Figure 128.) More commonly just the apices of the uterine horns containing yellow, tan to dark-reddish-brown mucus are present. This cystic apical dilation may vary from the size of an acorn to the approximate size of a 4-month pregnant uterus, containing a few ml. to a gallon or more of watery, thick, gummy or inspissated mucus. (See Figures 126, 127.)

Figure 120. Uterus Didelphys with Unilateral Mucocervix and Mucometra (Note the distention of the left uterine horn simulating a 50-day pregnancy and a CL in the right ovary.)

The cystic apices of the uterine horns may be oval, spherical, or nearly the shape of a normal horn, but they are thin-walled and are likely to be sacculated. In rare cases a cystic sacculcation of the Mullerian duct filled with mucus may develop in the region of the cervix (see Figure 120). These cystic dilations may be unilateral and of unequal sizes, depending on the extent of the aplasia. These above conditions as well as alternate constrictions and dilations of the uterine horns are called segmental aplasia of the Mullerian or paramesonephric ducts.

In rare cases 2 small, parallel, firm tubules or cords with a diameter of 1 to 2 cm. are present in the region of the missing vagina, cervix, and uterus for a distance of 10 to 25 cm. They are usually between the cranial portion of the vagina and the uterine horns or vestiges of the uterine horns. These tubules may fuse to form a rudimentary cervix but usually it is imperfectly formed

Figure 121. White Heifer Disease With a Marked Aplasia of the Vagina, Cervix and Uterus (Note the normal ovaries, oviducts and vulva).

or even absent. The vagina is usually short and narrow, or may have an enlarged or dilated caudal portion containing mucus or occasionally pus, and submucous vaginal channels may be present. These cordlike structures are considered to be primitive vestiges of arrested development of the Mullerian ducts.^{2,14,70} They might be vestiges of the primitive Wolffian ducts.⁶⁵ Further embryological studies of this condition may be necessary to establish the correct diagnosis and terminology. In rare instances there is a marked arrest in development, aplasia, or hypoplasia of the vagina and Mullerian duct system, characterized by a lack of a normal vagina, cervix, or uterus (see Figure 121).

Segmental aplasia involving the uterine horns is not uncommon and if only one horn is involved, the condition is called a uterus unicornis. (See Figures 125 and 126.) A hymenal constriction may be but usually is not

present. These animals may be fertile or infertile, usually the latter, with prolonged intervals between estrous periods and repeated services per conception because conception cannot occur if ovulation takes place on the side of the abnormal horn and normal involution of the C.L. may not occur due a prostaglandin deficiency caused by the missing uterine horn. In a total of 20 cases of uterus unicornis there were 14 with a normal left horn and a missing or defective right horn, and 6 had a normal right horn with a defective left horn.^{5,14,33,52,65,71} Twenty-six cases of uterus unicornis of which 17 were sterile or probably sterile were reported.⁶⁷ The hereditary nature of these defects of the tubular portion of the bovine genital tract and the danger of their spread by AI bulls was noted. A complete literature review on uterus unicornis was published.²³ The size of the cystic apex of the missing horn varies from 1 to 15 to 20 cm. in diameter. The rest of the anomalous horn is usually a dense, flat band of tissue. In 2 of these cases of uterus unicornis observed by the author the cervix was large and thick and filled with masses of dense mucus, like a cervical seal. In 5 cases the mucus in the cystic apex or incomplete, defective horn had become dried and appeared tan to brown in color, putty-like, gummy, or dried like a dense gum eraser into 2 to 7 irregular-shaped, 1 to 2.5 cm solid masses, with fluid mucus like heavy oil around the dried

Figure 122. Segmental Aplasia of the Cervix with Secondary Hydrometra in a Heifer. (Note resemblance to a 2-month pregnancy.) (Courtesy K. McEntee.)

Figure 123. Double External Os of the Cervix Due to the Persistence of the Median Wall of the Paramesonephric Ducts in a Cow. (Courtesy Ohio State Univ.)

or inspissated masses. These objects were composed of cellular and amorphous material. In most cases the mucus was fluid, watery in consistency and a translucent to opaque, yellow to reddish-brown color (see Figure 126).

Congenital lack of endometrial glands in the bovine uterus has been observed in a few heifers. (See section on anestrus.) These heifers exhibited a failure of estrus and a retained or persistent corpus luteum apparently due to a failure of the endometrium to produce the luteolytic factor or prostaglandin necessary for the involution of the corpus luteum. Manual removal of the corpus luteum results in estrus in about 3 to 4 days but the next corpus luteum also persists. The author has observed other sterile heifers that cycled normally but lacked caruncles or caruncular areas in the endometrium. Whether this is genetic or congenital is not known.

Genetic or congenital anomalies of the cervix of cat-

Figure 124. White Heifer Disease with an Imperforate Hymen Causing Mucovagina, Mucocervix and Mucometra.

tle is not uncommon. Segmental aplasia may rarely occur resulting in mucometra or a cystic enlargement of the cervix. (See Figure 120 and 128.) A high incidence of developmental defects of the paramesonephric duct system associated with infertility and sterility in Jersey and Shorthorn heifers in Australia was described.⁵⁰ Besides segmental uterine aplasia infertile heifers had sacculations 1 to 4 cm. in diameter, diverticulums 1 to 2 cm. deep, and dilations of the cervix due to defects at the third or fourth cervical rings. Similar defects have

Figure 125. Uterus Unicornis in a Cow.

Figure 126. Uterus Unicornis with a Cystic Apex Containing Bodies of Inspissated Mucus.

been observed in Jersey heifers and in other breeds in New York State.^{40,41} These defects are invariably filled with thick mucus and most affected heifers fail to conceive. These may often be diagnosed by rectal palpation of the cervix aided by a small metal probe such as a uterine catheter.

Double external os of the cervix in cattle is occasionally observed and is believed to be an instance of failure of the Mullerian ducts to fuse (see Figure 123). These seldom interfere with conception after natural service. The condition was described as being present in 118 cattle of the Swedish Highland breed, 2 percent of 5,940, sent to slaughter.³³ Many references to the condition in England and elsewhere were cited⁶³ stating that it was present in about 0.2 percent of the cattle. Examination of 514 genital tracts from dairy cattle, mainly Holstein, in New York State in 1969–70 revealed 12 cases or 2.3 percent with a double cervix; in nearly all

cases only the caudal half of the cervix was involved.⁵⁹ It is observed in many breeds, such as Shorthorns, British Friesian, Guernseys, Herefords, Holstein, and Brown Swiss. The condition is normally present in the 7.5-cm.-long bovine fetus but disappears during later fetal life.⁴⁵ There is evidence to show that this condition is hereditary and may be transmitted as a recessive gene. In an extensive review of the double cervix condition in cattle, the incidence varied from 0.1 to 18.2 percent with an average of 0.3 to 7 percent.⁶⁹ The condition was considered to be due to a dominant gene with incomplete penetrance transmitted by either or both the sire and the dam. This condition in Herefords was caused by a single

Figure 127. Segmental Aplasia of the Right Uterine Horn Resulting in an Accumulation of Inspissated Mucus. (Note the 90-day-pregnancy in the left horn. The right horn contents resemble a mummified fetus.)

Figure 128. Segmental Aplasia of Both Uterine Horns and Cervix in a Heifer.

autosomal recessive gene with low penetrance and variable expressivity.^{60,61} Most cases are apparently isolated or sporadic and are usually found on clinical examination for sterility or at the time of parturition or slaughter. A bull was reported that sired 18 heifers requiring many services before even 7 became pregnant. Many of the sterile heifers had double cervixes and other genital abnormalities.⁷

The lesion often occurs as a band of tissue 1 to 5 cm. in width and 1 to 2.5 cm in thickness caudal to or in the external os of the cervix. On speculum examination it may appear as if there were a double os. In other cases there may be a true double external os of the cervix and the band of tissue separating the 2 openings may extend for a short way into the caudal part of the cervical canal. Rarely a true double cervix or uterus didelphys may occur with a complete septum between the 2 cervical canals, each opening into its respective horn. (See Figure 120.) In rare instances in a double cervix the median septum between the 2 cervical canals may extend caudally for 4 to 6 inches, producing a doubling of the cranial portion of the vagina or a partially septate vagina.

Affected cows usually conceive and calve normally. Rarely a portion of the fetus will pass on either side of

this band of tissue and result in dystocia that is easily relieved by incising the band. Only slight bleeding will occur. Occasionally the placenta on expulsion may be caught around this band. On vaginal examination of the nonpregnant cow the finger may be passed around the band in the anterior vagina. If the median wall of the Mullerian duct persists in the caudal part of the cervix, a true double cervix or uterus didelphys will appear to be present. Passing metal catheters, probes, or narrow forceps, simultaneously into each external os will reveal whether there is a caudal band in the cervix or a true double cervix. (See Figure 123.) Rectal examination in a case of true double cervix or uterus didelphys reveals the cervix to be characteristically broader and flatter than the normal cervix. On rectal examination of cows with the band caudal to the cervix or the doubling of the external os of the cervix this structure may be felt as a thickening in that region; but more often it is considered as an ectopic or large cervical os, especially in older cows. In many cases diagnosis is not made unless a vaginal examination is performed. Many affected cows undoubtedly never have this condition diagnosed.

In cases of true uterus didelphys with a double cervix, conception may be delayed if the animal is artificially inseminated because the semen may be deposited in the cervix on the side opposite the ovary from which ovulation takes place. The author has observed several "repeat-breeder" cows with this type of uterus. Since only one horn takes part in the placentation of the fetus, abortions, premature births, retained placenta, and infertility are more common in these cows than in animals with a normal uterus and cervix. The cattle with the more extreme aberrations of development should be culled as soon as the condition is diagnosed. The offspring should not be used as breeders without recognizing that the condition is probably hereditary. The lesser abnormalities such as a band caudal to the cervix and possibly a median band in the caudal part of the cervix may be easily removed by surgery. If the band in the cervix is large and extends deep into the cervical canal it should be allowed to remain as it seldom interferes with conception or parturition.

Other anomalies of the bovine cervix may include: a short cervix with one or more transverse rings missing; a lack of development of the cervical rings; and as many as one to three percent of heifers may have a tortuous, a sharply-curved cervix or a hypertrophied transverse cervical ring so that an artificial insemination pipette may not be able to be passed.^{7,40,41} In heifers with a short or underdeveloped cervix, infertility is often due to an endometritis; while the bent, tortuous or stenotic cervix often is filled with thick mucus and infertility may be asso-

ciated with the inability of large numbers of spermatozoa to traverse the cervical canal.

In Brahman, Santa Gertrudis cattle or crossbred Brahman cattle, Beefmaster and Brangus, a marked hypertrophy of the cervix, probably genetic in origin, may commonly be noted especially in pluriparous cows. The cervix may be 10 to 15 cm. in diameter and 15 to 20 cm. or more in length and weigh up to 25 pounds at calving. This may be mistaken for a large mummified fetus on rectal examination. Because of its large size and weight the cervix pulls the vagina forward and downward, occasionally resulting in pneumovagina and a filling of the vagina with urine.^{46,71b} The cause of this hypertrophy is not known but infertility is often present in affected cattle, especially those bred artificially if intra-uterine insemination is not accomplished. Dystocia does not occur due to this hypertrophied cervix but pre- and postpartum cervicovaginal prolapse is common.^{71b} This infertility may be due to delayed involution of the pendent cervix and uterus, the difficulty of fixing the cervix with the rectal hand and passing the insemination pipette through the hypertrophied transverse rings; or be due to the lowered number of spermatozoa able to traverse the greatly hypertrophied cervix since these cows are fertile if bred naturally. The uterus is normal in size. An increase in the size of the cervix is progressive during pregnancy. Cows with hypertrophic cervixes are often culled in herds in which AI or embryo transfers (non-surgical) are performed. Herd managers and veterinarians have a definite impression that selection against bulls with large pendulous sheaths may also reduce the incidence of hyperophied cervixes in a herd.^{71b} Further study on this condition is indicated.

Infertile heifers with a double cervix, tortuous or kinked cervix or a cervix with a dilation or sacculum probably should be culled because of the possible genetic nature of the defect. However these heifers may conceive on repeated natural or artificial service even though in the latter instance the insemination pipette cannot be passed to the cranial portion of the cervix for the deposition of the semen. Careful expert manipulation of the AI pipette or the use of a metal uterine catheter of small diameter, such as the Luken's, or Woelffer catheters, may enable the operator to deposit the semen properly. These techniques are also indicated in the heifers of small breeds such as the Angus and Jersey with a normal but small, possibly juvenile cervix. The incidence of these latter cases with constriction of the cervix was reported to be about 0.1 percent.⁴⁴ In an attempt to overcome this constriction in certain heifers, some veterinarians have injected several doses of estrogens at intervals of several weeks to cause a greater growth or maturity in the gen-

ital tract and a larger cervix and cervical canal.

In most cases described above the cervical canal is not completely occluded otherwise mucometra would develop due to the inability of mucus to escape from the uterus. In rare cases when natural service and attempts at artificial insemination fail to result in conception in cattle with cervical defects, diluted or preferably undiluted semen may be injected by means of a long needle through the rectal wall, vaginal wall or ischiorectal fossa into the uterine lumen or into the region of the ovary and fimbria of the oviduct on the side of the ovary with the mature Graafian follicle.^{12,27,39,62} A small amount of air should precede the injection of semen into the uterine lumen to make certain of the location of the tip of the needle. Four of 6 heifers that had been bred repeatedly and had a tortuous, twisted cervix conceived on first service and calved normally when the semen was injected intraperitoneally adjacent to the ovarian follicle.²⁷ The prognosis for conception by this procedure to bypass a defective cervix is guarded and is probably seldom indicated or desirable.

Developmental defects of the vagina are largely limited to the partially persistent or imperforate hymen, unusual cases of obliteration of the caudal portion of the vagina,⁴⁷ and, as previously described, persistence of the median wall of the paramesonephric duct in the cranial portion of the vagina most commonly seen as a fleshy band just caudal to the external os of the cervix or as a median septum extending 3 to 6 inches caudally resulting in a septate vagina associated with a double cervix. These defects are also probably hereditary in nature although a few may be congenital. (See Figures 121, 123, 124.)

Thin fenestrated hymenal membranes or dorsal ventral bands in the region of the vestibular-vaginal border are fairly common in young heifers but are of no significance as they do not obstruct the genital passage and are easily broken at coitus.^{40,41} In cases where the hymen is imperforate the condition is also called "white heifer disease." This condition may be associated with segmental defects of the paramesonephric ducts. In one Shorthorn herd, 9 of 23 white heifers, 4 of 115 roan heifers and 1 of 94 red heifers were affected.⁵¹ The genital tract of all white Shorthorn heifer calves should be examined in a manner similar to a technique used for diagnosing freemartin calves. Shorthorn bulls known to be carriers of the gene for imperforate hymen or segmental aplasia should be bred only to dark roan or red females.^{64,65} The condition of an imperforate hymen may also be seen in Holsteins, Ayrshires, and other breeds of cattle. In these affected cattle the rest of the genital tract is often normal. The animals show regular estrous cycles and symp-

toms of estrum. The genital tract fills with mucus that is usually amber to dark reddish-brown in color due to metestrual bleeding and may vary in amount from several quarts to 2 or more gallons. Service by artificial insemination is impossible and normal or physiologic coitus by the bull is frequently followed by slight hemorrhage and straining or tenesmus. In rare cases rupture of the vaginal wall during natural service may occur with a secondary perivaginal abscess. Rupture of the hymen and a secondary pyometra may develop due to the introduction of infection into the genital tract without proper drainage being possible. If the vaginal distention becomes great, straining may result after service or even before puberty, and the distended, bulging hymen may show between the vulvar lips with each abdominal contraction or when the heifer lies down. Frequent urination may accompany the tenesmus. In areas in which rabies is endemic this disease may be confused with tenesmus seen in many rabid cattle. In a yearling Holstein heifer observed by the author the greatly distended vagina, containing about 3 to 4 gallons of mucus, caused pressure necrosis and rupture of the bladder, and death of the heifer due to peritonitis and uremia. (See Figure 124.) Another case was observed in a 7-month-old Shorthorn heifer in which an ulcer and perforation of the distended uterine horn occurred followed by peritonitis and death. In these heifers the cervix is usually somewhat dilated and the uterine horns are distended similar to a pregnancy of 60 days or more. Horns or portions of horns distended with mucus in segmental aplasia of the paramesonephric ducts may also lead to a mistaken diagnosis of pregnancy. If conception does occur with heifers having a nearly complete hymen, in some cases a dystocia may result at the time of parturition that will be relieved only by deep episiotomy incisions of the dorsolateral and lateral walls of the vulva. Bleeding may be severe. The prognosis in cases of imperforate hymen is guarded to poor.^{64,65} The author operated upon one heifer and the animal calved three times subsequently. Other veterinarians have reported similar results.

In affected heifers following the administration of epidural anesthesia the imperforate hymen may be incised over the point of the greatest bulge allowing the mucus to escape. The incision should then be carefully enlarged at right angles in 4 directions. Some veterinarians advise removing the imperforate hymen by a circular incision completely around the margin of the vulvovaginal border. If the heifer is to be kept for some time before slaughter, or if breeding is to be attempted, the vulvovaginal ring should be dilated with a speculum every 2 to 3 days for 2 weeks. Care and attention should be paid to cleanliness, to prevent the introduction of infection

resulting in pyometra or metritis. If the vestibulo-vaginal border is very small and stenosed the prognosis is poor and the animal should not be bred lest severe dystocia result at parturition. Two cases of imperforate hymen were reported that apparently healed following service by a bull.¹⁶ At the time of calving dystocia resulted requiring incising of the thickened hymen. The author observed an imperforate hymen in a Guernsey heifer that had been "inseminated" artificially on several occasions by a lay technician. The pipette had apparently been introduced through the urethra and into the bladder causing a severe pyelonephritis.

Twelve daughters of one Holstein bull that had various defects of the genital tract causing sterility was described. In 10 of these heifers the AI pipette could only be inserted 6 or 7 cm. or the length of the vestibule and the anterior portion of the vagina was distended up to 8 inches in diameter with mucus.⁴⁷ In these cases there was an obliteration of the caudal portion of the vagina, due to an incomplete recanalization of the vaginal anlage in the embryo, not just a simple imperforate hymenal membrane. About half of these cases also had a uterus unicornis.

Abnormal Wolffian or Gartner's Ducts—Abnormalities of Gartner's ducts which are vestiges of the primitive Wolffian or mesonephric ducts in the embryo are rather common in the cow (See Figure 129). It is not known whether these defects are hereditary. In hyperkeratosis due to chlorinated naphthalene poisoning the Gartner's ducts become greatly enlarged due to metaplastic changes in the epithelial linings of the ducts.⁴² Normally these ducts are located beneath the mucosa of the floor of the vagina. They are 2 in number and are usually difficult to detect. The duct may develop multiple cysts along its course toward the cervix or form a long, sometimes rather coiled, cord 0.5 to 1.5 cm. in diameter distended with fluid. In rare instances infection of the duct may occur, with small abscesses forming along its course. In one case calculi were found.⁷⁰ The ducts may be incised freely, if necessary, to correct these abnormalities but in most cases they are ignored as they do not affect fertility. There may be present in rare cases a cul-de-sac extending forward 5 to 7 cm on either side of the urethral opening.⁷⁰ This may be small and admit one finger or less; or it may be large admitting 3 to 4 fingers. This cul-de-sac represents an abnormally large terminus of Gartner's duct and may interfere with coitus.

Rectovaginal Constriction (RVC), Anovestibular Stenosis or an infantile, hypoplastic, small vulva was described in 1940 affecting the daughters of one Jersey bull. In 7 daughters the vulva was so small that at parturition a drastic episiotomy operation was required to

enlarge it so that the fetus could be removed. In one case cesarean section was necessary. Recently this condition has been carefully described as a simple autosomal recessive defect of Jersey cattle resulting in a severe stenosis or constriction of the anus and vestibule. Copulation and defecation can occur but rectal examinations in both bulls and cows and parturition in cows cannot occur and severe dystocia results.^{36b,c,43a} The strong band of connective tissue causing the stenosis or constriction encircles both the anus and vestibule.

Miscellaneous Hereditary Forms of Infertility in Cows

Freemartins, or sterile heifers born cotwin to a bull, occur in about 90 percent of the bovine twin births of opposite sexes. Twinning has been discussed and shown previously to be greatly influenced by heredity. This was reviewed and the hereditary aspects of this problem in cattle are fairly well understood (See Freemartinism).¹⁸

Cytogenetics in cattle and the inheritance of related defects has been reviewed.^{11,22} Fairly extensive studies have been conducted on freemartinism and the 1/29 Robertsonian or centric fusion translocation. A few XO and XXX female cattle have been described.^{11,37} Small ovaries and anestrus were observed in several of these heifers. The 1/29 translocation, which is believed to be an ancient mutation, is widely distributed in about 30 European breeds, especially the beef breeds of cattle. The incidence in these breeds varies from 0.5 to 20 percent.²² It has been reported in the U.S.A. The reduced fertility of heterozygous bulls and cows is well-established. Elimination of heterozygous A.I. bulls raised the

fertility rates in cattle bred artificially. Although not proven there is apparently a 3 to 4.5 percent embryonic death loss between 30 and 90 days of gestation in cows bred to heterozygous bulls.²² Cattle populations using artificial insemination should conduct routine cytogenetic investigations of their donor bulls. It would be desirable to conduct widespread cytogenetic surveys in cattle as has been done in humans in which more than 50 percent of spontaneous early abortions of human embryos are chromosomally aberrant.¹¹ About 5 of 1000 liveborn babies have chromosomal defects.

Intersexes or hermaphrodites are observed occasionally in cattle. There are no reports on cattle that this condition is due to heredity, as in goats, swine and possibly sheep.

Nymphomania or cystic ovaries is influenced by hereditary factors, as indicated previously. This hereditary predisposition toward cystic ovaries is closely associated with high levels of milk production but not to total fat or fat percentage. The relationship was a physiological-hormonal one and that genetic correlation between high milk yield and cystic ovaries had not been proved. Cystic ovaries are more frequent in daughters of cows having cystic ovaries and in daughters of certain bulls. (See Cystic Ovaries.)

Jersey and Holstein female sterility observed in heifers was reported.^{20,21,29} This data indicated that random inbreeding of selected sires and dams showed they carried autosomal recessive genes for female sterility as based on failures of heifers to conceive. The Jerseys showed regular estrous cycles whereas the Holsteins exhibited irregular estrous periods and usually anestrus. It is unfortunate that careful anatomical, histological, and bacteriological examinations of the genital tracts, ovaries, and pituitaries of these sterile heifers were not performed.

In Sweden the percent of heifers pregnant on first insemination is 6 percent higher in the SKB or Highland breed, despite the problem of gonadal hypoplasia, than the SRB breed. These breed differences are genetically conditioned.¹ In the U.S.A. the Guernsey breed is generally considered to have lower fertility than the Holstein or Jersey breeds based on nonreturn rates to artificial insemination. The pregnancy rate in over 10,000 beef cows was studied over a 5-year period. The pregnancy rate for Zebu purebreds or crosses, Brahman or Santa Gertrudis were definitely lower than the British breeds, Hereford and Angus, 57 vs 72.5 percent. Further study is desirable and needed.⁴³

Sexual behavior in the cow has been shown to be affected by heredity.⁷² The estrous cycles in an individual cow tend to be of similar length. Variations in cycle length were much more common between cows than

Figure 129. Cystic Gartner's or Mesonephric Ducts in the Floor of the Vagina. (Courtesy K. McEntee.)

within individual cows. When normal cycles of 18 to 24 days are considered there is a great tendency in each cow to maintain a consistent cycle length. In individual cows there was a definite tendency of the interval between parturition and the first estrus to remain similar after each parturition.^{48,49} Daughters had similar records to their dams, and daughters by the same bull also tended to be similar. The heritability for the time at which estrus occurs after calving was about 30 percent.

"Weak" symptoms of estrus were one of the most common or troublesome problems in artificial insemination. These "weak" or nearly "silent" estrous periods were observed most commonly in certain breeds of cattle such as the Swedish Red Cattle, while other breeds such as the Simenthaler, Telmark, and Swedish Highland cattle exhibited intense symptoms of estrus even in an unfavorable environment.^{30,32} The genetic difference in potency and strength of signs of estrus between dairy, beef and other breeds was noted.⁵³ This difference between breeds has not been as noticeable in the United States. It has been observed by the author as occurring in certain families of Guernsey and Holstein cattle, most commonly in the former breed. Repeat breeding is more common in cows with a weak estrus because of the difficulty of timing artificial insemination in relation to ovulation. When 34,063 cows with "weak" heat signs, as determined by the inseminator and the herdsman, were compared with 263,906 cows with normal heat signs and inseminations were made early, intermediate or late in the estrous period, the percent pregnant were 39.5, 45.6 and 50.2 and 55.3, 57.9 and 55.1, respectively. Thus cows with "weak" heats had a 10 percent lower pregnancy rate possibly due to delayed ovulation since the least difference occurred in the cows bred late in the estrous period.¹ A study of 29 bulls used artificially with regard to the heat symptoms in their daughters showed this trait to be partially hereditary.⁵⁴ Cows conceiving on first service had stronger heat signs than those cows failing to conceive.

Inbreeding and fertility—Several references were cited to show that inbreeding generally may result in reduced fertility, but that the degree of the infertility depends on the particular bull used. The effect of inbreeding on fertility is uniquely the property of a particular line or family.²⁸ Inbred lines of cattle usually experience reproductive trouble but if the line is not eliminated by its deleterious genes, as often happens, then fertility may remain fairly satisfactory. Inbreeding of the zygote and dam, and homozygosity for blood group factors greatly increased embryonic mortality.^{3,38} Lower conception rates occurred when the potential embryo was inbred rather than outbred and pregnancy loss was greater when the

dam was inbred rather than outbred. Heterosis improved fertility.

Production and fertility. On the basis of relatively small numbers, high-producing cows were no more often disposed of as infertile than were low-producing cows.⁷² The relationship between high-butter-fat yield and ovarian hypoplasia and high milk yield and cystic ovaries has previously been mentioned. Probably more study on this phase of fertility from the hereditary aspect is indicated but at present most data indicates that milk production is not associated with infertility.

The inheritance of normal fertility or lowered fertility may be studied from a number of aspects, including inheritance from bulls to their daughters, from dams to their daughters, from bulls to bulls, and from dams to bulls. Only the first 2 aspects have been studied. It has been noted that workers in estimating fertility have difficulty in obtaining a standard or means of measuring fertility.^{15,72} This was not a problem when specific genes were involved as in ovarian hypoplasia and segmental aplasia of the Mullerian ducts, but it is a great problem when measuring reduced or subfertility. The conception rate is a good measure but does not take into consideration those animals that fail to show regular estrus. It excludes barren heifers or cows, if figures are obtained from calving dates. If the figures include animals that abort, the results may be biased because some less-valuable animals may be sold as sterile after several breedings while more valuable animals may be retained and eventually conceive. Calving intervals may be used to measure fertility but they include only animals that have calved, and may be biased by a planned extension of calving intervals in cases of persistent or heavy producers. Completely sterile animals may be studied separately but this excludes the large group exhibiting reduced fertility. For these reasons most studies on infertility are not comprehensive. Some investigations using certain indices show that genetic factors are unimportant, but nearly all can be questioned on the basis of bias in the material. Similarly many investigations show genetic factors to be important but these can usually be criticized because they deal with only one breed or herd or family and one particular character. Thus care should be taken to avoid generalizations on the basis of only a few studies. Possibly the problems of inheritance of fertility in cattle cannot be arrived at until the problem of disease has been adequately controlled.

Research on the relative fertility of the daughters of different bulls has been summarized.^{4,18,48,49,53,68,72} There appeared to be a difference in the fertility of daughters of various bulls. Other studies showed that on the basis of nonreturns to first service and calving intervals the

difference in fertility between daughters of various sires was small.⁶ Thus preference in breeding should be given to those sires whose daughters were of high fertility. However, some inbreeding studies and studies in which certain sires transmitted a specific defect must be considered. Sex-linked genes for infertility in daughters of certain bulls was reported.^{20,29}

The inheritance of fertility from female to female, as shown by many workers has been studied from the standpoint of the recurrence of any given pattern of breeding ability.^{15,18,53,72} Most workers have concluded that the condition of "repeat-breeding" is not very permanent.^{48,49,68} However, there is a slight tendency to repeat the same breeding pattern from one service period to the next. In studying cow families, considerable differences in reproductive efficiency as measured by calving intervals and conception rates were reported.⁶⁸ Other workers reported little difference between cow families and noted that cows in cow families are not as a rule closely related.⁷² Thus in respect to cow families the inheritance of infertility based on a number of studies is contradictory and unpredictable. In studying **dam-daughter comparisons** the heritability of conception rate is not high and is probably under 10 percent.⁷² **Herd differences in fertility**, even though genetic composition varied greatly, were affected little or not at all by genetic differences.^{48,49,68,72} Since the genetic composition of a herd does not vary much from year to year and fertility may vary markedly, it is rather obvious that most of the herd differences in fertility are due to environmental rather than to genetic causes.

From the above studies about 80 percent of the variation in normal fertility in herds is due to environmental causes and that of the remaining 20 percent about one-half would appear to be due to various additive genetic effects.⁷² Selection for fertility cannot be very effective.^{6,8,15} Automatic natural selection against infertility is going on constantly. It is possible that epistatic effects are responsible for much of the permanent differences between cows. If this is true, cross breeding to produce heterosis is a better genetic method than is selection for improving fertility.⁷² It may be true that specific breeds adapted to certain environments would be necessary to obtain maximum fertility. In either case environmental influences would still make genetic progress very slow. Little attention need be paid to selective breeding as an effective means of raising fertility but should be considered constantly when advising farmers on aspects of inbreeding or on definite evidences of a single gene predisposing to or causing sterility. There is a great natural prolificacy in the dairy breeds.⁷² In the Dexter breed, despite the death of 25 percent of the bulldog fetuses,

and a ban on breeding another 25 percent of the Kerry type heifers, the breed can still continue to expand a little. It was concluded that although sterility is economically costly it would have to be very severe to cause a reduction in a breed or herd due to lack of replacements.

Other Pathological Causes for Bovine Infertility

The pathological causes of infertility or sterility due to genetic or congenital defects, hormonal disturbances, and venereal infections have been discussed. Most of the following pathological conditions are the result of trauma or infection or both. They are acquired most commonly at or after parturition, producing lesions that may interfere with the future fertility of the cow. Occasionally tumors of the genital organs may be found. The gross abnormalities and pathology of the bovine genital tract have been surveyed and reviewed by various authors studying clinical findings and slaughter house material.^{10,40,42,46,56a,64,72,77,86,94} These authors attempted to evaluate their findings with regard to infertility, sterility and repeat breeding.

Ovary

Most of the ovarian pathology has been previously considered under the endocrine and hereditary abnormalities of the reproductive tract. However; a few conditions remain to be described.

Ovarian Tumors in the cow have been described fairly often but they are uncommon in occurrence.^{54,67a} Two malignant tumors of the ovary of the cow, an angiosarcoma and a carcinoma were reported.⁹² A fibroma of cow's ovary was described.²² Seven carcinomas of the ovary have been described.^{21,90} In 6,286 bovine genital tracts examined there were 13 ovarian tumors: 3 were carcinomas, 3 granulosa cell tumors, a sarcoma, a fibrosarcoma, and 5 undiagnosed.⁴⁰ In rare cases primary tumors may metastasize to the ovary. Other ovarian tu-

mors include: dysgerminoma, mucinous adenocarcinoma, cystadenoma, arrhenoblastoma, vascular hamartoma, luteoma, dermoid cyst or teratoma containing hair, theca-cell and mixed theca-cell-granulosa cell and lymphosarcoma.^{2,5,11,46,48,54,63,67a,84,88} Thirteen ovarian teratomas were found in 4000 grade Zebu genital tracts recovered from an abattoir. These were cyst-like structures lined with stratified, keratinizing epithelium and respiratory epithelium. The affected ovaries varied in size from slightly enlarged to 75 gms. Seven of the thirteen cows with ovarian teratomas were pregnant.⁴⁵ In cases of cystadenomas, the tumor spread by contact to the peritoneum resulting in ascites.^{5,84} The author reported on two granulosa cell tumors, one in a 15-month-old Guernsey heifer, the other in a 14-year-old Angus cow. He cited references in the literature to 7 other reports on granulosa cell tumor of the bovine ovary⁷³ (see Figure 130). In 3 cases in which the breeding history was known, the animals showed symptoms of chronic nymphomania with frequent prolonged symptoms of estrus and relaxation of the pelvic ligaments. Two of these cases were heifers in which udder development and lactation occurred. A similar case was described in which the cystic fluid in the tumor contained progesterone and estradiol in a ratio of 6:1 parts, respectively.⁸¹ Continuous estrus was explained on the basis of progesterone potentiating the action of the estrogen. An aged Holstein cow exhibited nymphomania, masculinization and anestrus. A 20 lb. granulosa tumor was removed. Cysts on the other ovary occurred but following treatment the cow conceived. Prior to surgery plasma estrogens and testosterone were elevated to 36 to 75 pg/ml and 54 to 130 pg/ml respectively but progesterone levels were low <0.5 ng/ml.⁴ In other cases where the history was known either anestrus or no observable symptoms were noted, and the cows were pregnant or had normal estrous cycles. Granulosa cell tumors may be either solid and yellow in color, or filled with multiple cysts 1 to 7.5 cm in diameter or be composed of a single large cyst. Any cyst larger than a grapefruit, 10 cm., should be suspected of being a granulosa cell tumor. The weight and size of a large ovarian tumor tends to drag the ovary downward and forward into the abdominal cavity. The ovarian artery to large tumors is likely to be increased in diameter. Sometimes it is necessary to place forceps on the cervix and pull the uterus and ovary upward and backward in order to palpate the tumor. Granulosa cell tumors may affect cattle of all ages from calves to old cows.³⁶ Seventeen of 18 bovine ovarian neoplasms studied were granulosa cell tumors.⁴⁸ Granulosa cell tumors were most commonly observed in Guernsey cows. In 4 cases the tumors were found in related animals. In one cow, with a failure of

Figure 130. Bilateral Granulosa Cell Tumors of the Ovaries of a Cow. (The tumor on the left ovary is solid and lobulated and on the right the tumor is cystic. The uterine wall is flaccid and atrophied due to prolonged steroid stimulation.)

estrus for 6 months, mucometra developed. Three of the tumors were bilateral and only 1 was malignant (see Figure 130). The size varied from microscopic growths to tumors weighing over 25 lbs. The granulosa cell tumor is the most common one in cattle. It may rarely be malignant and spread to adjacent peritoneal surfaces.^{89b} It is usually unilateral. The earlier reported cases of some of the ovarian carcinomas in the cow may have been granulosa cell tumors. Some of these tumors produce estrogen, as shown by the symptoms of nymphomania, relaxation of pelvic ligaments, and lactation in heifers. In rare cases large cysts containing 1 to 2 or more quarts of fluid may be associated with a granulosa cell tumor of the ovary. In the cases observed by the author and his associates these very large cysts contain fluid with no estrogen content on assay or as shown by physical change in the cow. Cows can conceive with unilateral granulosa cell tumors if little or no steroid hormone is elaborated by the tumor. There are very few reports on the successful removal of these tumors, with the cow conceiving following treatment.

Ovaritis, Inflammation or Infection of the Ovary, may occur secondary to trauma, to infection from the uterus that passes through the uterine tubes, or by extension through the uterine walls causing a peritonitis and perimetritis. Trauma may frequently be produced by rough handling or massage of the ovary. Scars, usually starshaped or transverse, are common in the ovaries of

the cows where corpora lutea have been enucleated or cysts ruptured by manual manipulation per rectum. Bleeding may occur as previously described and a hematoma form around the ovary; subsequently this hematoma organizes and produces extensive adhesions. (See Figure 131.) Inflammation of the ovary or oophoritis will be considered more fully under the discussion of lesions of the uterine tube especially the distal, fimbriated end, or pavilion. Rarely abscessation of the ovary may follow removal of the corpus luteum in cows with pyometra.⁴⁵ Serosal granulomas may be present on the ovary in peritoneal tuberculosis. Particularly in heifers, small tags of fibrin from bleeding after ovulation are frequently observed attached to the ovary at the site of a previous ovulation or on the medial attachment of the ovary to the uteroovarian ligament. These do not interfere with subsequent ovulations or conceptions.

Parovarian cysts are occasionally found in the broad ligament of the cow around the ovary and uterine tube. These cysts are vestiges of the Wolffian or mesonephric duct system or the paramesonephric or Mullerian duct system and may be from 1 to 5 cm. or more in diameter. They are usually round or oval in shape. Most para-

Figure 131. Bilateral Hydrosalpinges with Adhesions Surrounding the Left Ovary of a Sterile Cow.

mesonephric duct cysts are located near or in the fimbria of the uterine tube. Germinal inclusion or "serosal" cysts about 0.2 to 0.5 cm in diameter may rarely be noted on the surface of the ovary. Occasionally the corpus luteum is black in color, **corpus nigrum**. This is apparently of no significance, as these corpora lutea apparently function normally. In rare instances the **tubules of the rete ovarii** may be confused with a neoplastic growth.⁴⁸ The **rete ovarii**, when found in the cow is a network arrangement of medullary tubules found near the mesovarium. Parovarian cysts are less common in the cow than in the bitch, ewe and mare.

Uterine Tube (Oviduct)

Disease of the uterine tubes or Fallopian tubes and ovarian bursae of cattle occurs more commonly than is generally assumed or diagnosed on rectal palpation. Pathology of the ovary and oviduct has been reviewed.⁵⁴ Only abnormalities associated with tubal enlargements and adhesions are detectable on rectal palpation. The incidence of these lesions affecting the uterine tubes should decrease in the future with the use of prostaglandins to cause involution of the corpora lutea rather than manual removal of the corpora lutea.

These many workers and others^{13,14} showed the incidence of disease of the bovine uterine tube and ovarian

bursae to be about 10 percent. Of those 25 percent may be bilateral lesions and interfere with passage of the spermatozoa, with ovulation, and with passage of the ova to the uterus resulting in infertility or sterility. Clinical examinations in over 20,000 cows revealed an incidence of uterine tubal disease of 1.3 percent including 0.2 percent of hydrosalpinx.⁹⁴ (See Table 20.)

The etiological factors causing these lesions are varied. Many lesions are secondary to an ascending infection from the uterus following abortion, retained placenta, septic metritis, and pyometra. Septic metritis with a perimetritis may cause extensive adhesions of the uterine tubes, ovaries, and uterus to the adjacent structures and organs. Abortions, retained placenta, and dystocia with forced extraction frequently lead to salpingo-ovarian-bursal changes.⁶⁷ In certain countries tuberculosis of the uterine tube is not an uncommon cause of lesions.

Anomalies such as segmental aplasia of the paramesonephric duct rarely involve the uterine tube. In rare instances periovarian cysts may obstruct the uterine tube; several cases have been described.^{46,56} (See the previous section on genetic defects of the reproductive tract.) Tumors of the oviduct have not been reported.

Diseases of the uterine tube are more common in the cow than in the mare, possibly because in the latter the uterine tube opens on a muscular papilla in the uterus. In the cow the uterine horns become smaller and blend into the uterine tube. A variety of infectious organisms

²An additional 5.8 percent had microscopic lesions of interstitial salpingitis.

³These were clinical not slaughter cases.

⁴Only 4.8 percent detected by rectal palpation.

⁵These were heifers (nullipara).

⁶Reference in first edition (1956).

may occasionally be found in the infected tube that are similar to those found in the infected uterus; these include streptococci, campylobacter, staphylococci, *E. coli*, *C. pyogenes*, ureaplasmas, mycoplasma, *Hemophilus somnus*, and other ubiquitous "wound" or lower genital tract infections. It is doubtful that coital infections result in salpingitis except possibly as previously described in "epivag," vibriosis, and myco- and ureaplasmosis.^{18a,b,c,41a} Cysts and nodules were found in the oviduct in 87 cases but these apparently were not significant inasmuch as they failed to prevent the passage of the ovum.⁴²

All authors indicated that sterility treatment was a common cause for lesions of the oviduct and bursa. Of these sterility treatments the most common cause of lesions was enucleation of the corpus luteum. The frequency and severity of bleeding due to removal of the corpus luteum has been cited. The majority of the lesions observed were of the descending type due to hemorrhages occurring at ovulation or manual ovarian treatment with removal of the corpus luteum, and the presence of the corpus luteum and hematomas in the bursa or adherent to some of the pelvic organs.⁵⁶ These hematomas organize and produce moderate to extensive adhesions. All serious cases with complete obstruction of the tube resulting in hydrosalpinx were due to extensive hemorrhage. Most authors have noted mild fibrous adhesions between the ovaries and the bursae of heifers

Figure 132. Ovarian Adhesions and Hydrosalpinx in a Cow. (Courtesy K. McEntee.)

Figure 133. Intramucosal Cysts or Cysts of the Diverticula of the Bovine Uterine Tube. (Courtesy K. McEntee.)

or cows that have never been examined or had an infected uterus. These mild adhesions probably follow the slight bleeding occurring at ovulation. Severe trauma caused by manual rupture of thick-walled follicular cysts, luteal cysts or cystic corpora lutea may result in adhesions, although in the former usually little bleeding occurs. Some authors have reported adhesions following uterine irrigation with or without perforation of the uterus.

The pathologic lesions may vary from a few slight fibrous threads between the bursa and ovary, partial adhesion of the edge of the bursa to the ovary, roughness of the internal wall of the bursa, shallow or narrow or closed bursa, to extensive ovario-bursal lesions, cysts of the bursa or ventricle, hydrosalpinx, and pyosalpinx. The histologic changes in the uterine tube due to chronic salpingitis and other changes have been described.^{42,46} Hydrosalpinx has been observed secondary to anomalies of the reproductive tract, such as segmental aplasia of the paramesonephric duct. It may occur secondary to adhesions of either or both the distal or proximal ends of the uterine tube (See Figure 131 and 132). On postmortem examination if the adhesion is near the distal end of the uterine tube, the mucus in the tube may be pressed into the uterus. The oviduct usually becomes distended to a diameter of 0.5 to 1 cm. or more with clear watery mucus and it is elongated, coiled, thin-walled, and fluctuating on palpation. Often a hard fibrous mass may be

palpated in the fimbrial area of the uterine tube. Hydrosalpinx may be observed in heifers; in these cases anomalies should be suspected. **Pyosalpinx** is less common than hydrosalpinx and usually occurs following severe uterine infections. Pyosalpinx is commonly associated with severe adhesions of the mesosalpinx and mesovarium. In pyosalpinx extensive perimetritis is not unusual. Pyosalpinx may follow the removal of a retained corpus luteum or the injection of large, slowly absorbed doses of estrogens for the treatment of pyometra. In rare instances the fimbrial end or pavilion of the uterine tube becomes attached around the edges and a large abscess or cyst may form between the bursa or pavilion and the ovary.

Mild cases of salpingitis have been described and found on histologic section but the oviduct is so small and the wall so thick that diagnosis of these minor cases of salpingitis cannot be made antemortem. Intramucosal cysts, cysts of the diverticula, (See Figure 133) have been observed in cows with a history of metritis and repeat breeding^{42,46} (See Figure 133). These may be seen grossly but cannot be palpated per rectum. These minute cysts result from a salpingitis where the epithelium of the free edges of the mucosal folds is denuded and these folds fuse. These cysts apparently do not prevent conception.

Diagnosis—The diagnosis of pathology of the uterine tube and ovarian bursa is difficult in most of the mild lesions. In severe, extensive lesions with marked adhesions involving the oviduct, ovary and adjacent structures the diagnosis is usually easily made. In the cow, cases of perimetritis and ovaritis, hydrosalpinx, pyosalpinx, and abscess or cyst in the ovarian bursa may be diagnosed by palpation per rectum. In hydrosalpinx the large, thin-walled, usually coiled and fluctuating uterine tube as well as the thickened area of adhesions causing the obstruction, can in most cases be felt by careful palpation (See Figures 131 and 132). In rare cases adhesions around the ovary may form as in pyosalpinx or a localized peritonitis, and the bursa or pavilion of the uterine tube may fill with clear mucus and resemble an abscess secondary to a suppurative pavilionitis with adhesions. When many severe adhesions are present it may be impossible to differentiate pyosalpinx or hydrosalpinx except on the basis of the history of the cow. In most cases adhesions resulting in hydrosalpinx are less pronounced than in pyosalpinx. Pyosalpinx is much less common than hydrosalpinx. In the milder cases of ovario-bursal adhesions 2 or 3 fingers may be inserted into the ovarian bursa and with the thumb placed on the outside of the bursa, the uterine tube and ovarian bursa can be palpated by rolling them between the fingers and thumb. Rectal palpation of the tube may also be per-

formed by carefully palpating the uterine horn to its apex and on to the oviduct to the ovarian bursa. Sometimes, working bimanually, the ovary is grasped with the vaginal hand the uterine tube and mesosalpinx are stretched caudally, making palpation easier. Palpation of the uterine tube per rectum requires experience and care. As noted from the references previously cited, only about 1/3 to 1/2 of the pathologic lesions of the oviduct and bursa are felt on palpation as compared to those observed on postmortem examination. The more frequent occurrence of pathology involving the right uterine tube and ovary is considered to be due to the fact that the right ovary is functionally more active. A greater number of slight adhesions from ovulations would be found between the bursa and ovary. Peritoneoscopy and visualization of the ovaries and uterine tube in the cow may be of diagnostic assistance in some cases.^{49,50}

The Rubin insufflation apparatus used widely in humans has been experimentally used in cows.^{56,92} After the cervix had been sealed, carbon dioxide was passed into the uterus under pressures of 60 to 100 mm. of Hg. If the uterine tubes were normal and open the pressure gradually fell to 40 to 60 mm. of Hg. This indicated that one or both uterine tubes were open. The escaping gas could usually be felt on rectal examination at the internal os of the oviduct or heard on auscultation as a gurgling or bubbling sound. The uterine tubes were distended up to 3 mm. in diameter and were firm. If the pressure failed to drop, this indicated that both tubes were obstructed. If it dropped rapidly this may signify that the air has penetrated the mucous membrane. Inserting a stethoscope into the rectum was recommended in order to hear the escape of the gas. Insufflation is not satisfactory at the time of estrum or immediately following estrum.⁵⁶ If this method is used during the diestrous stage of the cycle the danger of causing uterine infection must be considered. Presently there are no practical tests for obstructed uterine tubes in cows.

Prognosis. Generally this is considered guarded to poor in most severe cases of pathology of the uterine tube or bursa. Of 142 cases examined and diagnosed, 33 had bilateral lesions; of these, 30 were incurable and 3 eventually curable; of 109 which had unilateral lesions, 62 were curable, 36 eventually curable, and 11 probably curable.^{88b} In 84 cases with diffuse or extensive perimetritis, ovarian parametritis, caudal parametritis, hydrosalpinx, periophoritis, and closed bursae in which only 11 were bilateral, the conception rates were 13 to 40 percent.⁶⁷ In 349 cases in which 72 had bilateral involvement with mild lesions such as a narrow or shallow bursae, slight adhesions of the bursal borders, rough internal wall of the bursa, or thin threads of fibrous connective

tissue across the bursa, 63 to 79 percent of the cows conceived. In these cases about 75 to 80 percent were mild and the lesions noted had only moderate to slight adverse affects on the conception rate.⁶⁷ In 69 cases of cysts and nodules only 3 cases had complete obstruction of the tube.⁵⁶ Some quite strong adhesions were noted in pregnant cows. The prognosis in bilateral pyosalpinx and hydrosalpinx is hopeless. With conservative treatment and the passage of time, some acute conditions may markedly improve, with absorption of many adhesions, fibrin, and blood clots. Depending on the severity of the condition, the prognosis in chronic cases should be guarded to poor.

Treatment. The treatment of these conditions is in general not very satisfactory or specific. Some authors recommend the manual breaking-down of the chronic fine adhesions, while a few condemn this procedure as certain to produce greater adhesions. Treatment of pyometra or endometritis if present may prove helpful. Removal of a unilateral affected ovary and oviduct is of questionable value but it might improve the conception rate by having all subsequent ovulations be fertile ones.

Most authors do not approve of Rubin's insufflation method or similar methods for the treatment of cows because of the danger of rupturing the uterus and causing peritonitis especially if infection is present.

In general, conservative treatment such as mild, gentle massage of the uterus, possibly mild antibiotic douches or infusions of the uterus might be indicated together with a long period of sexual rest. In the mild salpingitis cases associated with an endometritis the former condition will usually correct itself spontaneously as the uterine endometrium returns to normal. Possibly systemic antibiotic treatment might be indicated in some cases.

The prevention of the pathology of the uterine tube, ovarian bursa, and ovary is more important than treatment. In treating retained placenta, metritis, or pyometra the use of large amounts of liquid, high pressures, and strong solutions should be avoided. Removal of the corpora lutea should be performed seldom, and only as a last resort. With the availability of the prostaglandins for luteolysis, manual removal of the corpus luteum should probably not be performed. Excessive, rough manipulation of the ovaries and oviducts should always be avoided, because once adhesions are produced they seldom disappear and may result in sterility and in the permanent loss of function of one or both ovaries. In areas where vigorous manipulation of the ovary and removal of cysts or corpora lutea are seldom performed and where conservative treatments of uterine infections is the practice, the incidence of diseases of the uterine tube have dropped markedly.

Uterus

Uterine pathology has been reported for many years as a cause of sterility and infertility.^{1,67,92} In recent years more work has been done and data are beginning to accumulate to indicate that the conclusions of these authors, largely based on clinical observations, were correct. These recent findings are substantiated by research into the bacterial causes of uterine infections and histologic sections of diseased uteri. This section of the chapter will consider uterine pathology including: endometritis, pyometra, mucometra, perimetritis, uterine abscess or abscess of the uterine wall, sclerotic metritis and uterine tumors. Previous sections of this text have covered acute or septic metritis, abortions, retained placenta, and postpartum metritis. A significant proportion of failures of conception have been ascribed to varying degrees of chronic metritis or endometritis. However it is important to note that the uterus and uterine tubes of the cow having estrous cycles have the ability to effectively eliminate specific or nonspecific infections within a varying period of time.

Endometritis due to uterine infection and secondary inflammation has been shown^{1,6,15,18a,b,c,27,30,31,34,37,41a,52,67,92} to be a common cause for infertility in cattle. Vibriosis provided the incentive and furthered this study (See Vibriosis and Trichomoniasis).

Etiology. All workers have shown that metritis and endometritis are likely to follow abnormal parturitions such as abortions, retained placenta, premature births, twin births, dystocia, septic metritis, postpartum metritis, pyometra and traumatic lesions or lacerations of the uterus, cervix, vagina or vulva. These factors are generally associated with a delayed involution of the uterus, chronic uterine discharge, slow recovery of the uterine endometrium, and delayed conception often associated with an increased number of services. In cows uterine infections and inflammations interfering with conception are likely to arise during even a normal calving period. As noted in Chapter VI and XI many bovine uteri become infected at the time of parturition and shortly thereafter. In the normal cow this infection is eliminated rapidly most commonly at the first or second estrus or ovulatory period.

Three reports have shown that, 90 to 100 percent of dairy cows have a uterine infection the first 10 to 15 days postpartum.^{27,30,31,93} This percentage declines to 30 percent by 30 to 40 days and to 10 to 20 percent by 60 days postpartum. These early uterine infections are usually a mixed culture of streptococci, staphylococci, *E. coli*, *Proteus*, *Pseudomonas*, *Corynebacterium pyogenes* mycoplasma, ureaplasma, *Hemophilus somnus*,^{41a} and others. Fertility was not affected by the mixed culture of

uterine flora or the endometritis present the first several weeks postpartum. However if *C. pyogenes* was present in the uterus after day 21 postpartum, especially if the infection persisted beyond day 50 with a delayed uterine involution, endometritis was severe and conception was usually delayed.³⁰ Transient infections of *C. pyogenes* during uterine involution did not affect fertility but transient *C. pyogenes* infections at a later period reduced fertility for one to three services whereas persistent *C. pyogenes* infections caused severe chronic endometritis or pyometra, and anestrus. Most cows that develop advanced endometritis and pyometra could be detected by rectal and more frequently vaginal examination before 42 days postpartum. Thus early and vigorous therapy to correct the endometritis could be instituted avoiding prolonged infections with severe endometrial lesions, pyometra and sterility.

Severe stretching or trauma to the vulva may occasionally cause "windsucking" or pneumovagina in cows. This is observed most often in older cows with a sunken anus and a nearly horizontal vulva (See Figure 135). The vulvar lips are often thin and atrophic. The vagina balloons, and air, feces, and urine (urovagina) may be drawn into the cranial portion of the vagina. In rare cases with chronic cervicitis or during estrum the uterus may become distended with air, causing a persistent endometritis as well as a cervicitis and vaginitis. The condition is similar to pneumovagina or urovagina in the mare and failure of conception, or "repeat breeding," is a frequent sequella.

Chronic uterine catarrh or endometritis may occur in cows and heifers following coitus. The importance and severity of trichomoniasis, vibriosis, mycoplasmosis ureaplasmosis and brucellosis have been discussed. The penetration of the uterine glands by *C. fetus* organisms has been well-described. For successful breeding results it is essential that these diseases be kept under control. The sheath of the bull usually contains many organisms of different types, and even though the introduction of antibiotics into the extended semen has proved helpful in controlling these organisms, it is of vital importance that the semen be collected in a clean manner, to prevent the possible introduction of many organisms into the cervix and uterus at the time of insemination. Insemination should be performed in a clean, sanitary manner and the semen deposited only in the cervix as infection may be introduced and established more readily by the intra-uterine deposition of semen. In ureaplasmosis and mycoplasmosis where ureaplasma and mycoplasma are often present in the caudal portions of the genital, some inseminators are using a sterile plastic tube introduced into the vagina and through which the AI pipette is passed to reduce the possibility of these organisms being intro-

duced into the uterus. Bulls with acute seminovesiculitis should not be used either naturally or artificially. In cattle the fairly tight, firm, mucus-filled cervix that assists in preventing infections from entering the uterus has great protective value. Besides the natural defenses against infection at the time of estrum in the cow, these factors help overcome the massive infection often introduced into the vulva and vagina at the time of natural service when little or no breeding hygiene is practiced. The more common streptococci, staphylococci, *C. pyogenes*, *Ps. aeruginosa*, *B. coli*, ureaplasma, mycoplasma and others may be secondary or accidental infections or contaminants. The severity of the endometritis is related to the type of organisms present. *C. pyogenes*, especially if it persists for long periods,^{27,30,85} causes severe endometritis as does *Br. abortus*.^{6,37} Whereas the other nonspecific organisms, or transient *C. pyogenes* infections cause no or only mild endometritis.^{27,30,85} Hemolytic types are generally more pathogenic than are nonhemolytic types. Since a variety of organisms may be introduced into the uterus or genital tract by various instruments or therapeutic practices, the inseminator and the veterinarian should use care, skill and cleanliness to prevent the possible introduction of infection whenever he inseminates, invades, examines, or treats the genital tract, especially the uterus. It is generally considered that unless much mucopurulent material is in the uterus probably fertilization would not be greatly affected but that normal development and attachment of the fertilized ovum in the uterus might be prevented, possibly temporarily by a variety of infectious organisms.

An extensive review of bacteriological studies of the normal nongravid and gravid bovine uteri over the past 60 years concluded that 20 to 40 percent of the non-gravid uteri contained bacteria, largely micrococci, streptococci, and occasionally *E. coli* and others.³⁴ The studies on the normal gravid uteri were less conclusive as positive bacterial cultures, with organisms similar to those found in the nongravid uteri varied from 2.5 to 88.7 percent. The uterine microflora of subfertile or sterile cattle was also reviewed and investigated. Although this review indicated that nonspecific infections of micrococci, streptococci, *C. pyogenes*, *Pseudomonas aeruginosa* and others may be responsible for bovine reproductive failures by causing metritis or endometritis in from 5 to 55 percent of cows, they played only a minor role in reproductive failures in "symptomless repeat breeders." This was indirectly confirmed by field trials with a wide variety of antibiotic and antiseptic preparations infused into the uteri of repeat breeders without a significant improvement in conception rates from control cattle. **Endometritis was shown not to be a major cause of reproductive failure in symptomless subfer-**

tile cows.³⁴ Thus one can conclude that if an endometritis is present due to a variety of possible organisms including viruses that infertility will occur in direct relationship to the severity of the endometrial lesions and the pathogenicity of the organism. If an endometritis is not present, a few nonspecific contaminating organisms present in the uterus, or introduced into the uterus by their presence in semen or on the intrauterine pipette will not have an adverse effect on fertility.

Biopsy of the uterine endometrium and submucosa found 70 percent of 110 sterile cows showing some degree of endometritis. Of these 110 cows 45, or 41 percent, had lesions sufficiently severe to probably prevent conception at the time the biopsies were taken.⁶ Of 82 sterile cows whose uteri were biopsied and cultured, 38, or 46 percent, had both infectious organisms and an endometritis present.³⁷ Most of the earlier clinical workers reported a higher incidence of infection because cultures were from the cervix or external portions of the cervix. Newer instruments and techniques have enabled workers to obtain samples from the uterus relatively free of cervical contamination.^{23,67} As a result these authors have reported a lower incidence of true uterine infections. Mixed cultures from the vagina or external portion of the cervix are common but pure cultures are frequently obtained in uterine cultures.³⁷

Signs. The clinical symptoms of an endometritis often cannot be demonstrated by rectal or vaginal examination. In the more severe cases there may be a mucopurulent discharge from the uterus in the vagina. Vaginal examination is important for the detection of a uterine exudate indicative of endometritis.^{51,85,87} At the time of estrum flakes of pus in the estrual mucus indicate a possible endometritis. The source of these flakes may be difficult to delineate clinically inasmuch as they may come from the vagina, cervix or uterus. The mucus of estrum may be cloudy or milky instead of clear or translucent and contain many leucocytes when endometritis is present.^{51,71} Bovine cervical mucus in proestrus may normally be slightly cloudy. In many cases a mild to definite cervicitis may be present with an endometritis or be secondary to it due to contamination from the uterus. In some cases douching of the uterus may wash out flakes of mucopurulent material and then the diagnosis is more certain. Massaging the uterus during estrus often will expel mucus into the vagina so it may be examined.⁸⁵ The seriousness of endometritis cannot be diagnosed from clinical manifestations except in cases in which purulent material is present or discharged. On rectal examination the uterus may occasionally feel slightly large, heavy, and thick-walled. These changes may be limited to one horn, possibly the gravid horn of the prior pregnancy. This evidence of failure of normal, prompt involution of

the uterus may accompany chronic endometritis and uterine infection. However diagnosis on the basis of a rectal examination is not reliable. The estrous cycle and periods are usually normal in length. In occasional cases the cycle may be shortened to 8 to 12 days due to acute endometrial inflammation preventing the development of a normal corpus luteum probably by the secretion of prostaglandin. Because of the abnormal endometrium and infection in the uterus the early embryo may die and the cow again come into estrus. The usually prolonged estrous cycle may vary in length due to early death and maceration of the embryo as in trichomoniasis, vibriosis, and possibly other infections. Repeated services and failure of conception may be common symptoms of endometritis. Because many or all of the above clinical symptoms are at times variable and frequently absent, with the exception of failure of conception following repeated services to a fertile bull or with fertile semen, accurate diagnosis in the field at present is often impossible. A careful examination and biopsy may eliminate other possible causes of infertility and the diagnosis of possible endometritis may be arrived at by a process of elimination or laboratory diagnosis by culture and histopathologic examination of carefully obtained and processed biopsy material. The most common lesions found in endometritis in cattle, were exudation, a periglandular fibrosis with leukocytic cellular infiltration and subsequent glandular degeneration and dilation.⁵²

The use of special equipment for culturing and taking a biopsy of the uterus in the clinical patient have been developed for cows,^{6,23,38,53,55,67,82} plus certain instruments used in treating humans, have made possible the further study of endometritis. For practical reasons this equipment together with some special equipment used for diagnosing vibriosis and trichomoniasis probably can only be used to a limited extent in the field, but it can be used for special diagnostic and research work on this important phase of sterility or infertility. In a study on 110 sterile cows, 27, or 87 percent, of 31 cows that showed some clinically diagnosable abnormalities had an endometritis.⁶² In 79 sterile cows without clinically detectable abnormalities 50, or 63 percent, had endometritis. The endometritis was generally more severe in the first group. It was found that slight cases of endometritis diagnosed by biopsy did not interfere with conception; therefore if these cows were eliminated from the above groups the percentage in each group having endometritis severe enough to cause sterility or infertility would be 57 and 37 percent, respectively. A group of 54 cows that had not been inseminated or served since their last calving were examined. Only 11 had been in estrus; 42 showed clinical abnormalities, mainly poor involution of the uterus; and on biopsy 50 of the 54 had evidence of

endometritis. The lesions were more severe the nearer the biopsy was taken to the time of calving. In general, lesions were more severe in cows that had not been in estrus. Inflammatory lesions were more likely to be found in the larger horn of the uterus if the horns were unequal in size.⁶ On the basis of biopsy examinations predictions could be made on the approximate time necessary before the inflammatory reaction would subside sufficiently so that conception could be expected.⁶ An excellent study reported that most abnormalities of the uterus including infection and endometritis recover spontaneously during involution of the uterus, and latent endometritis is not often responsible for reproductive failures in clinically normal cows.¹⁷ Because of the usual prompt natural recovery of endometritis in the involuting uterus, intrauterine infusions of antibiotics were of limited value. Of 99 cows examined at 10 days and 20 days postpartum and at the time of the first insemination, intrauterine infection was present in 49, 25, and 3 percent, respectively.¹⁷ Endometrial biopsy studies at various stages of the estrous cycle in normal cattle showed that such a procedure was safe and had no effect on fertility. Biopsies of the endometrium should be taken from the medial wall of the uterine horn by a suitable biopsy forcep.^{71,82}

Prognosis. The prognosis in most cases of endometritis is fair to good. With each repeated estrous cycle the natural body-defenses and the changes produced within the uterus and the genital tract by the estrogens tend to aid recovery. Thus endometritis is seldom static; nearly all cases recover spontaneously with the passage of a variable period of time and sequential estrous periods. Endometritis due to persistent infections of *C. pyogenes* or brucella have a more guarded prognosis. This effect of the estrous period in assisting in the elimination of infection has been described.^{3,32,37,78} This work showed that infection introduced into the normal uterus at the time of estrus was rapidly overcome and did not establish itself. When infection was introduced during the progestational phases of the cycle it more easily became established and pyometra might result. Of 463 cases of cows suffering from a purulent postpartum discharge without pyometra, 87 percent conceived after treatment.⁶⁷ In 111 infertile cows bred 2 or more times before taking a biopsy of the endometrium, the following results were reported;⁶ (see table, next column).

Endometritis, as other inflammatory processes in the body, tends to recover spontaneously. The more severe the endometritis the longer the time required for recovery. Slight endometritis may not prevent conception and from a biopsy the approximate length of time for recovery could be estimated.^{6,85}

Treatment—There are many therapeutic agents and procedures, used and advocated for the treatment of en-

Degree of Endometritis	Number of Cows	Percent- age Con- ceiving First Service After Biopsy	Percent- age of Total Con- ceptions	Services per Con- ception
None	27	74	85	1.57
Slight	31	74	90	1.36
Moderate	25	48	80	1.70
Severe	28	11	60	3.77

dometritis. If rectal and vaginal examinations and a clear vaginal mucus indicate a normal involuted uterus, there probably is not sufficient endometritis to cause repeat breeding or failure of conception due to an endometritis. However, until controlled experiments are performed using biopsy and cultural methods on large numbers of infertile or "repeat breeding" cows to define the severity of the endometritis (if this is the cause for the sign of failure of conception) and compare the various treatments, it cannot be stated with authority which treatment is superior, or whether the complete omission of treatment may not be best.⁸⁵ Routine biopsies and cultures of the bovine uterus, are not practical but are indicated in specific herd or individual cow problems. In vibriosis and trichomoniasis the development of a local immunity will in a few months overcome the intrauterine infection and produce recovery so conception can occur. When ureaplasma or T strain mycoplasma were introduced into the uterus, an endometritis and salpingitis developed but the uterus rapidly eliminated the infection within 10 days.¹⁸ It is likely that other accidentally introduced pathogens would share a similar fate. Most treatments are based on either promoting estrous cycling and/or overcoming the suspected or known intrauterine infection.

The treatments used to stimulate the muscle tone, blood supply, and flow of mucus of the uterus are varied. Regular warm-to-hot, mild antiseptic solutions such as the aromatic soap solutions, mild quaternary ammonium, neutral iodophor, or chlorine solutions, physiological saline, dilute potassium permanganate solutions, sodium bicarbonate solutions, weak "Lysol" solutions, and dilute iodine or **Betadine** solutions may be used in 500 to 4000 ml amounts as vaginal douches. Mild, gentle uterine massage per rectum 2 to 3 times a week may possibly be of value in producing similar effects. Applying 1 percent acriflavine ointment on the external os of the cervix and cranial portion of the vagina by massage, swabbing the cervix with Lugol's solution or other irritating iodine-base cervicitis mixture may also stimulate circula-

tion, uterine tone, peristalsis, and the secretion of mucus by the endometrium.

Either intramuscular injections or intrauterine infusions of estrogens alone or combined with antibiotics are presently seldom used because both are not recommended for use in lactating dairy cows because they are eliminated in the milk. Possibly repeated treatments with prostaglandins at 10 to 12 day intervals might hasten recovery of an endometritis by causing frequent recurring estrous periods.⁷⁰

Intrauterine infusions or douching of the uterus with

an irritant antiseptic such as dilute iodine solution, 2 ml. of Lugol's solution in 100 ml of water, will strongly stimulate uterine muscle contraction and tone and greatly increase mucous secretions. In fact, douching the uterus with any fluid including saline, acriflavine solutions, 1:500 to 1:3000 concentrations, chlorine, 200 ppm, chlorhexidine, or 200 ppm **Betadine** solutions or other antiseptics probably has a mild irritating action on the endometrium, results in the mobilization of leucocytes, stimulates uterine motility, and has an antiseptic and flushing action on any mucopurulent material. It is desirable to

infuse a mildly irritating chemical such as an iodine solution or certain antiseptics during the follicular or estrous phase of the estrous cycle to avoid a prolonged estrous cycle, 24 days, as may occur if the infusion is administered during late diestrus, about day 15, or a shortened estrous cycle of 8 to 10 days if the solution is administered about day 4 of the diestrus or luteal phase of the cycle.^{65,71,80}

By a combination of rectal manipulation of the cervix and the vaginal introduction of a 2-way-flow catheter of small diameter, the catheter or AI pipette can be passed into the uterus. By means of a funnel and tube, an intravenous outfit, a large syringe or a pressure bulb outfit attached to the end of the catheter, the douche or infusion solution is run into the uterus. This is most easily accomplished in heifers and cows at the time of estrum. If a cervicitis is present or an enlarged uterus has dropped down into the abdominal cavity, Knowles's or Hopper's cervical forceps may be applied to the cervix to pull it back toward the vulva. With the uterus and cervix pulled back by the forceps, one hand can grasp the cervix in the vagina and with the aid of a uterine catheter, or an AI plastic pipette in a rubber horse catheter to provide stiffness, the latter may be inserted into the uterus. After douching or infusing the uterus the cervix may be swabbed with gauze soaked in a strong antiseptic and fastened securely on a pair of narrow dressing forceps. Care should be used in passing the catheter through the transverse folds of the cervix and into the uterus so that neither of these organs is injured or ruptured. As an aid to passing the catheter or pipette, the rectal hand should grasp the cervix and push it forward to obliterate the folds in the vaginal wall. As the catheter is being gently passed through the cervix, the cervix should be manipulated in various directions to help "thread" it over the pipette. During the operation the cow should be well-restrained. Although douching the uterus with a metal catheter or infusing antibiotics or antiseptics into the uterus with a catheter or pipette usually causes no harm, great care should be exercised so that the uterus is not injured or perforated by the catheter and thereby producing more damage than any possible good that could be derived from the infusion. Infusing fluid in excess of 100 ml into the nonpregnant uterus of a heifer or more than 150 ml into a cow's uterus may rupture the uterus or force the fluid into the tissues of the uterus.⁸³ It was impossible to force fluid through the uterine tubes as rupture of the uterine endometrium occurred and the fluid passed between the peritoneal coverings of the uterus. If more than this amount of fluid is infused some of it should be allowed to flow out through the cervix. A spiralled indwelling plastic uterine infusing instrument was de-

scribed³⁸ that could be passed through the cervix into the uterus and it would remain in place so that repeated twice daily or daily infusions could be given without reinserting a pipette. This instrument if left in place for a period of time acts like an I.U.D. resulting in shortened cycles. Further study is necessary to ascertain its value and whether or not endometrial damage may result from prolonged retention in the uterus. Presently their use has not become generally accepted.

Other treatments have been used for endometritis with the idea that if the infection is overcome the endometritis will heal more promptly and the infertility will be overcome more rapidly. These treatments include the intra-uterine infusion of antibiotics such as: penicillin, streptomycin, **Aureomycin**, **Terramycin**, tetracycline, tyrothricin, neomycin, **Chloromycetin**, tylosin, furacin preparations, polymyxin, and others, alone or in combination, incorporated in saline solution, distilled water, oil, sodium sulfonamide solutions, or oil-in-water emulsions. The tetracycline preparations have been recommended for the treatment of mycoplasmosis or ureaplasmosis.¹⁸ Many veterinarians will infuse intramammary products with a broad-range of antibiotic activity into the uterus by means of a uterine pipette. Usually 500,000 to 1 million units of penicillin and 0.5 to 1 gm of streptomycin or 0.5 to 1 gm of the broad range antibiotics are infused in 10 to 50 ml of vehicle. Large doses of antibiotics infused into the uterus will result in their elimination in the milk. So milk should be withheld from the market for the proper period of time, approximately 24 to 48 hours.⁸⁰ The treatments using penicillin and streptomycin in saline or distilled water may be given within 3 to 6 hours before service. The other antibiotics or vehicles are usually given within 24 to 36 hours after insemination or breeding as they have a harmful effect on spermatozoa if administered shortly before service. By infusing the uterus at this time if bacterial infections are present they will be eliminated or reduced so the uterine environment for the fertilized ovum when it arrives several days later will be conducive in for its survival and growth. Infusing the uterus during estrum may result in some of the infusion escaping through the dilated cervix. For this reason infusing aqueous easily absorbed solutions during the luteal phase of the cycle has been recommended.⁷ Although more endometrial reaction to infusions occurs during the luteal phase of the cycle,⁸⁹ the author and others have observed no definite harmful effects from such a practice unless irritating solutions are given from 2 to 6 days or 12 to 17 days of diestrus and result in a shortening or lengthening of the cycle.

Weak Lugols' solution is quite irritating to the endo-

metrium. The author has used a weak Lugols' solution, 2 ml/100 ml of saline, at doses of 20 to 50 ml infused into the uterus from 12 to 36 hours post service for many years without reducing conception rates on the preceding or subsequent service, or causing luteolysis with a short 8 to 10 day cycle. The results of using this weak iodine solution have equalled or exceeded the results with other antibiotic or antiseptic products or mixtures. The effectiveness of antibiotic preparations is not known. In vibriosis a few limited experiments have been conducted on the effects of antibiotics, especially dihydrostreptomycin, on campylobacter organisms *in vivo* but the results, although not discouraging, leave much to be desired. More work on the value of these preparations will have to be done under controlled conditions to arrive at a true evaluation of the benefits derived.

Iodine is rapidly absorbed from the uterus. Its beneficial action may be due to its microbiocidal activity, the local irritation, leucocytosis, and hyperemia it produces; and it may correct an iodine deficiency.²⁰ Empirically providing iodine improved fertility.^{56b} The use of mixed bacterins, the oral feeding of sulfonamides, or iodide preparations are of questionable or no value.

If a **chronic pneumovagina or "windsucking" condition** is present due to a tipped or nearly horizontal flaccid vulva, and a vaginitis and probable metritis with repeated services occurs, it is necessary to scarify and suture the vulva in a manner similar to that described for Caslick's operation in the mare. (See Figures 142 and 85.) Interrupted vertical mattress sutures should be used, since skin clips are usually rubbed out by the cow's tail. Antibiotics applied locally to the uterus and vagina, and sexual rest may be indicated in these cases. After one to 4 normal estrous cycles, artificial insemination is performed. The author has had a high degree of success with this therapy when it was indicated. Urovagina (urine pooling) is rarely observed in cows. The condition requires surgical correction to restore fertility.

In the past many reports on the value of certain infusion products or treatments for failure of conception due presumably to endometritis or uterine infections have appeared in the literature.^{74a} Most of these reports proved nothing more than the fact that most cows respond to whatever treatment was used. Very few of the experiments included control animals and when they did the numbers were not sufficiently large. This is to be expected when work of this type must be done in a field practice where controlled conditions usually are difficult to establish. Whenever such a wide variety of treatments is reported as being successful, it indicates that no treatment would probably show similar results. From the figures the author cited in 1956 it was evident that any ef-

fective treatment of "repeat breeders" due to a possible endometritis must raise conception rates on the next service to well over 50 percent. No such treatment has been reported. Most cases of uterine infection and endometritis recover spontaneously.^{6,17} Sexual rest is indicated for cows with obvious and severe endometritis. In the suspected case of endometritis in the "repeat breeding" cow without any obvious symptoms, conceptions would probably occur sooner if breeding was continued rather than suspended. If the bull is to be conserved, then sexual rest for a month or so in these "repeat breeding" cows may be indicated. There is no evidence that repeated natural service or insemination into the cervix causes any delay in recovery from possible endometritis.

The Prevention of Endometritis or reducing the problem to a minimum requires proper care, sanitation, management, and handling of cows at the time of parturition and the early postpartum period to prevent infections of the uterus (See Chapter VI and XI). If infections occur, prompt and—if necessary—repeated treatments at 1- to 2-week intervals are indicated. Conservative treatment of retained placenta and postpartum uterine infections is usually desirable. If pneumovagina is present prompt closure of the vulva is indicated. Brucellosis, vibriosis, and trichomoniasis should be controlled. If artificial insemination is employed the semen should be free of possible infectious agents and be deposited in clean manner in the cranial portion of the cervix and not into the uterine horn. Vaginal examinations and uterine and vaginal treatments should be conducted in a clean, hygienic manner to prevent the introduction of infection.

Delayed postpartum involution of the uterus is seen most often in older pluriparous cows during the Fall and Winter months and especially in cows with abnormal parturitions including: dystocia, retained placenta, acute metritis, prolapse of the uterus, and cesarean section. Delayed involution was most noticeable the first 30 days postpartum⁶⁰⁻⁶² (See Chapters VI and XI). In general cows with abnormal parturitions required about 5 days longer for their uteri to involute than did cows calving normally. Severe uterine infections definitely retarded the rate of involution. An enlarged uterus 30 to 60 days postpartum is often diagnosed clinically by many veterinarians as having chronic endometritis. The disease condition(s) occurring at parturition and the length of the postpartum interval prior to breeding were of greater importance in determining the conception rate on first service than was the involutionary state of the uterus based on a rectal examination after 30 days postpartum in cows with a grossly normal uterus. This examination was conducted on 1634 cows at 30 to 50 days postpartum.⁸⁷ The

presence of a mucopurulent exudate in the vagina was considered diagnostic for the presence of an endometritis. Infertility was independent of uterine size, and delayed involution in the absence of disease was unimportant. The presence of endometritis had only a slight influence on uterine size and could not be diagnosed by rectal palpation alone. The average calving interval was 10 days longer, 394 days, for cows with endometritis than it was for the normal cows and conception rate on first service was 12 percent lower. Preventive therapy for postpartum endometritis of 2 gm oxytetracycline or neomycin placed into the uterus immediately after the placenta was dropped was of no value and even delayed conception and reduced fertility in 2 groups of 75 cows each compared to 79 controls.^{35a} Conception rate after first service, after 3 services and the number of breedings per conception were 49, 40 and 60 percent, 73.3, 72.9 and 85.3 percent and 2.24, 2.56 and 1.67 respectively. A recent controlled study with neomycin boluses came to the same conclusion.²⁴ Infusing cows' uteri 20 to 40 days after calving with 100 mg of oxytetracycline as an aid in controlling endometritis did not improve fertility.²⁵ Uterine infusions of antibiotics in the postpartum period were not advantageous.¹⁷ Conversely cows with clinically evident endometritis by the presence of a cloudy mucus had much lower conception rates than normal cows, 7 to 11 percent, vs 55 to 75 percent, respectively.⁷¹ When a large number of cows were infused with an antibiotic mixture of penicillin, chloromycetin and sulfonamide 24 hours after first service, the conception rate was 53.3 percent compared to 23.2 percent for untreated controls.⁷¹

In an extensive field trial of 3582 cows in 9 herds in California⁵¹ in which the cows were examined between 21 and 35 days postpartum and placed in 3 groups, normal, moderate endometritis and severe endometritis based on clinical examination by palpation of the uterus per rectum and for the presence of a uterine or vaginal exudate by a vaginal examination. The cows in the former group were not treated and the cows in the latter group were treated with several intrauterine infusions of antibiotics. The middle group with moderate evidence of endometritis alternate cows were infused with antibiotics into the uterus or not treated and kept as controls.⁵¹ There was no difference in the subsequent fertility between the normal or moderate endometritis groups. In the latter the results were similar for controls and treated cows. The group with severe endometritis had a significantly lower conception rate and a higher number of days open. A total of 216 cows in the moderate endometritis group were selected for bacteriologic and pathologic examination; 32.4 percent were positive on culture and 26 per-

cent had an endometritis with an inflammation of the endometrium. Thirty eight or 54 percent of the cultures were positive for *C. pyogenes* with nearly a 100 percent correlation between the culture of *C. pyogenes* and the presence of an endometritis. There were only 2.7 percent of cases where endometritis was present with no bacterial isolation. Cows in which other organisms such as streptococci, staphylococci and *E. coli* were cultured only had a 30 to 50 percent incidence of endometrial lesions. In this study the vaginal examination for the presence of a uterine exudate was more accurate in the diagnosis of endometritis than the rectal examination.⁵¹ The efficacy of the antibiotic therapy used was unable to be evaluated in this study.

If delayed involution is obviously accompanied by a chronic metritis or endometritis as noted by a mucopurulent discharge from the uterus or the presence of a variable amount of exudate in the uterus at 20 to 40 days postpartum, treatment as outlined in postpartum metritis or pyometra is indicated. The interval between calving and breeding should be extended in affected, diseased cows.

The author has observed that pluriparous cows with a long mesometrium and a deep abdominal cavity permitting the uterus and cervix to be located some distance below the pelvic floor tend to have a larger, heavier, thicker uterus and cervix and be less fertile than cows whose uterus and cervix is located higher in the abdominal cavity on a level, with the pelvic floor. Uterine lochia or infectious material drains out earlier and more completely and possibly the circulation to the uterus is improved resulting in less edema or passive congestion in the latter cows. The author has even considered the possibility of attempting to fasten the cervix in the pelvic cavity in some severely affected cows.

Endometritis whether due to a venereal disease, vibriosis, trichomoniasis, and brucellosis, or due to a transient uterine infection with a variety of organisms including streptococci, staphylococci, coliform organisms, mycoplasma, *Hemophilus somnus*, ureaplasma or even *C. pyogenes* following parturition, service, either AI or natural, or accidental invasion from the caudal genital tract secondary to a vaginitis or cervicitis does result in infertility, failure of conception and a prolonged postpartum interval to conception. Thus regular postpartum rectal and vaginal examinations should be practiced starting at 15 days postpartum, but especially at 30 to 40 days, to detect persistent or chronic uterine infections resulting in delayed uterine involution and infertility. Prompt, early and monitored treatments should be undertaken to correct the pathological condition as rapidly as possible. Venereal diseases should be prevented or

controlled. If repeated services at regular or irregular intervals occur, careful examinations, possibly supplemented by biopsy or culture procedures should be undertaken as well as a careful review of management, heat detection, and insemination or breeding practices. From the theoretical view the author agrees with his potential critics that treatment of the normal cycling or repeat breeding cows is probably unnecessary and possibly contraindicated.^{12,85} However the practical on-the-farm situation invariably calls for some type of therapy based on a clinical examination of the cow which is not always definitive. Therefore treatment is often administered or advised based on the veterinarians best judgment and perception of the problem. The treatment recommended or utilized however should not be detrimental to the cow, her chances for conceiving promptly, and the cost-benefit ratio should favor the owner.

Pyometra in cattle is characterized by the accumulation of pus or mucopurulent matter in the uterus, and by a retained corpus luteum with failure of estrum due to suppression of the endometrial luteolytic factor or prostaglandin secondary to the severe endometritis. Some authors consider any accumulation of pus or mucopurulent exudate in the uterus even though the animal has estrous cycles as pyometra. This author adheres to the former definition and terms the latter a metritis or endometritis. Uterine distention does not cause anestrus.²⁹ The retained corpus luteum is not the corpus luteum of pregnancy in postpartum pyometra but is the corpus luteum following the first to third ovulation that persists due to the uterine infection associated with endometrial pathology. Pyometra usually occurs following an abnormal parturition, a uterine infection, and a tardy involution of the uterus in such conditions as abortion, premature birth, twin birth, dystocia, retained placenta, septic metritis, or postpartum metritis (See Figure 135). True pyometra seldom recovers spontaneously. Some veterinarians speak of pyometra as the chronic mucopurulent discharge seen for 2 to 3 weeks following calving due to a postpartum metritis. In a narrow sense this may be correct since there is pus in the uterus, but most of these cases come into estrum, cycle regularly, and the pus is expelled within 30 to 60 days after parturition. True pyometra exists for 60 to 90 or more days after parturition with a failure of estrum. It may occasionally follow service and when it does it is usually associated with the early death and maceration of the embryo and its membranes. In these cases trichomoniasis should always be suspected and the pus examined for trichomonads. Other infections due to a variety of organisms, most frequently *C. pyogenes*, may also cause death of the embryo and pyometra, or be a secondary invader. Occa-

Figure 135. Chronic Postpartum Metritis and Pyometra due to In-spissated Necrotic Cotyledons and Caruncles.

sionally pyometra may be produced by the insertion of an inseminating pipette into the uterus of a pregnant cow that may have shown symptoms of estrum. Infection introduced in the semen or by the operation causes the death of the embryo, its maceration, and pyometra. This condition occurs more commonly when the semen contains no antibiotics. In rare instances pyometra may develop secondary to mucometra in a heifer with an imperforate hymen that has been bred by a bull or artificially and infection is introduced into the genital tract distended with the mucus or it may develop secondary to mucometra caused by chronic cystic ovaries.

Symptoms—Pyometra is characterized by the failure of estrum, a persistence of the corpus luteum, and the retention of pus or mucopurulent material in the uterus. The amount of this pus may vary from 2 or 3 ounces to 2 to 4 gallons. In most cases of postpartum pyometra the cervix is relaxed so that some of the pus escapes and is observed occasionally when the cow lies down, urinates, or defecates. On examination 3 to 4 ounces of pus are frequently found in the cranial portion of the vagina. The pus is usually thick mucoid and creamy, and yellow, white, or greenish-gray in color. In 67 cases of pyometra recorded by the author in an area where trichomoniasis was not seen, a mucopurulent discharge was observed by the owner in 57, or 86.6 percent, of the cases on various occasions before the condition was diagnosed and

treated. On rectal examination the uterine wall is usually thickened, flaccid, and atonic. The pus that distends the uterus may simulate pregnancy but the consistency of the pus is heavy and not watery like normal placental fluids. Pinching of the uterine wall does not reveal the slipping of the fetal membranes as in pregnancy. The fetal cotyledons, and enlarged whirling uterine artery of a normal pregnancy are not palpable in pyometra. The bovine animal rarely shows any signs of systemic illness even when gallons of pus may be in the uterus. If on the first examination, the diagnosis of pyometra cannot definitely be made, reexamination in 20 to 30 days will reveal a failure of normal developmental changes characteristic of pregnancy. Passing a metal catheter through the cervix will remove some pus, or an injection of 25 to 40 mg. prostaglandin F_{2a} or 500 ug cloprostenol will probably cause the evacuation or release of the pus from the uterus. A white-blood-cell count is of no value in diagnosing pyometra in the cow.

Prognosis—The earlier a case of pyometra is diagnosed and treated, the greater the possibility of its successful correction or cure. In long-standing cases the endometrium is destroyed, the uterine wall undergoes fibrotic changes, and in some cases complete recovery and conception cannot occur. In the cases that have existed for only 60 to 120 days, recovery and conception are more likely than in cases present for 120 days or longer. The type of organism and its effect on the endometrium and uterus play an important role. *C. pyogenes* is commonly found in severe or incurable cases. Recovery in cases with over 2 gallons of pus in the uterus seldom occurs because of the degenerative changes in the uterine wall, producing a marked lack of tone. Recovery of cases of pyometra associated with severe perimetritis is hopeless. In a series of 35 cases of pyometra 51.4 percent of the cases conceived.⁶⁷ The author in a series of 67 cases recorded a conception rate of 46.3 percent.⁷⁵

Treatment—The treatment consists of producing an involution of the retained corpus luteum so that the estrous cycle is reestablished, the cervix will dilate, the uterus will contract and the pus will be evacuated. The induction of estrus may be brought about by the injection of 20 to 40 mg of prostaglandin F_{2a} (**Lutalyse**) or 500 ug cloprostenol (**Estrumate**) intramuscularly. Douching the uterus with a horse catheter, draining the pus from the uterus, injecting antibiotics, and massaging may in rare cases produce recovery but the other procedures are much more effective in establishing a prompt return to the regular estrous cycle necessary for recovery. Excessive massage of the uterus should be avoided, as perimetritis and adhesions may occur.

In the past, manual removal of the corpus luteum was

practiced. Since these corpora lutea associated with a pyometra were retained or persistent they were difficult to enucleate and hemorrhage and/or extensive adhesions frequently resulted. Estrogens such as estradiol and stilbestrol were formerly used to involute the corpus luteum. Large and often repeated doses of estradiol, 8 to 10 mg., or stilbestrol, 80 to 100 mg, were necessary. Occasionally cystic ovaries or severe ovaritis and adhesions of the fimbria resulted. Oxytocin alone or combined with the estrogens or prostaglandins has not proven to be of value.⁷⁵ If the first dose of prostaglandin does not completely involute the C.L. and evacuation of the uterus is not complete, the treatment should be repeated in 10 to 12 days. In a total of 42 cows with pyometra treated with a luteolytic dose of either PGF_{2a} (**Lutalyse**) or cloprostenol (**Estrumate**) 90 to 100 percent of the cows showed estrus by the third day and discharged copious amounts of pus from 3 to 5 days after the injection.^{28,70,91} At 12 to 14 days later the uterus was completely evacuated in nearly all the cows. About 65 percent of the cows conceived after 2 or more (2.2 average) inseminations. In a large recent study^{21a} of pyometra or pyometritis in postpartum dairy cows 72 of 79 cows (95%) and 57 of 73 cows (78%) evacuated the purulent exudate from their uteri after one or two treatments 7 to 10 days apart of 500 ug cloprostenol and 7 to 12 mg estradiol cypionate, respectively. Treatment to breeding and treatment to conception intervals were similar for both treatments. Recurrence of pyometra developed in 9 and 5 percent of treated cows; follicular cysts developed in 16 and 7 percent and perimetritis and adhesions developed in 2 and 5 percent, respectively. Treatment with nitrofurazone was of no value in preventing relapses or improving conception rates.^{21a}

After treatment and expulsion of the pus from the uterus and the establishment of normal estrous cycles the cows should not be rebred for several normal estrous periods. Before breeding is permitted the uterus should return to its normal size and consistency and no metritis or cervicitis should be present. The use of antibiotic infusions or other therapy as described under endometritis may be of some value in hastening recovery.

It is rather obvious that pyometra can produce severe damage to the endometrium that either prevents conception even though the pus is evacuated, or delays conception so that the owner sells the cow as unprofitable. To prevent pyometra, cows having a postpartum mucopurulent discharge should be treated promptly to hasten involution of the uterus.⁵⁹ Insemination into the pregnant uterus and breeding to trichomonad-infected bulls should be avoided.

Perimetritis and Parametritis are observed occa-

sionally in the cow and are characterized by varying amounts of adhesions between the uterus and broad ligaments and the other pelvic and abdominal organs. (See Figure 136.) Endometritis and metritis are inflammations of the endometrium and the entire thickness of the uterus. Perimetritis and parametritis involve inflammation of the serosa and uterine ligaments, respectively. Adhesions associated with or secondary to inflammation are usually secondary to one of the following: a severe septic metritis; douching and perforation of the uterus with a catheter releasing irritant material into that area; a nonfatal rupture of the rectum due to carelessness in rectal examination or therapy; a perforation of the vaginal wall by the penis of the bull; an occasional severe hemorrhage, trauma, or rupture of the uterus at the time of calving due to torsion of the uterus, fetotomy, forced extraction, severe cervical or vaginal lacerations; a cesarean section; an extrauterine fetus; excessive bleeding following a manual removal of a corpus luteum; excessive massage or manipulation of an infected uterus such as rough removal of a retained placenta; and occasionally a parametritis due to a diffuse peritonitis secondary to tapping of the rumen or to traumatic gastritis. These

Figure 136. Extensive Perimetritis and Ovaritis with Adhesions Following a Severe Metritis after an 8-month-Abortion.

Figure 137. Abscess of the Uterine Wall Caused by the Improper Use of an AI Pipette.

conditions may be caused by tuberculosis of the genital organs in countries where tuberculosis in cattle is still common.

The lesions may vary from a few thin fibrous strands of connective tissue to firm adhesions between the uterus, broad ligaments, rumen, omentum, intestines, rectum, bladder, and other organs. The adhesions may be either diffuse or localized. In some cases abscesses may be found in the adhesions around the ovaries or broad ligaments or between the rectum and uterus. These localized abscesses may be either small or large. In rare cases one of these perimetrial abscesses may rupture into the rectum or bladder or may extend through the pelvic cavity to rupture alongside the vulva.

The symptoms of peritonitis in the pelvic region during the acute phase of the disease are the same as for any peritonitis: anorexia; arched back; slow, stiff gait; pain exhibited at the time of urination and defecation or at the time of a rectal examination; decreased rumen activity; and lack of ruminations. The temperature may be elevated for a day or two or may be normal. The pulse is elevated and the respirations increased. A "serous" or expiratory grunt may be heard at the onset of expiration or on percussion of the abdomen. The abdomen may be tense and the rumen slightly tympanitic. A diarrhea may be present. The hair coat may be rough. The drop in milk flow is usually marked. A hemogram may reveal

a slight leukocytosis and a shift to the left. A rectal examination in the acute case causes pain, tenesmus, grunting and an anxious expression. Fibrinous adhesions in this acute stage are usually easily broken down manually per rectum. If this condition is found, the rectal examination should be stopped immediately to prevent extension of the inflammatory process. If these acute symptoms are overlooked and the cow survives, the history will often reveal this period of illness. If death does not occur adhesions become chronic, areas of infection are walled off and become encapsulated abscesses that can readily be felt on rectal examination. Sometimes tumors or localized areas of fat necrosis may be confused with perimetritis and perimetrial abscesses. The prognosis in parametritis or perimetritis varies with the severity of the condition. Slight adhesions may cause no trouble, and sometimes can be broken by the hand in the rectum after the condition has become chronic. In severe, extensive adhesions the prognosis is poor to hopeless, especially if the ovaries and oviducts are involved in the adhesions or if the uterus is adhered to the abdominal organs over an extensive area. Such affected animals are usually sterile or fail to carry a pregnancy to term. In acute perimetritis conservative treatment with parenteral antibiotic and/or sulphonamide therapy is indicated.

Abscess of the Uterine Wall is occasionally observed

Figure 138. Ectropion of the External Cervical Os (three prolapsed transverse rings can be noted). (Courtesy K. McEntee.)

Figure 139. Lymphosarcoma of the Bovine Uterus. (Note the plaque-like thickenings of the uterine wall.)

in the cow. It is usually round or oval in shape and tense and firm on palpation. It may vary from 1 to 15 cm. in diameter, changing the normal outline or contour of the uterine horn. (See Figure 137.) It frequently occurs as a sequela to a severe metritis, rough or improper removal of a retained placenta, injury to the uterus due to improper or rough use of an inseminating pipette or other instrument and trauma especially to an infected uterus allowing infection to penetrate through the endometrium. Abscess of the uterine wall is easily palpated on rectal examination and should be differentiated from a tumor, cyst, or hematoma. Occasionally some perimetritis or adhesions may be felt around it. There are no general symptoms. In many instances the cow may fail to conceive. In several cases observed by the author the affected cows aborted at approximately 4 months of gestation on successive pregnancies and were sold as sterile. In another case the abscess ruptured into the uterus producing a pyometra. Treatment is usually impossible without the danger of causing a severe perimetritis or peritonitis. If the abscess is small the animal may recover but in many cases it is sterile. In rare instances adhesions form and the abscess may rupture into the rectum, bladder, or vagina. Parenteral antibiotic therapy might be indicated in early stages. Draining the abscess into the uterine lumen might be attempted as a last resort.

Figure 140. Adenocarcinoma of the Bovine Uterus.

Uterine Abscess is a condition similar to pyometra but characterized by a pathologic scarring or atresia of the cervix or vagina. It is usually due to severe trauma and necrosis caused by a dystocia or fetotomy operation. Cervical or vaginal atresia preventing the evacuation of the pus is very rare in the cow. If this condition is diagnosed the prognosis is usually hopeless and the cow is sold for slaughter.

Sclerotic Metritis is caused by a severe chronic metritis that has caused the complete destruction of the endometrium and fibrotic changes in the uterine wall. The endometrium is transformed into a thick, dense layer of connective tissue with foci of infection and purulent exudation into the uterine cavity. The uterus resembles a fistulous tract.⁴⁵ The condition often involves the cervix. This thickened indurated condition of the uterus usually follows a severe prolonged infection of the uterus such as chronic pyometra or fetal maceration. The uterine caruncles and endometrium are destroyed and the animal is therefore hopelessly sterile. The uterus on rectal examination feels very hard and firm, like cartilage or dense fibrous tissue. It is larger than normal and a chronic exudate may come from the uterus as well as from a thickened indurated cervix. In fetal maceration, bones may still be felt in the uterus. A sclerotic metritis should be carefully differentiated from an adenocarcinoma of the uterus which it may closely resemble. Usually the cow fails to show estrum and the corpus luteum is deeply

imbedded or retained. Slaughter is recommended.

Tumors of the Uterus in the cow are uncommon. In 6286 bovine genital tracts examined at slaughter there were 44 uterine tumors including 15 leiomyomas, 12 fibromyomas, 7 fibromas, 1 scirrhous adenocarcinoma, 1 lymphosarcoma, 1 spindle cell sarcoma, and 7 undiagnosed tumors.⁴⁰ In recent years a number of reports have indicated that lymphosarcoma and adenocarcinoma of the uterus are becoming more common.^{2, 11, 41, 46, 57, 63, 88} (See Figures 139 and 140.) The lymphoid tumor or malignant bovine lymphoma may involve the uterus and result in diffuse plague-like thickenings in the uterine wall. Affected cows may often be pregnant. The tumor is whitish-grey, compact and soft in consistency. Adenocarcinoma of the uterus is less common but this tumor may metastasize to other body organs and the peritoneum. In the uterus it feels hard, cartilaginous and umbilicated. It may ulcerate so that a bloody discharge comes from the cervix. Leiomyomas are usually single, firm, round and may resemble abscesses; they are benign. Careful rectal palpation of tumors of the uterus will differentiate them from abscesses, cysts, adhesions, tuberculosis and other uterine diseases.

Mucometra or Hydrometra is seen occasionally in cattle. Both mucometra and hydrometra are similar except for the degree of hydration of the mucin present in the uterus which may vary from a watery fluid to a semi-solid mass.⁴⁶ It has been described previously as a condition secondary to cystic ovaries and cystic endometrial hyperplasia usually associated with an anestrous period of 6 months or more. The ovarian cysts are usually small, 1 to 1.5 cm., two to four are usually present on each ovary. The cysts usually have a thick wall that resists rupture by manual pressure. The condition is further characterized by cystic degeneration of the endometrium and atrophy of the uterine wall, with an ounce to a gallon of thin to viscid mucus in the uterus. (See Figure 112.)

Mucometra is also observed in heifers or cows with arrests in the development of the Mullerian duct system or segmental aplasia of the paramesonephric ducts in which part of the vagina, cervix, or uterus may be missing or defective. (See Figures 120, 122, 126, 127.) Persistence of the hymen causing mucometra and muco-vagina has been previously described. (See Figure 124.) These genetic or congenital defects may result in a distention of both horns with watery, viscous, or even rather solid coagulated masses of mucus and cellular debris that may be confused with pregnancy. In these affected cattle the ovaries and endometrium are normal, and estrum therefore usually occurs normally. Rare cases of mucometra may be associated with retained corpora lutea.⁷⁶

In the cow, as in the dog, mucometra can apparently be produced by prolonged hormonal stimulation by estrogens and/or progesterone. The author has observed one case secondary to trauma and a fine adhesion obstructing the lumen of the cervix at the region of the internal os. In cases of mucometra no infection is usually present unless introduced accidentally by trauma, service, or treatment.

Cases of mucometra may be differentiated from pregnancy on a careful examination of the genital tract. Failure to slip fetal membranes, the presence of anomalies of the uterus, vagina, and cervix; the finding of ovaries that contain a single or multiple small cysts 0.5 to 0.75 inch in diameter; rarely the finding of a persistent corpus luteum on repeated examinations; the lack of enlargement or whirling of the uterine artery; the inability to palpate the fetus or cotyledons, although some cases with firm, gumlike-mucus in one horn or an apex of one horn may simulate a fetus or mummified fetus; the presence of a uterine wall that is usually thin and lacks tone when compared to the normal pregnant uterus; and the absence of regular developmental changes that occur in a normal pregnancy are the clinical findings on rectal examination of cattle affected with mucometra.

Cows with mucometra, or hydrometra due to defects of the genital tract are often sterile unless the case is a uterus unicornis and pregnancy occurs in the normal horn, or a simple imperforate hymen that can be opened. The advisability of using these cattle as breeding animals is questionable from an hereditary standpoint. In cows with mucometra and anestrus due to cystic ovaries, injection of a large dose of L.H., 20,000 IU of H.C.G. or more intravenously, or GnRH in large doses may occasionally bring about recovery. In rare cases of mucometra with a persistent corpus luteum an injection a luteolytic dose of prostaglandin F_{2a} or an analogue to involute the corpus luteum may be successful in correcting the condition.

Miscellaneous uterine diseases—A highly unusual **cystic placental mole** that follows embryonic death with the continued life and even growth of the membranes to a size corresponding to a 3 to 4 months' pregnancy together with retention of the corpus luteum has been described.⁴⁶ The mole has no lumen but consists of a mass of clear gelatin-like fluid. The "growth" may progress to pyometra or be expelled spontaneously. This condition should not be confused with the hydatidiform mole which appears as a grape-like cluster of translucent cysts or villi of the placenta and is expelled with the placenta. Chorioepithelioma in the cow is extremely rare.⁶³

Hyperkeratosis or X disease of cattle is caused by the ingestion of chlorinated naphthalenes formerly added to

oils and lubricants. It caused a marked lowering of the plasma vitamin A levels, a wrinkled, crusted, thickened skin, anorexia, depression, emaciation, abortion and even death. Retained placenta and metritis usually followed the abortion. In non-pregnant cows hyperkeratosis was characterized by metaplasia of the vaginal, cervical and uterine epithelium. Cystic enlargement of Gartner's ducts regularly developed.⁴⁷

Cervix

Cervicitis or inflammation of the cervix of the cow is commonly observed associated with metritis and frequently follows abnormal parturitions such as abortions, premature birth, dystocia, especially where forced extraction or fetotomy caused cervical lacerations or trauma, retained placenta, and postpartum metritis. Cervicitis especially of the external os of the cervix may follow injuries to the vulva and vagina allowing "windsucking" and vaginal contamination. Vaginal infections whether viral or bacterial usually produce a cervicitis of the external os. Occasionally a cervicitis may occur following trauma or puncture of the cervix by a catheter or insemination pipette. Care, patience, and gentleness should always be used in manipulating a catheter or pipette through the cervix. The cervix appears more resistant to infections than either the uterus or the vagina. The cervical infections are usually miscellaneous in nature and may be due to any of the organisms that infect the uterus or vagina. Certain organisms, such as *C. pyogenes*, are probably more pathogenic than others such as streptococci. It is possible that at coitus there may occur an introduction of infection that might cause some involvement of the external os of the cervix as well as the cranial portions of the vagina. The internal portions of the cervix appear rather resistant to the introduction of miscellaneous infections. Most cases of cervicitis originate at the time of or following parturition and often are associated with a metritis. Prolapse of the external transverse cervical rings or cervical ectropion is a possible factor causing cervicitis in older cows. (See Figure 138.) These prolapsed rings are often chronically thickened and fibrosed and circulation to the epithelium may be poor, permitting the establishment of infections. Severe purulent vaginitis or vaginitis associated with pneumovagina due to a lacerated or stretched vulva, atrophy of the perineal body and vulvar lips and horizontal tipping of the vulva may cause a severe cervicitis especially if urine and feces are present in the vagina. A poorly developed short cervix with very small transverse rings as described previously under genetic defects may readily permit an

endometritis to develop and a cervicitis may also be present.

Symptoms. Cervicitis can be diagnosed on vaginal examination with a speculum and light. The external os of the affected cervix is usually edematous and swollen, the external folds are often prolapsed, the cervical mucosa is a cherry-red to dark-purple color, and mucopurulent exudate may be seen in and on the cervix. There is little evidence that mild cervicitis without metritis prevents conception or causes sterility. Even when severe forms of cervicitis are present, conception may occur. Many clinicians have observed pregnant cattle with a mucopurulent vaginitis involving the external os of the cervix. The presence of a wide variety of bacteria, including streptococci and staphylococci, were demonstrated in the cervical mucus of 40 percent of postparturient cows. There was no evidence that the presence of these organisms had any effect on fertility.²⁶ Cervicitis was rather seldom a cause for sterility in the cases observed at autopsy.^{45,46} Since cervicitis and endometritis are closely associated and the former usually can be observed clinically, cervicitis may often be erroneously blamed for infertility. If a severe cervicitis is present endometritis or metritis may be present also and should be treated. Occasionally if pregnancy does occur even though a cervicitis is present the gestation may be insecure, with the possibility that abortion, retained placenta, and other uterine pathology may develop. Vigorous manipulation of the cervix will produce a marked hyperemia and congestion of the mucus membrane that should not be confused with infectious cervicitis. On rectal examination the infected cervix may be large and thick or may be normal in size. Hypertrophy of the cervix does not necessarily mean that cervicitis is present. Cervicitis does not occur commonly in the greatly hypertrophied cervixes noted especially in Brahman, Zebu and Santa Gertrudis cattle. Occasionally in severe chronic cervicitis the cervix may be very thick and sclerotic. The severity of the cervicitis will vary depending on the cause and length of time it has existed. The incidence of chronic cervicitis based on clinical examination was 0.6 percent.⁹⁴ It may be difficult to differentiate between cervicitis and metritis. If a metritis is present cervicitis is also present.

Cervical stenosis may follow severe infection or trauma. Cervical atresia or obstruction is very rare in the cow. If it occurs the mucus and exudate remain in the uterus, and the uterus becomes distended. Depending on the nature of the uterine contents a uterine abscess or mucometra develops. Cervical stenosis may occur due to severe cervical inflammation, or an enlarged cervical ring may extend into the cervical canal, making a sharp bend in the lumen so that passage of a catheter is difficult or

impossible. These cows frequently conceive promptly when bred naturally or when semen is deposited artificially in the cervix. In rare instances described previously, a severe sclerotic, fibrosed, indurated cervix may result in cervical stenosis at the time of calving causing dystocia. In occasional cases following a dystocia a necrotic cervicitis or a severely lacerated cervix may be present producing a severe scarring of the mucous membrane.

Prognosis—The prognosis in most cases of cervicitis is good and spontaneous recovery usually occurs as the metritis and vaginitis improve. As long as a metritis or severe vaginitis is present, recovery from a cervicitis cannot occur. The cervical infection usually is overcome by the natural body-defense mechanisms particularly if the estrous periods are regular. The more severe forms of cervicitis may take longer to respond. Cervical stenosis or sclerosis frequently fail to respond to treatment, and if the cow conceives these conditions are apt to cause dystocia at the time of the next parturition. Cervical ectropion, or prolapse of the external cervical folds, does not improve. Usually the prolapsed transverse rings become a more ectropic with each calving.

Treatment—If metritis or vaginitis accompanies the cervicitis then the entire reproductive tract must be treated. The same treatments usually are useful for all 3 conditions. It should be recognized that ordinarily the cow overcomes cervicitis spontaneously, as it does other infections of the genital tract. The following treatments may aid and hasten recovery. Warm or hot mild antiseptic douches of the vagina every 3 to 4 days as described for endometritis are useful in flushing out the mucopurulent exudate and stimulating circulation in the mucosa of the vagina, cervix and uterus. Douching the cervix and uterus may also be useful. Many veterinarians prefer to swab the cervix with one of the following: Lugol's solution; a cervicitis mixture such as (A) phenol 1 part, tincture of iodine 1 part and glycerine 2 parts, or (B) menthol crystals 1 dram, tincture of iodine 4 ounces and glycerine 4 ounces. The cervix is swabbed by pulling it back toward the vulva with cervical forceps and then with gauze wrapped around a long pair of dressing forceps soaked in Lugol's or cervicitis mixture the entire length of the cervix is thoroughly swabbed. Although this treatment probably does not completely eliminate infection it stimulates mucous flow, causes hyperemia, and apparently hastens recovery. The use of stronger preparations such as 10- to 20-percent silver nitrate solutions are not indicated as they may cause too much damage and may result in cervical adhesions. Some veterinarians inject antibiotic or sulfonamide solutions and preparations into the cervix and uterus and expect that as it is

expelled the material will help overcome the infection in the cervix. Some prefer to rub or infuse a sulfonamide or antibiotic ointment or 1 percent acriflavine ointment into the cervical lumen. If cervicitis is secondary to vaginitis and pneumovagina, a vulva-suturing operation should be performed as described under the treatment of vaginitis.

In certain cases of chronic cervicitis of the external os associated with severely prolapsed cervical rings that fail to respond to treatment, the external cervical rings may be amputated. This may be done readily with large serrated scissors. After the prolapsed rings have been amputated the vaginal mucosa may be sutured to the cervical mucosa to help control hemorrhage and promote rapid healing but this is not necessary.³³ Epidural anesthesia is not required as there are no sensory nerves in the cervix but it aids by controlling defecation during the operation. Trachelorrhaphy is the suturing of cervical lacerations after calving. Partial trachelectomy is the amputation of a portion of the cervix. This operation is probably not necessary since cervical infections of the external os seldom prevent conception and the internal portion of the cervix provides a firm seal even though the external os may be ectopic and inflamed. Usually within 3 to 4 weeks after amputation of the prolapsed cervical rings healing has occurred and breeding can take place. Regular estrous periods have as definite a healing

Figure 141. Atresia of the Internal Os of the Cervix Secondary to an Acute Cervicitis (Mucometra resulted).

Figure 142. A Horizontally-tipped Abnormal Vulva Causing Pneumovagina in a Cow. (Suturing of the vulvar lips was followed by conception in this "repeat breeding" cow.)

effect on cervicitis as they have on endometritis. If cervicitis is severe, sexual rest is indicated for two or more estrous periods. Manual or instrumental dilation of an atretic or stenosed cervical canal is useless. The bovine cervix usually ruptures before a significant dilation occurs.

Cervicitis may be prevented by the same precautions that can be taken to prevent endometritis or vaginitis. Trauma to the cervix should be avoided whenever possible.

Cysts of the Cervix are observed occasionally in the cow. These are sometimes called "Nabothian" cysts or follicles, after the terminology used for this condition in humans. These cysts vary in size from 1 to 5 cm. in diameter. They are apparently retention cysts of the cervical glands. They may be congenital but are usually acquired secondary to trauma or lacerations. Frequently they go unnoticed until they become large and palpable as a fluctuating mass in the cervix on rectal examination. Often a portion of the cyst may be observed in the external os on vaginal examination. These cysts apparently seldom cause infertility but they might be large enough to hold some mucus and debris in the uterus, prevent proper closure of the uterus by the cervical seal during pregnancy or possibly interfere with the passage of spermatozoa. They are easily treated by incising with a needle, teat bistoury, or small knife through the external os of the cervix. Following incision and draining of the mucus from the cyst, the cervix may be swabbed with Lugol's solution or other cervicitis mixture. In some cases a cyst may require differentiation from an abscess; it is usually thin-walled and covered only by mucous membrane whereas the abscess is deeper in the tissues of the cervix

and has a thicker, more fibrous wall of connective tissue. Cysts of the cervix should also be differentiated from occasional cystic dilations, sacculations, or diverticula of the cervical lumen in cattle due to arrests in the development or fusion or developmental defects of the Mullerian ducts. These may be genetic or congenital in nature (See hereditary defects of the cervix). The prognosis is usually guarded to poor.

Complete Stenosis or Obstruction of the Cervix, except secondary to trauma or severe inflammation, is probably very rare in the cow. In some heifers with a small or tortuous cervical canal an insemination pipette cannot readily be passed. If these animals fail to conceive the stenotic cervix may be considered to be the cause. In 1711 heifers and 11,112 cows the cervix was impenetrable to an inseminating pipette in 11.7 and 1.1 percent of the cattle, respectively.⁶⁹ When semen was inseminated into the cervix the conception rate in the affected heifers was 54.0 percent, and in the cows 36.5 percent, indicating that this condition should not be considered abnormal and a cause of infertility. The author and his associates have observed only one case of cervical atresia in the cow not associated with an anomalous condition, and this showed evidence of previous trauma. (See Figure 141.) If the cervix were actually obstructed the uterus should fill with mucus and other cellular debris similar to that observed in cattle with certain congenital defects of the reproductive tract, such as seg-

Figure 143. Carcinomas of the Vulva of a Cow.

Figure 144. An Anomaly or Wattle, Present on the Vulva of a Heifer. (Courtesy K. McEntee.)

mental aplasia of the Mullerian ducts or an imperforate hymen. In heifers with an infantile, abnormal, or stenotic cervix, treatment as described under hereditary defects of the cervix should be followed.

Mucocervix—In rare instances the cervix may be greatly enlarged to about 10 to 15 cm in diameter and 15 cm in length with an enormous pathological cervical seal of tough tenacious mucus. This condition is probably a hormonal disturbance due to a deficiency of L.H. or GnRH. It is usually associated with a failure of estrus with chronic cystic ovaries or a retained corpus luteum. The prognosis is usually very poor. The intravenous or intramuscular injection of a very large dose of L.H. or GnRH or possibly prostaglandin may be helpful in the treatment of these cases. An anomaly or defect of the cervix usually fills with mucus.

Tumors of the Bovine Cervix are rare. Fibromas, fibrosarcomas, leiomyomas, and carcinomas affecting the cervix have been described.^{11,63,88,90} Most of these tumors were benign. In rare instances adenocarcinomas may be malignant and metastasize to other organs.

Vagina

Vaginitis in the cow is observed as a primary or secondary condition. The secondary condition is often as-

sociated with metritis and cervicitis. Vaginitis may occur following trauma, lacerations, and bacterial, viral or protozoal infections produced or introduced at the time of service, abortion, dystocia, fetotomy, retained placenta, prolapse of the vagina, and postpartum metritis. Severe stretching or laceration of the vulva especially of the perineal body, and in older cows sinking of the anus and tipping of the vulva into a horizontal position, with an atrophy of the vulvar lips often results in pneumovagina and contamination of the vagina by feces, urine (urovagina), air, and miscellaneous debris and infection that often cannot be readily expelled because the uterus and cervix have pulled the cranial portion of the vagina forward and downward into the abdominal cavity (See Figure 142). A vaginitis may occur following coitus, especially in heifers bred to an old bull, but this is usually a mild and transient condition. Occasionally small abscesses may develop in the mucosa or in Gartner's ducts. In rare instances vaginitis may be due to treatment of the vagina with irritant preparations, introduction of infection on instruments, or examination of the vagina in a dirty, unsanitary manner. Most vaginitis is due to non-specific infections such as staphylococci, streptococci, coliform organisms, *C. pyogenes*, urea- and mycoplasmas and others. The vaginitis due to specific infections such as **IBR-IPV**, "epivag," and possibly other viral infections, trichomoniasis, vibriosis and granular venereal disease has already been discussed. Necrotic vaginitis and severe vaginal lacerations following calving, dystocia, and fetotomy have been discussed previously in Chapter XI.

Symptoms of Vaginitis—In the cow a mucopurulent, yellow-grey pus is usually discharged from the vulva at irregular intervals and mats the hair of the vulva, tail and buttocks. On vaginal examination the exudate is observed on the floor of the vagina and the vaginal walls are congested, edematous, and inflamed. The more severe the inflammation the more red and inflamed the vagina. In some cases ulceration of the mucosa, lacerations and secondary diphtheritic or necrotic lesions occur especially around the vestibulo-vaginal border and in the vestibule and vulva. In severe cases the cow may show tenesmus, irritation, and pain probably due to the concurrent vestibulitis and vulvitis.

If the vulva is stretched, damaged, torn, or deformed, so that pneumovagina results, the vagina may then contain fecal material, urine, and air as well as mucopurulent exudate. (See Figure 142.) This may frequently be a cause of failure of conception, particularly in older cows in the large breeds, such as Holsteins, Brown Swiss, Herefords, Santa Gertrudis, possibly Brahmas, and occasionally Guernseys. Under most circumstances an un-

complicated mild vaginitis may not prevent conception. Since vaginitis can be associated with cervicitis and endometritis it is probably the latter condition that in most cases causes the infertility, although a severely diseased vagina and external os of the cervix filled with pus and debris and having an altered pH may cause rapid destruction of spermatozoa and interfere with fertilization. In pneumovagina in old cows or **Bos indicus** breeds with a large heavy cervix pulling the vagina forward and downward, an accumulation of material in the vagina, often associated with an atonic uterus hanging low in the abdominal cavity, may cause some infectious material to pass through the infected and relaxed cervix and thereby cause an endometritis. Often in these older cows with the characteristically deformed perineum, the vulvar lips may be parted with the fingers and air will rush into the vagina. In 20 cases of infertility apparently due to pneumovagina treated by the author, the cows had been bred unsuccessfully 2 to 8 times, or an average of 4.5 times. After correcting the condition, 18 (or 90 percent) conceived within 21 to 60 days. Although this is too small a number upon which to base a definite conclusion the fact nevertheless remains that following the closure of the vulva the vaginitis cleared up very rapidly and conception occurred similar to the condition in mares. From what is known concerning the value of the operation in mares the author feels that this procedure has received too little attention in the treatment of sterility in cattle. The external os of the cervix is usually involved in any vaginitis. If metritis or cervicitis is present some of the vaginal discharge may actually come from those sites and the vagina is involved secondarily. Necrotic vaginitis, as described previously following a difficult parturition, may also follow the accidental use of caustic agents as in a douche. In rare cases secondary stenosis and even atresia of the vagina may follow a severe vaginitis. In urovagina it may be necessary to surgically create a fold or dam of the vaginal floor to prevent urine from entering the vagina.

The Prognosis in simple vaginitis due to the causes listed above is good, and most cases will respond spontaneously even without treatment unless pneumovagina is present or unless a severe chronic cervicitis or metritis is also present. The prognosis is poor if stenosis or atresia of the vagina is severe. If the vaginitis is caused by an infectious agent, local antibodies are usually produced that aid in the elimination of infections such as **C. fetus**, **Tr. fetus** and **IBR-IPV**.

The Treatment of vaginitis usually consists of mild aqueous douches of 200 ppm chlorine solution, antiseptic aromatic soap solutions, dilute potassium permanganate solutions, 1:1000 to 1:3000 acriflavine solu-

tions, 200 ppm quaternary ammonium compound solutions, sodium bicarbonate solutions, solutions of chlorhexidine, or betadine and saline solutions. Irritating douches are unnecessary and should be avoided. Usually 2000 or 4000 ml of a solution are used and introduced either by means of a catheter and funnel, an enema bag and tube, or by holding the extended hand palm upwards in the vestibule pinching down the cow's back, and pouring the solution over the palm of the hand into the vagina. This flushing of the vagina may be repeated several times to wash out mucopurulent material. Retreating may be helpful at daily or 3- to 4-day intervals. Besides douching, some veterinarians introduce sulfonamides or antibacterials such as: penicillin, streptomycin, neomycin, furacin, tetracyclines or others in an ointment form or in oil-and-water emulsions. Others infuse the vagina with bland antiseptics in oil, such as sulfonamides and bismuth formic iodide, 1 ounce in a pint of oil, or iodine in oil; this may be repeated twice a week. If a cervicitis or metritis is present these should be treated also.

In cases of pneumovagina the vagina is usually douched thoroughly, an antibiotic solution or preparation is placed in the uterus, cervix, and vagina. Then under epidural anesthesia of the vulvar lips, as in the Caslick operation in the mare, the mucosa of the outer 1 to 1.5 cm. of the vulvar lips is scarified from the dorsal commissure to the level of the ischial arch. Often only a 2.5 to 3 cm. ventral vulvar opening is left after suturing. Sutures should be of chromic catgut or nylon. Since the cow's tail rests and rubs on her vulva, clips are not satisfactory as they usually are rubbed out. The interrupted sutures should be about 1 cm. apart and not put in so tightly that the suture cuts the tissues. The sutures may be removed in 7 to 10 days. (See Figure 85.) The vulvar opening after this operation is small and service by artificial insemination usually is necessary. During the last week or two of gestation the vulva should be incised along the original suture line so that no tearing of the vulva will occur at parturition. The vulva needs to be resutured after calving. In certain cases the removal of a large elephant ear-shaped sections of perineal skin between the anus and vulva and the ischial tuberosities results in drawing the anus caudally when these lateral wounds are closed. This "plastic" surgery aids in restoring a normal vulvar configuration. Occasionally an area of skin below the ventral vulva commissure may be removed to draw the latter structure ventrally.⁹

Urine pooling in the vagina may rarely occur associated with pneumovagina, as in the mare, and in bilateral sacroiliac luxation. A simple, successful technique to correct urovagina and restore fertility has been described.^{35b} It consists of constructing a transverse fold or

dam about 5 to 7 cm. high in the caudal floor of the vagina cranial to the urethral orifice by a continuous horizontal mattress nylon suture that is left in place for 30 days to make the dam permanent by the development of scar tissue.

Cysts of the Vagina are not uncommon. Cysts of the mesonephric or Gartner's ducts in the floor of the vagina are usually small, 1 cm. wide and 1 to 3 cm. long. There may be several cysts along the course of the ducts. (See Figure 129.) These cause little harm and usually they are not found except on speculum or manual examination of the vagina. They are seldom treated. Gartner's duct cysts are described under congenital defects since these ducts are remnants of the Wolffian or mesonephric ducts. In rare instances these cysts may become infected. On rare occasions single cysts up to 3 cm. in diameter, not of mesonephric duct origin, may be seen in the mucosa of the cranial and dorsal or lateral portion of the vagina.

Tumors of the Bovine Vagina have been described and include: fibromas, fibrosarcomas, leiomyomas, hemangiomas, lymphosarcomas, and carcinomas.^{11,63,88,90,92} Vaginal tumors are unusual in the cow. They seldom cause infertility but may cause dystocia, as do those of the cervix, if they are large enough. Most of the tumors are benign and pedunculated. Occasionally they may protrude through the vulva and surgical removal may be necessary. Excessive bleeding may occur unless steps to control it are taken at the time of the removal of the tumor.

Vestibule and Vulva

Vestibulitis and Vulvitis are similar to and treated in the same manner as vaginitis. Most cases of vulvitis are characterized by granular venereal disease lesions. Severe inflammations of the vulva may cause straining, refusal to copulate, and pain on examination. In severe cases the vulva is usually swollen and a mucopurulent discharge such as in severe granular venereal disease due to ureaplasma or other organisms or IBR-IPV infection, is present. Severe injury and lacerations of the vulva or vestibule caused by tearing of the vulva at the time of parturition, or by horn wounds should be sutured at once to prevent pneumovagina. Necrotic vulvitis and vestibulitis may follow severe trauma, ischemia and infections such as *S. necrophorus*. An outbreak of necrotic vulvitis affecting 170 Hereford feedlot heifers was reported.⁶⁶ This was a localized necrosis of the vulva that varied in size from a small area of sloughing to one involving nearly the entire vulva. The heifers did not become clinically ill and recovered in 3 to 5 weeks. The cause of the condition was not known but a virulent *S.*

necrophorus infection or an allergic type of reaction was suspected. Edema of the vulva and perineal region in clinical allergies or urticaria is common.⁸

Cystic Vestibular (or Bartholin's) Glands are often observed in the lateral wall of the vestibule. They arise from an atresia or obstruction of the duct of the gland that usually opens on the lateral wall of the vestibule at the vulva-vaginal border. This small paired gland secretes a rather clear mucus. Obstruction of the duct opening is usually due to trauma or severe inflammation, such as a local necrotic vaginitis, at the time of calving. This gland may enlarge due to the accumulation of fluid, until it is 2 to 10 cm. in diameter. When the cystic gland becomes larger than 5 cm. in diameter it usually shows between the vulvar lips when the cow is lying down as a round pink mucosa-covered object that is often mistaken for the beginning of a prolapse of the vagina. The cystic vestibular gland is almost invariably unilateral in occurrence and is seen in older cows and only rarely in heifers. It causes no problems at parturition nor does it interfere with conception. Occasionally when it is large it protrudes through the vulvar lips and becomes covered with feces and dirt. When the cow rises and the cyst returns to the pelvic canal contamination of the vestibule, vulva and caudal part of the vagina may occur. These cysts are easily handled by making a liberal incision therein. Painting the opened cyst with Lugol's solution, although commonly done, is probably not necessary.

The Tumors of the Vulva include: fibromas, fibrosarcomas, angiomas, carcinomas and fibropapillomas.^{11,44,46,63,88,90,92} A report on 28 fibropapillomas from the vulva and vagina of cows and 27 from the penis of bulls concluded that, because these occur primarily in young cattle usually in several animals on the same premises, the fibropapilloma is a transmissible tumor of the external genital organs of cattle.⁴⁴ This tumor undergoes spontaneous regression in about one to 6 months. It is similar to or the same as the common wart or papilloma found on the body skin of young cattle and caused by a virus.⁴⁴ The prognosis on squamous-cell carcinomas of the vulva are guarded to poor as often the regional lymph nodes may be affected. Slaughter is usually advisable. A small finger-like wattle is rarely observed on the vulvar labia (See Fig. 144).

THE REPEAT BREEDER COW

The discussion of this important infertility condition has been intentionally left to the end of this chapter because most of the diseases previously described are causes of failure of conception. The repeat breeding cow is one that has normal or nearly normal estrous cycles and estrous periods and has been bred 2 or 3 or more times to a fertile full or with fertile semen yet failed to conceive. The clinical examination of the animal may fail to reveal any definite lesion or condition to explain the failure of conception. The major proportions of the problem have been outlined but limited advances have been made in studying some of the various causes and still less on the diagnosis of causes in the individual cow. The greatest advance in this problem of "repeat breeders" has been the demonstration of the role of vibriosis in early embryonic deaths. It is unfortunate that many of the experiments performed before the mid 1950's and cited below did not consider this important cause of infertility.

In recent years the problem of repeat breeders and infertility in cattle has been reviewed.^{3,17,49,71,100} Infertility and breeding efficiency in a large dairy herd over a period of 30 years that included 2607 cows and nearly 10,000 breeding periods was reported upon.²⁸ The most common causes for infertility in which the fetus was carried to term were: short cycles, 24.2 percent; cystic follicles, 11.3 percent; and infection of the genital tract, 15.1 percent. The conception rate on services carried to term in clinically normal cows was 51.9 percent. In a recent report on 9750 Holstein cows in 125 herds in New York

State the conception rate on first, second and third services were 50, 51 and 53 percent with total conception rate after two and three services of 76 and 89 percent, respectively.^{79b} The various causes of repeat breeding have been classified differently by investigators. Some workers in the field of reproductive physiology have divided the causes into two groups: (1) failure of fertilization and (2) early embryonic death.¹⁷ Others,^{99,100} including the author, prefer a more detailed classification based on pathological and managerial causes namely: 1. congenital or genetic anatomical defects of genital tract, 2. congenital, genetic or acquired defects of the ova, spermatozoa or early zygote, 3. infectious or traumatic inflammatory processes, 4. endocrine disfunctions, 5. managerial and nutritional deficiencies. Modern herds incorporating large numbers of cattle and employing artificial insemination have many problems in heat detection, timing of service, and in the care and handling of semen in which the herdsmen and inseminators can influence the incidence of infertility and repeat breeding. Because of the multiplicity of causes for repeat breeding that varies from herd to herd, cow to cow, and estrus to estrus, diagnosis and therapy by the veterinarian requires great diagnostic skill and knowledge.

A survey of the problem of repeat breeding has shown the overall incidence in two large studies to be about 10 percent (9.1 to 11.1) to 15.1 percent (6.7 to 20.9), respectively.^{44,99} Over 50 percent of the farms surveyed had this average incidence of affected animals. As the herd size increased so did the incidence of repeat breeders. In New York State herds with over 90 cows had 5 to 10 percent lower conception rates than herds with about 50 cows.^{79a} The highest seasonal incidence of repeat breeders was in the fall and winter months with the lowest incidence in the spring and summer months, 10.2 to 13.7 and 7.1 to 9.4 percent, respectively.⁴⁴ The incidence of repeat breeders is lowest in heifers that had calved for the first time, 5.2 percent and then in older cattle it rose and in 9-year-old or older cows it was 13.3 percent. In another large study dairy cows over 7 years of age had a 15 percent lower conception rate than cows under 3 years of age.^{79a} The calving interval also increased. There was a marked tendency for cows to revert to spring calving with increasing age. Repeat breeding was also more common in cows with higher milk production. Only 10 percent of the herds or individual cows affected with an infertility or repeat breeding problem one year continued to be affected the following year.⁷¹ The herds with infertility problems remained constant at 6.5 percent from year to year in Kentucky. A study of records on 75,000 cows in the Netherlands also showed fertility decreased as animals grew older, from 68 to 58

percent in virgin heifers to cows with their tenth calf.⁹¹ As herd size increased there was a decrease in fertility. The greatest fertility was on farms raising grade cattle.

A summary of five of the early classical experiments on repeat breeding cows and heifers was prepared.⁶⁹ Most were taken from herds artificially inseminated. The animals were examined clinically and those with obvious disease of the reproductive organs and over 10 years of age were eliminated. However, in these early studies **C. fetus** might have been an important cause for infertility. Not more than 2 cows were taken from any one herd. The cows were bred to a fertile bull by artificial insemination on the second estrum after arriving at the central location for the experiment. One-half of these were killed on the third day after breeding and the oviducts were flushed to recover the ova, which were then examined to see if fertilization had taken place. Fertilization was noted by cell division in the ovum. The other half of the animals were scheduled to be killed at 34 days after insemination. If they came back in estrus before this time they were rebred and killed the third day. At the time of slaughter on 34 days the presence or absence of a normal, living embryo was noted. Thus from the findings at these 2 times the percentages of fertilization and of early embryonic deaths were determined. In these five studies 313 ova were recovered with a **fertilization rate** of 65.5 percent.⁶⁹

In two later studies, the fertilization rate of 120 recovered ova in 97 normal virgin heifers was 85.5 percent.^{9,10,52} Fifty one heifers bred to highly fertile AI bulls (70 to 79 percent conception based on 60 to 90 day nonreturns), had a fertilization rate of 96.1 percent; while 46 heifers bred to AI bulls with low fertility (40 to 60 percent conceptions based on nonreturns at 60 to 90 days), had a fertilization rate of only 76.1 percent. In 299 repeat breeding cattle, 6.4 percent failed to ovulate, 5.4 percent had occluded oviducts and 4.7 percent had abnormal or defective ova which accounts for some definite causes of failure of fertilization.⁶⁹ There was no apparent cause for failure of fertilization in over 23 percent of the repeat breeding cows. Low fertility of semen and possibly improper timing of service might have accounted for some of this failure of fertilization due to no apparent cause. Using highly fertile sires for breeding cows, especially repeat breeders, is highly desirable.

An incidence of 28.5 percent **early embryonic deaths** was reported in 199 repeat breeder cows.⁶⁹ As mentioned before it was unfortunate that the status of these animals with regard to **C. fetus** infection was not ascertained. When 26 virgin heifers were inseminated with antibiotic-treated semen from bulls of low fertility and 29 virgin heifers with semen of high fertility; the percent of nor-

mal embryos present at 33 days in the two groups were 57.7 and 86.1, respectively, with an estimated embryonic death rate of 19.6 and 10.5 percent respectively. This latter difference was not statistically significant.^{9,10}

Embryonic losses were similar in another study in heifers inseminated with spermatozoa from bulls with a high and low fertility.⁵² Although the quality of semen will influence both fertilization and embryonic death rates the results are not consistent.³ The average incidence of embryonic death in virgin heifers was 15 percent.⁷¹ The evidence indicated that repeat breeding, when highly fertile bulls were used, was largely due to embryonic deaths; while in repeat breeders bred to bulls of low fertility both failure of fertilization and early embryonic deaths occur. Most embryonic deaths occur soon after 16 days of gestation.⁴ In a study of 183 normal and repeat breeding cows in Israel by slaughter at gestation days 3, 11 to 13, 14 to 16, 17 to 19, and 35 to 42, the following percentages of viable embryos in the normal and repeat breeder groups were found 83 and 71, 89 and 50, 47 and 43, and 69 and 35, respectively. The fertilization rates were about the same in the two groups and most embryonic deaths occurred from 11 to 42 days.⁴ Most early embryonic death loss that was going to occur by 26 days had already occurred by 12 days of gestation.¹³ A 15 percent failure of fertilization, a 7.5 percent early embryonic death loss by 26 days, and an 8.0 percent further loss of older embryos and fetuses later in gestation was reported in 112 fertile Ayrshire cows inseminated with fertile semen.¹³ In a recent study of 3 groups of 47, 51 and 57 virgin Brahman heifers slaughtered on days 3, 16 and 35 postinsemination, respectively, the conceptus was recovered. At 3 days the fertilization rate was 80 percent. The percent of viable embryos at 16 and 35 days were 78 and 72, respectively. Thus most early embryonic loss occurred by day 16.^{79b} Embryonic deaths occurring at 8 to 16 days after breeding usually do not affect the normal cycle length of about 18 to 24 days but embryonic deaths occurring at 16 to 25 days often result in longer periods between service and the next estrus.

Embryonic mortality was monitored by milk progesterone assays in two studies through 75 days of gestation in dairy cows in the U.S. and England. In the former study,⁵⁴ 153 cows had continuous high progesterone levels for 28 or more days after insemination. Of these, cycling was reinitiated in 11 cows or a 7.2 percent embryonic mortality. This was considerably less than the estimated rate of 22.7 percent based on delayed returns to estrus. In the latter study⁶ 200 cows were monitored from 17 to 70 days after insemination for two years with an embryonic death rate of 9.7 percent after elimination of 6 cases caused by insemination at a false heat during

pregnancy. The incidence of embryonic deaths ranged from 3.3 percent in primipara to 15.1 percent in cows after their third lactation. Most embryonic deaths occurred around 35 days of gestation. The exact interval from embryonic death and return to estrus with a decline in progesterone is not known. However it has been reported abortion and estrus occurs 14 to 35 days after physical destruction of the embryo or early fetus by rectal manipulation from 30 to 90 days of gestation.⁵ Estrus and embryo or fetal expulsion occurred within 5 days when the CL was removed manually.

Certain bulls have a higher fertilization rate than other bulls. In one study of 12 beef bulls the pregnancy rate following natural service for 9 bulls ranged from 61 to 80% with the other 3 bulls having pregnancy rates of 0, 12 and 95%. With the exception of the sterile bull with no conceptions, breeding soundness examinations before and after the trial, scrotal circumference and semen quality had low correlations with bull fertility in this and also other cited studies.^{56b} Also heterospermic insemination, the insemination of a female with a mixture of semen from more than one male has been reported to improve fertility over homospermic insemination, which utilizes semen from only one male. In one study⁶⁸ no increase in fertility occurred when a semen mixture from two bulls was compared with homospermic insemination but when semen from 3 bulls was mixed, conception rate was significantly higher, 70.6 percent vs. 62.7 and 62.2 percent from homospermic inseminations or the seminal mixtures from 2 bulls. Heterospermic inseminations with frozen semen mixture from 3 bulls produced a definite deviation from the expected equal number of progeny per sire with one bull siring 47.2% of the calves. Pregnancy rate to one natural service did not differ from that of multiple services by a single sire. However multiple sire matings by 3 sires increased pregnancy rate per estrus by 10 percent, 73 to 63 percent, over that by single sire matings, respectively. This difference, as well as those in studies using heterospermic semen from 2 or 3 sires artificially, was simply a reflection of the degree of fertility of the single sire, or the most fertile sire in the multiple sire matings.^{56b}

In an excellent review of the problem of early embryonic deaths a large part was due to genetic causes as evidenced by the unexplained differences in fertility between males and the decline in fertility associated with age.¹¹ Thus much of the embryonic death rate is unavoidable and should be regarded as a normal way of eliminating unfit genotypes in each generation at a low biological cost. Thus, if one accepts the reported conception and pregnancy rate in cattle of 60 percent or 1.6 services per conception, and breeds 100 hypothetically

normal cows, 60 will conceive on the first service, and 9.6 of the remaining 16 will conceive on the third service.²¹ Thus in this hypothetical example using normal cows and bulls 6.4 percent of the cattle will require 4 or more services. Thus a certain percentage of repeat breeders are normal fertile cows.

The possible causes for fertilization failure and early embryonic deaths will be considered in the following classification based on pathological or managerial causes for infertility and repeat breeding.

Pathological Causes for Repeat Breeders

Genetic or congenital anatomical defects of the genital tract—These defects include principally the anomalies or segmental aplasia of: the uterine tube which is rare, the uterus, the cervix, and the vagina as have been described earlier in this chapter. These defects and anomalies largely cause failure of fertilization (F.F.) by preventing the union of the sperm cell and the ovum. Bilateral defects usually result in complete sterility. In some conditions, such as a lack of a normal endometrium, fertilized ova could not survive and form attachments or in underdeveloped cervixes proper protection for the uterus is not provided so endometritis and embryonic deaths (E.D.) result. All of these defects are present in heifers at the time of puberty but in the less severe conditions, such as uterus unicornis, repeat breeding may occur but conception and a normal pregnancy may follow and the condition may not be diagnosed until the second or subsequent breeding period. The genetic or congenital anomalies of the genital canal are infrequent causes for repeat breeding and many can be diagnosed by a careful rectal and vaginal examination. Genetic or hereditary defects causing infertility or sterility and possible chromosomal abnormalities in cattle were discussed earlier in this chapter.

Genetic, Congenital or Acquired Defects of the Ova, Spermatozoa or Early Zygote—A low incidence of about 5 percent of grossly abnormal ova were observed in repeat breeding cows,⁶⁹ and 2 percent in normal heifers.^{9,10} The possibility of a greater number of ova with defective chromosomes seems likely from reports cited previously to indicate a higher incidence of infertility in Guernseys and Brahman cattle kept on the same premises and under similar conditions as other more fertile breeds. The lowered fertility of older cows may well be related in part to defective ova. In a study of 37 blastocysts from 23 repeat breeding heifers only 30 percent were normal. While examination of 31 blastocysts from 18 normal virgin heifers 74 percent were normal—a highly

significant difference between the two populations.⁵⁶ Postovulatory aging of mammalian ova often resulted in failure of fertilization or polyspermy and early embryonic deaths.^{55,69,70} This may occur by breeding cows too late following the end of estrus. Inbreeding of the zygote and the dam has a deleterious effect on the conception rate and embryonic survival.^{17,18,57} If intensive inbreeding is followed, certain lines may experience marked infertility. Daughters of certain bulls are apparently more fertile than daughters of other bulls. This may partly be a reflection of the chromosomal constitution of the ova.^{31,48} Superior reproductive performance is usually reported in cross-bred cattle.⁵⁹ Thus heterosis can dilute or render ineffective lethal genes possibly present in purebred or closely bred lines.

A chromosome translocation, 1/29, in the Swedish Red and White Breed was reported in which 14 percent were heterozygotes and 0.34 percent were homozygotes for the translocation.³⁴ Daughters of translocation sires returned to service more often than daughters of normal sires apparently due to an increased embryonic death rate. About 10 percent of embryos from apparently normal gilts had chromosomal abnormalities, mostly trisomies, that were probably incompatible with life.^{60,61} In the future probably more genetic chromosomal anomalies causing infertility will be found.

The literature concerning the deleterious effects of aging of the ova after ovulation and aging of the spermatozoa before and after ejaculation into the female has been reviewed.⁵⁵ Gross anatomic genetic defects of the male reproductive tract resulting in oligospermia and aspermia due to anomalies of the mesonephric duct system have been described and result in infertility or sterility in the bull. Many genetic or congenital microscopic defects in spermatozoan morphology and chromosomes that prevent fertilization or result in infertility in bulls have also been described in Chapter XVIII. Some of these affected bulls may have a nearly normal semen picture. Other sperm cell abnormalities such as atypical basic nuclear protein produce degrees of infertility. Testicular hypoplasia and degeneration result in abnormal, infertile or sterile semen.

In bulls used in AI service there was significant differences in fertility and this difference was generally not related to observed differences in semen characteristics.¹¹ Fertility differences were largely due to genetic factors carried by the spermatozoa and not due to the environment in the female reproductive tract. The possible incompatibility between the sex cells as in hybrids, and in defective embryos from certain males, as well as incompatibility or possible immunological factors between the spermatozoa and zygote and the dam were dis-

cussed.^{11,17} Immune sera produced against bull semen in cattle caused an antifertility effect, either failure of fertilization or early embryonic death, when used to treat bull semen prior to insemination of heifers. In a recent study no sperm-immobilizing antibodies were found in normal or repeat breeding cows and it was concluded that antibodies against sperm were not responsible for failure of conception in these latter cows.³⁰ In the human, correlations between sperm antibodies and infertility have been inconclusive.

The relatively slow aging of spermatozoa in the male reproductive tract was reviewed and evidence cited to indicate that increased embryonic deaths occurred when these aged sperm cells were used for insemination. In contrast aging of spermatozoa in the female reproductive tract occurs in a matter of hours and it appears that the fertilizing capacity of the sperm cell is lost before changes occur in the genetic material.⁵⁵ Liquid bull semen stored at 5° C. for five days progressively loses its ability to fertilize ova and the incidence of early embryonic death increases.⁷⁶ Fertility based on 180-day nonreturn rates declined from 60 percent for semen used on day 1 after collection to 47 percent on day 5. The results of aging of spermatozoa in frozen semen were similar in that the decline in fertility went from 66 percent with frozen semen used less than 30 days after collection to 55 percent in semen stored over 6 months. This loss of fertility was probably due to chromosome damage, possibly chromosome leakage.

Thus, genetic, congenital and acquired defects of the ova or spermatozoa may result in failure of fertilization or early embryonic deaths and repeat breeding.

Infectious or Traumatic Inflammatory Processes Affecting the Genital Organs—result in repeat breeding due principally to early embryonic deaths. In a few cases where inflammatory processes have resulted in unilateral or bilateral obstruction of the genital tract as described earlier in this Chapter, failure of fertilization may result. Failure of fertilization may also occur in cows with severe salpingitis, metritis, cervicitis or vaginitis characterized by much inflammatory exudate and large numbers of bacteria that would be toxic to the sperm cells resulting in their loss of motility and death. The intriguing new field of the possible role of viruses in the developmental biology and pathology of preimplantation embryos and pregnancy wastage was reviewed.¹⁶ Presently knowledge in this area is very limited.

The infectious bovine venereal diseases of vibriosis due to *C. fetus*, trichomoniasis due to *Tr. fetus* and probably brucellosis due to *Br. abortus*, IBR-IPV virus, "Epivag" virus in Africa, possibly BVD-MD virus and certain pathogenic mycoplasma, ureaplasma or He-

mophilus organisms if introduced into the uterus with semen by artificial insemination can cause infertility and repeat breeding due to early embryonic deaths probably secondary to an endometritis of variable duration. As discussed earlier in this Chapter the above infections, especially the first two, are well-known for their antifertility affects. The virus of "Epivag" produces a severe salpingitis and perisalpingitis in up to 25 percent of affected cattle resulting in sterility due to the obstructive nature of the lesions.¹⁰⁰ Other nonspecific infections of a great variety that can produce an endometritis have also been described and can cause a varying period of infertility. *C. fetus* and *Tr. fetus* are harbored for long periods of time or indefinitely in the sheath and on the penis of older bulls and migrate by their own motility through the cervix into the uterus after natural service. Other nonmotile organisms can seldom pass through the cervical barrier following natural service but can be introduced by artificial insemination. Some of these infections such as *C. pyogenes*, *Ps. aeruginosa*, streptococci, staphylococci, *E. coli*, mycoplasmas, ureaplasmas, *Hemophilus somnus*^{47b,55b} and others may be present in the prepuce and occasionally in infected seminal vesicles of bulls^{47b,55b} and thus be present in large numbers in each ejaculate. Other infections producing endometritis, as mentioned previously in this Chapter, may enter the genital tract at the time of parturition or soon after, in the act of artificial insemination if it is not performed in a clean and sanitary manner, or in miscellaneous conditions such as pneumo-vagina. As has been discussed previously, only metritis or the severe forms of endometritis characterized by exudate in the uterus can be diagnosed clinically. Refined culture techniques and uterine biopsies are needed to accurately diagnose moderate to mild endometritis in the live cow. Pregnancy, however, can occur in the presence of a mild endometritis.^{64,100} Seventeen clinically normal repeat breeder cows had the same infection rate of non-specific bacteria as 46 normal fertile cows 50 days postpartum, or 56 to 58 percent of each group had at least one positive sampling and 28 percent of cultures of both groups were positive. No *C. pyogenes* infection was present in either group. Thus the use of antibiotic treatment for repeat breeders was not indicated.³⁹

It is generally accepted that a young growing zygote seldom can survive in a diseased environment and for optimum fertility a normal or nearly normal endometrium is desirable or necessary. The genital tract, and especially the uterus, has excellent mechanisms of local antibody production, phagocytosis, mucous flow and uterine contractions that can usually overcome an endometritis at the first estrous period or within the span

of 2 to 6 estrous periods. This spontaneous recovery from infection has been well-documented in the postpartum involuting uterus and in vibriosis and trichomoniasis. Therefore by the time the infertile cow with endometritis is classified as a repeat-breeder she is often well on the way toward recovery or has recovered her fertility. This probably accounts for the divergent reports and observations on this subject as reviewed.^{17,23,41,46,69,78,82} Some authors reported only a very low incidence of pathological or inflammatory changes in the genital tracts of repeat breeder cows as cows with clinical infections were eliminated from the classification. Antibiotic and other infusions to correct possible uterine infections in repeat breeding cows may or may not, usually the latter, reveal significant results over nontreated controls. In many repeat breeding cows at slaughter, cultures of the uterus are negative for pathogenic bacteria. Nonspecific bacteria are commonly found in the cervix and caudal genital tract of cows and are always present as contaminants from the prepuce in semen. The presence of antibiotics in the semen used artificially controls or destroys certain infectious organisms such as *C. fetus* but the natural body or uterine defense mechanisms at estrus provide strong protection against infections due to these bacterial or other agents introduced into the genital canal with the semen. This author believes that endometritis due to various infectious agents is a common cause of infertility early in the postpartum period but within a variable time a rapid spontaneous complete recovery occurs. Thus if the repeat breeder cow has a normal genital tract on clinical examination, there is no reason for withholding service. The ability to ascertain this state of the genital tract will vary between veterinarians. Increasing the period of sexual rest to improve conception rates on the next service is uneconomical in the clinically normal cow. Neither a natural or artificial service will prolong the time before conception will occur. Rapid spontaneous recoveries followed by conception are common.

Endocrine dysfunction as a common cause of repeat breeders is probably unlikely since the estrous cycle in these animals has been generally reported as normal except for prolonged postservice periods when early or late embryonic deaths occur.^{17,40} However there is some evidence that a hormonal dysfunction can result in repeat breeding after treatment of cystic ovaries with LH or GnRH or after estrus synchronization with prolonged progestin therapy.

The author previously reviewed the controversial studies on delayed ovulation or anovulation.⁷⁴ The examination of repeat breeding cows 24 to 36 hours and later after service should reveal either delayed ovulation, anovulation, errors in estrus detection or the development

of cystic ovaries noted under stress conditions. The use of the milk assay for progesterone should aid the diagnosis. Delayed ovulation and anovulation are uncommon causes for repeat breeders.^{3,4,17,24,67} If these conditions are suspected the administration of 2000 to 5000 IU HCG or 100 ug GnRH and daily breeding until ovulation occurs might be indicated. The routine use of GnRH and HCG at the time of breeding have not given consistent results nor is there any evidence that the injection of these hormones, shortly after breeding, 3 to 10 days, improves the rate of conception. Therefore their use in these ways cannot at present be recommended.^{25a,89} HCG given 10 days after breeding prolonged diestrus about 5 days.^{25a} Two recent reports indicated that injecting GnRH (100 ug) at the time of insemination in repeat breeder cows improved the conception rate over 15 percent from untreated controls. This treatment did not affect first service conception rates.^{57b,77a} Further study is indicated.

The administration of small doses of estradiol to promote the LH surge early in estrus has not proven practical even with estrus synchronization. As noted under the prevention of conception in Chapter V injections of estrogens at the time of estrus or within several days after ovulation will affect the transport of the fertilized ovum in the oviduct resulting in too rapid transport or "tubal locking" of the ova and death of the zygote. Estrogenic mycotoxins, such as zearalenone, present in feed might cause infertility by inhibition of gonadotropin secretion and ovulation and cause abortion.¹² Injections of oxytocin from day 2 to day 6 after estrus and service causes hypoluteinization of the CL, early embryonic death and shortened estrous cycles. The normal CL at 15 days of gestation contained 270 mg total progesterone while a small hypoluteinized CL with less than 100 mg of progesterone could not maintain the early embryo (See Bovine Reproductive Physiology). A study reported that 57 percent of nursed beef cows conceived on the first service compared to 71 percent of milked cows that conceived.⁹⁷ Services per conception were 1.84 in nursed cows and 1.54 for milked cows.

In a clinical and endocrinological study of 37 first or second inseminations of 10 cows for their third pregnancy starting 80 days after calving comparisons were made between the fertile and infertile services.²⁷ Fertile cows conformed to the generally accepted pattern of regular estrous cycles (17 to 25 days) with termination of the cycle within 3 to 4 days after the C.L. started to regress. The plasma progesterone decreased from near maximum to near minimum (below 0.75 ng/ml) in about 2 days. The onset of estrus and the LH surge occurred in another 24 hours followed by ovulation in 20 to 26 hours. Infertile cows showed evidence of asynchrony

either before or after insemination. Fourteen of 26 cows (54 percent) did not show estrus or an increase in LH within 32 hours after plasma progesterone declined below 0.75 ng/ml. Thirteen of 26 (50 percent) infertile cows that ovulated had low plasma progesterone 6 or more days after ovulation. Nine cases had both defects. Variations in estrogen levels in plasma were large in the infertile cows and might account for failure of the fertilized ova to enter the uterus at the proper time.²⁷ It was believed that the low conception rate of 34 percent was associated with the frequent prolonged clinical ovarian examinations and blood collections. Plasma levels of progesterone during the first 10 days of the estrous cycle may affect fertility. Cows given PMSG in the midluteal phase of the cycle followed by a luteolytic dose of prostaglandin 48 hours later that had plasma progesterone levels of 1.2 nmol/l produced excellent embryos while those cows with levels of 3.9 nmol/l produced unfertilized eggs.^{49b} In another group of heifers receiving embryo transfers on day 7 or 8 postestrus, those having plasma progesterone levels less than 2 ng/ml on the day of transfer had a pregnancy rate of 20 percent compared to a 60 to 80 percent rate in heifers with levels of greater than 2 ng/ml.^{73a} Further similar studies of repeat breeder and normal fertile cows should be conducted.

In a later review of embryonic mortality prior data were summarized by Ayalon³ to show that repeat breeder heifers and cows had heavy fertility losses due to fertilization failure and early embryonic deaths. While normal heifers had fertility losses limited largely to embryonic death and normal fertile cows had low losses in both fertilization failure and embryonic deaths. In repeat breeders the critical period for embryonic deaths is when the morula is developing into the blastocyst at 6 or 7 days especially the latter day.³ This study also examined plasma steroid levels from estrus through day 7 and found progesterone levels for normal cows with normal embryos and repeat breeder cows with degenerating embryos were similar. But plasma estrogen concentration rose sharply on day 6 and 7 in cows with normal embryos but in cows with abnormal embryos it did not rise on day 6 and dropped on day 7. This difference correlated closely with marked rises in ion concentrations of potassium, zinc, phosphorus and especially calcium in the uterine flushings during the days 6 to 8 after insemination. Whether these changes in plasma estrogen and in concentration in uterine flushings were the cause of the embryonic deaths or due to the embryonic abnormalities and deaths will require further study. Protein levels in the uterine flushings were higher in normal cows than in repeat breeders despite the state of the embryo. These studies offer challenging new insights into the

enigma of the repeat breeder heifer or cow.

Although there was little evidence that repeat breeders are due to an imbalance of ovarian secretion,^{17,40} others have noted that progesterone or a progestagen administered 3 to 5 days after service and continued for a variable period of 2 to 3 weeks or longer improves the conception rate in repeat breeder cows over the controls.^{19,22,43,50,73,98} Products used have included progesterone in oil and repositol progesterone at doses of 50 to 100 mg daily. However, other studies have shown such supplementation to be of no value or if given during estrus or shortly thereafter actually was detrimental to conception.⁸⁹ This increased amount of progesterone the first few weeks after fertilization may improve the uterine environment for the zygote so a larger number of embryos survive. In repeat breeders most embryonic deaths occur before the corpus luteum regresses. In fact failure of fertilization or the death of the embryo is necessary for repeated cycles to occur in bred cattle. Starting treatment with progesterone before day 3 or 4 after service may suppress C.L. growth, hasten ova transport or in some other way lower the fertility of normal and repeat breeder cows.

Managerial deficiencies including nutritional deficiencies in the herd are a common cause of lowered fertility and repeat breeding. These must be differentiated from infectious venereal diseases such as vibriosis and trichomoniasis which also are often herd problems. The managerial causes of repeat breeding have become greatly increased with larger herds and the widespread use of artificial insemination. It will probably continue to increase with the trend toward each herd owner or herdsman inseminating his own cows with frozen semen.

It is a significant fact that the larger the herd the greater the infertility or incidence of repeat breeding.^{79b,99,100} Many herdsman can supervise and watch the cows in small herds but in large herds this is more difficult, more time must be spent in observation and more detailed records are necessary. A common cause of repeat breeding is poor or inadequate observation of the cows at frequent intervals each day for signs of estrus. If this is not done regularly, 2 to 4 times a day, up to 20 to 40 percent of the estrous periods may be missed and poor timing of insemination in regard to ovulation results and aging of either the ova or spermatozoa or both may occur (See anestrus). A study of 86 herds of cattle demonstrated that if 1, 2 or 3 cows are presented for service in the same herd at the same time that conception rates were 69.1, 64.5 and 59.2 percent, respectively.²⁹ The lowered fertility occurring when 2 or more cows were presented for service at the same time was due to the tendency to offer cows in suboptimum breeding condition. A summary of

data on fertility in relation to the length of the estrous cycle concluded that there was no practical reason for delaying service because of estrous cycle irregularity if the cow is otherwise normal and the cycle is at least 17 days long.²⁶ Shorter cycles are indicative of cystic ovaries or acute endometritis. The average length of the bovine estrous period is 10 to 28 hours and ovulation occurs 10 to 15 hours after the end of estrus. Cows should be bred within 10 hours before or after the end of estrus for best fertility. This requires frequent daily heat checks and regulated insemination. Bull spermatozoa have a variable life up to 48 hours in the female but highest fertility rates occur within 12 to 24 hours after service. If estrus and ovulation are normal there is very little increase in conception rates, only about 2 percent, in inseminating cows twice, once late in estrus and again 12 to 20 hours later. Calves resulted from insemination from 14 to 34 hours before ovulation.^{1,95} It was demonstrated in 1943 with a large group of cattle, that cows bred at the beginning of estrus had a conception rate of 44 percent, at midheat 82.5 percent, and at the end of heat 75 percent; 6 hours after the end of estrus 62.5 percent; 12 hours, 32 percent; 18 hours, 28 percent; 24 hours, 12 percent; and 36 hours, 8 percent; 48 hours after the end of estrus no ova became fertilized.^{86,87} This indicated that the ovum probably was unable to survive longer than a few hours after ovulation. There is evidence that spermatozoa might have to be in the genital tract about 6 hours before ovulation for optimum fertilization and conception. It seems likely that the excellent fertilization and conception rate reported in one trial may have been due largely to careful and frequent observations for estrus, and to artificial insemination at the proper time of estrus.^{9,10} In a limited study conception rates were similar in 97 cows bred as soon as estrus was detected and in 92 cows bred 12 hours after the onset of estrus.^{77a}

In recent years, in contrast to earlier trials, evidence has shown there can be considerable latitude as to the time of semen deposition in relationship to the time of estrus recognition.^{8,32} Data on 32,400 cows observed in estrus in the AM had a 67.1 to 69.9 percent nonreturn rate if bred that day and a 62.7 percent nonreturn rate if bred before noon the next day. In over 12,300 cows observed in heat in the PM the nonreturn rate for cows bred before noon the next day was 69.9, from noon to 2 PM was 67.4 and after 2 PM the next day the nonreturn rate was 63.8. This data from New York was confirmed in Virginia.⁸ In a beef herd in Colorado 2,091 cows were inseminated with a calving rate of 63.4 percent; 1,019 cows bred after 24 hours after estrus was detected had a calving rate of 60 percent.

However in Texas short estrous periods and low in-

tensity of estrus in Holstein dairy cattle made detection of estrus difficult. About 25 percent of estrous periods would have been missed on twice a day instead of 4 times a day estrous checks.¹⁵ Cows bred immediately after the detection of estrus had a much lower embryonic death loss, especially during the hot seasons of the year than cows bred 12 hours after estrus was detected. Further studies should be made to confirm this latter report.

The effect of nutrition, especially TDN intake and the need for a positive energy balance for high fertility was discussed earlier in this chapter. There is little question but conception rates are better when cows are increasing in body weight. This poses a severe problem for managers of herds with high-producing dairy cows to provide rations and see that cows consume sufficient energy to have a high fertility level. There is no evidence in cattle that increased embryonic deaths occur in overfed animals.³⁶ There is evidence that supplemental iodine, particularly in iodine deficient areas has a beneficial effect on fertility. When supplemental iodine was provided in a controlled experiment in 190 herds with 1572 cows, conception rates on first service in treated and untreated herds were 69.1 percent and 62.2 percent, respectively.⁶⁵ An organic iodine compound was fed orally for 8 to 12 days before the next service in 1036 repeat breeding cows and 58 percent conceived on the first service, while in the control cows conception rate was well below 50 percent.⁵⁸ It is possible that iodine absorbed from the uterus by uterine infusions of an iodine solution exerts a similar effect.

The Production Division of the Milk Marketing Board in England reported that the conception rate in 125 newly established herds was 60.8 percent as compared to 73.7 percent conception rate in 64 other herds in the same area.^{47a} The lowered fertility was probably due to a combination of stress placed on the animals by transport and new surroundings, and the difficulty of the new owners in evaluating the heat characteristics and having the cows inseminated at the proper time. Lowered fertility occurred after the stress of transport and in a new environment.^{47a} Conception rate in 634 cows bred artificially for the first service within 2 months after moving was 54.9 percent; while in over 32,000 first services in cattle born and remaining on a farm the conception rate was 68.6 percent.

Further evidence illustrating the effect of stress on lowered bovine fertility is the reduced fertility associated with high ambient temperatures of over 80° F for long periods in the summer months in the southern portions of the United States. Under hot climatic conditions the duration of estrus was shorter and the intensity of signs of estrus was reduced.³² High temperatures depressed feed

consumption and milk production and resulted in a 10 percent reduction in pregnancy rate.⁵¹ This decline was even greater than 10 percent when frozen semen collected from bulls during the hot summer months was used. Jerseys and Brown Swiss were more resistant than other dairy breeds to the effects of heat. Lowered conception rates to near 20 percent, during the summer months was reported in Arizona and Texas,^{45,80,81} due to low fertilization rates and high embryonic death rates. Monthly pregnancy rates in cows bred from June to October ranged from 17.1 to 36.1 percent, while from October through May they ranged from 44.4 to 61.5 percent. More prolonged postservice cycles are observed in the summer months. An excellent review on embryonic deaths discussed the stress produced by a rise in temperature affecting the spermatozoa before fertilization or the zygote immediately after fertilization resulting in embryonic deaths at a later date.⁸⁸ In reviewing problems of infertility in cattle in a tropical or sub-tropical environment it was noted that Zebu cattle did not increase their metabolism to the same extent when external temperatures rose above 73° F as did the European cattle.⁹² High temperature affected the latter breeds by suppressing estrus and ovulation, causing anestrus and anovulation and causing early death of the embryo.

Thus, during the hot summer months in the southern United States especially in dairy herds, every effort should be followed to keep the animals cool by providing shaded areas or sheds, evaporative cooling or even air conditioning for a portion of the day,⁸⁵ especially at higher elevations, that allow the free movement of air, plenty of fresh water and a nutritious diet with a minimal amount of fiber. This would reduce the severity of heat stress, improve feed intake and increase milk production besides resulting in a reduction in repeat breeding cows (See Anestrus).

In natural service the bull deposits his semen in the proper site, while in artificial insemination there are many possibilities for man to render infertile the bovine sperm cells. These possibilities include: (1) improper extension, freezing and storing of fertile semen. Warming of frozen semen above -79° is highly detrimental to sperm cell viability and fertilizability; (2) improper thawing of frozen semen. This must be done rapidly in a large volume of luke warm or ice water as slow or erratic thawing rates are harmful to sperm cells; (3) insemination should take place promptly, within several minutes after thawing. Thawing semen and keeping it at 5° C. or 40° F for an hour or more is very detrimental to sperm cells; (4) a proper insemination technique should be followed to place the semen in the middle or cranial portion of the cervix, not into the uterus, in a clean and sanitary man-

ner with little or no trauma to the genital tract. Directions provided by the supplier of the frozen semen should be strictly followed if satisfactory results are to be achieved. If liquid extended semen is used, it should be recognized that conception rates decline each day the semen is stored at refrigerator temperatures. In 5744 inseminations in 146 Holstein herds, the conception rate declined from 65.4 percent for first day liquid semen to 45.6 percent for over 3-day-old, stored semen.

For optimum conception rates on first service and a minimal number of repeat breeders, cows should be bred 60 days or later postpartum.¹⁴ The respective conception rates to first service were 39.5 percent for cows bred at less than 40 days postpartum, 51.2 percent for cows bred at 41 to 50 days, 59.4 percent for cows bred at 51 to 60 days, 63.7 percent for cows bred at 61 to 90 days and 65.1 percent for cows bred over 90 days. Similar results were reported by others. In a recent study and review⁹⁶ conception rates at first service postpartum under 30 days were 18 to 37 percent, from 30 to 40 days 45 percent, from 40 to 50 days 53 percent and from 51 to 59 percent for every 10 day interval to 120 days postpartum. In beef cattle a short breeding season was highly desirable. This often required that cows be bred before 60 days postpartum. The percent of cows calving when bred the following number of days postpartum, 11 to 30, 31 to 50, 51 to 70, 71 to 90, 91 to 110 and 111 to 130 was 11.1, 57.7, 77.5, 80.6, 94.14 and 81.8, respectively. The Milk Marketing Board (1968-1969)⁶³ reported the probability of conception was 40 percent if insemination took place between 11 and 31 days postpartum, 55 percent from 32 to 52 days, 62 percent from 53 to 73 days, 65 percent from 74 to 94 days and 68 percent from 95 to 115 days postpartum. If the service interval is shortened by a single breeding cycle, another 6.4 inseminations per 100 cows are required but the calving interval is shortened. These figures were based on hypothetically breeding 100 cows at 84 days postpartum. No harmful effects such as delayed conception, evidence of early embryonic deaths or abortions could be attributed to breeding cows at 35 days or less postpartum except that the cows had lower conception rates.^{70,96} For each 10 days sooner a cow was bred after calving, the calving interval was shortened 8.8 days. Thus, although there was a slight increase in the number of services required for cows bred less than 50 days, there was no increase in lost days and the economic value to the dairyman of calving intervals of 12 months or even less, might be worth the slightly increased number of services per conception.⁷⁰

Palpation of the ovary at the time of insemination should not be done by the lay technician. If an experienced veterinarian or researcher wishes to examine the ovaries to

palpate the Graafian follicle and determine the time of ovulation, it should be done in a gentle, skillful manner to prevent manually rupturing the very thin-walled follicle. The accidental manual rupture of the mature follicle during estrus resulted in conception in 1 of 7, 5 of 12 and 1 of 17 cases, respectively. Less than 20 percent conception resulted from service after this accident.^{1,90,93} Apparently the ova are washed away or possibly caught in the collapsing walls of the unphysiologically "ovulated" follicle.

Although evidence has been presented to indicate that clinically normal repeat breeding cows are similar in some parameters to normal fertile cows, limited embryo recovery, examination and transfer studies have shown significant differences between these two classes of cows.^{25b,56} Twenty-three repeat breeding heifers and 18 normal virgin heifers were bred AI to one highly fertile bull and embryos or blastocysts were recovered non-surgically and examined, the number and percent of normal blastocysts from the virgin and repeat breeding heifers were 23 (74.2%) and 11 (27.5%) respectively. The remaining blastocysts were degenerated or in the process of degeneration. Blastocysts were recovered in 70.4 percent of the collection attempts in virgin heifers and 57 percent of the attempts in the repeat breeding heifers. These differences were highly significant.⁵⁶ In another study it was reported that most infertile beef cows do not respond to superovulation with gonadotropins as efficiently as fertile beef cows.^{25b} Greater numbers of fertilized ova were recovered from the fertile dairy cow donors than the infertile donors, average 6.8 vs. 1.1, respectively. The infertile cows were divided into two groups, those with diagnosed causes of cystic ovaries, endometritis or adhesions which were treated and had two normal estrous cycles before ova collection and those cows with undiagnosed infertility.^{25b} When single ova were collected from unsuperovulated cows the quality of the fertilized ova from the fertile and diagnosed and treated infertile cows and the pregnancy rates (88 percent) following transfer were excellent and similar. But the pregnancy rates following transfer of embryos with similar quality from the undiagnosed infertile cows was only 33 percent and only 21 percent of these cows yielded viable embryos. Thus it would appear that these undiagnosed infertile cows produced viable embryos but had "abnormal" reproductive tracts causing poor zygote transport or a uterine environment unable to support embryos.^{25b}

The convergence of significant older data in several animal species^{32b,51b,57b,c} with a recent study^{39b} based on 984 bovine embryo transfers from superovulated donors compels the author to propose that repeat breeders or problem breeders, especially older females, probably is

due to a combination of factors including: (1) significantly fewer fertilized ova entering the uterus of infertile or repeat breeding females compared to healthy cows (2.6 vs 6.7), (2) significantly increased numbers of infertile bovine females with no ova or embryos entering the uterus compared to healthy cows (21 vs 4 percent), (Since non-fertile ova are retained in the oviducts of problem mares this finding would be more common in the equine species) (3) reduced pregnancy rates in young healthy recipients of visibly normal 6 to 8 day-old embryos from infertile older females compared to normal cows (58 vs 68 percent);^{39b} and (4) aging, "wear and tear" of pregnancy, birth, and uterine disease processes that result in an increase in uterine collagen in pluriparous rabbits,^{57b,c} mares,^{51b} and cows. Reduced blood flow and fewer estrogen and progesterone receptors were present in the older rabbits' uteri,^{32b} and possibly the uteri of older cows and mares, contributing to their infertility. Further studies on this frustrating complicated and multifaceted repeat breeder cow problem is indicated.

Conclusions on repeat breeding—The general and broad physiological and pathological causes of repeat breeding in cattle have been outlined. Many excellent studies on various aspects of the problem have been made and advances have been achieved in the past 25 years. However, the treatment or handling of the problem at present is essentially based on the experience, skill, knowledge and thoroughness of the diagnostic procedures employed by the veterinarian to arrive at the cause(s) and contributing cause(s) for this problem. In some instances it may be necessary to permit a degree of repeat breeding if offspring from a relatively infertile or old sire or dam are desired or if it is desired to shorten the calving interval by early postpartum breeding. If artificial insemination is practiced, a painstaking examination of the frozen or liquid semen and the processes employed in storing semen and inseminating the cow must be undertaken. Just because semen is frozen and labeled, its fertility is not assured! If natural service is used then the bulls and their semen, libido and servicing ability must be carefully evaluated. The diligence and care the owner or herdsman takes in observing and recording heats and services are important. Some owners and managers are not well acquainted with the behavior of cows and have difficulty recognizing estrus.

If repeat breeding is a herd problem, the semen or bull used, the presence of infectious venereal diseases or the improper observation, recording, breeding and management of cows or all three areas may be at fault. If individual repeat breeding cows are the problem, then a wide variety of causes may be considered. With the many causes for repeat breeding, it is highly possible that in

a poorly-managed herd repeat services in a cow could be due to a different cause or combination of causes at each infertile estrous period.

Occasionally genetic, congenital or acquired defects or obstructions may be present preventing the union of the spermatozoa and the ovum. Genetic or acquired damage may affect the ova or spermatozoa. In treating repeat breeding cows with normal genital tracts servicing the animals each heat period at the proper time with spermatozoa from a highly fertile bull is imperative. The few cows that have a history of repeat breeding each year for several years or more should be culled.

Endocrine malfunction in repeat breeder cows is apparently not common except in occasional cases of an-ovulation or delayed ovulation which requires further study by a number of investigators under a variety of stress conditions and in many herds. Administering progesterone therapy for a variable period starting 3 to 4 days after service and continuing for 8 or 10 days shows promise in the treatment of certain cows, but further study and trials are indicated. Administering progesterone, estrogens or other steroid hormones before or at service is not indicated.

Endocrine therapy in most repeat breeders is unsuccessful, especially if used empirically and without an understanding of reproductive endocrine physiology. In sporadic infections of the uterus causing repeat breeding, spontaneous recovery in a variable, usually short few weeks or months, is the rule. Infusions (20 to 50 ml) of weak (2 ml of Lugols/100 ml of saline) iodine solutions seem to be as good or better than any other intrauterine therapy given 12 to 36 hours post service. Antibiotic infusions given within 10 to 15 minutes after insemination may have a detrimental effect on conception.²⁰ In certain herd or individual cow problems uterine biopsy and culture might be helpful in making a diagnosis.

When one considers the multiplicity of the direct and indirect or predisposing causes for failure of fertilization or early embryonic deaths, the magnitude of the diagnostic problem posed by this problem is challenging. Particularly so in problem herds where careful study will usually indicate the cause and in individual problem cows where the exact cause may be impossible to determine with accuracy. Treatment of these latter cases should never become routine or empirical, but these cases should be studied more carefully and in greater detail and the recommended therapy should be given based on knowledge concerning reproductive physiology, use of highly fertile males, servicing at the proper time of estrum, repeated matings, patience and, if necessary, conservative therapy that will not interfere with or prevent fertilization and early embryonic development. Every decade has

brought forth new knowledge and insights on this complicated, multifaceted problem. Further studies on the causes and possible rational therapy of repeat breeding cows are needed.

The Postpartum Period

In attempting to achieve a desirable, economically necessary 12- to 13-month calving interval, the interval from calving to conception must be 85 to 115 days, respectively, since the duration of gestation is fixed at 280 days. To achieve this goal, breeding of cows that have normal calving and postpartum periods should begin at

50 days after two postpartum estrus cycles, 14 to 18 days and 30 to 38 days. These are necessary to result in good conception rates. This then allows two breeding periods between 50 and 85 days or three breeding periods between 50 and 115 days. Services per conception should be about 1.7 per conception or less which would result in 87 percent of the cows pregnant by 110 days (50% conceptions on 1st service, 50% conceptions on 2nd service or 76% of the cows and 50% conceptions on third service or 89.0% of the cows).¹⁶ Breeding prior to 50 days postpartum is generally not desirable because of reduced conception rates (more services per conception)¹⁸ and this practice could cause an abbreviated dry period. Forty-two days has been shown to be a maximum necessary for high milk production.³ For a herd to average a 12-month calving interval the largest number of breedings resulting in conception should cluster around 50 to 110 days postpartum. Economic losses occur when large numbers of conceptions occur earlier than 50 days or more than 100 days. In 56,000 cows in 376 herds it was shown that maximum, total milk production was achieved at a calving interval of 385 days or 375-395 days. Cows bred early in the postpartum period with a calving interval of 343 days averaged 15,700 pounds of milk vs 16,300 pounds produced by cows with a 385 day intervals, a difference of 600 pounds or about 1.6 pound per day.^{12b} Correction of factors causing prolonged calving intervals is more important than early postpartum breeding to an economically profitable production record for a herd. The frequency distribution of observed postpartum estrous periods, services, and calving intervals should be tabulated for study.

Therefore the early onset of the observation of and recording of regular postpartum estrous cycles of all cows is imperative. Cows with milk fever, retained placenta, metritis, postparturient diseases of ketosis, displaced abomasum, acute mastitis, failure to return to a level or positive energy balance, cows developing cystic ovaries and owners failing to detect cows in estrus, all result in a delayed return to service and a prolonged calving to conception interval.^{1,7,11,19,21} The incidence of reproductive disorders in the postpartum period was studied in 4093 lactations in 22 dairy herds in N.Y. State:^{15b}

	Incidence (Percent)	Aver. days to 1st service	Conception Rate 1st service	Breedings per Conception	Days open
Lactations with no reproductive disorders	78	81	51	2.1	103
Lactations with metritis*	15	89	36	3.1	110

	Incidence (Percent)	Aver. days to 1st service	Conception Rate 1st service	Breedings per Conception	Days open
Lactations with retained placenta, without metritis	4	88	42	1.6	106
Lactations with ovarian cysts treated more than once or after 60 days postpartum**	1.5	103	25	4.6	149

*Metritis occurred in 24% or 49% of dystocia and retained placentas, respectively.

**Ovarian cysts diagnosed prior to 60 days postpartum (2% incidence) did not impair performance.

In a study of 106 postpartum cow's genital tracts *C. pyogenes*, coliforms and streptococci were isolated most frequently. Abnormal uterine involution with a purulent discharge was most commonly associated with *C. pyogenes* infection and resulted in an increased number of services for conception and in cows culled for infertility.^{16b} Cows with a clear vaginal mucus at estrus do not require therapy while the presence of a purulent vaginal discharge should be treated even if the cervix and uterus are involuting normally. Young 2 to 3 year-old cows had a higher first service conception rate than did older cows, 61 vs 35 percent respectively. In this study, one or more postpartum diseases also reduced the first service conception rate and the latter was negatively correlated with milk production.^{16b}

Calvings should be in a clean, well-bedded with straw or hay, disinfected stall or a clean pasture to avoid postpartum retained placentas and postpartum infections (See Chapter XI). In older cows prompt treatment of incipient milk fever or retained placenta with calcium products and oxytocin and possibly parenteral antibiotics is imperative. Dry cow therapy and dipping of teats should be practiced when drying the cow off and teats should be dipped for a week or so before calving. Postpartum examination of the cow at about 21 and/or 35 to 45 days¹⁷ is indicated to be certain normal involution and estrous cycling is occurring and that postpartum infections or cystic ovaries have not developed. If cystic ovaries have developed prompt administration of GnRH or HCG is indicated. In older cows or high-producers it may be desirable to give 100 to 250 ug of GnRH on the 12th to 14th postpartum day, or when follicles 1 cm. in diameter are present, to promote ovulation, normal corpus luteum formation and estrous cycling and prevent the development of luteal or follicular cysts.²² Evidence reported to the author indicated that manual massage or examination of the bovine uterus per rectum 8 to 15 days postpartum might stimulate uterine activity, the estrous cycle and hasten uterine involution and result in a greatly reduced

calving to conception interval.^{1a,b} Uterine examinations 20 to 35 days postpartum did not result in such pronounced effects.^{1b} Further controlled studies are indicated.

A nutritional program should be established for the dry cow to avoid overconditioning and the problems associated with the "fat cow syndrome" at calving, and then as milk production increases after calving, energy intake should keep pace so the cow is not losing weight the first 90 days postpartum.^{1c,10} A negative energy balance is associated with postpartum anestrus. If this is prevented earlier estrous cycling occurs which improves the conception rate after 60 days postpartum. Careful, frequent observation of all postpartum cows during the early and late daytime hours and one-night time period is necessary^{7,19} to detect, record and breed or inseminate the cow with highly fertile semen at the proper time between the middle to just after the end of estrus. Insemination should be performed by a skilled technician. Heat detection aids such as Kamar heat detectors or chalk or paint on the rump may assist in estrus detection. Careful observation of all bred cows, especially 20 to 23 days after service and pregnancy examinations at 40 to 45 days are imperative to prevent many missed heat periods.^{19,23} All cows not previously diagnosed as definitely pregnant should be examined at each herd visit at preferably monthly or semimonthly intervals by a knowledgeable veterinarian.

For certain cows that are cycling as noted by the presence of a normal mature corpus luteum but estrus have not been observed, an injection of a luteolytic dose of prostaglandin (**Lutalyse** 20 to 35 mg or **Estrumate** 250 to 500 ug) injected IM once or twice at 10 to 12 day intervals should be followed by breeding at the next estrus in 2 to 5 days or at 72 and 90 hours after the injection of prostaglandin.¹⁴ (See Estrus Synchronization discussed in this Chapter.) If postpartum metritis or endometritis develop prompt intrauterine therapy with adequate antibiotics or antiseptics is indicated together with

prostaglandins to establish a normal estrous cycle. If natural breeding is practiced, cows should be vaccinated against vibriosis one month before breeding.

Beef cows suckling calves especially twin calves usually have a much longer interval from calving to first estrus than dairy cows not suckling calves. This is a serious problem in beef herds, particularly beef cows of Brahman or crossbred Brahman breeding.^{13,20} It is a lesser problem in the Angus breed. This "lactational or nursing anestrus" prevents many beef herds achieving a 12 or 13 month calving interval. A review of a number of studies on suckled European beef cows showed that variable periods of anestrus from 27 to 150 days followed calving.⁹ In Brahman or crossbred Brahman cows this period of anestrus may extend from 100 to 200 or more days postpartum. Apparently there is also a genetic component to the length of the postpartum anestrus. Other factors compounding this prolonged postpartum anestrus in beef herds is the level of nutrition and condition of the dam before and after calving and the age of the dam. Thin heifers nursing calves frequently have very prolonged postpartum anestrus periods.^{20,21} Increased dietary energy intake pre- and postpartum in suckled postpartum beef heifers increases LH secretion and shortens the anovulatory periods.^{2a}

Although much further study is required on the critical postpartum period, it has been shown that plasma levels of the prostaglandin metabolite were high for 7 to 23 days postpartum in cows with a normal parturition and uterine involution. If a uterine discharge with delayed uterine involution developed elevated prostaglandin secretion was present for a longer period of time.⁸ Progesterone levels remained low until prostaglandin release from the uterus had ceased which in normal cows was about 15 days postpartum. During this early postpartum period circulating LH levels were low and secretory spikes or episodic releases of LH were suppressed by suckling.⁹ Weaning resulted in an increased number of secretory spikes of LH followed by estrus. The suckling intensity of single or twin calves is correlated closely with the length of the postpartum anestrus. Since suckling releases corticosteroids in nursing cows these hormones may suppress the release of pituitary LH by GnRH. When calves were weaned at 3 days postpartum, estrus and ovulation occurred at 17 days. If calves were allowed to suckle only once a day starting at 30 days postpartum, the postpartum interval to first estrus was 69 days vs 168 days in Brahman crossbred heifers allowed to suckle their calves normally.¹³ After weaning of their calves 25 to 42 days postpartum, most anestrus beef cows show estrus within 10 days. However about 80 percent of these cows return to estrus, a short cycle, in 7 to 12 days.

Insemination at the first estrus is usually infertile even though ovulation and fertilization occurs. But insemination at the second estrus followed by a normal length cycle resulted in a normal conception rate. The cause of the failure of pregnancy on the first breeding after weaning is apparently due to early regression of the corpus luteum, about the seventh day that also causes this common short first estrous cycle.^{12a,13a,b} The cause of this early CL regression after the first ovulation and estrus after weaning requires further study.

In another study, suckled beef cows developed small follicles by 16 to 18 days postpartum but estrus and ovulation did not occur. However, if 250 mg GnRH was given on days 27 to 29 about 50 percent of the cows ovulated. If calves were weaned for 24 hours before given GnRH the response improved. Apparently suckling suppressed the release of LH necessary for follicle maturation and estradiol secretion.^{4,6} However, weaning is not a practical solution for postcalving anestrus in most beef herds. Modified weaning programs of once daily suckling starting at 30¹³ or 50 days postpartum or weaning for 48 to 60 hours (Shang treatment) combined with a short progestogen treatment,¹⁵ have resulted in some success in establishing earlier estrous cycles when combined with other synchronization programs such as progesterone, and GnRH^{2,15} (See the Postpartum Period and Estrus Synchronization in this Chapter). Further studies on the hormonal, nutritional and managerial aspects needed to shorten the postpartum anestrus period in beef cows suckling calves are needed.

Herd Reproductive Health Programs

Foote reviewed the inheritance of fertility and concluded:

"The fertility problem of greatest economic importance in a herd or population is over-all breeding efficiency. As this has been measured by services per conception, percent nonreturns, first service to conception, calving interval, etc., additive genetic variance has been very small and heritability has been approximately zero. Thus, selection for these traits would not be effective and would be at the expense of other traits of economic importance which show a greater response to selection. **Infertility in cows appears to be primarily a management problem.**"⁷

Reproductive health programs for both dairy and beef herds are practical and essential for successful herd management. The veterinarian plays a highly important role as a consultant and advisor to the herd manager or owner in setting up the reproductive health program and maintaining its effectiveness to achieve the goal of a calf per cow every 12 to 13 months. In dairy herds fertility can be measured by a number of criteria and realistic herd goals are: a pregnancy rate of 60 percent on first service, an average of 1.5 to 1.7 services per conception, a calving interval of 12 to 13 months per cow or a maximum of an average of 100 days from calving to conception. A calving interval of 12 months produces the highest milk yield and the greatest number of calves. The most common causes of a longer calving interval are long intervals between parturition and first service, long intervals after service if conception has not occurred, or too many services, 5 or more, before conception. Thus the calving interval is more important than services per conception in measuring herd fertility.⁵ Records should be set up so that periodically they may be reviewed to see

if the herd is reaching, maintaining, or failing to reach these criteria necessary for a successful reproductive health program. Small, practical reasonably priced computers are or will shortly be available for farmers and veterinarians. In the dairy areas Dairy Herd Improvement Associations (DHIA) offer computer services on many aspects of dairy herd and farm management. With larger herds of cattle becoming more common the computer is or will become an essential tool for the manager and veterinarian. The computer is primarily an information storage, retrieval and analysis system and all 3 functions should be utilized.²¹ Records should be maintained in such a fashion that the cause or causes for infertility such as anestrus, silent estrus, repeat breeders, cystic ovaries, semen from certain bulls and etc. can be readily ascertained. In beef herds an achievable goal is a 90 percent calf crop within a 3-month breeding period. To reach and maintain these goals requires the close cooperation of the herdsman, manager, owner, inseminator, and veterinarian.

In dairy herds a herd reproductive health program requires a visit by the veterinarian to examine the cows every one to two months or in larger herds more frequently. Less frequent visits are unsatisfactory. Charges for such regular visits have been made by various veterinarians based on the visit, on an hourly rate, or on a flat rate per cow per visit or year. The former two methods of charging are generally preferred because then the manager or owner of the herd prepares for the visit by getting his records in order, has his cows in and his help organized so the visit goes smoothly and rapidly. Since reproductive health is the core of a general herd health program, the reproductive health program is usually established first and then other aspects of herd health are added to it as the farmer and veterinarian desire. Education of and cooperation with the farmer and concern for the herd by the veterinarian are essential.

Records must be maintained in a herd reproductive health program. Each cow must be properly and permanently identified. In large herds this identification should be readily ascertained by observation, often from a distance, to facilitate recording and isolation or restraint for breeding or examination. Reproductive herd health forms should be fairly simple and practical for the average dairy farmer to maintain on a daily, monthly and yearly basis. The type of record used should be tailored to the preference of the veterinarian and farmer. Different record forms have been described and used by many veterinarians.^{3,6,12,14,15,16,19,24} Records must identify the cow, indicate the time of calving or abortion, heats, services and pregnancy examinations. They should also include all genital examinations noting normal and abnormal

findings and the therapy administered.

These records might also be expanded to include the sire and dam, the number and sex of offspring, abnormalities at calving, vaccinations and time administered, the bull used for service of the cow and whether AI or natural service was employed, and the results of blood or other diagnostic tests. These records may further be expanded to include other health records and examinations such as mastitis and other disease problems and even production records. Records of the date of purchase of cows and the name of the previous owner are often desirable.

Any herd reproductive record system should include provisions for daily referral to the records or placing entries in them. In larger herds a herdsman's **daily report form** is helpful to record calvings, breedings, vaccinations and other abnormalities and treatments. **Estrus expectancy charts** are available from feed companies, AI organizations, and extension services and are very helpful to dairymen to note heat dates and service dates so they are reminded when to watch certain cows. More permanent records may be made on forms kept in loose-leaf notebooks, Kardex files, and card files specifically designed for reproductive health programs. These may be made up by the veterinarian or stock forms obtained from one of the above sources. These records should be available in the barn or near it in a clean, dry location free of dust, dirt and excessive moisture.

Several interesting recent innovations to herd reproductive health records have been made. One is the method followed in North Carolina to computerize these records so each month a farmer receives this reproductive record on his cows along with the DHIA record so he knows the calving intervals, breeding dates, and when to have the cows checked for pregnancy. This greatly aids him in maintaining the goals of good reproductive health and requires a minimum of record keeping by the farmer.^{10,11,16} Other states have adopted this program. A practical breeding control "wheel" now being produced by Agway Inc. of Syracuse, N.Y. was invented³ that is an ingenious device that is kept in the dairy barn and records the current reproductive status of every cow which can be determined at a glance. It has proven to be an incentive to herdsman, by its simplicity, to maintain reproductive health records, watch cows for estrus and breed them at the correct time. Other methods for keeping reproductive records including peg boards, black boards and etc. have been reported. Most good record systems require the veterinarian to assist the farmer in developing and organizing a practical system both can follow and use. Then it requires constant encouragement on the part of the veterinarian to have the farmer maintain the rec-

ords in a careful, routine, up-to-date manner.

Management practices—In most cattle herds the major cause of infertility and repeat breeding is improper or negligent management practices. Most infertility problems, such as improper heat detection, are herd problems and require a preventive medicine program in which the veterinarian must become an active part of the farm management to be effective.

Young breeding stock should be properly reared by providing nutritious and balanced rations and proper disease and parasite control including vaccinations so that early and planned breeding of virgin heifers can occur at the desired time.

The breeding herd should be fed sufficient balanced rations so that regular estrous cycles occur and the females are in an optimum breeding condition and on a positive energy balance at the time of service. Nutrition should be such that cows at the end of gestation are not too fat nor too thin as both of these conditions predispose to calving and postpartum disease problems that affect the fertility of the herd.

Sanitation and hygienic practices at the time of calving should be followed to prevent postpartum uterine infections and delayed conception. **Diseases affecting the reproductive system** such as brucellosis, vibriosis, trichomoniasis, IBR-BVD, leptospirosis and others may be controlled by eradication and quarantine methods so as to maintain, as nearly as possible, a disease-free closed herd. Since this is usually not possible in large commercial herds a proper and regular vaccination program should be instituted. All purchased stock should be isolated from the herd for 30 to 150 days and tested for possible infectious diseases. It is preferable to purchase young animals under 6 months of age as replacement stock to avoid the common venereal diseases. Decisions in regard to the various methods of disease control must be made on the basis of the herd history and management practices, the possible dangers from exposure to disease by neighboring cattle, and the nature of the diseases common in the area. Inbreeding should be avoided and close line-breeding should be carefully monitored so that hereditary defects can be culled from the herd and good fertility can be maintained.

The **detection of estrum** is of great importance especially in a herd being bred by artificial insemination. There is no substitute for frequent careful observation of the nonpregnant cows, recording of the estrus and prompt notification of the inseminator so that future estrous periods may be detected or so that a high conception rate on first or subsequent services can be achieved. Cows should be watched closely for estrum. The herd should be turned out or watched closely for thirty minutes or

more a minimum of two and preferably three or four times a day. (See Anestrus.) Cows should be checked for estrus at times other than milking or feeding and particularly at least once during the late evening or early morning hours. This is necessary in tropical climates where estrous periods are shorter and the intensity of estrus is reduced. This practice is necessary during the winter months when dairy animals may be closely confined in stanchions. Utilizing some form of heat expectancy chart or the regular veterinary examination of the genital tract of open cows to predict the time of estrus are very helpful in breeding cows at the proper time in the postestrous period when a bull is not turned with the herd. Normal cows should be bred at the proper time of each estrous period with highly fertile semen to achieve the best and earliest conception rates.

Highly fertile active bulls with a strong sex drive and free of infectious venereal diseases should be used as sires. If artificial insemination is employed the fertility record of the bull should be noted to be certain of the high fertility of his semen. The semen should be stored, handled, thawed and inseminated in a manner to maintain and promote the high fertility of the spermatozoa. If cows in the herd are handbred naturally to a number of breeding bulls, the records of all cows bred by each bull and the date should be recorded so that if infertility occurs in the cows the bulls' fertility records can be examined for evidence of decreased fertility in a certain or several bulls. Switching cows back and forth between bulls at different natural services is a poor practice as venereal diseases are readily spread in this manner. If a cow fails to conceive to natural service to a certain bull, she should be bred by artificial insemination to other bulls on subsequent services.

All cows in the herd, not already safely pregnant should be examined at each regular monthly, or more frequent, visit of the veterinarian to 1) determine pregnancy if breeding has taken place 35 or more days ago, 2) to determine if normal uterine involution is occurring by an examination between 15 and 40 days postpartum, 3) to determine if any pathological condition such as metritis, adhesions of the oviduct, cystic ovaries and other lesions or diseases, including anestrus, may be present that require treatment, and 4) to determine the physiological state of the normal nonpregnant genital tract and the approximate time to expect estrus and whether service at the next estrus is desirable. If the decision of which dairy cows to examine is left to the farmer or herdsman some infertile, diseased, or nonpregnant cows might be omitted from the examination. It is very helpful for the farmer to prepare a list of all the nonpregnant cows and their breeding history prior to the visit by the

veterinarian. This requires the farmer to keep his records up-to-date and to have all the cows to be examined confined. It also saves much time for the veterinarian as he examines each cow. This type of complete examination of all nonpregnant cows gives an accurate herd picture of the nature of the fertility or infertility in the herd at the initial visit or at regular intervals throughout the year.

Miscellaneous herd management factors The herdsman, owner or manager who is in daily close continuous contact with the herd is the most important person determining the success of a reproductive health program. He should be a person who is properly educated and motivated or the program is bound to fail.

Beef herds, besides some of the aforementioned practices, may require different measures for controlling reproductive diseases than do dairy herds.^{4,23} In beef herds each cow must calve each year to be profitable. The breeding season is shorter than in dairy herds, 45 to 90 days, and conception early in the breeding season is highly desirable requiring proper nutrition of the herd. The best means of expressing reproductive efficiency in the commercial range beef herd is the total pounds of calf weaned divided by the number of cows and heifers exposed to breeding in a calendar year. Calf crop equals the percent of cows bred times the percent of conception times the percent of conceptions weaned. If only 50 percent of the cows are bred and only 50 percent conception results then the calf crop is 25 percent or less. Early prompt conception of heifers and cows is essential because of the short breeding period necessary to produce heavy, large calves. To produce early puberty and to obtain early estrus after calving, heifers should gain 1 lb per day from weaning through breeding and weigh at least 650 lbs at the start of the breeding season, and cows should be in good condition at calving and should gain 0.5 to 0.75 lbs per day until the end of the breeding season. Thus adequate rations and sufficient energy are essential for the onset of the estrous cycle and good conception rates.²³ Provision for adequate numbers of fertile, active bulls is essential. If young bulls are used more "bull power" is necessary. Cows that fail to conceive should be detected by a pregnancy examination of the herd in the Fall and probably culled. In range cattle where it is nearly impossible to maintain a "closed" herd, vaccination, especially against vibriosis, brucellosis, leptospirosis, IBR and BVD and possibly other diseases, is highly desirable. If the beef herd is to use artificial insemination, the riders, preferably two or more, should bunch the cows at the feed bunks twice a day, usually morning and evening; the cows should be divided and put into small pastures and pregnant cattle should be kept separate from nonpregnant cattle for easier observation of estrus. Often

sorting the fat range cows and thin range cows into separate herds and feeding according is economically advantageous.

Newly assembled herds often exhibit an infertility problem because of a variety of diseases that may be present. It is best to breed these herds by artificial insemination with highly fertile, disease-free semen. If females are brought into a closed herd, they should be bred by artificial insemination for several years. Every effort should be made to avoid the introduction of a venereal infection carried by a bull into the herd. All aborting animals should be carefully and promptly isolated and the fetus and placenta should be examined by a veterinarian and a good laboratory and blood samples taken to detect the possible cause of the abortion. The aborting animal should be treated and maintained in isolation until genital discharges cease. In tropical or subtropical areas measures should be taken to reduce the stress of high ambient temperatures and its effect on fertility in both the heat-tolerant bull and cow.^{9,18} Other diseases especially parasitic diseases should be controlled. Lame cattle lose weight, fail to show signs of estrus and have lowered fertility. Impotency in bulls is frequently due to overgrown, diseased feet that need trimming, and arthritic lesions. There is little evidence that stress or fright in cattle due to restraint at the time of service has any significant effect on the conception rate. Emphasis should be placed on diagnosis and prevention rather than treatment in herd reproductive health programs. Four major areas for improved efficiency and economic returns for a dairy or beef herd in which a trained veterinarian can have a major role are: control or prevention of disease-related losses, maintenance of good reproductive performance, and to provide advice, and possibly analysis, to achieve the maximum conversion of feed to milk or beef at the lowest cost, and prevent continuing problems associated with rapid genetic improvement.²⁵

Since the veterinarian that specializes in herd health or herd reproductive health programs is occasionally not the "regular" veterinarian that handles sporadic emergency problems and regulatory tests in the herd, it is highly important that he conducts his practice in an ethical manner, consults with the local veterinarian and AI technician, as well as the herd manager or owner and thinks and speaks well of his colleagues. He should practice the "Golden Rule." Often times it is necessary for the local practitioner to carry out recommended treatments and therefore it is important that he understand the reasoning behind the therapy.

The literature on uterine involution after calving and the earlier work on the optimum time to breed cows following calving was reviewed.¹⁷ (See also the Post-Par-

tum Cow.) Although optimum conception rates on first service occur from 60 to 120 days after calving, breeding cows from 40 to 60 days after calving if no abnormality was present, resulted in about a 50 percent conception rate with no subsequent adverse effects on the pregnancy period. Thus if diseases of the postpartum uterus could be avoided or reduced and earlier breeding, down to 50 days postpartum, was practiced, it would be a highly valuable method of reducing the calving interval with only a very slight increase in the number of services per conception.

Ideally only normal, healthy, highly fertile females and males should be mated. It is recognized, however, that both bulls and cows may vary greatly in their level of fertility. As the fertility of the female declines the fertility of the male she is bred to is of greater importance if a good conception rate is to occur. This was illustrated and discussed in humans.²⁰ The fertility index of a couple resulted in prompt conception when both partners were relatively quite fertile. Delayed conception occurred when either the male or female was subfertile or below the borderline index of fertility, and conception was unlikely when both male and female partners were subfertile or below the borderline fertility index. Therefore since highly fertile bulls, especially in AI service, are well known, cows of lowered fertility should be bred to them.

Bartlett has proposed an interesting and significant model to explain the importance of the major factors that enter into the determination of the fertility level of any herd.² These major factors concerning herd fertility are: 1) the fertility of the cows at the time of service, 2) the fertility of the bull or semen, if AI is used, and 3) the efficiency of the management including heat detection, nutrition, timing of insemination, efficiency of the technician, veterinary consultant and etc. If theoretical percentages of 90, 90 and 90 were applied to these three factors on a series of first inseminations the percent of calves born would be 73 percent, or $90 \times 90 \times 90$ since these factors are not additive. If the fertility of the bull was only 50 percent then $90 \times 50 \times 90$ would equal 40.5 percent calves born. The pregnancy rate can be no higher than the lowest value of any of the 3 factors. This illustrates the importance of careful veterinary supervision of the reproductive health of the herd to insure that all factors are maximal. The great economic importance of a herd reproductive health program has been illustrated.^{8,14,15}

In concluding this chapter on infertility in cows the following quotation from Bartlett is concise and applicable: "For some infectious diseases, relatively effective prophylactic and combative procedures have been developed; dairymen and veterinarians need only to take

cognizance of the established precepts. However, our present inability to cope rationally with certain other conditions and the meagerness of the knowledge of their total effects and causes must be recognized. Well-directed, well-supported scientific research is the only source from which the necessary facts can be obtained. Such research merits the encouragement, interest and support of the cattle industry and veterinary profession alike. It is obvious that the causes of lowered reproductive efficiency are exceedingly numerous and the problems of achieving optimum reproductive efficiency exceedingly complex and broad in their ramifications. No panaceas must be expected. Precise diagnoses whenever possible, rational corrective actions when indicated, and trained, intellectually honest advisors mark the sound course. There should be no place for the triflers, five-day specialists, self-confident, self-styled, handyman experts and quack remedy peddlers parasitizing and exploiting the field today."

"For the cattelman, consistent observance of sound management and animal hygiene practices is imperative. The keeping of precise, permanent records, together with a system of regular, physical examinations for pregnancy, will reveal any general occurrence of reproductive failures at the onset and by permitting early treatment or disposal of affected animals, will keep to a minimum the economic reverses resulting from infertility."^{1,2}

Chapter XIV

INFERTILITY IN THE MARE

With the near demise of the draft horse industry early in the twentieth century in the United States and other countries very little research and study was undertaken in theriogenology in the horse compared to that in food-producing animals. In the last 20 years with the advent of increased interest and development in, and income from, the recreational and racing aspects of the horse industry, much equine research and increased knowledge has been developed. This renewed basic and applied research in equine physiology, pathology, endocrinology and infectious diseases undertaken in many countries has resulted in the recent outstanding publications and reviews by Ginther (115), Rossdale and Ricketts (239) and Proceedings of the First and Second International Symposia on Equine Reproduction (Supplements 23, 27 and 32 of the *Journal of Reproduction and Fertility*) edited by Rowlands, Allen and Rossdale.

Fertility in mares is generally considered to be lower than that of the food-producing domestic animals. This impression or fact has been largely caused by the photoperiodicity of mares resulting in a normal breeding season extending from March to September in northern latitudes and by further restrictions imposed by man on the breeding season of mares in the equine racing industry. The Thoroughbred and Standard bred breed organizations by their acceptance of the artificial requirement of the January first birth date for racing horses imposed by the English Jockey Club in 1833, changing the physiologic original date of Mayday established in 1751, has contributed importantly to the fertility problems in these and other sporting or recreational breeds of horses.²¹²

Caslick⁷⁵ stated that the three chief reasons for infertility in mares were (1) the shortness of the breeding season, (2) failure of the mare to have a normal estrous cycle, and (3) genital infections. The latter condition can be largely controlled by preventive practices, hygiene and treatment so is the least important of the three causes for infertility in the mare even though certain "infection-prone" older mares may not be eliminated as promptly as they should be from the broodmare band. The former two causes of infertility, the shortness of the breeding season and irregularities of the estrous cycle of the mare,

are closely related. Usually less than 30 percent of barren or maiden mares, unless they have been stimulated artificially by a lighting regimen, are cycling and ovulating at the beginning of the breeding season, January through March in the racing breeds in northern latitudes.^{157,211} Furthermore, the requirements of a short breeding season in these breeds abruptly terminates the season in July just as nearly 100 percent of these mares are exhibiting normal reproductive cycles and ovulations.

Other factors that may play a role in the reduced fertility of racing and recreational mares and stallions, different from the food-producing animals, is that they are selected largely for their racing ability, pedigree or owner's whim rather than for their fertility. One can speculate that prior to the description and wide-spread adoption of the Caslick vulva-suturing operation in 1937,⁷⁴ these mares, especially in the Thoroughbred breed, with poor peri-vulval conformation would have remained barren and not passed their genital configuration on to their female foals¹⁸² and the frequency with which this operation is now performed would not have risen to its present level.

In 1940 Day⁸⁸ estimated the average fertility of draft mares usually bred to a stallion that was transported around the country was 60 percent, the fertility of Thoroughbred mares managed under better conditions was 66 percent and the fertility of ponies running the year around on pasture with a stallion was over 90 percent. These estimates, even with our improved knowledge, remain similar to conception and foaling rates from 1950 to 1972 in the Australian Stud Book averaging 66 to 73 percent and 60 to 64 percent, respectively.²¹² In 1968 fourteen breeding farms in the US comprising 6 breeds reported nearly 100 percent fertility in one pony stud; but only 75 percent and 66 percent conception and foaling rates respectively in 5 intensively managed Thoroughbred farms. Farms with Appaloosa, Arabian and Quarter-horses had from 73 to 93 percent conception rates and 65 to 93 percent foaling rates with the highest rates being achieved on farms that practiced some pasture breeding.¹⁴⁵ Ginther⁴⁵ summarized data on published equine pregnancy rates which ranged from 75 to 84 percent per

breeding season. In another report from England on 852 Thoroughbred mares on 82 farms or studs, 229 or 27 percent of the mares were not covered in 1971. Of the remaining 623 mares that were bred, 77.9 percent conceived and 69.7 percent produced a live foal that survived 6 weeks.¹⁶⁶ But of the 852 total mares in the survey only 50.9 percent produced a viable six-week-old foal. In another survey 838 Quarterhorse mares on 5 farms and 939 Thoroughbred mares on 7 farms the pregnancy rate for service(s) in the first estrus the mare was bred was 51 and 43 percent, respectively, and the cumulative pregnancy rate after 5 service periods was 84 and 75 percent, respectively.²⁶⁸ The first-service-period pregnancy rates for maiden, barren and foaling mares were 44, 40 and 54 percent, respectively. The pregnancy rate for foal heat breeding vs non-foal-heat breeding for Quarterhorse and Thoroughbred mares was 58 vs 65 percent and 41 vs 67 percent, respectively. A significant difference was noted between the fertility of the two breeds of horses and foal-heat and non-foal-heat conception rates in Thoroughbred mares.^{18,268}

All mares should be fed an adequate ration of green roughage with some legume, preferably clover. Legumes contain a higher supply of minerals than does timothy. Good pasture supplies roughage in the best form as well as exercise. Grain intake should be adequate to maintain condition and supply the energy and protein needs of the mare. Fresh water and iodized salt should be available at all times. Most breeding mares are fed and cared for in an adequate manner but if they are not, the same deficiencies and symptoms affect them as affect cattle. If the feed is adequate, trace minerals and vitamin supplements are seldom necessary.^{248,265}

Because of the shortness of the breeding period it is essential that all mares to be bred are normal and healthy at the beginning of the season. This requires that barren mares be examined in the fall months and treated if necessary. All apparently pregnant mares should be examined at this time to make certain that an early abortion at 25 to 90 days did not occur. Pregnant mares are usually vaccinated to prevent equine herpes I virus abortion. Normal but barren mares are put in winter quarters, allowed to exercise and maintained in a fair to good physical condition but should not be allowed to become too fat. The reproductive physiology of mares has been discussed in Chapter XII but a more detailed presentation of the clinical aspects follows.

Reproductive Physiology of the Mare

Puberty in the female horse has been reviewed by Ginther¹¹⁵ (also see Chapter XII). By three months of

age the cortex of the ovary located beneath the fimbria completes its invagination into the medullary portion forming the ovulation fossa necessary to contain the large preovulatory follicles and to permit the fimbria to retrieve the released ova from the large equine ovary.³⁰² Between birth and about 4 months of age the equine ovary changes from the large oval shape of the fetal gonad to the adult bean-shaped ovary with a definite fossa. Ovarian follicles and occasional luteal bodies were observed between 6 and 9 months of age but evidence of ovulation was lacking. By 10 to 18 months of age well-nourished fillies reach puberty and develop a normal estrous cycle and ovulate. Of 137 yearling fillies run with stallions in small groups, 95 or 69% became pregnant. However 44 or 46% of these pregnant fillies aborted spontaneously between 30 and 160 days of gestation.¹⁹⁶ The high incidence of early pregnancy loss in these pubertal fillies was probably due to immaturity, inadequate nutrition, stress and possibly inadequate levels of progesterone.

The Breeding Season—In the northern hemisphere the breeding season of mares normally extends from March to October with the greatest degree of functional activity in May, June, July and August.¹⁵⁷ In data transposed from Australia to the northern hemisphere estrous cycles and ovulation occurred in June through August in 80 to 90 percent of 6763 equine genital tracts examined at slaughter by Osborne.²¹¹ During the winter months of December through March cycling and ovulation occurred in 18.5 to 26.9 percent of the 6763 mares' genital tracts examined and in 16 to 63 percent of the 792 mares' tracts examined in England.^{1,11} Thus some mares if fed adequately and housed will have regular estrous cycles throughout the year but there is a natural and common anestrous period from November to April for ponies and most mares, especially those on pasture (see Table 21).^{115,157,211} The horse being a photoperiodic animal with a breeding season regulated physiologically by the length of daylight has the lowest incidence of estrous cycling, about 25%, in January and February after the winter solstice in late December in the northern hemisphere when the length of day is about 9-1/2 hours.¹⁵⁷ As the amount of daylight increases in the spring increasing numbers of mares pass through a transition stage and commence regular reproductive cycling which reaches a peak incidence of about 100 percent in late June, the summer solstice, or July when daylight lasts about 15-1/2 or 16 hours. Ovulation usually lags behind the occurrence of estrous cycling and results in lower conception rates due to failure of ovulation early in the breeding season. Also longer periods of estrus occur early in the breeding season, 7 to 14 days vs 5 to 6 days later in the breeding season.¹⁵⁷ The monthly conception rate therefore follows this same pattern. Thus the physiologic normal breeding season

Table 21. A Frequency Distribution Graph Representing the Monthly Percentage of Ovulation for 5198 Normal Mares in the Years of 1959–1965*

* Adapted to the northern hemisphere from data published by V.E. Osborne, Dept of Vet Med, Univ of Sidney, Australia. Immature and senile mares excluded (Austral Vet. J. 42, 1966, 149)

** As evidenced by the presence of corpora hemorrhagica or corpora lutea in the ovaries of mares examined at autopsy. These mares come from an area of eastern Australia between latitudes of 23° 5" and 35° 5" corresponding to Southern N. Car through the tip of Florida or the northern to southern borders of Texas

*** The range of monthly variation in double ovulation was 7.2 to 21.4 percent

begins in late April or May after the spring equinox and ends in late September or October after the fall equinox, while the "operational" breeding season for breeds recognizing January 1st as the universal birthdate of each year's foals usually starts February 15 and ends the first week in July thus accounting for the major cause of horse breeding problems.

The photoperiodic reproductive pattern in the horse, as in certain other animals, is regulated in a complex, and not completely understood manner by the effect of increasing or decreasing daylight perceived through the eyes and transmitted to the pineal body and hypothalamus.¹¹⁵ The former releases melatonin that interacts with the hypothalamus to release GnRH to raise the levels of FSH and LH and promote follicle development, estrus, ovulation and CL formation in the early spring or summer and reverses this process in the late fall and winter.

Mares with 3 types of seasonal anestrus have been described:¹¹⁵ those, especially ponies, with a clear-cut period of anestrus of 2 to 4 months duration during the winter, mares that have some cyclic activity of a very irregular nature during the winter season, and mares, about 20 to 25 percent, that have regular cycles the entire year,^{140,176,177} (See Normal & Abnormal Estrous Cycling).

In the northern hemisphere most barren and maiden mares pass through a "transition" period of erratic, abnormal, irregular, anovulatory but receptive estrous cycling usually in the months of March, April and early May, between the winter anestrus and the normal breeding season characterized by regular estrous cycles and ovulation from mid May through September.¹⁵⁷ Every spring horse breeders invariably complain about the cold, dark or overcast weather and lack of grass to explain the

apparent delay in onset of the mares' physiologic breeding season. This impatience is readily transferred or expressed to the veterinarian who is expected within a few days to "speed up" a physiologic process that usually requires weeks to bring about. **The estrous cycle in the normal mare** is 19 to 23, average 21 to 22, days.^{7,16,17,18,115,239,261} The duration of diestrus averages 15 days but the duration of estrus was more variable, 2 to 11 days, with an average of 5.5 to 8 days. Breeding has no effect on the length of heat or the time of ovulation. Foaling mares usually come into their first estrum or foaling heat and ovulate between 4 to 18 days after parturition.^{239,269} In one series of cases 93 percent of the mares showed foal heat between 5 and 18 days and 77 percent showed foal heat between 7 to 10 days after parturition.²⁸⁵ Ovulation may occur from days 4 to 18 postpartum.²³⁹ Most foaling mares have normal or regular estrous cycles. A few may exhibit a prolonged foal estrum and a few more may fail to show estrus and exhibit anestrus for a variable or long period, sometimes called "lactational" anestrus. Often these anestrus foaling mares had a history of this pattern of behavior as a barren mare; this may simulate lactational anestrus in sows, or this may be seen in nervous overly-protective mares that fight the advances of the stallion approaching them and their foals.

The estrous cycles and estrous signs, and ovulation were very irregular, but ovulation did occur in female mules.⁴² In 47 pairs of mule ovaries atretic follicles were found in 12 and corpora lutea were present in 15 of the 94 ovaries. Female mules were infertile and primordial follicles in the ovary were rare.

The uterine endometrium did not return to its normal state by 10 days post-partum. But complete recovery did occur between days 13 and 25.⁷ Some mares had follicles on the ovaries one day postpartum and all mares had palpable follicles by day 5 postpartum.¹⁸¹ Four mares were in estrum to the teaser on days 6, 6, 7 and 8 postpartum and ovulated on postpartum days 7, 7, 10 and 14, respectively. Thus a short estrous period occurred in 3 of the 4 mares. In other mares the postpartum interval to the first estrus was 7 to 12 days in 7 of 9 mares and the duration of estrus was 2 to 3 days in 4 of the 7 mares. Further study is needed on the involution of the uterus and ovarian activity in the postpartum period of the mare.

Breeding on foal heat is generally contraindicated in mares that had an abnormal parturition with dystocia, a stillbirth, retained placenta, a placenta that weighed more than 14 pounds, or any contusions, or lacerations of the birth canal. As in cows nearly 100 percent of mares have a contaminated or infected uterus after foaling. In healthy normal mares this infection is eliminated early during

foal estrum. In 110 normal mares bred on foal heat only 43.7 percent conceived, while in 54 mares not bred on foal heat 67.3 percent conceived later on one service.^{18,151,285} The abortion rate in mares bred on the ninth day, or foal, heat was 12.8 percent, slightly greater than foaling mares not bred the ninth day. In another study of 304 mares bred on foal heat 39 percent conceived while 49 mares bred on the second post-foaling heat 55 percent conceived. The subsequent abortion rates and foaling rates of the two groups, even though rebreeding was necessary in each group, was nearly similar 16.5 and 13.8 percent and 66.4 and 66.2 percent, respectively.¹⁷³ In Kentucky 533 mares bred on foal heat had a 36.5 percent conception rate; 304 of these came back in heat and on the second service 56.6 percent conceived. Of 130 mares bred after 21 days following foaling, 58.5 percent conceived on first breeding.⁷⁵ Breeding on the foal estrum should be done advisedly, especially in old mares and in primipara.

The lowered conception rate on foal estrus may be due to breeding on a fixed date,^{183,218} such as the ninth day postpartum, instead of timing the service based on daily teasing and examination and manual palpation of the genital organs including possible culture. It is a common practice on many Standardbred and Quarterhorse farms to routinely breed all mares that foaled normally and had a normal postpartum period on the foal estrus even though it is generally recognized that conception rates at this period are lower than subsequent estrous periods. This is done to obtain the most foals from a band of mares each year and to avoid holding over until the following year a late foaling mare or a mare with a history of lactational anestrus as a barren mare. Furthermore most foaling mares are quite fertile and if they foal in February through April and conceive on foal heat, they are "out of the way" at the end of the breeding season in May and June when the stallion is being worked very heavily on mares that have foaled late or infertile mares that have failed to conceive. There is no evidence that mares that are bred on their foal heat and fail to conceive may have a reduced fertility at subsequent estrous periods.

Hormonal control of the estrous cycle has been reviewed and described.^{115,140,148} In the mare FSH is secreted in a periodic 10 day rhythm of surges, one in late estrus or early diestrus and the other in late diestrus, about days 8 to 12 of the cycle. There is evidence that these two surges of FSH per cycle, resulting in plasma levels of 10 to 15 and 20 to 25 ng/ml., respectively, may be reduced to one, the latter, late in the breeding season.¹¹⁵ Under the stimulus of FSH from the anterior pituitary gland follicles with an antrum are stimulated to grow.

Those follicles in the first "wave" become atretic about the middle of the estrous cycle because LH is not present to complete their growth, cause ovulation, and development of the CL. A nonsteroidal protein "inhibin" and estradiol present in follicular fluid suppresses FSH secretion and stimulates LH secretion. Waves of follicular growth and estradiol production occur every 10 days during the breeding season even though a corpus luteum may be present.^{115,149,261} Plasma levels of LH are high, 40 to 45 ng/ml. during the latter half of estrus and for several days after estrus and low from days 5 to 16 of the cycle.¹⁴¹ Progesterone concentrations in plasma are below 1 ng/ml. during estrus but rise rapidly after ovulation to a peak 6 days later of 6 to 10 ng/ml.

Regression of the CL around days 14 to 17 is due to a sharp rise in plasma levels of prostaglandins from the uterus, 60 to 240 pg/ml. The luteolysis caused by the uterine production of prostaglandins in the mare is accomplished by transfer of the prostaglandin through the systemic circulation to the ovary rather than the local utero-ovarian pathways described in the cow, sheep and pig. With follicular development estrogen levels increase a few days before estrus reaching a peak of 20 to 25 pg/ml. in plasma in mid-estrus several days before ovulation. Ovulation results from a complex series of biochemical reactions from progesterone and estrogens in the follicle, LH, cyclic AMP, prostaglandins and proteolytic enzymes.^{115,141} The hormonal levels and changes during the estrous cycle of the donkey have been described.²⁹⁰

Follicle development and ovulation—The size of the Graafian follicle ranges from 2 cm to 10 cm, or 0.75 to 5 inches or more in diameter, with amounts of fluid ranging from 6 to 112 ml. or more. Most follicles are 3.5 to 5.5 cm, 1-1/2 to 2 inches in diameter at the time of ovulation.^{115,239,261} Larger horses tend to have larger follicles. The follicular fluid during estrum contains estradiol-17B and estrone at levels of 48.0 ug and 3.4 ug per 100 ml., as well as a variety of other steroidal compounds.^{16,115,253} Almost all Graafian follicles are tense and firm on rectal palpation the first few days of estrum but within 16 to 24 hours of ovulation many follicles lose their tone and become softer and slightly fluctuating. It is possible they may already be losing some follicular fluid. The follicular fluid is probably a filtrate of blood plasma containing the steroid secretions of the theca interna.²⁵³ Urinary estrone varied from 15 to 20 ug per liter one week before ovulation to 60 ug per liter the day before ovulation.¹²⁹ Behavioral signs of estrus paralleled the urinary and plasma estrogen levels as did the changes in the genital tract associated with estrus. The major steroids secreted by the ovary were estradiol, progesterone,

estrone, androstenedione, a weak androgen, and other sex hormone steroids and their metabolites.^{239,253} Although the rate of exchange between the steroids in the follicular fluid and the blood were very slow, at the time of ovulation large amounts of estrogen were released.²⁵³ This may be related to the anticoagulant and enzymes in the follicular fluid. The size of the follicle is not related to sexual behavior but as the follicle increased in size during estrum, signs of estrus were more intense.⁷

The mature Graafian follicle is somewhat triangular or pear-shaped with the largest portion of the follicle palpable during estrus on the convex curvature of the ovary or at either pole of the ovary. The narrow stalk-like portion of the follicle protrudes toward the concave portion of the ovary or the ovulation fossa where ovulation invariably occurs in close proximity to the rather small fimbriated portion of the equine uterine tube. Only rarely does ovulation occur more than 2 cm. away from the ovulation fossa.^{9,11,12,38,210,225,226} Ovulation usually takes place toward the end of the estrous period, about 24 to 48 hours before signs of estrus cease; only occasionally is ovulation early or delayed so it occurs 48 to 96 hours before the end of estrus or 24 to 48 hours or more after the end of estrus.^{16,139,218} As described previously (see Abortion in Mares) double ovulation may occur in 4 to 40 percent, average 16 percent, of estrous cycles and only occasionally result in twin pregnancy due apparently to an efficient natural mechanism that eliminates one embryo early in gestation.^{115a,b} These double ovulations may be either synchronous, occurring within 48 hours; asynchronous, occurring 2 to 10 days apart, or be a single ovulation at estrus with a diestrus ovulation soon after the end of estrus. Ovulations without signs of estrus occur in about 24 percent of the diestrus periods of mares.^{138,139,289} Although equine follicular fluid has many properties of normal blood plasma it does not clot due to its having a lowered fibrinogen content and also to the presence of an anticoagulant heparinoid substance. This prevents the ovum from becoming trapped in a plasma clot.²⁶⁴ Since the mature follicle is highly vascular and the theca interna layer is hyperemic at ovulation, rupture of some vessels occur and clotting is delayed, hemorrhage occurring into the large cavity of the former follicle produces a soft, pulpy hematoma that can be palpated per rectum as a soft, mushy depression on the greater curvature of the ovary for 24 to 36 hours after ovulation.^{88,89,90b} The mare has by far the largest corpora hemorrhagica of all domestic animals.

The corpus luteum develops rapidly following ovulation and it also is triangular or pear-shaped. It occasionally protrudes as a button-like structure 1 to 2 cm. in diameter and 0.5 to 1 cm. in height beyond the ovar-

ian capsule through the ovulation site into the ovulation fossa where it may be palpated around the second day after ovulation.⁷ By 72 hours, range 1 to 6 days,^{115,130,132} after ovulation the corpus luteum, which is about 1.0 to 2.5 cm. in diameter, definitely smaller than the follicle, cannot be palpated readily unless the site of the recently ovulated follicle is known, because of the dense tunica albuginea and the central location of the corpus luteum in the mare's ovary. The corpus luteum actively secretes progesterone for 14 to 16 days when it begins to undergo involution or regression unless the animal is pregnant. Upon corpus luteum regression, follicle growth occurs under the influence of FSH released from the pituitary gland.

Fossa cysts or cysts of the germinal epithelium are common and may occasionally be palpated in the region of the ovulation fossa especially in older infertile or nonbred mares.^{8,186,187,210} These cysts were present in 64 percent of 42 ovaries.²¹³ These persistent small cysts could be single or multiple; they varied from 1 mm. or less up to 0.65 cm. and in rare cases could resemble a bunch of small grapes. These large accumulations might rarely interfere with the collection of the ovum by the fimbria at the time of ovulation. These cysts most commonly arise after an ovulation from the infolding of the epithelium, which is probably of paramesonephric origin, in the ovulation fossa region. These cysts are lined with ciliated columnar epithelium surrounded by a dense connective tissue layer. Fossa cysts resemble fimbrial cysts except for their location. There is no evidence that the contents of these small cysts have any hormonal activity.

As in other animals two to six or more follicles in two waves, early in estrus and at mid-estrus are stimulated to grow by the release of FSH from the equine anterior pituitary gland under the stimulus of GnRH from the hypothalamus. Ovulation occurs in one, or occasionally two, Graafian follicles under the stimulus of LH. Why some follicles develop and then become atretic and why one or two mature is not known.¹¹⁵ Irvine suggested that as soon as one follicle develops sufficiently to produce the inhibitor substance to lower FSH concentration in plasma the rest of the smaller follicles in the cohort become atretic.¹⁴⁸ Ovulation usually occurs from 1 to 24 hours apart in twin ovulations or synchronous ovulations. In some cases two or more days may elapse between ovulations in the same cycle or asynchronous ovulations.^{115,117b,218}

Fertilization occurs in the proximal end of the uterine tube. Unfertilized oocytes may remain in the tube for several months and degenerate before finally passing into the uterus. Thus the fertilized eggs can influence their own transport to the uterus probably by producing hu-

moral agents.^{41,115,239,294} Removal or loss of the cumulus cells occurs in the uterine tube.²⁶¹ The fertilized egg undergoes its first cleavage about 24 hours after ovulation and enters the uterus about 5 to 6 days after ovulation.^{115,239} Following ovulation the remaining follicles undergo atresia within 3 to 10 days.^{88,89} Mature follicles are highly vascular while atretic follicles become avascular and pale.

Since the duration of estrus is quite variable, generally longer in the Spring months and shorter in the Summer months, and variable between mares, determining the time of ovulation which usually occurs 24 to 48 hours before the end of estrus is difficult without repeated rectal palpation of the ovaries. Knowledge concerning the time of ovulation would be desirable so that copulation or insemination can be performed within 24 hours of the release of the egg.^{88,89,178,207} Of 353 mares 78 percent ovulated within 48 hours before the end of estrus. Nearly all of the remainder of the mares ovulated equally either 72 hours before or 24 hours after the end of estrus. Most mares are out of estrus within 48 hours after ovulation.

The administration of a luteinizing gonadotropic hormone, usually about 3000 IU HCG IM or IV, early in estrus, the first to third day, usually results in ovulation within 24 to 48 hours and a shortening of the estrus period one to three days.^{88,115,178} Ovulation occurred in 82 to 90 percent of the mares within 48 hours with three-quarters of them ovulating between 24 and 48 hours of the HCG injection. This HCG treatment did not adversely affect the conception rate.¹¹⁵

There is some evidence that repeated injections of HCG on successive estrous periods may be ineffective in reducing the interval to ovulation or the length of estrus possibly by the development of antibodies to HCG. Large doses of HCG may have an adverse effect on conception rates but further study is needed to verify this observation. GnRH has also been used in daily doses to promote the secretion of LH and hasten ovulation. Results to date have been inconsistent and further study on GnRH treatment protocols are indicated. GnRH could be used repeatedly in successive cycles without the production of antibodies that might affect the ovulatory response.^{115,149,309} After 2 to 5 injections of HCG, 2500 IU per cycle, 5 of 12 mares developed antibodies to HCG. The half-life of these antibodies varied from 30 to 60 days or more. No significant ovulatory refractoriness was observed in the mares.²³⁸ The use of HCG to hasten ovulation and shorten the estrous period is of value when it is desired to conserve the stallion by breeding a mare only once in an estrous period, to synchronize ovulations for AI or embryo transfer and to minimize trauma and infection in older "infection prone" mares or mares with

a Caslick operation or sutured vulva.

The time of survival of highly fertile equine spermatozoa in the genital tract of mares is up to 6 days.^{70,90a,115,261}

The survival time of less fertile semen may be shorter.

Sperm transport in mares is similar to that in cows, ewes and sows. When 7×10^9 spermatozoa were placed at the junction of the cervix and uterus during estrus only a very few, 0.06 to 2.2 percent, could be recovered from the genital tract 12 hours later. The uterus as in the other animals, is a hostile environment for spermatozoa. More spermatozoa from one stallion with the greatest sperm motility were found in the uterine tubes than from 2 other stallions, 17,000 vs 7,000 and 9,000 respectively.^{90a,214}

Whether copulation is performed 24, 48 or 72 hours before ovulation, conception rates are similar.^{88,90a} However, most veterinarians prefer to breed mares 12 to 24 hours before ovulation, especially if the stallion has a reduced fertility. No conceptions occurred in mares bred 2 to 4 hours after ovulation. Others have reported conception in mares bred 2 to 14 hours, and even to 36 hours after ovulation.^{16,28,32,115,135,239}

In the mare the sperm capacitation time in the female genital tract is short if indeed capacitation occurs in the horse.²⁵⁶ Thus if a mare is bred on the second day of the cycle and is still in estrum on the fifth day she probably should be rebred if she has not ovulated. With less fertile stallions more accurate timing of breeding in respect to ovulation will improve the conception rates. Where artificial insemination is employed mares are usually inseminated every 48 hours during estrus. In mares bred artificially at 48 and 72 hours intervals during estrus, the conception rates are similar.⁷⁹ Further studies are needed to accurately determine the survival time of spermatozoa and unfertilized ova in the mare's genital tract.

Equally good conception rates were obtained for breedings each of 4 days before ovulation.^{88,89,90a} The second to the fifth day before the end of estrus proved the most fertile time to breed to mare.²⁸⁵ To conserve stallions it was recommended that mares should be bred on the second or third day of estrum and teased daily thereafter. If they were still in estrum 4 days later they should be rebred.⁸⁴ Of 1187 mares bred, 80 percent had only 1 service per estrum and the overall percentage of pregnancies was 77.7. This method conserved the stallions and by reducing the number of copulations the dangers of establishing infection at the time of service were reduced. In a series of 1543 cases 2 or more services by a stallion during one estrum resulted in only a 3 percent higher conception rate than when there was a single service per estrum.²⁸⁵

Ovarian palpation—Usually four to six or more follicles can be palpated on the mare's ovaries during es-

trus. Because of the size of equine follicles especially the maturing or ovulating follicle, an erroneous diagnosis of "cystic follicles" or "nymphomania" may be made if they are compared to those in the bovine ovary. Follicles of various sizes and numbers are present on mares ovaries during the transitional or anovulatory periods in the Spring and Fall, or before and after the physiological breeding season, during all stages of the estrous cycle, including diestrus and during the first 4 months of gestation. Cystic ovarian disease as described in the cow does not occur in the mare.^{90b,152,186,187} "Persistent," or "autumn" or atretic follicles^{68,69} may remain in the ovaries for several months late in the fall. All follicles in mares that don't ovulate become atretic and involute usually by the next estrous period. Ovulation can occur in the mare when the reproductive tract is under progestational influences such as during diestrus,²⁸⁹ with a persistent CL and possibly during the first trimester of pregnancy. This has not been reported in the other domestic animals. One case was cited in which a non-pregnant mare with an active corpus luteum as revealed by plasma progesterone levels of 3 to 7 ug/ml. developed a follicle, was given HCG, bred artificially, conceived and delivered a live foal. Such mares with an active CL and follicle do not show behavioral signs of estrus.^{138,289}

Regular palpation per rectum of mare's ovaries during estrum has been practiced by some veterinarians to predict the time of ovulation, to detect the presence of two large or twin follicles and to determine when ovulation has occurred. The author and others^{115,239,261} have confirmed that prediction of the time of ovulation by daily ovarian palpation is not reliable and is highly subjective. The size of the maturing follicle is greatly variable from 0.75 cm to 7.5 cm or more. Changes in the consistency of the mature follicle as ovulation approaches is also variable. Most authors indicate that the follicle that is near ovulation becomes softer and less tense but this sign was observed in less than 30 percent of the follicles in one study²⁶¹ where daily palpation was performed and was not consistent in another where palpation was done every 12 hours.^{114,115} Furthermore, following ovulation the follicular cavity usually fills slowly with blood forming the corpus hemorrhagicum before the next palpation and can easily be mistaken for an unruptured follicle. Both the equine Graafian follicle and corpus hemorrhagicum are the largest of domestic animals.

In a study in which daily rectal palpations were performed during estrus, first cycle pregnancy rates were significantly lower in the treated mares than in the non-palpated control mares, 46 vs 79%, respectively. In a subsequent study palpation of mares every 48 hours during estrus only resulted in about a 10 percent reduction

in pregnancy rates compared to non-palpated control mares.^{297,298} The adverse effect of palpation on fertility occurred during or shortly after estrus, and may be due to an alteration of embryo transport in the uterine tube. During estrus in mares excessive palpation or palpation by inexperienced persons should be avoided.^{297,298}

Twin ovulations were highest during the summer months with a yearly incidence of 14.5 and 18.5 percent.²¹¹ Arthur reported a few cases of triplet ovulations and an incidence of 33.7 to 37.5 percent double ovulations in the summer months.^{9,11,12} He also noted the incidence of twin births to be 1 to 1.5 percent indicating a high early embryonic and fetal death loss in twin conceptions. Other authors have reviewed and reported similar findings.^{115,116,117,140,235} This great loss of early twin embryos may be a more important cause of infertility than is generally recognized. Twin or double ovulations are usually nearly synchronous as in 83 multiple ovulations 75 percent occurred within 24 hours and 90 percent within 48 hours of each other.²⁶¹ Twin ovulation in ponies is rare.¹¹⁵ Asynchronous double ovulations, with one occurring late in estrus and another 2 to 12 days later during the luteal phase of the cycle are uncommon, probably occurring in about 25 percent of the cycles.^{115b,116,117,261,289} Most twin pregnancies are the result of double ovulation but rarely identical twins are observed in a single allantochorion.²³⁷ About 52 to 60 percent of the ovulations occurred on the left ovary.^{7,9,211} As mentioned previously slightly more pregnancies occur in the right uterine horn than in the left uterine horn indicating that transuterine migration of the zygote in mares is common. A review of transuterine migration of the spherical early conceptus showed that about 50 percent migrated from the side of ovulation to the opposite horn early, 20 to 70 days, in pregnancy. Migration after day 40 is probably uncommon.¹¹⁵

Failure of ovulation or delayed ovulation in mares has been described.^{12,87,88,90b,129,218,295} It may be noted by repeated rectal palpation of the ovaries and is seen in mares early or late in the breeding season when cycles are often irregular. In failure of ovulation the Graafian follicle will become atretic and regress in 10 or more days and if this occurs in the Fall the mare may go into anestrus. In the spring of the year regression of the first follicle may occur to be followed in several weeks by a normal estrous period, ovulation and the commencement of regular cycles. Diagnosis of delayed ovulation or anovulation is difficult and subject to error unless the ovaries are palpated frequently by a skilled examiner. Clinically if this condition was suspected an injection of HCG, 1500 and 3000 IU, might be indicated to produce ovulation of a large follicle during estrus within 24 to 48 hours. Ovu-

latory failure during the estrous periods occurring during the physiologic breeding season is probably rare, 1 in 300 periods.²⁶¹

Infertility in Mares Due to Abnormalities of the Estrous Cycle: Their Recognition and Treatment

Abnormalities of the estrous cycle of mares, maiden, barren and foaling, is the most common cause of equine infertility or delayed conception.^{75,115,239} The abnormalities or irregularities of the mare's estrous cycle are closely associated with seasonal changes in length of daylight, nutrition, climate, or ambient temperature, "social" interactions or degree of stimulus by a stallion, and various stresses, including transportation and introduction into a new barn or environment, similar to those affecting the estrous cycle of sheep, goats and cats, the other photoperiodic animals.

Various routine, regular and common practices are followed on equine breeding farms to detect the stages of the estrous cycle, particularly estrus, where mares are "handbred" and not "pasture" bred. These practices include: teasing by a stallion, manual examination per rectum of the cervix, uterus and ovaries, and vaginal examination with a speculum of the cervix and vagina. Other less common examinations or tests might include hormonal assays, especially progesterone, on blood plasma or possible tests on vaginal mucus for the presence of elevated electrolytes during estrus by means of an instrument to measure electrical resistance.

Teasing or "trying" of mares by a stallion should be performed regularly on an every 24 or 48 hour, daily or alternate day, basis. During estrus teasing every day is desirable. All mares and stallions on the breeding farm should be carefully marked or identified by halter plates, hoof branding, or skin (freeze) branding. The clinical signs or behavior of the mare in estrus have been described^{7,17,40,110,115,239,261} as follows: the degree of resistance to the stallion decreases slightly 1 or 2 days before estrus. The greatest estrual response or receptivity to the stallion occurs 1 or 3 days before the end of estrus or just before ovulation. This is followed by a decrease in sexual desire for the next day or two before estrus ends. This increased receptivity noticed during estrus is probably related to and parallels the rise in plasma estrogen levels that causes the LH surge and ovulation late in estrus.^{115,239} However, the signs of estrus are not closely related to the plasma levels of steroids, estrogens or androgens. Mare with "silent" estrus may have the same levels as mares showing strong signs of es-

trus.^{201,239} Receptivity or acceptance of the advances of the stallion is usually characterized by the mare seeking out or associating with the stallion, swinging of the rear quarters toward the male, elevation of the tail, squatting or flexing the rear limbs, urinating small amounts of urine, and "winking" or rhythmic exposure or protrusion of the clitoris between the vulvar lips. This is caused by the contractions of the muscles at the base of the clitoris and in the perineum. The mare stands immobile and will allow the stallion to approach, sniff or nip her in the inguinal region, flank or buttocks and stand firmly to be mounted. Homosexual behavior such as mounting between females rarely occurs. When mares are not in estrus they violently resist the stallion's advances by laying their ears back, squealing and kicking at him.^{17,115,239} Some mares are phlegmatic or undemonstrative or impersonal before and after estrus or in diestrus and show neither much response nor resistance to the stallion. A few mares are always phlegmatic and never show external symptoms of estrus when teased. In these mares showing no receptivity toward the stallion at any time, the estrous cycle is nevertheless usually occurring, as evidenced by typical changes in the vagina, uterus, and ovaries and when adequately restrained such mares may passively or even actively, accept coitus with the stallion.

For a successful breeding program it is advisable and necessary to tease mares regularly in order to accustom them to the teasing procedure so they will not be frightened by confinement or by the teaser stallion's advances. Changes in their attitude toward the stallion can thus be accurately noted and estrus can be detected early. Teasing should be part of the daily routine and not performed before feeding or turning out and not performed outdoors in inclement weather. Some mares react promptly to the teaser while others must be gently teased for 5 or more minutes to develop their true reaction. On some farms a stallion is not available as a teaser and in these cases a gelding may be used. If he is too passive, injections of 250 mg. or more of testosterone, "Repositol" form, every 10 days to 3 weeks will usually make most geldings a satisfactory teaser. The masculine behavior usually disappears by 4 to 6 weeks after the last injection of testosterone. Detecting estrus in most mares is nearly impossible without regular teasing. Some may show signs of estrus when groomed about the rear quarters. Swelling, relaxation and edema of the vulva is slight but fairly common in mares in estrus. Regular examination of the vagina and external cervical os with a speculum or palpation of the cervix, uterus and ovaries per rectum by an experienced veterinarian can supplement or replace regular teasing of mares. Although these methods are

possibly more accurate than teasing in detecting true estrus and the time for service they are also more time consuming and costly under most situations.

Behavioral patterns during the estrous cycle including the submissive mouth clapping during estrus, have been described in the donkey.²⁹⁰

Teasing of the barren and maiden mare should begin 30 days or so before the breeding season or the date of desired breeding. This is done so that the mare will become accustomed to her surroundings, to the teasing stocks and the teaser, and not be frightened, excitable, or nervous when teased during the early part of the breeding season. These latter attitudes make it difficult for the handler, manager, or veterinarian to tell when estrus is present. This practice also acquaints the men observing the mare with her reactions toward the teaser stallion both in estrus and diestrus. This is of great importance in certain mares who do not show marked symptoms of receptivity or rejection toward the teaser.

The teasing stocks or bar is usually a solid partition about 5 feet high and 12 feet long often located about 3.5 feet from a solid wall, into which the mare is led and tied. No projecting posts or spaces between the boards should be present to cause injury to the mare or the teaser. The teaser is led up to the head and then the side of the mare and allowed to tease her. The mare's reactions are closely observed for signs of estrus or approaching estrus. A procedure that can be used where many mares are to be teased, as on a ranch, is to drive 10 or more mares in a long narrow chute and head the teaser stallion down the line of mares watching each mare's reaction.¹⁷ There are other techniques for teasing mares, including teasing of mares in their stalls by leading the stallion up to the door and if necessary backing the mare up to him. Mares teased in their stalls should be watched as the stallion enters the barn, as he teases them over the stall door, and after he leaves them. Some mares will "fight" or resist the teaser at their stall especially if they have a foal by their side, but will indicate estrus by relaxing the vulva and urinating after or before they are teased. A few managers tease their mares by leading the stallion through the pasture and circulating among them to determine their reaction toward the stallion. This requires an excellent and knowledgeable observer and it can be dangerous if a mare attacks the stallion. On other farms a Shetland or small pony stud is run continuously with the mares to detect estrus. Because of his small size he is unable to copulate with them. A surgical technique, to direct the penis of a teaser stallion to the rear so that copulation is impossible when he is placed with mares on pasture has been described.³⁰ A male pseudohermaphrodite with defective development of the penis could

also serve in a similar capacity. In range areas the stallion is often kept in a large stall or pen near the only source of water. The mares running in the adjacent corral or pasture can go to his pen when they are in estrum. This form of teasing only detects about 50 to 60 percent of mares in estrus.¹¹⁵

Teasing a foaling mare should be begun on the second or third day after foaling. The foal is usually left in the stall and watched so it can't injure itself, while the mare is led away to be teased, or if the mare objects too much a small box or pen in which to put the foal may be built in front of the teasing rack.⁷ A few mares fight or resist the teaser at all times even though in estrum. Some of these mares will show estrum promptly when a twitch is applied to their nose, thus distracting their attention so that their true reaction to the teaser is exhibited. Other mares have definite preferences in a teaser so teasing by 2 or more stallions may be desirable.¹⁰³ Occasionally a mare may show nearly typical heat one day and then not show it again. This symptom is observed most commonly in pregnant mares. Other mares are very phlegmatic and show little reaction to a teaser at any time. The use of a bold, aggressive teaser is very useful with these mares. Occasionally these phlegmatic, unresponsive mares come into estrum so gradually the casual observer might not notice it, but when they pass out of estrum the difference in their reaction to the teaser is usually observable. Then it is too late to breed the mare. Oftentimes a good teaser may recognize estrum in a mare and react accordingly with increased signs of libido, although the man observing the mare cannot see signs of it. Excessively fat mares may often be phlegmatic toward the teaser and fail to show estrum. The person who is responsible for the teasing of mares should be a keen and careful observer and accurately record his observations. The teaser on a large breeding farm is usually a stallion kept for that purpose or one that is seldom used. On smaller farms where stallions are used sparingly the breeding stallion can act as a teaser. Occasionally a "teaser" stallion may lose interest and libido. Allowing him to tease and breed a mare usually restores his ability to tease mares properly.

Although it is not frequently performed except on well-managed farms with a resident or contract veterinarian, mares that show estrum to the teaser may be examined by speculum, and/or their ovaries examined per rectum, at least 12 to 24 hours before being bred to make sure they are actually in true estrum and that ovulation is approaching. Speculum examination causes ballooning of the vagina and within an hour or so of coitus may interfere with the proper deposition of the semen. Rectal examination just before a natural cover may dilate the

anus and favor false entry by the stallion. Both of these practices should be avoided just prior to service. All mares should be teased daily or every other day until they are bred the second or third day of estrum, and daily teasing should continue until the end of estrum. If the mare is still in estrum 2 or 3 days after service she is usually rebred that same estrum. For the next 2 weeks teasing is necessary only every third to fourth day, and then 2 weeks after breeding teasing should begin at daily or every-other-day intervals. If estrum does not recur, teasing every third to fourth day may be continued for several weeks more and a pregnancy examination should be made. If a pregnancy examination is not performed by a veterinarian about 30 to 40 days after service, regular teasing every third to fourth day should continue during the breeding season, inasmuch as a few barren and foaling mares may show marked irregularities in the estrous cycle or lose an early embryo or fetus. Of the three procedures used for determining the stage of the estrous cycle, the stage of estrum, the time of ovulation and the best time for service, the external manifestations of estrus of the mare in the presence of a teaser or stallion is the most variable and inaccurate but is the only method available for most horse owners. The speculum examination of the vagina and cervix, or "spec exam," is the next most accurate procedure when performed by a knowledgeable observer. There is danger of introducing infection into the genital tract if this is not done properly. The most accurate procedure is the rectal examination of the ovaries, cervix and uterus by a skilled, experienced veterinarian. Although each of these procedures is rather subjective when they are combined the conclusions or diagnosis is quite accurate especially if repeated examinations to note changes are made at short intervals of 24 to 72 hours.

The physical signs of estrum in the genital tract of mares are characterized on vaginal examination by congestion and hyperemia of the mucosa of the vulva, vagina and cervix that increase in intensity from proestrus to ovulation and then decrease to a pale, quiescent state during metestrus and diestrus. During estrum the mucosa is very pink, hyperemic, or congested. There is an increased secretion of vaginal mucus that makes the mucosa appear shiny and allows the vaginal speculum to slide or slip with ease over the mucous membrane. Most mares in estrum seldom object to, and will stand quietly for, the vaginal examination. In the mare the amount of mucus is greatest and its viscosity lowest during estrum. Seldom is mucus observed at the vulva of a mare in estrum as it is in the cow. Also excess mucus is seldom observed on the floor of the vagina unless infection is present. The cervix does not contain tubular

mucus glands that secrete copious amounts of mucus, as in the cow. In late metestrus, diestrus, and early proestrus the vaginal speculum on introduction slides over the mucosa with difficulty, since the mucus is scant, sticky, and dry. During gestation this mucus is copious, sticky and gummy. The cervix during proestrus and estrus gradually relaxes, becomes flaccid, edematous, and quite hyperemic until it is very relaxed, hyperemic and edematous at the time of ovulation. The cervix, during estrus, especially in older mares, does not protrude noticeably into the vaginal cavity but blends into the cranial ventral vaginal wall. During metestrus the cervix may be red and moist but has more tone.^{115,172,239} At the time of ovulation the cervix is usually relaxed sufficiently to readily admit 1 to 3 fingers of one's hand. The endometrium at the time of estrus in a mare is very edematous and appears as large parallel and scalloped, thickened folds when examined by an endo- or fiberoptic scope. The old belief that mares require an attendant to insert his arm into the vagina and dilate the cervix with the fingers or "open the mare" before breeding has no basis in fact, and is contraindicated because of the danger of introducing infection. Furthermore if this is done just prior to breeding, pneumovagina may result and this interferes with the normal drawing of the semen into the uterus at coitus. **During late metestrus and diestrus** the cervix is tightly closed, pale, white and dry, and the external os appears puckered. At this time the contracted cervix protrudes into the anterior vaginal cavity.

On rectal palpation during diestrus the cervix is tightly contracted and has a distinct outline and occasional follicles may be noted on the ovary. **During proestrus, into estrus**, there is a progressive relaxation of the cervix, its tonicity decreases and near ovulation it is difficult to define the cervix because of its edematous, relaxed and flaccid walls. **Rectal examination at estrus** will reveal follicles present on the ovaries. 8 to 9 follicles are produced each cycle; normally only one or occasionally two, enlarge, mature and ovulate and the rest become atretic and decrease in size.¹⁶ The ovaries in young mares 3 to 4 years old are largest. Often the ovary containing the Graafian follicle or recently ovulated follicle is somewhat sensitive on palpation per rectum. During estrus, different from the cow, the mare's uterus is rather flaccid, edematous and soft on rectal palpation compared to the pregnant mare's uterus which is usually tonic and tubular. The uterus during diestrus is fairly firm, thicker and less relaxed.^{115,239} Endometrial biopsies show definite morphologic changes between the estrogenic and luteal phases of the cycle.^{115,239}

The vaginal smear in the mare is indefinite and of no value in differentiating the various stages of estrous

cycle.^{16,207} The pH of vaginal mucus during estrus in the mare is 7.4. A recent limited study reported that the vaginal pH of mares dropped from 7.4 to 6.8 on the day of ovulation. Further studies should be made to confirm this observation.²²²

The electrolyte or sodium content of vaginal mucus increases during estrus. Several studies with an instrument (Ovumeter) to measure the electrical resistance of vaginal mucous electrolyte changes as a means of detecting estrus and ovulation were conducted.^{54,258} This technique was of value in only about 50 percent of the estrous cycles in predicting ovulation within 48 to 96 hours as noted by a decline in transmittance. Thus this instrument is of limited value in the mare. Palpation of the ovaries to detect the time of ovulation or the presence of two mature follicles has been discussed. The plasma levels of progesterone and estrogen and their assay during estrus, diestrus and pregnancy of mares have been noted in Chapters II, IV, XII and under hormonal control of the estrous cycle in this Chapter. When a stallion is not available for regular teasing nor an experienced veterinarian to routinely examine a mare such assays if done every 2 or 3 days could be helpful in determining the stages of the estrus cycle or persistence of the CL.

On well-managed and veterinary-supervised equine breeding farms a combination of regular careful, closely observed teasings by a skilled observer, rectal palpations and/or vaginal examinations by an experienced veterinarian and the careful complete permanent recording of all findings at each examination or breeding must be followed. Certain mares, especially barren, older or maiden mares have lower conception rates and should receive more careful scrutiny than foaling mares which usually have fairly regular estrous cycles and also have proven their fertility. Since most mares have similar patterns of behavior, estrous cycling and ovulatory patterns from year to year, these accurate, complete breeding and examination records are very helpful.

Abnormalities or Irregularities of the Estrous Cycles in Mares

Most non-foaling mares, especially pony mares and those kept out-of-doors in the late fall, winter and early spring in the temperate zones are in deep seasonal anestrus during most of this period with small, hard, inactive ovaries, a flaccid uterus and a pale relaxed, flaccid cervix that in occasional mares may be partially to fully dilated.^{115,129,139,140,157,239} The vagina and cervix on speculum examination are pale, white, dry and sticky with-

out much mucus. If mares are stabled and well-fed up to 20 to 25 percent may exhibit occasional or fairly regular estrous periods or cycles. The transitional periods of anovulatory receptivity at the beginning and end of this seasonal anestrous period occur over a period of about 2 months in the late fall and spring in northern latitudes.^{115,157,239} Since mares are not often bred in the fall, and early spring breeding is usually desired, the latter transitional period between February and April characterized by either anestrus, prolonged estrus, erratic follicular growth and ovulation or anovulation and other cyclic and reproductive irregularities is a cause of concern to owners, managers and veterinarians. It has been remarked that during this transitional period between winter anestrus and the physiological regular estrous cycles in the late spring and summer, "the only consistency in mares is their inconsistency." In earlier years,⁷⁵ before 1960 to 1970, careful, regular teasing, examination of the genital organs and breeding, some mares would conceive during this frustrating transitional period but for most mares waiting until the physiologic breeding season arrived in the late spring and summer was the only alternative. Although more nutritional studies on mares are needed it has been generally noted and accepted that mares in good health and not overly fat when fed a properly balanced ration and/or pasture in adequate amounts to cause a gradual weight gain hastened the onset of the physiologic breeding season. Also regular frequent teasing or close continuous contact with stallions during the spring apparently favors the onset of the regular breeding season as in ewes and sows.³¹ Further controlled studies are needed to confirm this observation.

About 25 years ago it was shown that artificially increasing the amount of exposure to light each day will hasten the onset of estrous cycles and the shedding of the winter hair coat of mares.^{68,177,207} But only within the last 15 years has this technique been used on a practical basis. In the U.S. this has been done largely on Standardbred farms where foals born in November and December are registered on January 1st as their official birth date. By gradually increasing the amount of exposure to light by 30 minutes per week starting on October 1st for Standardbreds and December 1st for Thoroughbreds, most mares will be cycling and ovulating normally within 60 to 90 days or when the total daily exposure to light reaches 15 to 16 hours. Exposure to continuous light for 24 hours per day was less effective in hastening the onset of the physiologic breeding season than 16 hours per day of natural and supplemental artificial light. Thus, this technique will induce the earlier attainment of a fertile breeding state. This is advantageous in the racing breeds because it results in earlier foals, better distribution of mares

served by the stallion and by a greater number of exposures of infertile mares to stallions during the breeding season. This is especially valuable in mares that normally fail to show estrus until late May or June. During the early breeding season under lights, the same erratic or irregular reproduction periods such as prolonged estrus, irregular estrus, and failure of ovulation occurs as it does at a later period in mares not under lights. It was demonstrated that a 200 or more watts non-frosted incandescent or fluorescent light bulbs that provided 2 to 7 foot candles of light, 5–12 feet above the floor were satisfactory.^{176,177} If the mare is normal, artificial lighting should result in the conception of the mare in December through March or April, but if the mare is infertile for a variety of reasons, artificial lighting has no curative properties.^{80,115,157,239,250}

Gradually increasing light up to 16 hours per day or a constant 16 hours of light per day will result in the early induction of the physiological breeding season in mares. This artificial light regimen should be started in the fall October 1st through January 1st in the northern hemisphere. The lag time for follicular activity and ovulation with normal estrous cycles is about 60 to 90 days.^{115a} When this light regimen was started in October mares did not go into the seasonal anestrus period and came into regular cycling and ovulation by mid December or January.⁸⁰ It was also recommended that breeding stallions and teasers also be placed on this same regimen, because of the length of the spermatogenic cycle, about 60 days. Mares that foal prior to April 1st should also be placed on this regimen of 16 hours of daylight prior to foaling. After 5 years on this program 50 percent of the mares foaled from November through January compared to only 3.8 percent initially.⁸⁰ In another large study of Thoroughbred and Standardbred farms 50 percent of the mares under this lighting procedure foaled by March 31st compared to none on an unlighted control farm.^{176,177}

The transition from the anestrous state in to the breeding season whether artificially stimulated by lighting or occurring naturally is a gradual process characterized by certain definite changes especially in the ovaries as detected by palpation. The transition from "deep" anestrus, to "shallow" anestrus, and to estrus and regular estrous cycles with ovulation is characterized initially by an increase in size of the ovaries a number of days before follicles can be palpated.^{67,68,69} This is usually associated with a shedding of the winter hair coat, and an increased vascularity observable in the mucosa of the vagina and cervix. The ovaries feel spongy or rubbery compared to the firm fibrous ovaries of anestrus. In a few cases these mares will show estrus even though follicles cannot be palpated. Probably this is due to small follicles in the

ovarian substance that secrete estrogen. Then later in this transitional period due to artificial or natural light of about 16 hours duration per day and after irregular or prolonged estrus without ovulation, ovulation occurs with the commencement of regular estrous cycles.^{115,250} At the present time provision of artificial lighting, even with its long lag time is the most satisfactory and practical procedure for hastening or prolonging the normal physiologic breeding season in mares.

Hormonal methods, as in ewes, have been attempted to bring mares into regular estrous cycles during the winter anestrus period. Trials and studies have been conducted with progesterone, GnRH, equine pituitary extracts high in FSH and HCG and various combinations of these hormones with limited and inconsistent results.^{115,157,239,261} Further studies are indicated. HCG in doses of 1500 to 3000 IU, as discussed previously, induces ovulation within 24 to 48 hours in Graafian follicles capable of ovulating. Thus this reduces the duration of estrus and extra services by the stallion.

Progesterone treatment, 100 mg of progesterone in oil IM daily for 7 to 10 days, given late in the spring transitional season or early breeding season before regular physiologic estrous cycles and ovulation have been established have, in limited trials and in the author's experience, been quite effective in producing a normal estrous cycle within 3 to 5 days after the cessation of treatment with ovulation about 8 days after treatment.^{140,157,293} Normal cycles usually result thereafter with conception rates of about 50 percent on this first service. This procedure by its nature is limited to individuals or small groups of mares. Since the presence of definite follicular activity is necessary, this treatment does not significantly hasten the onset of the physiologic breeding season but it does appear to have promise in the treatment and control of the common irregular, prolonged estrous periods in non-foaling mares that delay the onset of the physiologic breeding season. Further studies are indicated including the use of the orally active progestogen, allyl trenbolone.²⁶⁰

Other factors such as stabling and adequate nutritive intake also influence the time of onset of the physiologic breeding season of mares. Stabling by conserving energy, providing warmth and often light, especially in the early morning and late evening hours, has hastened the onset of the spring breeding season in mares. Early spring pasture if available, provides an excess of energy and protein and is often associated with a marked increase in estrous activity and ovulation in the temperate zones. Frequent or constant exposure to a stallion has also been reported to hasten the onset of the breeding season as in ewes and sows.³¹ However further controlled studies are

needed on this phenomena in mares since another similar study indicated only a small but not significant difference between pony mares penned with a stallion and control mares.¹¹⁴

Clinical signs of abnormal or irregular estrous cycles resulting in infertility in mares may be due to physiological, genetic, nutritional, managerial or pathological causes. They may be classified on signs of receptivity toward the stallion as either prolonged estrus or prolonged diestrus or anestrus. Ovulation may or may not occur in these conditions. Ovulation nearly always occurs, however, in mares with normal length estrous cycles and estrous periods.

Prolonged estrus or irregular prolonged periods of estrus including "split" estrus. The former periods of prolonged estrus or frequent irregular estrous periods are natural and are common, in up to 90% of maiden or barren mares in the late transitional period or early physiologic breeding season in the spring and in mares in which the breeding season was moved forward by the use of artificial light.^{75,115,250} These prolonged estrous periods ranged from 8 to 30 days, average 18 days.²⁵⁰ They have been occasionally reported as lasting up to 60 days or more,^{75,140} during which the mare shows receptivity toward the stallion at nearly all times. Later in the breeding season this prolonged receptivity ceases and a normal estrous cycle with ovulation is established. As foaling mares these mares with a history of prolonged estrum early in the breeding season usually have an excellent sexual rhythm, regular estrous cycles and good fertility.⁷⁵ In the latter uncommon condition, "split estrus" the mare is in estrus to the stallion for one or more days, out of estrus for one or more days, then back into estrus for several days. Ovulation may occur at this latter time. "Split" estrus may on occasions, be a psychic phenomena, especially in maiden mares, related to stress, improper teasing, transportation or other factors.

Treatment of the condition of prolonged or irregular estrous based on the response of the mare to the teaser is most easily accomplished in most mares by waiting a month or so until regular estrous cycles are established in the physiologic breeding season. However vaginal and rectal examinations of these mares every 48 to 72 hours may detect a normal physiologic estrus with a large follicle at which time possibly HCG and breeding might be indicated. Repeated breeding of mares during these prolonged receptive periods may be harmful to the mare and is wasteful of the stallion. Hormonal therapy that might be useful in this condition would be the administration of HCG, 1500 to 3000 IU, when a mature, large follicle was present with other changes in the genital organs indicative of a physiologic estrus. In this condition pro-

gesterone therapy, 100 or 200 mg in oil, daily for 7 days takes the mare out of her receptive state even though on examination of the genital tract no signs of physiologic estrus are present.^{157,293} An oral progestin, allyl trenbolone fed at a rate of 22 mg per day for 12 days to 500 kg mares effectively regulated estrual behavior early in the year and synchronized estrus in cycling mares and had no effect on subsequent fertility.²⁶⁰ In another trial this orally active progestin reduced the protracted period of estrus and follicular development that commonly precedes the first ovulation of the breeding season but did not hasten the onset of the ovulatory season.²⁸⁶ This product is not yet available commercially in the U.S. Usually these mares come into a normal estrus 3 to 5 days later and ovulate about the 8 days after the termination of the treatment. Normal fertility and conception occurs at this estrus and subsequent estrous periods that follow this establishment of regular estrous cycles. The use of artificial lighting as described previously hastens the onset of the physiologic breeding season so that this common phenomena of the late transitional period doesn't interfere with the advanced breeding season.

Psychologic or false estrus or receptivity may occur with inactive ovaries or ovaries with no or only slight follicular development and the genital tract is pale, inactive with a closed cervix, no edema and a sticky dry mucosa and the reproductive or estrous cycle is absent. Mares may infrequently exhibit psychologic signs of estrus at any stage of the estrous cycle other than estrus during the winter anestrus season and even pregnancy.

Prolonged periods of anestrus or diestrus are common in mares as a cause of infertility or delayed conception. This condition is characterized by long periods of non-receptivity toward a stallion and is caused by a variety of physiological or pathological, temporary or prolonged, entities.

Physiologic anestrus is observed during pregnancy and during the winter season in most, 75 to 85%, of mares. The mares ovaries are small and inactive from 150 days to term in pregnancy and in ponies and pastured or "roughed out" mares in the winter, November through February or March.^{115,158,239}

Spontaneous prolongation of luteal activity or persistence of the corpus luteum has been recently documented as a common phenomena in mares.^{115,139,140,239,262} It is the most common cause of anestrus during the physiologic breeding season. The period of anestrus or non-receptivity lasts for 1 to 3 months, average 60 days, and is characterized by a failure of estrus, good uterine tone, a tight, pale, dry cervix, and elevated plasma progesterone values of 1 to 5 ng/ml that also persists for the length of the anestrus period. This occurs in mares with

normal genital tracts and the cause of the condition is unknown but probably is associated with a failure of the release of prostaglandin from the uterine endometrium about day 12 to 14 of the estrous cycle. This condition of a persistence of the CL occurred most commonly during the summer or the physiologic or breeding season, but may occur at any season in mares of all ages. It could occur in mares that were bred but failed to conceive. But a diagnosis of embryonic death or resorption would be incorrect. Ovulation, but not receptivity, may occur during this condition and in one instance pregnancy resulted from artificial insemination just prior to ovulation.^{137-140,262}

Treatment of this condition of prolonged luteal activity characterized by anestrus is the injection of prostaglandin, 10 to 15 mg of PG F_{2a} (**Prostin**) or 250 to 500 ug of fluprostenol (**Estrumate**) or other prostaglandin analogue that produces luteolysis of the persistent CL. The time of ovulation after treatment with a prostaglandin may vary from 1 or 2 days to 9 days. If a large follicle 4+ cm. is present ovulation may occur promptly with a short period of receptivity. About two-thirds of the mares ovulate from 3 to 7 days, average 5 days, and in the remaining third the large follicle regresses and a new follicle forms and ovulates at 6 to 12 days, average 9 days. Mares with follicles smaller than 3.5 cm. ovulate about 5 to 9 days, average 7 days, post-treatment.¹⁴⁰ Prior to 4 to 5 days post ovulation neither prostaglandins nor douching of the uterus is effective in causing luteolysis as the young CL is refractory to prostaglandin.

Douching a mare with 500 ml. of sterile saline to which antibiotics or antiseptics have been added to prevent infection or endometritis after the fourth or fifth day post ovulation and during diestrus when the CL is mature was shown to rapidly release uterine prostaglandins and cause luteolysis.^{13,203,239} This treatment was not as reliable as an adequate dose of prostaglandin.¹⁷⁴ If this spontaneous prolongation of the CL is caused by a lack or deficiency of uterine prostaglandins then uterine douching would not be effective and there would be a possibility of introducing infection into the uterus. In a large study of anestrus mares treated with a saline douche or prostaglandin the return to estrus within 2 to 7 days and the pregnancy rate were 40 and 39 percent vs 63 and 55 percent, respectively, for the two treatments.¹⁷⁴ The technique of douching the uterus was described in the 2nd edition of this text, and omitted from this edition because it is outdated, not as effective and more hazardous than the injection of a prostaglandin.

Saline infusion of the uterus in 25 mares that were determined to be non-pregnant prior to 40 days postservice all returned to estrus within 2 to 4 days after treatment. If such mares were not infused this anestrus state,

probably due to early embryonic deaths, lasted to 80 days or more.²⁹² A similar luteolytic response in anestrus mares occurred when they were given 250 mg. of stilbestrol intramuscularly and the mares were bred by natural service on the induced estrus 24 hours later. Within 7 to 8 days many mares so handled came into a true standing estrus and ovulated, conception frequently occurred if they were bred in this "second" physiologic estrus.²¹⁸ It is possible that the old empiric technique of "opening up" the mare by the groom manipulating and dilating the cervix was based on the physiological effects and the induction of estrus by such an act. One study showed that uterine biopsy, uterine culture, or cervical dilation and possibly AI, embryo transfer, uterine infusions or fiberoptic examination of the uterus if performed on the fourth or fifth day after ovulation or later in diestrus could shorten the estrous cycle or interestrus period and lengthen the subsequent estrous period due to the luteolytic effect caused by releasing uterine prostaglandin and regressing the CL.¹⁴⁴ Uterine "curettage" in the barren or infertile mare by drawing the cervix posteriorly with forceps fastened just lateral to the external cervical os has been accomplished by gently scraping the endometrium of both uterine horns and body with a sterile 70 cm. curette. This was supposed to simulate the stimulating effect of infusing the uterus with saline.^{167,256} The indications for and the value of this empirical technique are questionable. Controlled experiments and studies have not been undertaken. From these types and kinds of therapy to correct anestrus one can deduce that any significant invasion of the cervix and uterus if a CL is present may cause luteolysis of the corpus luteum and produce estrus in 2 to 10 days. The suggestion has been proposed that such practices possibly introduce organisms into the uterus resulting in endometritis and prostaglandin release and an abbreviated estrous interval which is well documented as a sequel to acute uterine infections. (See Infections of the Mares' Genital Tract.) The use of estrogens to correct anestrus or cause luteal regression in the mare has proven to be of no or very questionable value. Estrogens given to mares with a mature corpus luteum prolongs its activity and is not luteolytic as it is in the cow.²⁰⁷

Anestrus due to abnormal behavior, psychological anestrus, "silent heat" or subestrus is noted in mares that fail to show receptivity toward a stallion even though the estrous cycle, follicle growth, ovulation and CL formation occur regularly.^{75,115,137,239} These mares may show external signs of estrus only occasionally even during the physiologic breeding season but when they do show estrus they ovulate. Foaling mares, especially nervous mares that show great concern for their foals, are quite prone

to show psychological anestrus for several months after foaling. This may be termed "**lactational anestrus**" but it is not a true lactational anestrus as seen in sows, ewes and cows nursing young.¹¹⁵ This apparent "lactational anestrus" may also occasionally be due to persistence of the CL. Nervous, shy maiden or foaling mares may represent up to 10 to 15 percent of mares on a farm in which inadequate teasing fails to elicit estrous signs in the normally cycling mares. Some of these very protective foaling mares fail to show estrus and breed while a foal is at their side, the so-called "every other year mares." Frequent persistent quiet teasing by a vigorous male, free access of mares in a paddock to a penned stallion or pasture breeding to a quiet stallion, or careful repeated rectal and vaginal examinations and breeding by artificial insemination might be considered. These mares, either nervous or phlegmatic types, if presented to a stallion for service or teasing at the time they are approaching ovulation and restrained by a twitch or possibly hobbles will often "break down" and show external signs of estrus and acceptance of the stallion.

Conversely, certain fat, phlegmatic "impersonal," quiet, undemonstrative mares may also have normal regular estrous cycles and ovulation detectable on rectal or vaginal examination but be unreceptive to teasing similar to the former nervous or shy mare. Treatment is similar. By the use of a vigorous aggressive stallion as a teaser, frequent teasing, pasture or paddock contact with a stallion will often elicit signs of receptivity. The use of hormones such as estrogens in this type of mare is of no value. Occasionally mares will be nonreceptive to one stallion and exhibit estrous signs to another. One controlled study¹²⁶ on restricting suckling of foals to 4, 1-hour periods per day had inconclusive results. However two mares with a history of failing to exhibit estrus while nursing ("lactational anestrus"), ovulated and were bred and one conceived. Restricted suckling did not impair foal growth and development but when mares were stressed in late gestation by restricting their nutritive intake the onset of foal estrus and ovulation was delayed. This delay was apparently prevented by restricting the suckling of foals, even though the treated mares were more active and lost more weight due to the enforced separation from their foals for long periods each day. All mares with normal or long postpartum intervals, 17 to 30 days, to foal estrus had low plasma progesterone levels, less than 1 ng/ml, until after they ovulated. Further studies on this postpartum period are indicated.¹¹⁵

Anestrus due to various pathologic conditions will be discussed in more detail later in this Chapter. These are pathologic conditions involving the uterus and ovaries or systemic diseases. They are usually characterized

by a failure to exhibit signs of estrus on teasing and can be detected by a careful physical examination or laboratory tests. The conditions resulting in anestrus include:

1. **Pyometra** in which chronic advanced endometritis has caused the loss of uterine endometrial cells capable of producing prostaglandins. Injection of prostaglandins may produce estrus by regression of the CL but anestrus usually recurs depending on the degree of uterine pathology. The prognosis is poor. With a lesser degree of metritis and uterine infection, mares often cycle regularly or occasionally have short 15 day cycles.¹⁴⁰
2. **Hysterectomy and ovariectomy** will cause anestrus. After hysterectomy the lifespan of the corpora lutea were 67 to 137 days and after their regression estrus and ovulation again occurred. These conditions are incurable and rare.
3. **Granulosa—theca cell tumors** are the most common ovarian tumor in the mare. These mares exhibit either anestrus, stallion-like behavior or continuous or intermittent estrous behavior. The opposite ovary from the affected ovary is usually small, firm and inactive. Removal of the diseased ovary is indicated.
4. **Gonadal dysgenesis** similar to Turner's syndrome in humans is seen occasionally. These mares usually have a 63, XO karyotype. In one study 21 of 32 mares with chromosomal disorders were of this type.^{133,140} The ovaries of these mares are very small, smooth and firm and follicles seldom develop because of a lack of germ cells. The uterus and cervix are usually flaccid and relaxed and signs of estrus are not exhibited. Cytogenetic studies of these mares are necessary for a definitive diagnosis. Any mare with very small, hypoplastic ovaries should be regarded as a possible mare with chromosomal abnormalities.
5. **Anestrus associated with emaciation** may also be seen in old mares with pituitary tumors, old debilitated mares with poor teeth, heavily parasitized mares, mares with a chronic debilitating disease or mares that have been nearly starved or underfed or overworked and are extremely thin. Mares stressed by heavy exercise and restricted rations may exhibit "deep" anestrus.²⁰⁸ In these conditions the ovaries are very small, hard and inactive, the uterus and cervix are flaccid and relaxed and no signs of estrus are exhibited. Correcting the disease condition and improving the ration will in time often overcome anestrus due to these causes.
6. **"Nymphomania"** is a rare psychotic condition in mares, characterized by long standing severe

aggression and viciousness toward other horses and man. It is probably often caused in nervous, aggressive, horses by cruelty, or even timidity, of an owner or handler. Once the psychosis is well established, ovariectomy often has little or no effect on the mares behavior. These mares usually cycle regularly during the physiologic breeding season but are dangerous to work with and react violently toward a teaser or breeding stallion. In the stable the severely affected mare is vicious and may kick, bite, "run over," intimidate or jam her handler against the wall.

She tends to squeal, kick, squirt urine, and switch her tail if handled about the rear parts. For these reasons many owners think they are in constant estrus and call them "nymphomaniacs." Two types, a mild and severe, have been described.¹⁰ The former responds to ovariectomy, the latter does not. In the former the mare is often normal and tractable except when in estrus. These attitudes may be related to the elaboration of estrogens, progesterone and even androgens in the ovary. However, they will not tolerate the approach of another horse, a teaser or stallion; nor will they stand to be covered. They are dangerous to examine per rectum. They are useless as riding or draft animals. Because of the long-standing nervous derangement in these neurotic, unstable individuals, the vicious tendencies are well-ingrained and recovery even after an ovariectomy seldom occurs unless a skilled and knowledgeable horseman will retrain the animal so that it behaves sufficiently well in competent hands to be useful. Relapses to a violent behavior are common. Most of these advanced and long-standing cases of nymphomania or neurotic behavior should be destroyed before they injure a person or another animal. About a 60 percent recovery rate occurred after ovariectomy. The other 40 percent were long-standing vicious mares and response was not achieved.^{34,127} In another study 10 mares with nymphomania and frequent estrus all responded after ovariectomy; while many of the 15 mares with an unmanageable temperament during both estrus and diestrus showed marked improvement after ovariectomy. In all 25 cases the ovaries were normal with evidence of regular cycling.²¹⁹

7. **Anestrus, pseudopregnancy, or "spurious conception"**^{2,3} usually, but not invariably, occurs when an equine pregnancy terminates spontaneously or is intentionally interrupted after the endometrial cups have developed at 38 to 40 days of gestation. The cups remain and continue to secrete

PMSG. In Thoroughbred mares anestrus with hard, inactive ovaries may persist until the endometrial cups involute 80 to 110 days after their formation. Prostaglandin injections are ineffective during this period. Pony mares with pseudopregnancy may return to estrus but the associated follicles don't ovulate but often luteinize during this period of irregular cycling.

8. Two commercially-available anabolic steroid preparations were injected intramuscularly every 3 weeks, starting in December, for a total of 5 injections into 12 to 18 month-old fillies. These injections suppressed estrus and ovulation in most of the fillies for two breeding seasons, resulted in enlargement of the clitoris that persisted in some fillies for six months and caused various forms of stallion-like behavior including mounting that lasted for several months following the treatment.^{258a} Thus anabolic steroids should not be used in mares intended for breeding purposes.

Estrus synchronization and synchronization of ovulation has been generally successful in other large species of domestic animals. In the mare this is more difficult because of the long estrous period and the variable time of ovulation. But it would be desirable for artificial insemination, embryo transfer, planned or "spaced" matings and the control of the time of postpartum ovulations.¹¹⁵ The ideal goal of synchronization would be to be bred at a certain time without the need to detect estrus or ovulation. This goal is apparently a distant one in mares.

The four methods of control of the mare's estrous cycle that are currently available are:¹¹⁵

1. use of artificial lighting to hasten the onset of the physiologic breeding season. No practical hormonal therapy is currently available to induce ovulation and conception during winter anestrus period in mares,
2. use of HCG, 1500 to 3000 IU, early in the estrous period to induce ovulation within 24 to 48 hours and shorten the estrous period has been well-established and has been discussed in this Chapter,
3. use of progesterone in oil, 100 to 200 mg, IM, or a progestin, allyl trenbolone, 22 mg orally²⁶⁰ daily for 7 to 20 days to prolong the luteal phase of the cycle by suppressing estrus and ovulation in normal cycling mares resulted in estrus in 2 to 7 days after the end of treatment and,
4. use of prostaglandins, PGF_{2a}, 10 mg, prostaglandin analogues (fluprostenol) 100 to 250 ug, parenterally after the fifth day of the cycle to terminate the luteal phase of the cycle by luteolysis, or regression of the CL, and produce estrus within 2

to 4 days. In some synchronization trials two injections of prostaglandin were given to mares about 14 days apart when the stage of the estrous cycle at the time of the first injection was not known.¹¹⁵

The above products had no effect on fertility and might be used in combinations such as progestins and HCG or prostaglandins and HCG to produce estrus during a certain short period and to cause ovulation within a few days, respectively. Ginther¹¹⁵ has discussed the problems of synchronization of estrus in mares as they relate to the breeding season, the estrous cycle, the breed differences, for example ponies vs horses, the long estrous period and the variations in ovulation time. However with careful monitoring by an owner and a veterinarian individual or small groups of mares might achieve a satisfactory synchronization of estrus, ovulation and conception.

In one synchronization trial¹⁴⁶ two injections of prostaglandin (PG) were given 116 mares in 3 groups 15 days apart. Two of these groups were given HCG, 5 days after the last prostaglandin injection and bred AI. One group was bred once 21 days and the second group twice 21 and 23 days after the first PG injection without heat detection. The third group of mares was not given HCG and bred every other day of estrus. The conception rates for the three groups of mares were 57, 59 and 72 percent, respectively. Mares returning to estrus were bred by natural cover the next estrus and 98 percent of all mares were pregnant within 5 weeks of the first injection of PG. In another similar experiment²⁹⁹ PGF_{2a} was given twice 14 days apart and one-half of the mares bred AI after HCG and the other half bred AI after GnRH analogue on the fifth day after the last injection of PGF_{2a}. Although 81 percent of the mares were in estrus within 6 days after the last PGF_{2a} injection, conception rates were only 25 to 40 percent compared to 67 percent in a group of untreated mares. The use of progesterone impregnated sponges to synchronize estrus in mares during the breeding season as reported in ewes was only successful in 6 of 11 mares. Furthermore the sponges adhered to the vaginal wall, were difficult to remove and severely irritated the vagina.⁹⁸ PMSG given several days before the removal of the sponges was ineffective in causing superovulation or increasing the estrous response.

As discussed earlier and subsequently in this Chapter breeding on foal heat or estrus between 7 and 12 days postpartum results in 11 to 20 percent lower conception rates^{18,115} and possibly higher pregnancy loss than breeding later on the second postpartum estrus. An important postpartum interval of about 20 days is lost by routinely breeding on the second estrus. Furthermore, some mares

may exhibit silent estrus or anestrus following the foal heat due to their protective nature toward the foal even though ovulatory cycles may be fairly regular. Of 57 foaling anestrous mares, 42 or 75 percent had been bred on their foal heat. So the belief that only mares not bred on their foal heat go into anestrus is erroneous.⁸⁴ Some of the mares bred on foal heat and showing anestrus conceived but aborted or resorbed an early embryo.^{18,234} However in general foaling mares have regular estrous and ovulatory cycles with foal heat occurring between 6 and 12 days postpartum and ovulation between 10 to 12 days. This short cycle is usually followed by a regular cycle of 21 days and the second estrus occurs between days 25 and 35 postpartum. About 10 percent of mares may not have their first heat until 14 or more days postpartum. In order to breed mares on the second estrus or ovulation postpartum and gain the benefits of a higher conception rate yet not lose a valuable 20 day period, prostaglandin can be injected into foaling mares about 7 days after the foal heat ovulation or about 20 days postpartum. In 44 mares so treated 95% showed estrus and 82% conceived. In 36 mares not showing foal heat and treated on day 20, 68% came into estrus and 79% conceived.²⁸³ Thus delaying breeding for 18 days greatly increased pregnancy rates. Further trials should be undertaken. Delaying foal heat ovulation by the daily injection of progesterone, 100 to 200 mg. did not consistently block or delay ovulation and did not depress fertility.¹⁸⁰

An important recent clinical trial⁵ with 61 Thoroughbred mares in England illustrated the benefit of progesterone therapy at the end of the transition period and before the beginning of the regular cycling or breeding season during the months of February through May where no artificial lighting was utilized, as well as after parturition in mares in "lactational" anestrus. Thirteen to 20 mares each in shallow anestrus or prolonged estrus just before the regular ovulatory season and mares showing no estrus within 35 days after foaling, with plasma progesterone levels less than 1 ng/ml, were given 30 mg. of allyl trenbolone (**Regumate**) for 10 to 15 days. All 46 mares were in estrus within 8 days and all but 2 (4.4%) ovulated by 18 days after the end of the treatment period.⁵ This confirms Van Niekerk's early studies that progesterone therapy hastened the onset of the true breeding season in mares by apparently releasing LH to cause follicle maturation and ovulation.²⁹⁸

Early spring breeding mares need a regressing CL to prevent a long shallow anestrous period and prolonged spring estrous periods. Of 12 mares in deep anestrus 6 did not respond to progesterone therapy in the above trial. Increasing light artificially to 16 hours daily and giving progesterone therapy in 8 to 10 weeks would be indi-

cated.⁵ In mares showing prolonged "lactational" anestrus with plasma progesterone levels greater than 1 ng/ml, prostaglandin injections would be indicated as these mares are probably exhibiting a prolonged diestrous period with a persistent CL.

Attempts at superovulation and producing ovulation in the seasonally anestrous mare have only had very limited success.^{148,166,308} Large doses of purified equine FSH given daily for nearly two weeks were necessary and the frequency and cost of treatment made these trials impractical, considering the poor results obtained.

Nutrition and Infertility in Mares

In the past 10 to 15 years much research, using modern methods, has occurred in field of nutrition in horses at Cornell, Ohio State and other universities and research centers.²⁴⁸ The pregnant mare should be kept on a maintenance ration in only moderate body condition until the ninth month of gestation when a modest increase in protein and TDN should be provided until foaling. The barren mare should be kept on a maintenance ration also. During the breeding season both barren and foaling, lactating mares should be in a positive energy balance and gaining weight slowly. The pregnant mare might need increasing nutritive levels the last few weeks before foaling, and then a rapid increase in TDN intake after foaling to realize the highest conception rates on foal heat. It is important that mares to be bred on their foal heat and for a month or more thereafter be placed on a high energy ration. This may cause a problem in some mares that milk heavily by causing scouring in the nursing foal 1 to 2 weeks after birth. The feed intake of the foal may have to be monitored and the mare milked out manually. Thin animals and animals losing weight rapidly, usually fail to cycle and ovulate normally. (See infertility due to nutrition in cattle.)

Racing mares in training may remain in true or "deep" anestrus, even in the breeding season, due to stress, overwork, adrenal insufficiency and a probable lack of energy or TDN.^{35,208} In the former report changing to a pelleted feed resulted in a resumption of ovarian activity.³⁵ A low level of nutritive feed intake has no effect on fertilization.^{33,292} No embryonic resorption took place in mares that conceived on a low nutritional plane and thereafter received supplemental feeding before 18 days after ovulation. Eight mares on a low plane of feeding and a low protein intake after 18 days of pregnancy had an early death and resorption of the embryo between 25 and 31 days after ovulation as determined by rectal palpation. Mares placed on the poor ration after they were

35 days pregnant maintained normal embryos.³³ Mares having early embryonic deaths usually came back into estrum 40 to 80 days after service. Mares being provided additional hay and grain did not have the early embryonic deaths. The observation was made that supplementation of the diet with vitamins A and E appeared to improve the conception rate. However, a more recent study indicated that supplementation of an adequate ration had no beneficial effects on reproduction in mares.^{265,296} A properly balanced ration with sufficient TDN, protein, minerals, vitamins, salt, and water should be provided together with exercise for the foaling and breeding mare.

Overly fat, obese mares on lush pasture often are reported to be poor breeders. Possibly the reason they are fat is that they are poor breeders and do not nurse or carry a foal to use up the excess TDN consumed. Some veterinarians have empirically used 1 gm. per 100 lbs. body weight of iodinated casein with a 3 percent thyroxine potency (**Protamone**) daily in the feed of these obese mares to cause loss of weight. These mares should have been reduced in weight sufficiently during the winter months by restricted feeding so that in the spring months they could be placed on a slowly rising plane of nutrition and a positive energy balance to promote the onset of a normal estrous cycle, ovulation and conception.

Genital Infections Causing Infertility in Mares

Etiology and Symptoms. Infectious venereal diseases, other than contagious equine metritis (CEM) due to *Hemophilus equigenitalis*, do not occur in horses in the United States. Presently vigorous control measures

Figure 145. Ovaries in a 5-Month-Old Equine Fetus. (Note their size in relation to that of the fetal kidney located between them.)

have eradicated this disease, as well as dourine, from the United States. Genital infections in mares arise basically from four conditions. These are 1) pneumovagina due to an abnormal conformation or injury to the vulva and perineal region, 2) a normal or pathological parturition, 3) introduction of pathogenic bacteria at the time of copulation particularly in mares with a lowered resistance to infection and 4) introduction of pathogenic organisms on hands, instruments, infusion or AI equipment.

The first and most common condition causing a genital infection is pneumovagina, "windsucking" or aspiration of air into the genital tract. The normal mare's vulva should be at an angle of about 80° to 90°, or nearly vertical. The lips of the vulva should be full, firm and evenly closed their entire length. Pneumovagina is predisposed by a conformation that includes a flat croup, elevated tail head, sunken anus, and small underdeveloped vulvar lips that are pulled nearly horizontal by a sunken anus (See Figure 146). It is also caused by lacerations, scarring, stretching, or tearing of the vulvar sphincter muscles or the vulva or perineal body at the time of foaling. The perineal body, perineal center, or perineum in the narrow sense, is the complex joining of muscles and fascia between the anus and vulva.¹²² Whether pneumovagina is caused by the conformation of the perineal region or due to injury to the vulva, it results in infection of the vagina, the cervix, and oftentimes of the uterus. The question has been raised,¹⁸² but not answered, whether the conformation of the perineal area, especially in Thoroughbreds, American Saddlebreds and those horses with a high tailhead and flat croup, is inherited and surgery commonly used to correct pneumovagina to get affected mares pregnant is not perpetuating or increasing the numbers of these abnormally conformed animals. The vulvar lips in these "windsucking" mares becomes atrophic, flaccid, rolled in, gaped, or are sunken just below the dorsal commissure, allowing contamination of the genital tract with feces, air, and contaminating organisms. Once pneumovagina develops, the habit of aspirating air into the vagina becomes confirmed and it will usually become progressively worse unless treated. This condition is seen more commonly in old and thin mares but may be found even in young thin nulliparous mares. Standardbred or Quarter horses with more sloping croups and a lower tailhead are less commonly affected. (See Figure 146.) The peculiar gurgling, sucking sounds and expulsive blowing sounds occurring in well-developed cases, especially at the time of urination or defecation or at the time the mare is exercised are characteristic. Pneumovagina is more common at the time of estrum.⁷⁵ In fact aspiration of air into the vagina

Figure 146. Appearance of the Perineal Region of a Mare with Pneumovagina. (Note the sunken anus, horizontal tipped vulva and the atrophic vulvar lips.)

may occur in some mares only during estrus. At this time the perineal region and the folds and sphincter between the vestibule and the vagina are more relaxed due to the influence of endogenous estrogens. Pneumovagina may occur in maiden mares in training, especially during the breeding season. The rare case of the outwardly-tipped vulva in maiden mares may also predispose to pneumovagina.⁷⁵ Pneumovagina may be a cause or a sequela of infection of the genital tract. In some mares the condition may be mild, infrequent and not suspected unless the mare fails to conceive and speculum examination or culture reveals evidence of a chronic infection of the genital tract. The presence of a small amount of foamy or frothy exudate in the vaginal cavity or a purulent discharge from the vulva about 5 days following coitus are almost pathognomonic symptoms of pneumovagina.⁷⁵ By introducing air and foreign material this condition may

involve not only the vagina but also the cervix and uterus. Many veterinarians^{75,96} have observed mares with definite symptoms of "genital windsucking" in which air and bubbles of vaginal exudate are sucked through the cervix resulting in ballooning and contamination of the uterus. Pneumovagina and pneumometra are associated with the reflex ballooning of the vagina and the development of a negative pressure in the uterus which occurs in the normal mare at coitus. These ballooned organs may readily be palpated on a rectal examination. Air does not normally gain access to the vagina and uterus at coitus when the vagina balloons, since the vulva is effectively closed by the penis.¹⁹³ The author has observed a few mares with only pneumovestibule. In these cases air is drawn into and expelled out of the vestibule causing a vestibulitis. The closure of the folds and the sphincter at the cranial or vaginal end of the vestibule apparently has effectively prevented the drawing of air into the vagina. This may be the initial state of pneumovagina. Measuring the length of the vulva from the dorsal commissure to the level of the pelvic brim in centimeters, the effective vulva length, and multiplying that by the angle of declination of the vulva gave a "Caslick Index" that could be related to the fertility of the mare.²¹⁵ Mares during estrus, with an effective length of vulva of 2 to 3 cm. rarely required suturing even as the vulva lengthens with age. Those with an effective vulva length of 5 to 9 cm. during estrus had a high Caslick Index and often required an operation at a young age. In this study 2110 mares (23%) had been operated upon; a low figure compared to about 30 percent of Thoroughbred broodmares in Australia upon which the operation had been performed.²¹⁵

The second source of genital infection in the mare is the normal and pathological parturition, characterized by dystocia, a dead or diseased foal, retained placenta, or severe trauma to the genital passages. Incomplete or delayed involution of the genital tract and uterine inertia following a pathological parturition has been stressed as a common cause of sterility.^{89,90b} The genital tract of all mares becomes infected during or just after parturition.^{58,59} This massive infection usually enters the genital tract when the mare rises soon after foaling and the vagina and uterus balloon with air. Cultures from mares the first 5 days postpartum invariably show bacterial growth but in normal healthy mares this infection is overcome or eliminated by the ninth or tenth day after parturition or sooner if foal estrus occurs early. It has been reported that the incidence of infections of the uterus and cervix at the onset of foal estrus can be greatly reduced by carefully washing and disinfecting the perineal region and rear parts of the mare before foaling, wrapping the tail in a sterile or plastic bandage, by allowing

the mare to foal on a sterile heavy rubber sheet covering the foaling stall floor, and temporarily closing the vulva with skin clips immediately after foaling.⁷³ Genital infections, injuries and lacerations following a pathological foaling, however, may cause pneumovagina which prevents the normal elimination of the infection.

Apparently the same but even more efficient mechanisms that eliminate infection at the time of estrus in cattle, sheep and swine are also operative at estrus in mares. This is an effect due to estrogens and other natural defense mechanisms causing a massive invasion of leucocytes, the "leucocytic tide," into the endometrium and lumen of the uterus to phagocytize and destroy infective organisms. The increased blood supply, mucus production, and the relaxation of the cervix all combine to rapidly restore the uterus to its nonpregnant, bacteriologically-sterile state in the healthy mare. This acute massive reaction to intrauterine infection also occurs at any stage of the estrous cycle and results in release of prostaglandins, luteolysis of the CL if it is present and the prompt onset of estrus with a shortened estrous cycle.^{134,137}

Thirdly, some cases of genital infection in mares may be due to infections introduced at the time of copulation from failure to observe hygienic procedures or by stallions that are carriers of a venereal infection such as *Hemophilus equigenitalis* (CEM), or possibly *Klebsiella* or *Pseudomonas*. Excessive frequency of breeding during an estrous period, especially in older, often infection-prone, mares should be avoided as it favors the establishment of a uterine infection. The mare that is to be bred should have her tail bandaged with clean, sterile gauze; the buttocks and perineal region and the wrinkles of the vulvar lips and skin should be thoroughly cleaned and washed with soap and water and wiped dry with pledgets of cotton to be certain that the perineal region is clean and free of dirt and epithelial debris. In a similar manner the stallion's penis and prepuce should be carefully washed with soap and water and rinsed both before and after service. If a mild antiseptic such as quaternary ammonium compound, chlorhexidine (Novalsan), or (Betadine) povidone iodine is used on the external genitals of the mare, the washed area should be rinsed with clear water before service. Excessive frequent use of such antiseptic solutions either on the mare or the stallion may result in a significant increase in *Pseudomonas*, *Klebsiella* and *E. coli* organisms, especially the former, that are resistant not only to the antiseptic solutions but also to antibiotics.^{51,202} Since the external genitals of the mare only require cleansing occasionally, excessive or frequent use of antiseptics should be avoided mainly in the stallion. The place in which

the mare is to be bred should be clean and free of dust and dirt and protected from wind that would blow dirt or chaff. Occasionally a mare will develop an acute endometritis after service due to *Str. zooepidemicus*, contagious equine metritis (CEM) organism or other infectious bacteria, these mares may have a short estrous cycle of about 12 days. These short cycles resemble those seen in cows with acute endometritis. It should be recognized that no matter how frequently or thoroughly the perineal region and vulva of the mare and the penis and prepuce of the stallion are washed and cleansed, a certain number of infectious organisms are going to be carried into the vagina and uterus by the penis and semen. The purpose of breeding hygiene is to minimize the numbers of organisms and the amount of foreign debris that are introduced. Because of the heavy bacterial flora in the sheath and on the vulvar lips, all semen, even that collected in a sterile artificial vagina, is usually fairly heavily seeded with a variety of organisms. If the accessory glands are infected then large numbers of infectious organisms will be in the semen and gain access to the uterus. Fortunately the normal protective mechanisms active at the time of estrus in most mares prevent these infectious organisms from becoming established in the mare's uterus and causing an endometritis and sterility.

A group of 97 mares free of genital infection was bred naturally. Careful and thorough breeding hygiene at the time of service was carried out. Twenty-four hours later a cervical culture of these mares was made. The incidence of infection in foaling mares, foaling mares bred on foal heat, barren mares and maiden mares was 90, 84, 87 and 81 percent. Six species of infectious bacteria and fungi were recovered. None of the above mares became chronically-infected following this natural service at the time of estrum.⁶¹

Fourthly, occasional carelessness on the part of the owner, handlers or veterinarians may introduce infection into the mare by means of improperly sterilized instruments such as speculums or douching equipment or contaminated gloves, sleeves or hands exposed to the genital tract of infected mares. Artificial insemination or impregnation may also result in the introduction of infection.

The Infectious Agents Causing Equine Endometritis and Infertility

A large number of infectious bacteria and fungi have been cultured from the genital tract of mares and stallions and on this basis have been reported to cause genital infections, endometritis and infertility or sterility. A

definite relationship between culture results and subsequent breeding performance has been demonstrated.^{20,77,101} In the latter study in New Zealand about 44 percent of mares with a positive culture produced a live foal while about 67 percent of mares that had negative cultures produced a live foal.¹⁰¹ Many of these organisms are commonly found in the external genital tract of mares, in the vulva and vagina, and in stallions on the penis and in the prepuce without producing an inflammatory reaction or disease. Thus positive cultures or contamination do not necessarily indicate active infection with a vaginitis, cervicitis and endometritis that could cause infertility. The wide variety and types of bacteria and occasionally fungi and yeasts that have been recovered from the genital tract of mares have not changed over the years,¹³⁷ except for the finding of *Hemophilus equigenitalis* as a cause of contagious equine metritis (CEM) in 1977.²⁷⁹⁻²⁸¹

The common organisms reported by Dimock and Edwards⁹⁷ and others^{20,77,137,144,230,234,239,252} include:

Hemophilus equigenitalis

***Streptococcus zooepidemicus* (genitalium)**

***Klebsiella aerogenes* (pneumoniae)**

Pseudomonas aeruginosa

Escherichia coli

***Staphylococcus aureus* and**

Enterobacter agglomerans

Other less common or miscellaneous organisms recovered from the normal or diseased genital tract of mares include: *Corynebacterium equi*, *Actinobacillus* (*Shigella*) *equuli*, *Aspergillus fumigatus*,^{48,144} *Candida albicans*, *Mucor* sp., micrococci, other streptococci, staphylococci, *Salmonella* sp.,¹⁷¹ mycoplasmas¹⁹⁸ and many others.

Other than a day or two after natural service or a few days after foaling when 80 to 100 percent of the mares are culturally positive, the highest reported incidence of bacterial infections based on culture occurs in barren mares, with foaling mares having a lower incidence and maiden mares the lowest, 20 to 45 percent, 14 to 20 percent and 5 to 10 percent, respectively. A total of 19 possibly pathogenic bacterial species were isolated from uterine swabs out of 498 (32%) of 1,539 barren mares over a recent 4-year period by 5 veterinarians.²⁵² Beta-hemolytic streptococci mainly *Streptococcus zooepidemicus* was isolated most commonly, 39 percent, while *E. coli* was found in 27 percent of the positive cultures and *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Staphylococcus aureus* in 7, 4.5 and 3 percent, respectively. Bacterial contamination was minimized by scrupulous attention to cleansing the external genitalia and perineum and in the handling of the culture speci-

men which was cultured by the veterinarian and sent in Amies transport media with charcoal to a diagnostic laboratory. The laboratory recovered and confirmed all but one of the positive cultures found by the veterinarians. Whereas of the total 81 samples cultured by both, 50 percent that were positive in the laboratory were not confirmed by the veterinarians. The normal healthy non-pregnant equine uterus, as in the cow, is free of infection. However a positive culture without clinical or histopathological signs of disease is of little significance and is often an inaccurate standard for measuring the status of the endometrium. In evaluating or interpreting the cultural findings a number of factors must be considered including: the mare's reproductive history, the age of the mare, the stage of the estrous cycle, the method used to obtain a culture, the site of the culture whether cervical or intrauterine or both, the degree of care used in cleansing and preparing the mare for taking the culture including the nature of the surroundings or location, the procedures and media used in inoculating, incubating, and identifying the cultures, or the media and transport techniques used in sending the cultures to a laboratory, and finally attempts by cytological or biopsy and histopathological examinations to determine the degree of endometritis and the possible pathogenicity of the recovered organism or its significance. Pure cultures of one organism in large numbers (many colonies on a plate) with evidence of endometritis is much more significant than mixed cultures of organisms or only a few isolated colonies with no evidence of the presence of many neutrophils.^{15,252} Furthermore if swabs are taken and placed in nutrient media that is not refrigerated or frozen, a few contaminant bacteria may multiply rapidly like in milk cultures for mastitis, so that those organisms overrun the culture plate and cause an erroneous diagnosis. When cultures are positive and no histological evidence of inflammation is present, the swab should be considered to be contaminated. Contamination of the swab before, during or after passage through the genital tract is an important factor in erroneous intrauterine swab culture results.⁴⁴ A completely guarded swab was superior to a partially guarded swab. However in this study, 63 percent of mares with histologic evidence of endometritis were negative on intrauterine culture.⁴⁴ When three sites, the vaginal fornix, the cervical os and the uterine lumen, were cultured at the same time on a large number of mares, there was only a 55 to 60 percent agreement on positive cultures between the various sites. A major pathogen was recovered from the uterus in 15 to 25 percent of the comparisons without being found at another site. Good correlation occurred in mares with a purulent uterine discharge.²⁰⁴ Although used for many years, un-

guarded cervical swab cultures taken visually using a vaginal speculum are not considered as satisfactory as the partially or completely guarded swabs for uterine culture.

Streptococcus zooepidemicus has been reported to be responsible for about 25 percent of the infertility in mares in Kentucky.⁹⁴⁻⁹⁷ This organism is a beta-hemolytic coccus that ferments lactose and sorbitol and belongs to the Lancefield Group C type of streptococcus. Besides being one of the most common causes of abortion and disease in foals it is the most common infection causing infertility. **Streptococcus zooepidemicus** is constantly present as a saprophyte on the external genitals of the mare and stallion and usually does not cause disease until the resistance of the genital mucosa is lowered by parturition, pneumovagina, breeding, old age, "wear and tear" changes in the endometrium, lowered resistance to infection and other unknown factors which allow the infection to become established.^{134,137,239} This lowering of resistance in susceptible or infection-prone mares is not due to a lack of immunoglobulins but is probably associated with a deficiency at the cellular level.^{14,112,134,137,220}

Nearly 100 percent of the mares have **Streptococcus zooepidemicus** as a contaminant of the genital tract for 3 to 6 days following parturition. Normal mares overcome this infection by 6 to 10 days following parturition, while other mares may not rid themselves of the infection until the second estrus or may remain chronically infected, especially if pneumovagina develops. Mild infection may not prevent conception but pregnancies in infected mares are likely to terminate in early embryonic death, abortion or a diseased foal. The incidence of early abortion, from 25 to 150 days, is greatly increased in mares with genital infections, especially streptococci.^{53,152} Most mares that have been sterile for 3 to 4 years usually have a pneumovagina and are infected with streptococci.^{89,90b} Often a spontaneous, persistent secondary infection with **Ps. aeruginosa** may follow these streptococcal infections.^{97,134} Infected mares are likely to exhibit a discharge from the genital tract. This exudate soils the vulva and perineal region including the buttocks and tail and the hair may become matted. The vulva may gape and the mucous membrane may be visible. Some cases show a marked loss of tone of the muscles and supporting structures of the vulva. The perineal region may be sunken. The vulvar lips are generally thin and atrophic. Examination of the genital tract will reveal a congested, inflamed mucous membrane. The cervix instead of being a pink color is more of a brick red to purple color with the cervical folds being edematous and the os relaxed and open. The mucous membrane is moist and the blood vessels are prominent, distended, and tor-

tuous. A thin, slightly cloudy mucropurulent exudate or a thick yellow-white exudate containing flakes of pus may be present in the vagina. Sometimes no exudate is found but in some cases a thin, clear, slightly frothy exudate may be seen coming from the cervix. These evidences of a vaginitis, cervicitis, and endometritis are most noticeable when the examination is made during estrus, since infected mares show a hypersecretion of mucus at that time. It may be difficult to distinguish between an acute and chronic infection, but the breeding history and the fact that old mares are more likely to be chronically infected may assist in the diagnosis. In chronic cases the exudate is mucopurulent and may be quite copious. In some advanced chronic cases, as pyometra, the uterus is dilated. The uterine wall may be atonic, and the mucopurulent exudate that accumulates cannot be readily expelled. In rare cases the uterine endometrium may be destroyed over extensive areas and be replaced by scar tissue. Evidence of pneumovagina is usually apparent.

Mild or recent cases require experience to detect or suspect on vaginal examination, as changes are not pronounced. For this and other reasons, many stallion owners require a health certificate on the mare before service. The certificate requires among other things a cultural examination of the cervix and/or uterus during estrus. As previously noted these cultural examinations require careful interpretation and accompanying clinical and histological examinations may be desirable.

Contagious equine metritis (CEM) is a recently-described, highly contagious venereal diseases of horses and donkeys. The causative agent of this disease is a microaerophilic coccobacillus organism, **Hemophilus equigenitalis**. It was first described in 1977 in outbreaks of the disease on stud farms in Great Britain and Ireland.^{12b,15b,23b} It has since been found in France, Belgium, Australia, Denmark, Austria, West Germany, Italy, Sweden, Japan and the U.S.^{8,66,109,113,131,159,223,224} In the latter country two outbreaks of the disease occurred in 1978 in Thoroughbred horses in Kentucky and in 1979 in Trakehner horses in Missouri. A small rapidly controlled outbreak occurred in Kentucky in 1982.³⁰⁶ Both former outbreaks in the U.S. were caused by infected, carrier stallions imported from Europe. On the two Kentucky farms where the disease was originally diagnosed, 412 mares were covered by 58 stallions. Based on cultures of the contagious equine metritis organism (CEMO) from the mare's genital tracts or the complement fixation test, 54 mares were infected. These mares had been covered by 16 stallions.^{65,66,131} The original source of the disease that appeared in England and Ireland in 1977 is unknown.

The causative organism, **Hemophilus equigenitalis** is

a Gram-negative nonmotile, short rod or coccobacillus that cannot be grown on conventional media but grows slowly on Eugon chocolate agar in 5 to 10 percent carbon dioxide at 37° C. Strains exist that are sensitive or resistant to streptomycin. Since media containing streptomycin inhibits the growth of contaminating organisms present on swabs from the genital tracts of mares and stallions and aids in the recovery of the CEMO resistant to streptomycin, it is necessary to also culture the swabs in media without streptomycin so the less common sensitive strains of CEMO can be recovered.^{113,245,274} There was no evidence of antigenic cross reactions of *H. equigenitalis* with other bacterial strains.²⁷⁴

Contagious equine metritis is clinically observable only in mares. The stallion is an inapparent or nonclinical chronic carrier of this infection on his penis or in the prepuce, urethral fossa, urethra and the urethral sinus or diverticulum in the glans penis dorsal to the urethra. Contagious equine metritis in the susceptible mare is usually characterized by the development of a profuse watery, mucopurulent, non-clumpy discharge or exudate associated with an endometritis, cervicitis and vaginitis within 2 to 12 days after service by an infected stallion. This exudate may drip from the vulva and mat the hair of the buttocks and tail. Short estrous cycles of 8 to 12 days are common during the acute stage of the disease. About 70 percent of susceptible mares bred to infected stallions show these typical signs.¹⁶⁰ Some mares may only exhibit the latter symptom with little or no vulvar discharge. CEM is characterized by a temporary infertility or failure of conception due to the acute endometritis following coitus. Irregular, long estrous cycles or early or late abortions have not been described in this disease. The CEMO may be transmitted from mare to mare by contaminated instruments, materials or personnel.^{8,66,113,131,223} There is no evidence the infection spreads directly from mare to mare. The mucopurulent discharge from the acutely infected mare contains large numbers of neutrophils containing many ingested organisms. No systemic signs of illness are observed. The genital discharge will last 10 to 20 days with clinical recoveries occurring without treatment. Both local and systemic defense mechanisms and antibodies are produced that assist in the rapid elimination of the uterine infection.^{65,113,131} Some infected mares will recover from the endometritis and conceive that breeding season. However, the level of conception and pregnancy may be reduced markedly to about 30 to 50 percent in acutely infected mares on a farm.¹³¹ In the initial English outbreak of CEM in Newmarket the percentages of "in-foal" mares dropped from 80 to 42 which, when combined with the cessation of breeding, resulted in an estimated loss of 30

million dollars.¹⁶⁰ Some of these mares that show spontaneous clinical recovery from the infection become carriers of *H. equigenitalis*. Besides these carrier broodmares and breeding stallions, teaser stallions may also be implicated in the spread of this organism on a farm.^{223,224} The carrier-state of mares and stallions may persist for months to a year or more and in the former may persist through a normal gestation period.^{8,66,131,223,224} In carrier mares the infection may occasionally persist in the pregnant uterus but most commonly persists in the clitoral fossa and sinuses which are homologues of their male counterparts, the glans penis, and the urethral fossa and sinus or diverticulum.^{161,255} These sinuses in the mare are usually three, or rarely more, in number located on the dorsal cranial aspect of the clitoral glans. They have narrow openings and contain varying amounts of greyish smegma-like material. The openings of these sinuses cannot be observed until the clitoris is extruded caudally and ventrally to pull the glans away from the thin fold of mucous membrane that separates the clitoral fossa from the vestibule. The central sinus is larger than the lateral sinuses. Heavy growths of CEMO and *Klebsiella* organisms have been obtained from the clitoral sinuses.²⁵⁵

The diagnosis of contagious equine metritis (CEM) is made on the profuse exudate developing a few days after service and the presence of many neutrophils in the exudate together with the finding of the Gram-negative intracellular and extracellular coccobacilli. Isolation and identification of the organism *H. equigenitalis* from the exudate is the only positive way to confirm the diagnosis. The isolation and identification of the organism is also the only procedure one can use to confirm the diagnoses of the infection in the stallion and the clinically-infected mare.^{8,66,113,131,159,223,224} In the stallion, sterile swabs soaked in sterile water or saline^{223,224} are taken for culture at weekly intervals for 3 or more weeks from the prepuce and penis, the urethra and the urethral fossa, around the end of the urethra, and the urethral sinus or diverticulum. In the mare sterile swabs are taken for culture from the cervix, clitoral fossa, clitoral sinus(es) and uterus, early in estrus^{245,246} and at weekly intervals for 3 or more weeks.⁸ In the pregnant mare swabs of the clitoral fossa and sinuses should be taken for culture. After the mare foals (or abortions) the placenta should be cultured as well as the prepuce, urethral diverticulum and penis of the newborn colt or the clitoral fossa and sinuses of the newborn filly, since occasionally CEMO are found in these sites.^{113,131,160,224,280} The latter sites on the newborn should be swabbed and cultured at weekly intervals on 3 or more occasions before the foals reach 3 months of age.^{109,131} Foals born of chronically-infected mares may

also be potential or possible long-term carriers of this organism and when bred the first time spread this infection to the stallion in the case of the infected filly or to the mare in the case of the infected stallion and thus initiate a new outbreak of this disease.¹⁶⁹ After foaling, and before breeding, the mare should be swabbed and cultured at 3 or more weekly intervals including once during early estrus. All swabs should be smeared on a sterile glass slide and placed in Amies media with charcoal or Stewart's media, refrigerated at 4 to 6° C and transported within 24 to 48 hours to an approved laboratory for the special culture and identification procedures necessary for this fastidious CEM organism. It was further recommended that on farms previously infected with CEM or others with much traffic from visiting mares that all stallions and teasers be swabbed and cultured twice at weekly intervals before the start of the breeding season.¹⁰⁹

After the outbreaks of CEM in other countries late in the 1970's the U.S. banned all imports of mares or stallions over 731 days of age from countries known to have the infection. In 1981 regulations were changed to permit older mares and stallions from these countries to enter the U.S. under quarantine and with certain restrictions including certified routine treatment and testing in the country of origin, similar to that required of animals after they arrive in the United States, with the last swabbing and culture within 30 days of the export date to the U.S. A clitoral sinusectomy is required in imported mares. After arrival in the U.S. horses are now consigned to an approved quarantine station in certain states with approved facilities where they are examined carefully to see if all the clitoral sinuses have been removed. If not, treatment is delayed and a quarantine imposed until proper surgery has been completed. The genital organs are then treated daily for 5 days. Seven days after treatment, routine weekly swabbings and cultures are conducted. Pregnant mares are examined and cultured, quarantined until foaling and then treated followed by routine weekly swabs and cultures starting 7 days after treatment.⁸ Stallions, especially those with streptomycin-sensitive CEMO, must be further tested after treatment, swabbing and culturing by breeding to two noninfected test mares. These mares are then cultured repeatedly on the 2nd, 4th and 7th days after coitus and again at the next estrus and two complement fixation tests are conducted 15 to 40 days after service at least 7 days apart.⁸ A possible supplemental test for suspect carriers of CEM was described that consisted of the infusing of smegma from stallions or mares diluted in sterile water into the uterus of a noninfected test mare. The contaminating bacteria were eliminated from the uterus of the estrous mare and the CEM or-

ganisms were recovered in pure culture from the uterus and cervix within 3 days. This technique was particularly useful when the CEMO was sensitive to the streptomycin used to control contaminants in the culture media. Also the CF test could be used 15 days after the inoculation to check for CEM antibodies.²⁷³ Specimens and all samples submitted to the laboratory must be documented and carefully identified.

Of the serologic tests available the complement fixation test is most sensitive and specific for detection of acutely infected mares from 15 to 40 days after the mare was initially infected. This test is of no value in the contaminated carrier stallions, chronic carrier mares, carrier foals or possibly pony mares.^{65,66,131,270}

Klebsiella pneumoniae var genitalium (formerly called Friedlander's bacillus or **Encapsulatus genitalium** or "viscid rod" infection) is observed much less commonly than **Streptococcus zooepidemicus** as a cause for mare sterility. *Klebsiella* infection is characterized by a thick, viscid, tenacious, slimy exudate that may contain flocculi.⁹⁷ The color of the exudate varies from dull-grey to yellowish-white. On speculum examination the vaginal and cervical mucous membrane is usually a dull reddish-brown color. During estrum exudation is profuse and may soil the vulva and tail and mat the hair of the tail and buttocks. These signs may develop within 2 to 7 days after infection and be able to be transmitted in a manner similar to a venereal infection, that is by a stallion or by contaminated equipment. This may be associated with certain highly pathogenic strains of *Klebsiella*.²³⁹ Following treatment the mare may remain a carrier as in CEM by the organism persisting in the clitoral fossa and sinuses. Since *Klebsiella* organisms are commonly found in sawdust and are a common cause of acute mastitis from that source in dairy cattle, the possibility of *Klebsiella* infection of the mare's genital tract from sawdust bedding should be considered. The presence of other infections tends to increase the inflammatory response of the genital tract to the *Klebsiella* infection. The inflammatory processes affect mainly the cervix and uterus and the principal changes are in the mucous membranes and the underlying structures. Often several hundred ml. of exudate is found in the uterus. On rectal examination the uterine wall feels thickened and the uterus is enlarged. If adhesions occur in the cervix, pyometra results; but these advanced lesions of genital infections are less likely to occur with *Klebsiella* infection than with the other types of organisms. The symptoms and lesions will vary depending upon the age of the mare, the length of time infection has been present, the time of the estrous cycle, the number and frequency of services during the breeding season. **Klebsiella pneumoniae var geni-**

Salmonella is a gram-negative encapsulated rod. It is readily transmitted from infected to healthy mares by the stallion at the time of service and by the hands or instruments of veterinarians or others who examine and treat mares. This infection is much more difficult to overcome than is the streptococcal infections and CEM. The sterility produced in chronic *Klebsiella* infections tends to be more lasting than in the streptococcal infections. This organism belongs to the *Klebsiella-aerogenes* group, and the paracolon bacteria, that are so difficult to treat even with antibiotics in cases of bovine mastitis.¹²³

Pseudomonas aeruginosa infection of mares' genital tracts was studied.^{135,137,239} Of 70 mares forty-two had a slight to definite hyperemia of the cervix and 15 mares had a milky-white exudate containing flocculent material that turned green, watery-grey, or yellowish-green on exposure to light. This exudate was noted from 6 to 38 days after service to an infected stallion.¹³⁷ *Pseudomonas* infection may spread to mares by stallions with normal conception rates. Older mares are more apt to develop endometritis and clinical signs of disease. Sporadic outbreaks of *Pseudomonas* infection may be caused by certain more pathogenic strains of the organism.²³⁹

The differential diagnosis of these and the other miscellaneous infections should be confirmed by bacteriological examination, as clinical symptoms are not sufficiently distinctive for an accurate determination of the etiologic agent. Routine cultures on suspicious mares should be made to confirm the diagnosis and on obviously infected mares to determine the etiologic agent and its sensitivity to antibiotics.^{227,228,239} Occasionally a mixed infection may be found on culture of the cervix. This is seen more commonly in pneumovagina. The genital tract of the normal mare, with the possible exception of the vulva, vestibule and caudal portion of the vagina, is free of infection or bacteria.²²⁰ A reliable culture may be obtained by culturing the cervix, or preferably the uterus during estrus since at other times of the cycle the diagnosis of infection in the tightly closed cervix causes some difficulties.

Other infectious organisms, especially *E. coli*, may be found on culture of the mare's cervix and uterus. The possibility of these coliform organisms, that grow rapidly on culture, being contaminants of the genital tract should be considered. Likewise fungi or yeasts may be found as contaminants but may rarely cause endometritis and even abortion. ***Candida albicans*** has been reported following prolonged antibiotic therapy of the uterus and vagina. To establish the diagnosis of a fungal or yeast endometritis it is necessary to culture the organism from the uterus, demonstrate the presence of endometritis and demonstrate the presence of the organism in the uterine

lumen or within the endometrium or endometrial glands.^{48,144} Thus to establish a diagnosis of a true uterine infection that could affect fertility the causative organism(s) must be found as well as clinical, cytological or histopathological evidence of an endometritis. The latter can be determined by a uterine biopsy. The procedures for taking endometrial biopsies and their evaluation will be described later in this Chapter.

The technique for culturing contagious equine metritis organisms^{44,169,170,205,239} (CEMO), *Klebsiella* and other organisms from the mare, is easiest while the mare is in estrus and the cervix relaxed and dilated. Swabs should be taken from the cervix or uterus and for CEMO and possibly other organisms, such as *Klebsiella*, from the urethra and clitoral fossa and sinus(es). The mare should be restrained, in favorable surroundings that are well-lighted, clean and free from dusts and drafts. Stocks, hobbles, a twitch, tranquilizers and extra trained help are often desirable. A new pair of disposable gloves should be worn for each mare. The tail should be bandaged with a 3 to 4 inch sterile gauze bandage or placed in a clean disposable plastic obstetric sleeve. The external genitalia should be carefully scrubbed, similar to a surgical site, with separate pledgets of cotton or gauze saturated with a disinfectant such as **Novalsan** (chlorhexidine) or **Betadine** surgical scrub working from the vulvar lips and opening and radiating outward until no soil is noted on the pledgets. The area should finally be dried with clean, moist pledgets to remove excess disinfectants.

Prepare the Tieglund* or similar guarded swab^{44,276} by removing the red plastic cap from the end of the plastic speculum or tube while still in the protective plastic envelope. The culture swab should be drawn into and protected by the tube or speculum. The opposite end of the envelope from the swab should be cut and the enclosed paper for identification should be shaken out. On the handle end of the swab place a pencilled circle next to the plastic tube or speculum. This mark indicates to the operator the distance the swab is passed and whether it is fully protected when removed from the mare.

Using an 8-inch sterile culture swab, the clitoral fossa is swabbed after spreading the vulvar lips with the cleaned gloved hand and exposing the clitoral fossa and sinus(es). A smear on a sterile glass slide is prepared and the tip of the swab is broken into the Amies transport media. A second 8-inch sterile culture swab is passed 1 to 2 inches into the urethra after locating the urethra with a clean gloved hand. A smear of the swab is prepared on

*Modified Tieglund Swab, Haver-Lockhart Laboratories, Shawnee, Kansas, 66201.

a sterile glass slide and the swab placed in transport media.

The prepared Tiegland or similar guarded swab is directed into the cervix or uterus, either with a disposable clean plastic sleeve on the operator's hand or with a sterile vaginal speculum.²⁷⁶ In the former preferred method, a disposable plastic sleeve is removed from a clean pack and drawn over the hand and arm without touching the outside to any contaminating object. Sterile lubricant is placed only on the back surface of the hand and the arm, not in the palm of the hand. The prepared open Tiegland tube or speculum with contained swab is placed in the palm of the gloved hand to protect it as the hand and tube with swab are passed into the vestibule and forward to the cervix. The tube or speculum is directed by a finger into and through the cervix and into the uterine body. The swab is pushed forward to the endometrium and moved back and forth and rotated. It is then withdrawn well back into tube or speculum as determined by the pencil mark on the shaft of the swab. The open end of the tube or speculum is returned into the palm of the hand and protected as it is removed from the genital tract. The swab is smeared on a sterile glass slide and the tip of the swab removed and placed in Amies media for transport.

In the double sterile glove or sleeve technique^{204,205} the culture tube containing the swab is placed alongside the index finger between a sterile glove and plastic sleeve, or two plastic sleeves, and carried to and through the cervix, even in diestrus. The tube containing the swab is forced through the index finger of the glove, the swab extruded and rotated and withdrawn back into the tube and guarded by the hand before the tube is removed from the genital tract. A smear is made on a sterile glass slide for staining and cytological examination and the swab placed in transport media along with proper identification and sent to the laboratory.

In the vaginal speculum method²³⁹ the sterile vaginal speculum is passed through the vagina and centered on and surrounding the cervix. However this technique may carry organisms from the vestibule to the region of the cervix. The open Tiegland or similar swab in its speculum is passed visually to the os of the cervix and into the cervical canal with gentle manipulation. The Tiegland speculum should not be forced through the cervix if it doesn't slip through easily. This is accomplished most readily during estrus. The swab is pushed forward 2 to 7 cm. into the cervix or uterus noting the pencil mark on the shaft to determine the depth of the passage of the swab. After moving the swab back and forth and rotating it, it is retracted well back into the speculum and the speculum and swab are withdrawn through the

vaginal speculum followed by withdrawal of the latter.

If abundant exudate is in the vagina, a sample should be aspirated with a sterile disposable plastic treatment pipette and syringe. Put about 5 ml. of the exudate in a sterile vial and chill immediately and keep refrigerated until it reaches a laboratory for culture.

The technique for culturing CEMO or other organisms from the stallion¹⁷⁰ is as follows. The stallion should be adequately restrained by a stallion shank, twitch and/or tranquilization or sedation. Teasing may be necessary for extension of the penis. The stallion should be approached on the left side with the handler on the same side staying close to the shoulder and girth area and forward from the rear leg. Using an 8-inch sterile swab, swab just inside the preputial orifice or if the penis is extended the reflected preputial membrane. Use another swab to swab the orifice and fossa of the urethra after grasping the extended penis with the hand caudal to the glans. While still holding the penis, a third swab is used to swab the urethral diverticulum or sinus. After collection, each swab should be smeared on a sterile glass slide and the swab broken and placed in a properly labelled vial of transport media, refrigerated and sent to an approved laboratory.

After washing the penis and prepuce with mild soap (Ivory) and water and rinsing with clean water and drying, pre-ejaculatory fluids may be collected in a sterile disposable beaker by proper teasing of the stallion. Five ml. of this fluid should be placed in a sterile vial and submitted with the above samples.

The procedures used to obtain satisfactory cultures of the uterine cavity and their interpretation have been discussed. Smears of swabs taken immediately after removal from the uterus are useful when stained, especially with Gram's stain, to determine the type of bacteria present and their numbers and also the presence of neutrophils and their number which is indicative of the degree of endometritis. Culture of this swab by the veterinarian and even sensitivity testing will give more prompt information than sending the culture sample to a laboratory in suitable media and under refrigeration. However a good diagnostic laboratory can provide more accurate information on the types of organisms and their sensitivity to antibiotics than can most field laboratories.

Endometritis due to the introduction of bacteria naturally at the time of service, at parturition or experimentally^{14,47,112,134,137,220} usually results in varying degrees of distention and turgidity of the uterus with an increased blood supply, enlargement, edema and relaxation of the cervix and a flow of flocculent pus and mucus through it into the vagina at any stage of the estrous cycle, luteal or estrogenic, in the young normal healthy

mare. A marked invasion of the endometrium and uterine lumen with many neutrophils rapidly phagocytize the infecting bacteria and eliminate the bacteria, especially streptococci, within 3 or 4 to 15 days with a return of the uterus to normal. Occasionally secondary infections due to organisms, such as *Pseudomonas*, may last through several estrous cycles before being eliminated by the well-developed defense mechanisms of the mare's uterus. These mechanisms include hormonal factors whereby estrogens cause a significant increase in phagocytic activity that enhanced the bacteriostatic uterine mechanisms while progesterone inhibited the immune response in ovariectomized mares.^{112,303} However in intact mares the endometritis produced by the infecting organisms caused the apparent release of prostaglandins from the endometrium and caused luteolysis of the CL with the prompt onset of estrous with a short estrous cycle. Immunoglobulins, based on a preliminary study, do not play a significant role in this uterine defense mechanism.¹⁴

Chronically infected, "infection-prone" mares with a chronic persisting endometritis or recurring endometritis are usually older, barren mares or mares with a poor reproductive history which when experimentally infected with bacteria into the uterus exhibit little if any reaction.^{134,137,220} The uterus doesn't become enlarged and turgid but the uterine lumen continues to contain a cream-colored exudate that may occasionally be noted in the cervix and vagina during estrus. Apparently the uterine defense mechanism in these mares is disrupted, probably at the cellular level, and the marked invasion of neutrophils and monocytes and the phagocytosis of the bacteria does not occur as in a normal healthy often younger mare.

Thus all degrees of endometritis may be observed from mild to severe, acute, subacute or chronic depending upon the pathogenicity of the organism, the numbers of organisms introduced into the uterus and the degree of resistance or ability of the uterine defense mechanisms to overcome the infection. Endometritis is a major cause of infertility in mares because of the resulting "hostile" environment for spermatozoa and the embryo. Cytological or histopathological examination may be required to detect endometritis as only 44 (39%) of 114 mares with endometritis showed significant bacteriologic findings on culture.²³⁹

Metritis and pyometra due to these same wound-infection type of organisms often results in rather pronounced pathological changes in the uterus especially in older "infection-prone" mares with defective uterine defense mechanisms.^{137,239} Deep red, hemorrhagic areas and intervening areas of whitish-yellow mucosa may be scat-

tered irregularly in the endometrium. In severe cases the endometrium may be denuded at many points and have a dull, red, granular appearance. The amount and consistency of exudate present may vary from less than 100 ml. to 5 to 10 gallons and from watery, to mucoid to inspissated or cheesy. In metritis, as in cervicitis and vaginitis, the changes, depending on the stage of the cycle, the type of organism, and the predisposing causes, vary from a mild superficial involvement of the endometrium or endometritis readily cured by proper treatment or sexual rest to severe, advanced, and permanent pathological lesions of the endometrium with small abscesses of the uterine glands and chronic fibrotic, degenerative and proliferative changes in the endometrium and uterine wall. In cases in which the cervix is closed by adhesions or induration the uterus may contain several quarts or gallons of mucus.¹⁸⁶ In this unusual type of pyometra, or uterine abscess, the endometrium may be severely degenerated and eroded and the mare is anestrus. The uterine wall may be thin and atonic and in advanced cases the endometrium is almost completely destroyed. The mucosa in some cases becomes a tough, thick, yellow-white fibrous pyogenic or diphtheritic membrane. In the occasional pyometra case due to subinvolution of the uterus with an open or patent cervix, the endometrial pathology is not so severe although edema, degeneration, desquamation and sloughing of small areas of the endometrium may occur. In these cases estrous cycling may result in evacuation of the mucus. Pyometra in the mare may be associated with a retained or persistent CL and failure of estrus up to 12 months or more as in the cow. If the endometrium is sufficiently diseased so that prostaglandin is not released to cause luteolysis, the progesterone levels remain above 2 ng/ml. in blood plasma. A neutropenia without a left shift and occasional lymphopenia with mild erythropoiesis and an increase in monocytes and eosinophiles have been reported in mares with pyometra.¹⁴²

In rare cases of pyometra, or of uterine abscess due to adhesions or obstructions in the cervix it may be necessary to break the adhesions or to make an incisions through them to release the pus. Placing a gauze pack or plastic pessary^{172,190} in the opening for several weeks will allow establishment of a fistulous opening for drainage into the vagina and prevent the uterus from refilling with pus. Prognosis for future breeding of such mares is poor. Successful removal of the uterus and ovaries, ovariectomy, in mares with severe pyometra or uterine abscess has been reported.^{195,307} In one case observed by the author nearly 15 gallons of pus were drained from the uterus of a small mare with cervical and vaginal atresia due to adhesions. The mare had suffered a severe

dystocia 6 months previously. Such mares are incurably sterile. Perimetritis in the mare is apparently very rare, or else when it does occur the results are fatal due to peritonitis. In severe chronic metritis, particularly due to *Klebsiella* infection, a typical chronic productive inflammation results that may produce an atrophy and fibrosis of the uterine wall from mucosa to serosa.

Cervicitis due to a variety of infections is common and injury to the cervical mucous membrane can occasionally be serious in nature. In cervicitis the mucosa as seen at the external os is usually congested and dark red to purple in color; the os is generally edematous, pendulous, and dilated. In rare cases the cervical glands become cystic; deep suppuration and abscess formation may occur. Fibrosis of the cervix is usually not as pronounced as it may appear clinically, nor as severe as in the cow with advanced cervicitis. The inflammatory process involves mainly the mucosa of the cervix. In rare cases membranous or solid, thick adhesions may completely obstruct the cervical lumen and since uterine infection is usually present, pyometra or uterine abscess is likely to develop. Severe lacerations, scarring, and malformation of the cervix may occasionally occur in the mare at the time of parturition and produce a chronic cervicitis or cause a failure of the normal closure of the cervix, or incompetency of the cervix, resulting in repeated early embryonic or fetal deaths due to recurring infection, endometritis and permanent sterility. The surgical repair of cervical lacerations resulting in an incompetent cervix performed a month after foaling during the diestrous period where after debridement, the cervical mucosa, the cervical muscle and the vaginal mucosa are sutured separately is described.¹⁰⁵ A simple retention or purse-string suture placed around the caudal portion of the incompetent cervix after breeding or early pregnancy diagnosis is also described.¹⁰⁵ This suture must be removed a few days before foaling. Repeating these surgical procedures is usually necessary after each foaling.

Vaginitis and vulvitis due to a variety of infections is commonly observed. The vagina and vestibule appear to be more resistant to irritation and permanent damage caused by infections than does the cervix and uterus. In severe metritis and cervicitis with a catarrhal exudate the vagina is usually involved. Mares that develop the habit of pneumovagina or pneumovestibule usually exhibit a vaginitis and vulvitis often with a mucopurulent exudate. Fecal material and urine may occasionally be found in the cranial part of the vagina. Injuries, trauma, lacerations, or severe infection of the vulva and vagina at parturition may cause chronic vaginitis, pneumovagina, and in rare instances stenosis of the vagina. A rectovaginal fistula causes a severe vaginitis. Occasionally the cloudy,

turbid, light-colored urine of the mare may be confused with a vaginal discharge by the owner. In rare instances cystitis in the mare may develop but is usually secondary to a vaginitis or metritis.

Urovagina, "urine-pooling" or vesicovaginal reflux in the fornix of the vagina is occasionally noted in barren, old, pluriparous mares with a large pendulous uterus, sunken anus and horizontal vulva that allows urine to flow into the cranial portion of the vagina especially during estrus. This condition is often associated with pneumovagina and sterility. A few cases may occur around foal estrus and as uterine involution progresses urovagina may terminate after 2 or 3 postpartum estrous cycles. In early cases of persistent "urine-pooling," carefully douching the vagina with several liters of sterile physiological saline solution to which antibiotics have been added and then removing the saline just before natural service or preferably A.I., followed promptly by the Caslick, vulva-suturing operation often results in conception. In long-standing cases or those in which vaginitis and endometritis are severe, vaginoplasty or urethral extension by surgery on the caudal vaginal floor and/or vestibule can be successfully performed to prevent urovagina.^{56,197,239,301} Caslick's operation is usually also performed on these mares.

Salpingitis is rare in the mare. An enlarged uterine tube was never found on rectal examination of the mare.⁹⁷ On postmortem examination of 83 mares with metritis, only 18, or 21.7 percent, showed evidence of salpingitis as determined by gross and microscopic examinations. Not all oviducts that showed inflammatory changes were positive on culture. Salpingitis in the mare is an ascending infection from an infected uterus. Some infected uterine tubes undergo no pathological changes while most others exhibit only a slight catarrhal inflammation. In very rare cases, inflammation may be severe enough to cause fibrosis and occlusion of the lumen with inflammatory exudates. In no cases were the uterine tubes thickened and enlarged. In 700 equine genital tracts examined in Belgium all were patent and cases of hydrosalpinx were not present.²⁸⁸ Two cases of hydrosalpinx and one occluded oviduct were reported by other authors. This latter condition was due to an oviductal cyst. However infundibular adhesions, infundibulitis, and ampullitis was commonly found in 40, 37 and 21 percent of the tracts, respectively. Endometritis was noted in 31 percent of the tracts and often associated with isthmitis that occurred in only 9 percent of the tracts. The cause of the infundibulitis was unknown but factors such as bleeding at the time of ovulation as occurs in cattle or possibly *Strongylus edentatus* larvae were suggested. The degree to which this common nonocclusive chronic

salpingitis reduces fertility is not known. A safe, reliable accurate means of checking the potency of equine uterine tubes by injecting starch granules on to the ovaries and finding them in the cervix one to 7 days later has been described.^{4,239} The presence of a papilla containing a smooth muscle sphincter through which the uterine tube opens into the uterine cavity may furnish a possible explanation of the rarity of severe salpingitis in the mare.

Ovaritis in the mare is very rare. Evidence of acute inflammation of the ovary was rare in any postmortem cases.^{1,50,97} Two cases of an ovarian abscess in which **Streptococcus zooepidemicus** was found in one were reported.^{50,97} One was secondary to the tapping of an ovarian cyst. Adhesions between the ovary and surrounding tissues is rare except in association with ovarian abscesses.

Prognosis of Genital Infections in Mares. Uterine, cervical and vaginal infections in mares due to pneumovagina or infection of the uterus after parturition, abortion or service usually respond to treatment. In many acute cases of endometritis in normal, healthy mares resistant to infection prompt recovery without treatment, except in cases of pneumovagina, may occur within several days or weeks as discussed previously. The sooner a persistent infection is diagnosed and the proper treatment given, the more favorable the prognosis. In long-standing, severe cases due to virulent pathogenic bacteria, endometrial damage may be severe and permanent and result in sterility. Massive purulent metritis with cicatrization causing a loss of endometrium, and extensive cervical lacerations are two conditions that may render a mare hopelessly sterile.²²⁷ Usually it is much more difficult and takes longer, and may occasionally be impossible to correct chronic infections due to **Ps. aeruginosa**, **E. coli** and **Klebsiella** than streptococcal and CEM infections, as the former organisms are more resistant to antibiotics and other treatments and cause greater tissue damage than the latter. In early mild infections proper treatment may result in prompt recovery within 1 to 2 months. In severe or chronic cases treatment and sexual rest for 6 months or more may be necessary in order to effect a cure. In pyometra due to an obstructive lesion in the cervix causing cervical stenosis the prognosis is usually poor or hopeless for the future breeding life of the mare. In urovagina, "urine pooling," the prognosis is guarded to poor.

A uterine biopsy and a knowledgeable prognosis based on the histopathological findings in conjunction with a complete clinical history and examination of the genital tract is very helpful in the prognosis of endometritis which may vary from mild to severe and be associated with other pathology including endometrial fibrosis, atrophy,

degeneration, hypoplasia or hyperplasia. The prognosis for recovery and future breeding success should be guarded in older barren mares with a history of abortion, pyometra, and infertility. The technique of uterine biopsy will be discussed later in this Chapter.

Treatment of genital infections in mares. The suturing of the upper part of the vulvar lips, the Caslick operation,⁷⁴ sexual rest, and possibly antibiotic intra-uterine infusions enable the veterinarian to give a much more favorable prognosis in cases of uterine infections than was possible previously.^{58,227,240} Early detection and treatment of genital infections of mares is essential to prevent sterility, early embryonic deaths, and abortions.

Most genital infections in mares can be prevented by proper hygienic handling of the mare and stallion at the time of breeding, by proper attention and hygiene applied to the mare at foaling, by close observation, culturing, and proper sanitary procedures in examining and treating mares, if necessary, prior to breeding. The control of genital infections causing sterility or infertility in mares is mainly a matter of preventative therapy and hygiene. This point cannot be stressed too strongly.

The vulva-suturing or Caslick operation, to prevent pneumovagina or the sucking of air and debris into the genital tract has been well-described^{239,301} and is performed as follows: the tail is bandaged and the perineal region and vulva carefully cleansed with soap and water. The mare is restrained by means of a twitch being placed on the nose and one foreleg being picked up. If the mare is excitable or vicious, a tranquilizer such as zylazine HCL or promazine HCL may be given intravenously for sedation. The mucous membrane of the vulvar lips is anesthetized by infiltration with a local anesthetic solution such as procaine, lidocaine or carbocaine, from 1 inch (2 cm.) below the level of the floor of the pelvis or ischial arch to and including the dorsal commissure, to a depth of .5 inch (1 cm.) from edges of the lips of the vulva at the mucocutaneous junction. In the hypersensitive mare it is desirable to anesthetize a small area of the mucous membrane at the border of the vulvar skin by holding a pledget of cotton that has been soaked in lidocaine or a similar anesthetic that can be applied locally before the 22 to 23 gauge needle is inserted. The mucous membrane elevated by the local anesthetic solution is removed by scissors after stretching each vulvar lip with forceps applied at the dorsal commissure. The scarified edges of the vulvar lips are brought together by separate nylon sutures placed about one-fourth to three-eighths inch apart or by a continuous interlocking suture. An oily antibiotic may be applied to the suture line to prevent dry scabs and make removal easier. The sutures are not tightened too firmly inasmuch as they may cut

the tender tissues. Union takes place rapidly and the sutures can be removed about the tenth day after the operation. The administration of tetanus antitoxin is probably not necessary but in valuable mares not protected by tetanus toxoid, it may be a justified precaution. This operation effectively prevents pneumovagina in most barren, infected mares and should be used on any mare if this condition is present or suspected. In mares in which pneumovagina is well-established, the vulva must be kept carefully sutured for the rest of the mare's breeding life since once this operation becomes necessary, seldom does the mare return to normal. An exception to this is the occasional young maiden mare that was sutured at the track that can be "opened" at the breeding farm and doesn't require further suturing. If the vulvar opening is too small, the adhesion between the vulvar lips should be incised after injecting the area with a local anesthetic solution to make the vulvar opening large enough to admit the penis at breeding. A stay or protective suture is usually inserted at the dorsal portion of the incised vulvar lips to prevent tearing or trauma to the vulva or intact previously sutured area at the time of coitus. If the mare is to be bred again in 2 to 3 days, this stay suture may be allowed to remain in place. The stay suture is usually made of a double thickness of one-fourth- or one-eighth-inch umbilical tape or heavy linen thread inserted into the anesthetized vulvar lips one-half to three-quarter inch, 1 to 2 cm. from the edges and tied rather tightly. A breeding or stallion roll should be used at the time of all natural covers on sutured mares.²⁴⁰⁻²⁴³ Following service in cases in which incision of the vulva was necessary, it should immediately be resutured. At the time of parturition, or 7 to 14 days beforehand, if a veterinarian is not to be present at the time of the mare foals, the vulva is opened by a blunt-pointed bistoury or sharp scissors after local anesthesia has been administered. After foaling the vulva should be resutured promptly. In the mare the vulva-suturing operation is the single most important procedure in the treatment of pneumovagina and sterility due to infection of the genital tract. Once it is indicated and undertaken it usually must be continued for the breeding life of the mare. As mentioned previously the easy and successful performance of the Caslick operation to greatly improve fertility in many Thoroughbred mares may be perpetuating and increasing the number of mares with poor perineal conformation that require this operation.¹⁸²

The vulva of normal mares may be temporarily sutured or clamped after foaling, especially if vulvar lacerations or a retained placenta occur, to prevent pneumovagina until the genital tract returns to normal in 1 to 2 weeks. In a few mares windsucking may occur only

during estrum or after service when the vulva is relaxed. These mares benefit from temporary closure of the vulva until the vulvar tone returns. When the vulva is temporarily sutured or clamped, scarification is not performed. The vulvar lips are simply pulled firmly together, usually by means of nylon sutures.

Following the Caslick operation most mares overcome the infection of the genital tract within 1 to 6 months, depending on the severity of the infection, without further treatment, since reinfection due to sucking of air and debris into the vagina is not recurring. These mares should not be bred until the infection is overcome. This emphasizes the necessity of checking and treating barren, infected mares during the fall season or a number of months before the breeding season. Although some mares with mild streptococcal infections may conceive, early or late abortion may result, or the foal may be diseased at birth, or the placenta retained at the time of parturition. The use of antibiotics parenterally and locally as intrauterine and intravaginal infusions or douches in the genital tract may precede closure of the vulva and result in a greater number of cures in a shorter length of time. The Caslick operation alone, together with a proper period of sexual rest, results in a high rate of recovery.⁸⁴ Of 36 infected mares on which this operation was performed because of vaginitis and cervicitis and evidence of pneumovagina, 22 or 61 percent became pregnant the next season. No other treatment was used.

In rare cases of pneumovagina associated with a horizontal vulva and a sunken anus in which the Caslick operation does not correct the pneumovagina or urovagina (urine-pooling), more extensive perineal surgery is indicated. This may require removal of skin in the lateral and caudal areas of the perineal region to draw the anus caudally, separation of the anus and vestibule to permit the vulva to assume a normal horizontal position, urethral extension or other procedures or combinations of "plastic" surgery to permit possible conception. In these severe cases the prognosis should be guarded to poor for future fertility.

The value of sexual rest following the Caslick operation, to allow the natural body defenses to overcome infection, is well proven. It has been observed frequently that apparently normal mares infected on the ninth day or foal estrus, if not bred, will in many cases free themselves of infection by the second estrum, about 25 to 30 days after parturition. Breeding on foal estrus, should not be practiced: if the placenta weighs over 14 pounds; if the foal is weak, deformed, or dead at birth or dies soon after birth; if the mare needs assistance in foaling; if the mare has abnormal discharges either in color, quantity, or consistency during the first week after par-

parturition; or if the genital tract is not free from any sign of infection, inflammation, or trauma when examined¹⁵² and possibly cultured on the seventh or eighth day after foaling. In some mares even longer periods of sexual rest are required. If a mare foals late in the breeding season and is infected, it may be desirable to hold her over until the next breeding season for service. In mares having difficulties such as retained placenta, dystocia, or severe infection and metritis at or after parturition, treatment and sexual rest for 2 to 3 months or until the following year may be indicated. As discussed previously mares may be treated locally and systemically by antibiotics on foal estrus if parturition was abnormal. Some mildly affected mares may be treated with PGF_{2α}, 10 mg, 7 days after foal heat and bred on the second induced cycle about a week sooner than if a prostaglandin had not been administered.

Some mares suffering from one or more of these conditions at parturition or after an abortion have a metritis and a delayed involution of the uterus. This can be determined by the breeding history, by the presence of a chronic uterine infection and discharge, and by a rectal examination that reveals a large, thick-walled uterus possibly containing varying amounts of mucopurulent exudate. Frequent douching of the genital tract of the mare at estrus with a mild antiseptic solution, such as weak **Betadine**, or **Novalsan** (chlorhexidine) solution, may assist in correcting mild inflammatory conditions. Too irritating solutions should be avoided as they may cause prolonged endometrial inflammation, ulceration, and possibly adhesions in the uterus and cervix.^{37,184} A 10% (3 ml. in 30 ml. of saline) Lugol's solution was irritating to the endometrium. A plastic indwelling uterine infusing instrument was developed^{165,239} permitting frequent infusions of the uterus with antibiotics or antiseptics. The value of such a catheter is limited and questionable. The author has experienced difficulty in having mares retain the instrument. Nevertheless douching under sanitary procedures at intervals of 1 to 2 days during estrus with a very mild chlorine solution, 50 ppm, a warm physiological saline solution alone, or physiological saline solution to which some penicillin, streptomycin, or broad-range antibiotic, such as a tetracycline, nitrofurazone or furacin, polymyxin B and/or neomycin combinations, have been added, may aid in hastening involution of the uterus and correction of the metritis and vaginitis. If the type of organism(s) causing the infection is known and the sensitivity of these organisms to the various antibiotics has been determined, select the antibiotic that will be most effective. These solutions may be pumped into or run into the uterus by gravity. If a mucopurulent exudate is present in the uterus,

this should be removed by douching and siphoning from the genital tract. Some veterinarians use antibiotics infused or inserted in an oil or tablet form into the uterus and left there to hasten recovery. Stilbestrol or estradiol in 20- to 30-mg. doses intramuscularly may be useful. In some of these cases the Caslick operation may be necessary. Exercise in moderate amounts may have value in improving the tone and hastening the involution of the uterus after foaling.

In recent years the use of antibiotics for uterine infections in mares has become widely practiced.^{239,243} With the large number of antibiotics and combinations of sulfonamides and estrogens available, each veterinarian treating genital infections of mares uses his favorite intrauterine preparations or combinations. In general, penicillin, nitrofurazone and the broad-range antibiotics such as terramycin or oxytetracycline, aureomycin or chlorotetracycline, tetracycline and ampicillin are most effective against streptococci and the Gram-positive organisms. Streptomycin, neomycin, chloramphenicol, polymyxin B sulphate, gentamicin¹⁹⁹ and amikacin sulfate⁵⁵ are most effective against *E. coli*, *Ps. aeruginosa*, *Klebsiella pneumoniae* and other gram-negative organisms.^{78,278} Some veterinarians put these products into oil or into saline.^{227,239} Amounts of 50 to 250 ml. are usually used for instillation into the uterine lumen. Most veterinarians prefer to treat the uterus 2 to 5 times at 24 to 48 hour intervals during estrus when the natural uterine defense mechanisms are active. Clitoridectomy and or sinusectomy as in the therapy for CEM may be necessary in persistent *Klebsiella* infections in mares.

Because of official regulatory requirements for the treatment of this reportable disease of CEM, therapy is given separately from other genital infections of mares. **H. equigenitalis** is sensitive to a wide range of antibiotics and antiseptics including penicillin, ampicillin, neomycin, chloramphenicol, gentamicin, tetracyclines, nitrofurazone and chlorhexidine. The latter two drugs are used most commonly in the local treatment of the genital organs of infected mares and stallions with a high percentage of cures when properly applied.

Presently it is necessary to perform a clitoral sinusectomy on suspected or infected mares before antimicrobial treatment of the genital tract. Because of the small openings of the sinuses, swabbing for culture and treatment is difficult or impossible.⁸ After sedation, often with zylazine (**Rompun**) and restraint, 20 to 50 ml. of lidocaine or carbocaine is infiltrated in the region around and under the clitoris. Stay sutures are placed in the lower vulva and clitoris to assist in the careful surgical removal of the entire sinuses (sinusectomy) and fossa or the complete removal of the sinuses, clitoris and fossa (sinusec-

tomy and clitoridectomy). The use of a small probe to delineate the depth and location of each sinus is essential to its complete removal. After either type of operation the wound produced may be left open to heal or sutured to more completely obliterate the clitoral fossa.^{106,161} This operation could be performed on the pregnant mare but in most cases it is deferred until after foaling. Excised sinuses of possibly infected mares should be sent promptly under refrigeration to an approved laboratory for culture. Although swabbing, culturing and treatment of quarantined mares and stallions, along with adequate records has resulted in the apparent eradication of the disease (CEM) in the U.S., the use of artificial insemination of mares with CEM-free semen or semen from an infected stallion to which antibiotics have been added, particularly gentamicin^{23c} may be of value in the future under certain extenuating circumstances.

Treatment of infected or suspect stallions or mares require their isolation and quarantine until the treatment and subsequent repeated swabbings and cultures are completed.^{8,109,159} These animals should have their external genitals cleansed thoroughly with warm clean water. This should be followed by a thorough cleansing and "surgical" scrub with a 2 percent chlorhexidine in a detergent base (**Novalsan Surgical Scrub**, Ft. Dodge Laboratories) of the erect penis, prepuce, and urethral sinus of the stallion and the external genitalia, vulva, vestibule and clitoral area of the mare. This is followed by a wash of clean warm water and drying. Then 0.2 to 0.3 percent nitrofurazone ointment (**Furacin Ointment**, Eaton Laboratories) is carefully applied in and to the above areas. This treatment is repeated at daily intervals for 5 treatments. After a rest of 7 days, swabbing and culturing in the aforementioned manner is then carried out. The uterus, cervix and vagina may also be infused daily for 5 days with 50 ml. of a lower concentration, 0.05 to 0.25 percent of a chlorhexidine gluconate solution, as higher levels are irritating. Most open mares spontaneously eliminate the infection from the deeper areas of the genital tract, vagina, cervix, uterus and uterine tubes after a few weeks or months. Parenteral and local antibiotic treatment of mares for CEM has not proven to be necessary or highly effective. Acute cases of CEM may not require treatment as the mare's natural defense mechanisms rather rapidly eliminate the organism from the uterus of the cycling mare.^{63,66}

Since CEM is a highly contagious venereal disease, spread of the disease in the breeding shed is highly possible as it was with vibriosis in bull studs.^{234,300} Strict aseptic carefully supervised procedures in the breeding shed are essential including the use of disposable plastic gloves and plastic pail liners, careful breeding hygiene

before, during and after service or semen collection, and the use of sterile individual equipment and material for cleaning the genitals, examination and insemination. Veterinarians supervising breeding shed hygiene should eliminate all possible avenues of genital contamination or spread of organisms between all animals except the two animals being bred. This requires establishing a rigid step by step procedure, training and acceptance of these procedures by the attendants in the breeding shed and the continued monitoring of these procedures by the veterinarian. Such a practice could also control infections other than CEM.

If present control and eradication measures are not adequate or are ineffective, artificial insemination and the development of a vaccine might be developed to minimize or control the infertility associated with CEM. Vaccination of ponies against CEM with a killed bacterin from *H. equigenitalis* provided a degree of immunity but did not protect them from developing the disease when challenged.^{107b}

CEM is a reportable disease and any suspected outbreaks with signs of a genital discharge soon after service, short estrous cycles and infertility should be reported to the state and federal regulatory officials as well as to owners of mares and stallions possibly exposed to the infection. Because of the great mobility of equine racing, breeding and show animals within and between countries and states, most animal regulatory agencies in each country have formulated and put into law regulations, codes or requirements pertaining to the importation and movement of horses to control or prevent the spread of CEM.^{1,6,10} and other diseases. These codes or regulations require strict adherence to testing, identification, treatment and quarantine procedures. These codes or regulations are promulgated yearly and changes in them are made as further information on CEM and its epidemiology are developed.

Most cultures positive for molds or fungi and yeasts, *Aspergillus*, *Mucor* and others and *Candida*, are a result of contamination of the upper genital tract and they do not cause severe inflammatory reactions with endometritis and are rapidly eliminated spontaneously.⁴⁸ Occasionally they do produce a severe inflammation with invasion of the endometrium and a well-established infection as determined by biopsy. This may occur after intensive prolonged antibiotic therapy for a bacterial infection resulting in the introduction of the opportunistic fungi or yeast into the uterus, especially in infection-prone mares. Fungi are common in the environment of mares and frequently contaminate culture swabs, plates or media and provide erroneous readings. Although weak iodine solutions, Lugol's and Betadine, and systemic io-

did therapy have been used in the past for treatment, presently nystatin, 500,000 I.U. daily for 5 days, amphotericin B²³¹ and clotrimazole 400 to 600 mg. uterine infusions every third day for 3 to 4 treatments have been recommended. This latter drug, a human product, is available in suppository form which may be inserted into the mare's uterus.¹⁴⁴

Antibiotics given parenterally are of little value in chronic uterine infections.²⁴¹ Local treatment is indicated. Systemic treatment is indicated in acute or severe uterine infections causing a pyemia or septicemia as may occur after parturition. Autogenous bacterins have been used with some success in genital tracts infected with *Klebsiella* or *Pseudomonas* organisms in mares.^{26,58,59} Further controlled studies on the value of autogenous bacterins against specific infectious organisms are needed since spontaneous recoveries in mares after a period of several months or more of sexual rest are not uncommon. If the Caslick operation is indicated it should be performed, since antibiotic therapy alone cannot permanently correct a genital infection due to pneumovagina. Genital rest will aid recovery, and bacteriological and cytological or histopathological examinations of the uterus will indicate when breeding can be undertaken with an expectancy of conception.

In mares with pyometra not due to an obstructed or sclerosed cervix, that are anestrus due to a persistent CL with an elevated, >2 ng/ml, plasma progesterone level should be treated with a luteolytic dose of prostaglandin or prostaglandin analogue²⁵ to evacuate the uterus and followed by antibiotic therapy of the uterus during the induced estrous period.

Infections of the genital tract secondary to severe injuries to the perineum or from recto-vaginal fistulas require the repair of the trauma-induced lesions in order for subsequent conception to occur. However, the author and others^{241,243} have observed rare cases of mares that have had a recto-vaginal fistula that conceived and delivered a normal foal. Conception in mares with severe injuries involving the recto-vulvar area are not uncommon because of the protection provided the vagina by the vestibular-vaginal sphincter and folds of mucous membrane in that area that prevent pneumovagina.

Barren older mares with a history of recurrent chronic endometritis even though they were free of infection in their genital tract at the time of service or experimental exposure to infectious bacteria such as streptococci or *Pseudomonas* organisms, showed a greatly reduced uterine and cervical reaction with an increase in polymorphonuclear leucocytes as well as eosinophiles in the endometrium. These older susceptible, infection-prone mares exhibited less mucopurulent exudation and a persistence

of the infection and developed a chronic endometritis. There was definite evidence that these chronically infected mares or those that readily become infected had a breakdown or alteration in the non-cellular defense or bactericidal mechanisms in the uterus which set them apart from the normal, healthy, often young mares which exhibit an excellent, prompt, highly effective defense mechanism. There apparently is a delicate balance between the pathogenicity of the infective bacteria and the susceptibility of the mare to infection.^{134,135,137,220} Infection-prone, often older, mares are highly susceptible to uterine infections or endometritis after foaling and after each service period unless preventive therapeutic procedures are taken.

Twelve to 24 hour postbreeding or postovulation antibiotic treatment of the uterus using 250 to 500 ml of an antibiotic solution reduced the uterine bacteria present from the natural service or present in the uterus at the time of service and prevented the infection from becoming established in many susceptible mares.^{163,275} This greater susceptibility to infection and infertility after service in older pluriparous mares that often had a local dilation of the ventral portion of the base of the uterine horns or in the body of the uterus was noted.¹⁶³ In these locally dilated areas the mucosal folds were flattened and the endometrium was atrophic and aglandular. The rest of the uterus was normal. In a subsequent large study employing post-breeding antibiotic uterine treatment of mares no benefit was demonstrated by such therapy.³⁰⁴

A review of the antibacterial drugs used in the uterus of the mare concluded that this therapy is of secondary importance to good management and breeding hygiene. But in individual mares following proper diagnostic procedures, antibiotic therapy along with induced estrus, using the prostaglandins, and sexual rest could be useful in restoring fertility in certain mares.⁸⁶

Many stallions may harbor *Pseudomonas*, as well as *Streptococcus zooepidemicus*, *Klebsiella* and other bacteria, fungi and yeasts.^{26,27,134,137,257} Elimination of these infections from stallions is very difficult and usually unsuccessful. Most of these infectious organisms in stallions are not highly pathogenic, but a few stallions may apparently carry and transmit virulent organisms that infect a large number of mares bred to him. This fact further accentuates the necessity of careful hygiene in the breeding act. As noted previously excessive use of antiseptics on the stallion's genital organs such as Novalsan and Roccal, may cause the development of resistant gram-negative bacteria that cause more serious problems.^{51,202}

In breeds of horses where artificial insemination is practiced the control of the bacterial flora in the extended

semen with antibiotics is indicated especially for the infection-prone mare where the infection has been eliminated, but coitus would probably reestablish the endometritis.^{135,239,289} These authors recommended adding 1000 units of potassium penicillin, 1 mg. of dihydrostreptomycin and 200 units of polymyxin B. sulphate per ml. of skim-milk or cream-gelatin diluter (see Artificial Insemination in horses) and inseminate with semen extended 1:1 or 1:4. The latter report²⁸⁹ recommended that 1000 units of polymyxin B per ml. be added to fresh skim-milk extender to control both *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*. The warm semen should be added to this warm semen extender containing antibiotics and incubated at body temperature, 38° C, for 15 to 30 minutes before it is used to inseminate mares. In breeds permitting the registry of foals conceived by artificial insemination, the use of this practice with semen extender with antibiotics, along with strict management and hygienic practices, has resulted in improved, 10 to 20 percent, foaling rates versus natural service and less supervised management.⁹⁹

Thus for infertile, infection-prone, usually older, mares who often have a moderate degree of endometrial fibrosis and infiltrative endometritis as determined by endometrial biopsy, careful breeding management and hygiene at the time of service is imperative. Limiting the number of services in an estrous period to one or possibly two and/or the use of HCG to shorten the estrous period and hasten ovulation is desirable. The use of the post-service uterine infusions of antibiotic solutions and the use of artificial insemination with extenders containing antibiotics have been practices that have been proven to be of value in improving the foaling rate of these infertile mares.

Because each of these above procedures or practices have shown merit, Kenney and Rosedale and Ricketts have developed and modified them into minimal contamination techniques (MCT) for breeding mares.^{156,239} The former study¹⁵⁶ reported that even when the penis and sheath of stallions were carefully washed with soap and water and rinsed before service, the ejaculate from most stallions contained 4 to 36 million colony-forming units (CFU) of a variety of Gram-positive and negative bacteria. Thus this semen could readily reinfect the susceptible uterus. The following minimal contamination techniques were designed for breeds which permit artificial insemination and those mandating natural service.

A. Minimal contamination technique for artificial breeding:

1. The stallion is trained to mount a phantom located in a clean, dust-free area and ejaculate into a clean, sterile artificial vagina. The latter

is sterilized by washing in hot water and non-residue soap, rinsed thoroughly with hot water and disinfected in 70% ethanol for several hours. Before use the artificial vagina (AV) is rinsed in hot water and physiological saline solution. A thin film of a non-spermicidal lubricant such as KY jelly is spread through the AV with the arm covered by a plastic sleeve.

2. The stallion, before semen collection, is sexually aroused and the penis and sheath are carefully washed with a warm soapy non-detergent water which is removed by multiple warm water rinses. (If a quiet mare is used for a mount instead of a phantom her tail should be bandaged and her buttocks and perineal region carefully washed and rinsed. Before permitting the stallion's penis to enter the AV the penis of the mounted stallion should be drawn to the side to allow the discharge of some of the urethral gland or preperm fraction to flush and remove bacteria from the urethra.
3. After collection of the ejaculate in the AV, it is poured through a sterile in-line milk filter into a sterile warmed beaker to remove the gel fraction. The semen is evaluated for motility, number of normal spermatozoa and pH.
4. The ejaculate is "washed" by adding equal parts of a warm extender containing antibiotics followed by centrifugation at 1500 rpm at 300 Gs for 3 minutes. The supernatant is removed and the spermatozoa are suspended in warm extender and drawn into a sterile syringe and capped. Depending on the fertility of the stallion 200 to 500 million motile normal spermatozoa are used for each insemination. This warm syringe after being wrapped in paper towels for insulation is placed in a bag and put at refrigerator temperature, 4° C, for at least one hour before insemination to permit the antibiotics to eliminate any bacteria that might be present.
5. The mare to be bred is then inseminated after wrapping her tail, and thoroughly scrubbing and rinsing her perineal and vulvar region with Betadine or Novalsan scrub followed by 3 warm water rinses. The inseminator uses a sterile plastic sleeve over which he places a sterile disposable rubber glove. The back of the hand is lubricated with KY jelly and with the tip of the inseminating pipette covered by the index finger, the vulvar lips are parted and the hand and arm are inserted into the vagina. The index finger guides the pipette into the cervix and then

the pipette is pushed a few inches further cranially and the extended semen is infused into the body of the uterus.

B. Minimal Contamination Technique for Natural Service:^{156,239}

1. Both the mare and stallion are prepared as described in A above but just before service the uterus of the mare is filled, so that slight overflowing into the vagina occurs, with 100 to 300 ml. of warm semen extender containing antibiotics. Care should be taken so that ballooning of the vagina, pneumovagina, does not occur before service that follows immediately after the introduction of the extender. Thus the stallion ejaculates directly into this antibiotic containing extender.

Satisfactory results have been reported for the use of this technique. Usually only one service per estrous period is desired so careful estimation of the time of ovulation or the use of HCG are indicated. These infection-prone, infertile mares in which the above MCT technique is employed should be cycling regularly and bred during the most fertile portion of the breeding season.

A simple easily prepared semen extender has been described^{156,239} consisting of:

Instant, non-fat or low-fat skimmed milk—	2.5 gms
Glucose—	5.0 gms
(Gelatin BP) (optional)—	(0.5 gms)
Sterile distilled water—	100 ml.

Antibiotics added to this extender may be either—

300 mg or 150,000 units of crystalline penicillin and
 300 mg or 150,000 micrograms of crystalline streptomycin or
 100 mg of gentamicin sulphate

Other extenders with antibiotics at levels that don't effect spermatozoan activity or fertility have been described.²⁵⁹ (See Chapter on Artificial Insemination.) Several authors^{99,156,239} have indicated that careful breeding management and hygiene, service to highly fertile stallions and a minimum contamination technique either by AI or natural service should be used on the infertile, infection-prone, often older, mares in Categories II and III as defined by endometrial biopsies, breeding history and clinical examination. If obvious clinical endometritis is present, correction of the pathological condition is necessary before breeding can be recommended. This therapy may require several months or more.

Endometrial Biopsy

Although earlier studies reported on endometrial biopsy techniques^{121,164,282} the technique for collection of a suitable sized biopsy and the variety of histopathological findings and their relation to fertility in mare were first adequately reported by Kenney¹⁵⁴ and since corroborated by others.^{92,99,154,239,251} Presently endometrial biopsies are used widely as an aid in evaluating the degree of fertility in mares, particularly those barren mares without clinical lesions or infections of the genital tract.^{92,154}

The procurement and processing of an endometrial biopsy specimen should be preceded by a careful physical examination of the genital tract, obtaining a detailed breeding history and a careful collection of a swab specimen of the uterine lumen for the detection of bacteria that has been described. The specimen is obtained by means of a sterile alligator-jawed (rounded) biopsy forceps 55 to 70 cm. in length with a basket 20 by 4 by 3 mm. in size. The mare should be restrained for a rectal examination. The tail should be bandaged and the feces removed from the rectum. The perineal area and vulva should be washed with soap and water and rinsed 3 times with water. The arm should be covered with a plastic sleeve and this is in turn covered by a sterile rubber glove lubricated with sterile lubricating jelly without disinfectants. The vulvar lips are parted and the hand cupping the punch or forcep is inserted into the anterior vagina. The biopsy forcep is guided through the cervix with the index finger. After the forcep has entered the uterine body the hand is removed from the vagina and inserted into the rectum where it guides the forcep to the area of the bifurcation of the horns, near the implantation site. The jaws of the forceps are opened and uterine wall and endometrium are gently pushed laterally into the jaws by the rectal hand and the jaws are shut tightly. The biopsy forcep is withdrawn from the genital tract. Care should be taken to avoid penetrating the uterine wall with the forcep, as might occur if a straight cranial bite is made.

Usually the biopsy specimen is taken from the cranial dorsal portion of the uterine lumen. A single biopsy specimen has been shown to be representative of the entire uterine endometrium.³⁹ However if any abnormality of the mare's uterus is noted a biopsy specimen from that area or from several areas may be obtained. The biopsy specimen may be taken at any stage of the estrous cycle and even within a few hours after breeding. However if the mare has been bred and ovulated, taking the uterine biopsy a number of days later, as discussed previously may result in luteolysis or regression of the CL and the induction of estrus with a shortened estrous cycle. If biopsy specimens are taken at the end of the breeding

season from barren mares a mid-diestrous sample was recommended.²³⁹

The suitable-sized endometrial specimen is removed from the forceps with a hypodermic needle and placed preferably in Bouin's fluid instead of 10% formalin. After 2 to 24 hours the specimen is placed in 70% ethanol or 10% formalin and sent to the laboratory for skilled histopathological examination. The prognostic or diagnostic value of a satisfactory endometrial biopsy specimen in predicting the fertility of a mare not only requires an evaluation of the breeding history and a careful complete clinical examination of the mare with appropriate laboratory tests but also the examination of the biopsy specimen by an individual who has experience and training to interpret the lesions observed.

These endometrial lesions have been reviewed and categorized.^{92,99,154,155,239} They include varying degrees and combinations of histopathological conditions of: (a) **periglandular fibrosis**, either focal or widespread, often associated with cystic distention of the uterine glands, slight to severe, (b) **inflammation or endometritis** which may be acute, chronic, infiltrative degenerative, widespread or focal, (c) **lymphatic stasis** with lacunae, (d) hypertrophy and hyperplasia, focal or diffuse, (e) atrophy and hypoplasia, focal or diffuse.

The many variable lesions observed in these histologic sections, especially during various stages of the estrous cycle, require skilled experienced observers to assess their significance. Atrophy of the endometrium is commonly associated with seasonal anestrus and inactive ovaries. Hypoplasia is noted in postpuberal fillies and mares with congenital or chromosomal abnormalities.^{49,57} Inflammation if mild or moderate may not be associated with uterine infections. The stage of the estrous cycle also importantly influences the findings observed. It is possible that degeneration of the endometrium and infertility as discussed earlier in cattle associated with delaying service until heifers were 4 or 5 years of age (DeLange) and in unspayed nulliparous dogs (Dow and others) may be implicated in the decline in fertility in nulliparous mares of middle or older age and be an important factor in susceptibility to endometritis in older mares as it has in older dogs. Most pathologists and others^{92,99,251} trained and ex-

perienced in noting the endometrial histologic or pathologic changes have followed the general three categories outlined by Kenney.¹⁵⁴ However Ricketts^{233,239} has listed 14 histopathological groups of various combinations of lesions for predicting the fecundity of mares.

The three categories outlined by the former¹⁵⁴ are:

Category I—the endometrium is essentially normal with no pathologic changes or if a few are present they are slight and widely scattered,

Category II—frequent scattered mild to moderate fibrotic changes and light to moderate diffuse infiltrations or scattered but numerous foci of inflammatory changes. Widespread lymphatic lacunae or atrophy of the endometrium may be present,

Category III—widespread severe periglandular fibrosis of the endometrium and widespread severe inflammatory changes with moderate to heavy infiltration of plasmacytes. Lymphatic lacunae are extensive causing the uterine wall to be edematous or flabby- or jelly-like on palpation. Endometrial hypoplasia due to chromosomal anomalies and severe chronic pyometra should also place mares in this category.

Ricketts²³⁸ has shown the poorest post-biopsy breeding performance of mares is associated with endometrial atrophy not associated with winter anestrus, chronic infiltrative endometritis, chronic degenerative endometritis and endometrial hyperplasia and especially combinations of these pathologic changes.

Categorizing mares based on endometrial biopsies together with clinical examination of the genital tract, the mare's age, and the breeding history, number of years barren, has been shown by a number of studies^{92,99,154,239} to be of value in estimating and predicting the future fecundity of mares.

Although the time of and diagnostic methods for determining pregnancy or conception and the time interval from biopsy to the termination of the study varied, pregnancy loss from mare categories I, II and III were 10, 24 and 44 percent, respectively.^{92,251} This indicated that endometrial disease is probably an important cause of embryonic or early fetal death. Further, more continuing and refined studies should be conducted. In 92 clinically normal infertile mares only 30.4% (28 mares) were pos-

Foaling Rates Based on Endometrial Biopsy

Kenny (244 Mares) ¹⁵⁴		de la Concha-Bermajillo and Kennedy (79 Mares) ⁹²	Doig et al. ¹ (403 Mares) ⁹⁹	Shideler et al. (332 Mares) ²⁵¹
Category I	68%	78%	82%	61%
II	51%	55%	74%	48%
III	11%	36%	46%	35%

¹Of 4 categories listed the last was omitted as 8 mares none foaled.

itive on culture and only 18% of the 28 mares, had evidence of endometritis on biopsy examination.⁹⁹ Furthermore in this study 75 percent of the mares had varying degrees of endometrial fibrosis and although exceptions occurred generally older mares were in the lower categories. Thus endometrial biopsy is only one of the aids in predicting the fertility of a mare.¹⁵⁵ No mare should be classified as incurably sterile except in exceptional, severe, advanced and obvious pathologic conditions that would prevent conception or a normal termination of pregnancy.

Other Infectious Diseases of the Genital Organs of Mares

Coital vesicular exanthema, genital horse pox or equine venereal vulvitis or balanitis, is a viral disease of horses reported worldwide. The causative agent is equine herpesvirus 3 (EHV3).^{45,62,216,217,267} This virus does not cause abortion. It may cause a mild nonclinical upper respiratory infection if inoculated intranasally. The disease is rather uncommon in the United States. It is generally believed to be transmitted by coitus but the virus apparently may be readily transmitted by other means as it spreads very rapidly through a band of mares. In rare cases even young foals may be affected.^{287,305} The incubation period is short, 2 to 10 days. No fever, anorexia, or other signs of a systemic reaction are present. The disease appears suddenly, and often the source of infection is unknown. The disease is characterized by the early appearance of many papules, vesicles and pustular scabby erosions 1 to 3 mm in diameter that may become confluent of the skin of the vulva, penis and prepuce.^{62,216,217} These lesions exude serum that dries and forms crusts. (See Figure 147.) When these crusts are rubbed off, a punched-out, irregular ulcer or erosion 0.5 to 1.0 cm. in diameter is observed. These erosions enlarge and coalesce and become filled with exudate and dried scabs. The duration of the acute disease is about two weeks. Intracellular inclusion bodies may be seen in the cells obtained from scraping the vulvar or preputial lesions. Lesions on the skin of the vulva heal leaving small nonpigmented spots. Antibodies to EHV3 are found in the blood serum. Occasionally lesions may be noted on the nose, lips and conjunctiva as well as the vulvar and vaginal mucosa resulting in a purulent discharge.^{216,267} The duration of the persistence of this virus is not known. In stallions coital exanthema develops on the penis, glans and prepuce. Some stallions may be reluctant or refuse to cover a mare due to pain until the lesions heal. Occasionally a secondary bacterial infection may occur. Some veterinarians will use mild astrin-

Figure 147. Coital Vesicular Exanthema or Genital Horse Pox in a Mare. (This is due to a herpes virus.) (Courtesy T. Clark, Iowa State Univ.)

gent protective preparations such as calamine lotion or other similar products on the lesions. Healing is usually rather rapid within 10 to 14 days even without treatment. Breeding activities should be suspended for 3 to 4 weeks or more until the infection has subsided and the lesions have healed. The disease does not affect fertility or cause abortion, but may cause a reduced libido in the stallion during the acute phase of the disease.²¹⁶ One attack does not confer permanent immunity. Affected animals should be quarantined for 60 days.

Dourine is a disease of horses due to *Trypanosoma equiperdum*, and is transmitted almost entirely by coitus. This was the only trypanosome disease of importance in domestic animals in the United States. Dourine is widespread throughout the world in temperate as well as tropical countries. It was first recognized in the United States in 1885 by W. L. Williams in Illinois, where it was believed to have been spread by a Percheron stallion imported from France. By the use of the complement fixation test and the destruction of all reacting animals, the disease was apparently eradicated from the states west of the Mississippi to which it had spread. In 1939 and 1940 another outbreak occurred in Nevada, California, Colorado, Arizona, New Mexico and apparently Mexico, affecting mainly the wild horses and horses of Indians living in rather isolated areas. Vigorous efforts at eradication were again undertaken and it is believed at

Figure 148. Granulosa Cell Tumor of the Mare's Ovary. (Note the hemorrhages interspersed throughout the tumor.) (Courtesy K. McEntee.)

present that dourine is probably eradicated from the United States.^{24,45}

Dourine is transmitted at coitus as a venereal disease. Members of the horse family are the only animals that contract the infection and therefore no other reservoirs of infection exist. Except in Europe the disease is chronic and the onset is slow. The incubation period is 1 to 8 weeks, or occasionally it may be much longer.⁴⁵ The disease may exist in the animal for months or years with the affected animal alternately improving and relapsing. In the terminal stages emaciation and nervous symptoms develop, rendering the animal worthless and it is usually destroyed.

The early symptoms of the disease are characterized by swelling of the vulva and vagina of the mare with a mucous discharge containing trypanosomes. The affected stallion's penis, prepuce, and scrotum become swollen and reddened and paraphimosis may develop. The swelling may vary in size. There may be a mucopurulent urethral discharge. On palpation the swollen area is nearly free from heat and pain. In mares genital irritation caused by this organism is evidenced by frequent urination and tail switching. After the acute genital symptoms subside, peculiar raised plaques appear in the skin over the body. These are often called "dollar" plaques because of their similarity in size to a silver dollar, though some may be much larger. They appear suddenly and

disappear within a few hours or days and are replaced by others. These plaques are said to be pathognomonic of the disease. Occasionally abortion may occur.³⁰⁵ Depigmentation of the mucosa and skin of the vulva, penis, and prepuce may occur. There are irregular periods of fever in the late stages of the disease and symptoms of paralysis, involving the facial muscles, the limbs, and the penis gradually develop. Emaciation progresses until death occurs. Mortality is estimated at 50 to 75 percent. The course of the disease may be a few weeks to several years with recurrent attacks or it may remain subclinical. Infected animals are spreaders. Treatment is expensive and impractical as results are poor. This is a reportable disease in the U.S.

Miscellaneous Pathological Factors in Infertility of Mares

Tumors of the genital tract in mares are uncommon. On examination of over 2,000 mares only 6 true tumors

Figure 149 Squamous Cell Carcinoma of the Vulva of the Mare.

were reported.⁹⁷ Of these 6, 3 were in the ovary. Equine ovarian tumors, especially granulosa cell tumors are more common than tumors of the tubular genital tract.^{82,83,97,107,186,187,200,221}

Beta-cell adenoma in the pars intermedia of the pituitary gland in mares over 13 years of age causes a syndrome characterized by weight loss, muscle wasting, thin abdominal walls, poor, long hair coat that persists into the summer months with excess sweating, and often polydipsia, polyuria, hyperglycemia, glycosuria, posterior weakness or paresis, and elevated plasma levels of adrenocorticoids (Cushing's syndrome).^{94,104} These debilitated mares are usually anestrus. The condition becomes terminal within 6 to 18 months. Rarely adrenocortical tumors may produce similar signs.

Ovarian Tumors

The granulosa-theca cell tumor is the most common equine ovarian tumor. These tumors occur unilaterally and on palpation are greatly variable in size with a smooth, firm or lobulated surface with large fluid-filled cysts. On incision these granulosa cell tumors are yellow to white in color. Solid tissue and cysts along with areas of hemorrhage and necrosis are observed. Mares with reproductive failure, changes in sexual behavior or temperament and signs referable to abdominal discomfort should have their ovaries examined by rectal palpation. The granulosa-theca cell tumor should be differentiated from an ovarian hematoma that can reach a size of 20 or more cm. and persist for months. Mares with hematomas usually continue to cycle normally with no behavioral changes and the hematoma will regress in size while the tumor will gradually increase in size. Affected mares may have a history of anestrus or continuous estrus like a nymphomaniac mare. Others may exhibit stallion-like behavior of teasing or mounting mares along with squealing or roaring and the development of a heavy neck. Occasionally these animals may be hard to handle and aggressive toward other horses. Enlargement of the clitoris occurs in some cases. The ovary opposite from the affected ovary is usually small and inactive probably due to suppression of its activity by the steroid hormones from the tumor. As in cattle the mare may rarely become pregnant even with a granulosa cell tumor in its early stages of development when cycling is still regular.⁵⁰ All of the granulosa-theca cell tumors and probably related arrhenoblastomas^{194,263} produce hormones. Male-like behavior was associated with testosterone levels over 100 pg/ml that declined to about 20 pg/ml after removal of the granulosa cell tumor.²⁶³ Granulosa tumor cells do not

produce progesterone. Meagher et al. reported that 29 of 63 mares, nearly 50 percent, with ovarian neoplasms manifested male behavior. Anestrus behavior may also be due to high testosterone levels observed in 9 of 10 mares. Endocrine patterns in mares with granulosa cell tumors and exhibiting anestrus or estrus were similar although the latter had higher estradiol levels. Following removal of the affected ovary in 12 mares the unaffected ovary that was small and firm without any follicular growth returned to cyclic activity and ovulated a follicle 83 to 392, average 209, days later. Eight of the 12 mares did not show estrus until the next breeding season. One mare did not show cyclic activity following removal of the affected ovary before being killed 524 days later.²⁶³

The 78 mares with granulosa-theca cell tumors ranged from 2 to 20 years with an average age of 10 years.¹⁹² Mares that had foaled previously and maiden mares were equally affected. All tumors were unilateral with equal numbers affecting the left and right ovary. The tumor diameter ranged from 6 to 40 cm. with most in the 10 to 20 cm. range. Only 1 of the 78 granulosa-theca cell tumors metastasized; thus metastasis is much less common than in cows and humans. Only 6 of the 78 mares died from surgical complications. Normal behavior occurred postsurgically in most of the mares with regular estrous cycles developing in about 75 percent of the mares. Thirty, 77 percent, of 39 mares bred, conceived and produced live foals. The tumors may be surgically removed using the ventral midline, paramedian or flank approach.^{192,249} Great care is used to control hemorrhage and to invert the serosa over the ovarian stump to prevent adhesions.¹⁹²

Other uncommon equine ovarian tumors or cysts that have been reported are:^{50,82,83,97,111,125,175,186,187,192b,200,206,221,305}

Melanoma	Arrhenoblastoma ¹⁹⁴
Teratoma ^{50,111,186,192b}	Cystadenomas and cystodeno-
	carcinomas ^{50,83,107,125,187,200,206}
Lymphosarcoma ^{175,206}	Hemangioma ^{186,187}

Occasionally small masses or "rests" of adrenal cortical tissue are found in or near the equine ovary.^{157,187,210}

Germinal inclusion cysts or "fossa-cysts" are formed by peritoneal fragments that become imbedded in the ovary following ovulation. These "serosal" cysts may be large enough or numerous enough to be of clinical significance by possibly interfering with ovum transport in older mares.^{141,186,187,210} A case report described a 7 cm. ovarian cyst containing a bot, *G. intestinalis*.¹⁰⁰

Hematomas of the ovary are common.^{50,141,187,210} Hemorrhage into the ovarian follicle regularly occurs at ovulation and in anovulatory follicles.^{2,210} Hematomas

may vary in size from 5 to 20 or more cm. in diameter and persist for weeks or months. Normal cyclic activity usually continues in most cases.^{50,141} Depending on the age and stage of development of the hematoma repeated rectal examinations may reveal they are decreasing or increasing in size. The author observed a 20-year-old mare that bled to death from a follicle that ovulated during the third month of pregnancy. Histologic section did not reveal evidence of an early or small granulosa-theca cell tumor. These latter tumors may contain blood or rarely rupture and bleed intraabdominally. Varicosities of vessels in the equine ovary are common and may become large enough to palpate on rectal examination. Hemangiomas and hamartomas of the ovary have been described.^{187,232} Removal of large hematomas by unilateral ovariectomy has been described where an absence of normal ovarian tissue was observed.⁵⁰

Parovarian cysts are common in the mare and may vary in diameter from a few mm. to 5 to 6 cm. They are often found in the fimbria as small fimbrial cysts, hydatids of Morgagni, that usually cannot be palpated. The larger parovarian cysts originate from other remnants of the mesonephric or paramesonephric tubules or ducts and are located in the mesovarium near the ovary.^{187,210,234}

The epoophoron, a cystic remnant of the mesonephros is about 0.5 to 2.0 cm. in diameter and located in the ovarian capsule at the dorso-cranial-medial pole of the ovary. These cysts have no effect on the reproductive cycle or fertility. Large pedunculated parovarian cysts that caused strangulation of the rectum have been reported.³⁰⁵

Cases of ovarian hypoplasia and/or gonadal dysgenesis with chromosomal abnormalities associated with infertility, a phenotypic small to normal-sized mare, absence of an estrous cycle or only occasional estrus of a passive type, a small flaccid uterus, a flaccid cervix with an open os and small to very small ovaries, have been described with increasing frequency in recent years in many breeds of horses.^{64,49,57,133,141,143} The older reports of bilateral ovarian hypoplasia were probably associated with gonadal dysgenesis.^{210,234} Unilateral hypoplasia of the ovaries should be diagnosed with great caution, especially in nulliparous mares. Repeated examinations during the breeding season in these mares is indicated. As noted above small inactive ovaries are often associated with a granulosa-theca cell tumor in the opposite ovary.

The most common chromosomal abnormality found in 28 or 58%, of 48 mares¹³³ with gonadal dysgenesis was the 63,XO karyotype. This karyotype is similar to that found in women with Turner's syndrome but some phys-

ical differences exist. Affected mares have very small but palpable ovaries and a few germ cells may be in the ovaries.^{46,47,57} No sex chromatin or Barr bodies were found in these XO mares.^{46,49,57} Other chromosomal abnormalities included 63,XO/64XY, 64XY, 63XO/64XX and 64XO/64XY, 65XYY/64XX, 65XXY/64XX and 65XXX.^{46,57,141} Because of a lack of germ cells in the ovaries follicles usually don't develop and the ovaries are small, smooth and firm. It is likely that chromosomal abnormalities may be an important cause of infertility in mares. Cytogenetic studies are indicated in infertile mares showing some or all of the above signs. The relatively high incidence of mosaicism in sex chromosome anomalies of mares may reflect, as in women, that aging of the ovum and post-fertilization errors of mitosis may be fairly common in horses because of the long estrous period and variable time of service and ovulation.⁴⁶

Clinical effects of the XO anomaly in mares is limited to the abnormal development of the primary or secondary sex characteristics which may be difficult to recognize in mares.⁵⁷ Since mares with chromosomal abnormalities are nearly always sterile their detection by cytogenetic techniques would save considerable expense.

Lesions of the uterine tube in the mare are rare. As discussed previously, mild salpingitis associated with endometritis may be fairly common but obstruction of the uterine tube is rare. Infundibulitis with small fibrous adhesions in the fimbria around the ovulation fossa is common in the mare.²⁸⁸ Pyosalpinx has not been described in mares. Hydrosalpinx is also very rare although two cases; both unilateral, were described.⁹ The author is unaware of any reported genetic defects or arrests in development of the equine uterine tube. Rare cases of small under-developed fimbriae that might have difficulty in picking up ova have been reported.²¹⁰

Tumors of the Uterus, Cervix, Vagina and Vulva: Uterine tumors include **leiomyomas**, which are usually small and 1 to 2 inches in diameter or they may be multiple or rarely large, **fibromas**, **rhabdomyosarcomas**, and **carcinomas** which are rare.^{82,83,97,119,187,200,284} These tumors may also be found in the cervix and vagina. Squamous-cell carcinomas often in pintos, melanomas that frequently "metastasize" in white horses, and papillomas are the three most common tumors of the vulva of mares.^{82,83,107,200,221,266}

Other Pathological Changes in the Equine Uterus include:

Ventral uterine enlargements near the bifurcation of the body and uterine horns in older pluriparous mares have been described^{157,163} due to mucosal atrophy or focal myometrial atonia. The former probably follows the

latter and may be a natural consequence of the anatomy of the uterus and its supporting ligaments and the site of implantation and fetal development. Myometrial lymphatic lacunae or varicosities in this area may also contribute to this uterine enlargement.

Lymphangiectasis of the myometrium or lymphatic lacunae and possibly cystic endometrial hyperplasia^{153,157,187} with a flaccid, edematous, soft, thick, doughy or spongy uterine wall which in the opened uterus shivers like a gelatinous mass when jarred. Numerous submucosal cysts, 1 to 5 cm. in diameter under the glistening, moist mucosa may bulge into the uterine lumen. Advanced cases especially in older mares may have a mucometra with the uterine contents having a milky, gray to dark-brown color.^{9,11,157,187,277,310} If this condition is severe the mare is usually hopelessly sterile.^{97,227} Knudsen^{162,163} described 24 mares with lymph stasis of the endometrium in which lymphocytes predominated in the endometrial biopsy smears. Most of these mares had poor fertility; in 2 cases pregnancy terminated in early fetal death. These mares cycled normally and appeared normal on speculum examination. On rectal examination the uterus was large and edematous. Only 3 of 24 mares were positive on bacteriological culture of the uterus. On postmortem examination the endometrium was very edematous. Knudsen indicated that rarely these mares recovered without therapy, and conceived after being barren for one to two years. There is no specific treatment for lymph stasis but uterine massage and hot saline infusions have been recommended. If persistent CL with high plasma progesterone levels are a possible cause, injections of prostaglandins or a uterine infusion might be helpful in a few cases but the prognosis is poor.

Endometrial cysts in large numbers have been described and may be associated with periglandular fibrosis and cystic distention of uterine glands. Some individual cysts or lymphatic lacunae may be small, 1 or 2 mm. or large, up to 4 or 10 cm. in size that may be found by careful palpation especially if the uterine wall is atrophied.^{9,11,237} They may be mistaken for a chorionic vesicle and pregnancy on palpation or ultrasonography early in gestation, 20 to 35 days.^{157,168b,187} These may be differentiated from pregnancy by repeated examination and finding that the chorionic vesicle grows rapidly while endometrial cysts enlarge very slowly.

Segmental aplasia of the equine uterus is rare.^{195,247}

Lesions of the cervix and vagina are rare in the mare. The most common lesion is an acquired occlusion of the cervix with adhesions due to severe irritation of the cervix at the time of foaling, from severe infectious cervicitis, or from the use of irritating procedures and drugs that produce a severe cervicitis. Mild obstructions may

be broken down and a pessary introduced and left in place for 2 to 4 weeks until healing has occurred.^{172,190} A recurrence of the adhesion across the cervical lumen is not uncommon. **A double cervix and vagina** and a band in an incomplete double cervix in 2 mares was described.²⁹¹

A segmental aplasia of the paramesonephric duct resulting in a missing cervix and a small uterine horn was reported.²⁴⁷ In this case the ectopic ureter entered the antero-lateral wall of the vagina. The author has observed a young Standardbred filly with an ectopic ureter that opened into the lateral wall of the vestibule and resulted in constant dribbling of urine from the vulva. Also rarely seen in the cervix of the mare are ampullary diverticula or cysts, homologues of glands of the male ampulla.^{6,210}

A condition described as a **congenitally short incompetent or hypoplastic cervix** has been described to the author by a number of veterinarians and reported in the literature.⁴³ These young 2-year-old fillies, usually Thoroughbreds, have a severe persistent pneumovagina despite a correctly performed Caslick operation. These fillies have normal-sized ovaries with follicular activity. The cervix is very short, 1–2 cm. compared to a normal cervix of 5 to 8 cm. and is relaxed and widely dilated allowing the examiners hand to enter the uterus, which was normal on fiberoptic examination and on culture and biopsy although a slight endometritis was present.⁴³ The blood progesterone level was 7 to 8 ng/ml. indicating an active CL. The prognosis in these cases is poor for the future breeding life of the filly particularly if the condition is congenital. A somewhat similar condition of a dilated cervix has been reported in fillies with chromosomal abnormalities and in occasional mares during the winter anestrus period. Further study on this condition is indicated.

Cysts of Gartner's duct or remnants of the mesonephric or Wolffian duct in the floor of the vagina are rarely observed.^{6,210} Previously mentioned was the severely lacerated, scarred or incompetent cervix that cannot close properly; affected mares are infertile or sterile.

Persistence of a Portion of the Hymen is not unusual in maiden mares. It is usually ruptured at the time of service. (See Figure 150.) Some veterinarians advise rupturing it with a vaginal speculum 1 to 2 months before service so it is healed before a natural service.^{124,227} In rare cases an imperforate hymen is noted in a maiden mare and requires incising to release the mucus and epithelial debris trapped in the vagina and uterus. Occasional tenesmus may be exhibited in these mares, with a slight protrusion of the distended hymen between the vulvar lips. Occasionally a severe vaginitis or vestibulitis may result in a stenosis of the vulvovaginal border.

Figure 150. Persistent Hymen in a Filly (Note the urethral orifice caudoventral to the hymen.)

It is not uncommon to note on speculum examination varicose veins in the hymenal folds. Occasionally one of these may break down and a chronic slow dripping of blood may be observed from the vulva. This is most commonly seen in late gestation in fat old mares after exertion. Bleeding is slight and not serious. These mares despite the owner's concern do not abort. Cautery of ulcerated varicosity or ligation may be performed. Usually the intermittent bleeding ceases after foaling.

Congenital Defects, Developmental Arrests, and other anomalies of the reproductive system of the mare are rare. **Hermaphroditism** has occasionally been described and is usually characterized by a large, protruding clitoris and irregular sexual symptoms. (See Figure 37.) McEntee cited Levens (1911) who described 15 cases of male pseudohermaphroditism in stallions descended from the same sire.

There is some evidence to show that certain Thoroughbred female lines, as in cattle, are characterized by infertility of a hereditary nature resulting in a particular mare's female descendants being "shy breeders." The relative importance of this factor requires more scientific appraisal.

Evaluation and Assessment of a Mare for Fertility

This evaluation is routinely required of barren mares at the end of the breeding season on all farms. It may also be requested by a prospective purchaser of a broodmare or a maiden mare.^{22,120,128,130,132,239} This evaluation examination should be thorough and detailed. The interpretation of many of these assessment procedures and final decision requires experience, skilled training, excellent laboratory support, careful observation, excellent records and common sense. Generally one should assess or predict the fertility of a mare in a percentage range or as excellent, good, fair or poor. The veterinarian should seldom indicate a mare is hopelessly sterile unless the severity of the pathological lesions warrants such an extreme opinion. Furthermore the number of examination procedures and their cost should be considered in reference to the value, economic or sentimental, of the mare and the expected breeding costs, such as service, boarding and transportation fees. All mares to be examined for fertility should be carefully identified and all specimens taken from them for laboratory tests should be carefully labelled. A routine procedure of evaluation should be followed and conducted in a professional very clean or sterile manner that poses no danger to the mare or the operator. Careful, complete records should be kept during the examination.

The various factors to consider in this fertility evaluation or assessment include:

1. **Reproductive history**—This should include the animal's age, use, prior illnesses, surgical operations, nutrition, worming and vaccination, practices, and drug therapy, especially the steroids. The pertinent information on number and date of foalings and foaling problems, number of live offspring, and if the mare is barren should be noted. The length of this latter condition, history of services either by AI or natural to what stallions, prior possible exposure to venereal diseases like CEM or infected stallions, history of uterine infection and treatment, teasing and service records, endometrial biopsy report, history of early embryonic deaths or abortions and possible causes, ge-

netic or hereditary background of familial infertility and etc. should be recorded.

2. **Physical or clinical examination**—The mare's physical condition, obese or thin, state of health, presence of an infectious disease(s), examination of the body systems such as teeth, eyes, hair coat, locomotor, circulatory, respiratory and nervous systems for conditions that could affect her fertility or ability to carry, deliver and nurse a foal are necessary to carefully ascertain.
- 3a. **Genital organs**—**Visually examine** the mare externally for the presence of a vulvar discharge, the length, thickness and angle of the vulvar lips and conformation of the perineal region and tailhead that might indicate the presence of or need for a Caslick's operation for pneumovagina. Examine for vulvar or perineal scars, or tumors. **Visual or speculum examination** of the vestibule, hymenal region, vagina and cervix for the presence of a hymen in maiden mares, scars, stenoses, vaginal or cervical exudate, color and condition of the vaginal mucosa, pale, pink, red or inflamed moist, dry and character of mucus, and the external cervical os, the relaxation or edema of the latter should be conducted. These changes may indicate the stage of the estrous cycle or indicate the presence of intrauterine infection (See fibroscopy).
- 3b. **Manual palpation per vaginam and rectum** of the mare's genital organs is necessary. The former examination should further check the external tubular genitalia. The index finger should be gently inserted into the cervix to determine cervical competency and the possible presence of adhesions, scarring or stenosis. The rectal examination should be performed carefully and thoroughly noting and recording the size of the ovaries, presence and size of follicles, the ovulation fossa and any abnormalities such as parovarian cysts, adhesions, tumors, hematomas, varicosities and etc. The uterus should be palpated for pregnancy, or twin conceptuses. If non-pregnant the size, shape, tone, thickness, width and any irregularities or abnormalities of the uterus such as adhesions, endometrial cysts, uterine dilations, edema, atrophy, excessive small size, or mucometra, or pyometra should be noted. The cervix should be palpated for size, width, length and tone. The uterine tubes are seldom palpable in the mare. The size and shape and any abnormal conformation of the pelvic cavity or pelvic bones should also be noted.
- 4a. **Bacteriological culture** of the uterus of barren mares should be taken, especially if a uterine discharge is observed, to determine the organism and its sensitivity to various antibiotics. This test is complementary to the endometrial biopsy examination if evidence of an endometritis is noted on the latter test. This examination should be performed in such a manner as previously described so a true evaluation of the presence or absence of infection is determined. Occasionally repeated cultures may be required. The uterine culture is superior to the cervical culture. In mares with a history of a chronic infection with *Klebsiella* or *Pseudomonas* or to check for CEMO (*Hemophilus equigenitalis*), the urethra and clitoral fossa and sinuses should also be cultured, possibly repeatedly.
- 4b. **Cytological examination** for the presence of leucocytes can be performed on smears from the uterine culture swab.
5. **Biopsy examination of the endometrium** requires a suitable-sized specimen, properly preserved and sectioned, examined and evaluated by a skilled, experienced pathologist or veterinarian trained in this area. The interpretation of the results of both the endometrial culture and biopsy requires an understanding of the findings and their limitations.
6. **Other examinations or tests** that may be helpful or necessary include:
 - a. **Fiberoptic or endoscopic examination** (fibroscopy/hysteroscopy) of the cervix and uterus for the presence of adhesions, cysts, tumors, fluid accumulation, fibrosis and etc.^{22,184,239}
 - b. **Ultrasound examination** of the uterus and ovaries for pregnancy, cysts, follicles or exudate or mucometra.
 - c. **Endocrine assays** for progestins, estrogens, luteinizing (LH) and follicle stimulating (FSH) hormones and prostaglandin metabolites. The former is used most often to determine a persistence of the CL associated with prolonged anestrus.
 - d. **Chromosome analysis or cytogenetic study** of the mare's karyotype is a definite value in certain infertile maiden mares.

The final prediction or assessment of a mare's future reproductive status should also consider the managerial factors and competence of the breeding farm personnel as well as the fertility of the stallion to whom the mare will be bred.

Infertility, "Repeat Breeding." Early Embryonic Deaths and Early Fetal Loss or Early Pregnancy Wastage in Mares

Since infertility and "repeat breeding" in cattle has been studied intensively, much information of general value from these studies can be utilized in developing hypotheses to explain early losses in horses. Limited studies of this area of concern, other than those of a statistical or retrospective nature have been made on mares.

In a large survey of Quarterhorse and Thoroughbred farms the pregnancy rate for the first service period was about 45 to 50% and the cumulative rate for the breeding season was 75 to 85 percent.^{64,268} If only healthy fertile mares were bred to healthy, highly fertile stallions these percentages would probably rise about 10 percent considering the limited length of the breeding season of mares. It is estimated that early embryonic or fetal losses after pregnancy is established as 5 to 8% before the fourth month and 8% thereafter including stillbirths.⁶⁴ On certain farms in certain years early pregnancy loss may occur in 10 to 30% or more of the mares and the cause is seldom ascertained.^{18,52,64,251}

In an excellent retrospective study¹⁸ of 639 Thoroughbred mares on one farm with 2466 coverings in 1528 mare years, the fertilization failure and early embryonic death rate based on a return to estrus within 30 days of a previous cover was 31.7%. While the late embryonic death rate of 26.5% was based on a return to estrus after 30 days after a previous cover (9.4%) and a diagnosis of nonpregnancy at 42 days, often after the end of the breeding season (17.1%). In this study evidence was presented that indicated few "missed" or "silent" estrous periods occurred. But the data suggested that prolonged persistent CL, together with the short breeding season, may have played a significant role in the high incidence, 26.5%, of late embryonic deaths diagnosed at the time of pregnancy examination at or after 42 days post service. The average live foal per cover rate on this farm was 39.8% and the observed late abortion rate was 2.3%. Mares bred late in the breeding season after May 15th had a slightly better foaling rate per cover than mares bred before that date, 44.4 vs 39.0%. Mares bred before 16 days postpartum or on foal heat had a fertilization failure and early embryonic death rate of 40% and a foaling rate of 29% compared to the next or second normal heat of 25.5 and 49%, respectively. Statistics for lactating and nonlactating mares were nearly similar. Foaling percentage for mare age groups of 2 to 4, 5 to 7, 8 to 13, and 14 years and over was 85, 71, 63, and 45%, respectively. This decline in fertility as mares became

older was reflected in the foaling rate per cover, 57 to 25%, combined fertilization failure and early embryonic death rates, 27 to 37%, late embryonic death rates, 15 to 34%, and observed abortion rates 1.2 to 3.1%, respectively, for the youngest and oldest groups of mares.¹⁸

Infertility or "repeat breeding" in cattle is probably due to three major categories, failure of fertilization, early embryonic death and uterine disfunction (See Chapter XIII). Failure of fertilization is characterized by the occurrence of regular intervals between estrous periods while early bovine embryonic death if it occurs after 14 to 16 days postservice often results in a prolonged interval between the time of service and the next estrous period. In mares a similar effect may be noted or the CL may persist even if failure of fertilization of the ovum or very early embryonic death occurred before day 12 post service. This phenomena of persistence of the CL is common to the mare and increases the need for early accurate pregnancy diagnosis. Furthermore, mares that abort after 40 days of gestation when the endometrial cups have developed usually fail to show estrus for a number of months and often not that breeding season. Early embryonic or fetal loss or abortion in mares prior to 90 to 120 days of gestation is seldom observed and may be due to resorption of the embryo or the early fetus within the genital tract. The efficient natural mechanism in most mares that eliminates one of twin embryos early in gestation greatly minimizes the infertility associated with twinning. (See abortion in mares.) In the mare the round to oval small chorionic vesicle of early pregnancy may be expelled rapidly and unseen compared to the cow that has an elongated vesicle that may occasionally be seen hanging from the vulva between 20 to 80 days of gestation. No discharge or blood is observed at the vulva in most mares that abort early. Thus in the mare a regular postservice teasing routine should be followed for several months or more. Errors in early pregnancy diagnoses causes an apparent elevated early embryo or fetal loss. When a pregnancy diagnosis is in doubt repeated examinations either manually or with ultrasonography or even blood tests for PMSG should be conducted as too early incorrect pregnancy diagnoses may contribute, along with inadequate teasing procedures and disease incidence, to an apparent increase in pregnancy losses on certain farms.

Thus management including improper teasing and breeding procedures and erroneous pregnancy diagnoses²⁵¹ may contribute significantly to an apparent increase in early pregnancy wastage. Other management factors may include **nutrition** since one study showed that restricted energy intake between 25 and 31 days of

gestation caused a high incidence of early embryonic loss.²⁹² This loss may be related to the losses of embryos and fetuses caused by stress factors discussed under causes of abortion in mares (Chapter V). In cows and ewes heat stress particularly around the time of fertilization of the ovum and a few days thereafter cause definite large embryo losses and "repeat breeding." This factor has not been studied in mares. Another managerial factor in broodmare management that results in a probable increase in early embryonic losses is the **breeding on foal estrus**. In two studies conception rate on foal estrus was 39 and 41 percent compared to the second estrus after foaling which was 55 and 65 percent.^{18,173,268} However, the abortion rates after the two breedings were similar 16.5 and 13.8 percent, respectively in one of the studies.¹⁷³

A uterine infection, such as CEM, and occasionally *Klebsiella*, *Pseudomonas* or even *Streptococci*, introduced into susceptible mares at the time of service by the stallion may cause an acute endometritis and a "hostile" environment for the spermatozoa and fertilized ovum. The estrous cycle may also be shortened due to luteolysis of the CL by the released prostaglandin. These uterine infections must be prevented or controlled to avoid early embryonic deaths and infertility. Endometritis resulting from the introduction of miscellaneous organisms at the time of service particularly in the infection-prone, usually older mare¹⁸ may also cause early embryonic or fetal deaths.

Endometrial pathology particularly periglandular fibrosis, lymphatic lacunae, large endometrial cysts, endometrial atrophy, hyperplasia and degrees of endometritis often in older mares as revealed by a biopsy of the endometrium is a cause of infertility and early embryonic death. Pregnancy losses in three studies were 10 to 20 percent in Category I mares with essentially a normal endometrium and 35 to 44 percent in Category III (abnormal endometria).^{92,154,251}

Chromosomal abnormalities as a cause for early embryonic loss in the horse is probably the same as in other animals and man. In sows about 10 percent of all ova or 30 percent of released ova that fail to develop had chromosomal anomalies, mainly triploid blastocysts probably due to polyspermy.¹⁸⁸ A similar incidence of chromosomal anomalies, 36 percent, occurs in spontaneous abortions in women.⁷² Although further studies, which are difficult in the mare, are indicated evidence has been presented⁴⁶ of the probable role of chromosomal abnormalities in early embryonic or fetal deaths in horses based on the relative frequency of chromosomal defects in adult horses. The high incidence of mosaicism in sex chromosome anomalies in mares¹³³ indicates that aging of the ovum before fertilization, which

is probable in certain mares due to the long estrous period and uncertainties in the time of ovulation and breeding, results in post-fertilization errors of mitosis.⁴⁶ Also the maternal age effect on the incidence of chromosomal anomalies of the embryo, fetus and newborn commonly seen in women may also be a factor in the incidence of this condition in horses.

In 39 attempts at recovery of embryos from infertile older (16 to 28 years) mares only 10 embryos (26%) were collected compared to an embryo recovery rate of 76%, 119 embryos in 156 attempts in fertile younger, 3 to 15 year-old mares. Since pregnancy rates from embryo transfers from infertile and fertile mares were similar, the lowered reproductive efficiency in the infertile mares appeared related to **failure of fertilization and transport** through the uterine tube, probably due to retention of unfertilized ova in the tube which is common in mares.¹⁴⁸

Although further studies are needed clinical evidence has been presented that **certain infertile stallions** may have twice the early abortion rate of fertile stallions used on the same group of mares.^{52,53} In some instances as cited previously this may be due to certain genital infections carried by certain stallions but it may also be due, as in bulls, to chromosomal defects in the fertilized embryo. Apparently normal semen from infertile bulls has been shown to result in a much higher rate of failure of fertilization than similar appearing semen from fertile bulls (See Repeat Breeding in Chapter 13). A similar condition might exist in horses.

Two further causes of early embryonic or fetal deaths are **twinning** and **trauma to the chorionic vesicle and embryo** by rectal palpation for the early diagnosis of pregnancy. This latter occurrence is probably uncommon in mares over 40 to 45 days of gestation when palpated in a careful gentle manner. However palpation at 15 to 30 days should be done very gently by an experienced operator to avoid possible damage to the embryo or chorionic vesicle. Twinning has been discussed by Ginther.^{117b} Although further studies are needed, it is evident that the mare, in which double ovulations of fertile ova are common, has a well-developed biological embryo-reduction mechanism for the elimination of excess embryos early in the gestation period. Thus factors that contribute to a mare's (or a band of mares) failure to conceive or produce a live foal include the following.^{130,132}

- A. Factors over which the veterinarian often has limited or no control:
 1. Selection of broodmares and stallions is usually based on athletic ability rather than reproductive performance.
 2. The breeding season starts before the physio-

logic breeding season of mares and is shortened by human mandate.

3. Culling of aged, relatively infertile mares and stallions.
 4. Possibly non-selective breeding of mares on foal heat, especially late in the breeding season.
 5. Use of artificial insemination.
- B. Factors over which the veterinarian should have supervisory or direct control:
1. Teasing procedures and practices including visual and manual palpation of the genital organs to overcome behavioral anestrus or continuous or long estrus and prolonged or persistent CL with anestrus in mares; and aberrant sexual behavior in stallions.
 2. Abnormal or pathologic conditions of the reproductive organs including endometritis, pneumovagina, other genital infections, endometrial fibrosis, adhesions, tumors, chromosomal defects and etc. in both mares and stallions.
 3. Nutrition, housing and breeding practices as well as worming and vaccination programs for mares, stallions and foals.
 4. Accurate, complete up to date reproductive and preventive health recording system.

Breeding Farm or Stud Management

Management practices on breeding farms are basically similar to those described for cattle. The veterinarian and stud manager and/or owner must work closely together in a program designed for the farm to secure the highest number of mares pregnant at the end of the breeding season. These pregnant mares should be handled so that they will produce normal, live, strong foals. A goal of over 80 percent conception in the band of mares is considered a satisfactory goal on most farms raising racing stock where the breeding season is short and some of the stallions and mares being used as sires and dams are not highly fertile. Conceptions below 60 to 70 percent are definitely unsatisfactory and require remedial measures.

In a study of reproductive efficiency on 14 horse farms encompassing 6 breeds and a total of 1876 mare-years, conception, foaling, and weaning efficiency averaged 80.1, 73.8 and 70.8 percent, respectively. It was significant that on 2 farms using pasture breeding, conception rates were 94 and 100 percent. The conception rates were very low in February, 27.8 percent, and rose in May through July to a peak of 57 to 59 percent and declined thereafter. Conception efficiency in young mares

fluctuated until age 7, reached a peak at age 9 of 89.6 percent, remained on a plateau above 70 percent until age 15 and declined thereafter. Conception rates on 5 Thoroughbred farms ranged from 53 to 80 percent and on 5 Quarterhorse farms from 72 to 92 percent.¹⁴⁶

Every effort should be made in the Fall to examine, assess or evaluate the reproductive status, treat, if necessary, and outline a plan of breeding of all barren mares for the coming spring season. Infected mares should be treated and cured or eliminated well before the breeding season. Infertile mares and especially maiden mares should be booked to the most fertile stallions. Barren mares that have failed to conceive in a number of years should be culled. The use of increased lighting for barren mares should be considered to prolong the physiologic breeding season. Incorporating artificial insemination using extender containing antibiotics in breeds permitting registration of foals conceived in this manner and using a program similar to the described minimal contamination technique has been helpful in getting more barren mares to foal. If a stallion's conception rate is low his semen should be examined carefully on a number of occasions during the breeding season or preferably before the season. If a stallion is of low fertility, his book should probably be reduced and close attention should be paid to having the mare bred within 24 hours before ovulation. The time of breeding may be determined by careful rectal palpation or the use of HCG. Foaling mares should be properly cared for during foaling, given exercise and examined critically before being permitted to breed on the foal estrus. Teasing all barren, foaling or recently bred mares on a regular daily or every other day basis before and during the breeding season is essential. If this is not done regularly a veterinarian should examine the mare's ovaries for the presence of a mature Graffian follicle and impending ovulation on the same frequent 48-hour schedule. Frequent speculum examinations or services should be avoided especially on the infection-prone mare.

Breeding shed hygiene and restraint should be thorough and on a routine basis. The external genitals should be carefully washed and rinsed. Excessive use of disinfectants on a stallion's genitals should be avoided. Care should be taken not to have disinfectant on the stallion's penis at the time of service. Mares with Caslick operations should be carefully supervised and the number of services should be reduced to the bare minimum consonant with good conception rates. The use of HCG to promote and hasten ovulation may be helpful in these and other older, infection-prone mares. The stallion's semen should be examined to determine if ejaculation occurred and to observe the quality of the semen. If artificial insemination is employed this should be carefully

supervised, monitored and performed in a clean, sanitary manner.

Careful, continuous and complete daily and even lifetime records on all animals and aspects of the breeding program must be kept up-to-date, accurately and in an easily accessible form. These records should be analyzed for each stallion and for the mares during and at the end of the breeding season. All the breeding history, treatments, services, teasing, pregnancy and genital tract examinations must be recorded. A variety of breeding record forms have been devised and used by veterinarians and managers of stud farms. Daily record and permanent record forms are essential. Satisfactory record forms may be purchased from The Lifetime Horse Record Company, 6060 South Broadway, Littleton, Colorado. Records used by Andrews and McKenzie and Beeman were excellent.

The mares and stallions must be on a balanced ration²⁴⁸ and maintained in good condition being neither too fat nor too thin. Mares at the time of breeding should be in a positive energy balance on a rising plane of nutrition. Daily exercise is essential for all breeding stock. It has proven to be a helpful practice, if it is possible, to allow a fertile stallion to run at pasture with barren or infertile mares if infection or other contra-indications are not present.

As in cattle careful and constant attention to many and all details by the veterinarian and the farm manager are essential to a successful reproductive program. Vaccination, worming and other measures are essential for a good foaling rate and the limiting of losses of newborn animals.

It is "unfortunate" that the breeding season of racing mares does not extend from April 15 to September 15, instead of the present February 15 to June 15 in the northern latitudes. The conception rates on many farms would probably rise 10 to 20 percent by this accommodation to the physiologic breeding season of the mare.

Chapter XV

INFERTILITY IN FEMALE SWINE

The incidence of infertility in sows may approach that seen in cattle. Because of their lower value and the difficulties of diagnosis and treatment, sterility in sows has not been studied as much as has infertility in cattle or horses. The farrowing rates in over 50,000 matings of sows and gilts in the Midwest was about 72 percent.⁸¹

The incidence of sterility in a herd where brucellosis was present was 21.9 percent in 382 sows over 1354 breeding seasons. This varied from 13.9 to 36.9 percent in various breeds.¹¹⁹ Currently the incidence of brucellosis in swine herds in the U.S. is greatly reduced. Five percent of sows and gilts were sterile, another 5 percent were hard to settle, and another 10 to 15 percent showed some impairment of fertility by a small litter size due to high intrauterine death rate of the embryos or fetuses.¹⁰⁴

On postmortem examination 1.4 percent of 1000 sows and gilts were completely sterile and another 2.2 percent had lowered fertility.⁶³ Because swine are multiparous or polytocous, complete sterility in swine is lower in incidence than in cattle but reduced fertility is common.⁸³ In 250 sows, 42, or 16.8 percent, failed to conceive or farrow. Of the rest, 84 percent conceived on 1 service, 12 percent after 2, 2.5 percent after 3, and 1.5 percent after 4 services.¹¹⁹ Several studies showed that litter size rose to a peak at the fifth to sixth litter and then decreased. Ten percent of female swine were sterile.¹⁰⁵ The most common causes of sterility were hydrosalpinges and cystic ovaries; these two pathological lesions accounted for about one-half of the obvious failures to conceive.

Stillborn pigs were classed as a form of infertility.⁸³ Stillbirths occurred in 259, or 23.1 percent, of 1121 litters. Litters of over 12 pigs had an incidence of 11.7 percent stillbirths, while medium-sized litters had an incidence of only 3.9 percent.⁹⁸ The birth weight of stillborn pigs was higher than that of normal pigs. An incidence of 6 percent stillborn, occurring usually in large litters, old sows and in spring farrowings, was reported.⁶ Stillborn pigs were more common in the latter half of the litters as they were born or in those fetuses nearer the apex of the horns. Attempts to hasten parturition with oxytocin gave inconclusive results. According to the literature the incidence of stillborn pigs is 8 to 9 percent. The mortality in the two sexes was about equal.⁶

Sow productivity or piglets per sow per year weaned is based on ovulation rate, fertilization rate, embryo loss and fetal and newborn losses. The farrowing interval, as in cattle, is based on conception rate and lactation length and other possible genetic and environmental factors.^{29,76}

Physiology of Porcine Reproduction

Puberty occurs in gilts at 6 to 7 months of age with a range of 4 to 9 months. Spring born gilts reach puberty 1 to 3 weeks later than gilts reaching puberty during the winter months. High environmental temperatures result in delayed puberty and an increased incidence of anestrus. In contrast to other species the age of the gilt was more important than weight, nutrition or "flushing" on determining the onset of puberty or number of ova released.^{76,80,81} Puberty may be delayed slightly by inbreeding or severely restricting the TDN or protein intake to one-half recommended amounts. It may be hastened by crossbreeding and by allowing boars to contact the gilts.¹⁶⁹ Moderately cold temperatures, and transport or environmental stress also hastened the onset of puberty. Certain breeds of swine such as the Landrace reach puberty earlier, 160 to 180 days, than other breeds, 200 to 230 days. Length of daylight or exposure to artificial lighting had no effect on reproductive cycling or puberty in sows or gilts.^{81b} Gilts that have not reached puberty by 240 days of age should be culled. Exogenous hormones were of limited value in promoting estrus in prepubertal gilts.⁷⁶ Total confinement significantly reduced the proportion of gilts attaining puberty by 9 months since about 25 percent were noncyclic and of these one-third were prepubertal and one-half were behaviorally anestrus.^{23,24,81} The greater the number of estrous cycles after puberty and before service in gilts, the greater is the ovulation rate.^{33a}

There is enough FSH and LH in the pituitary gland of gilts for several weeks before puberty to cause the onset of the estrous cycle. If prepubertal gilts are stressed by transport or by a marked change in environment, estrus will often occur within 4 to 7 days after the stress indicating the release of FSH. This same period of time is required to produce estrus in prepubertal gilts after the

injection of PMSG. Recurrent estrus may not follow this early induction of estrus and ovulation in gilts. In general, increased amounts of PMSG injected to induce follicle formation and estrus and HCG to induce ovulation results in a greater number of ova released at the induced ovulation. However, there is a great inconsistency in the number of ova released by exogenous gonadotropins injected into different gilts in various seasons, herds and years.^{2,33a} Gilts that reach puberty and conceive at an early age and have 9 or more piglets in the first litter should be retained as brood sows.²²

The estrous cycle—The sow is polyestrous the entire year. Estrus usually does not occur during lactation or for at least 30 days after farrowing. Estrus usually occurs 3 to 7 days after weaning. After 6 to 10 years of age senility may affect the estrous cycle. The estrous cycle averages 21 days in length and may vary from 18 to 24 days.^{2,7,3,29,42,76,144} The estrogenic phase of the cycle is 6 to 7 days and the luteal phase is 14 days with CL regression beginning on day 16. The duration of estrus is 1 to 4 days, with an average of 2 to 3 days, or about 60 hours. Ovulation usually occurs between 24 to 42 hours, or an average of 36 hours, after the onset of estrus. Nearly all sows examined had ovulated by 40 hours. Older sows have a slightly longer estrous period and cycle than gilts. Failure of ovulation results in a longer estrous period, and premature ovulation will shorten the period. Ovulation is spontaneous in sows. It takes about 4 to 6 hours from the rupture of the first follicle to the rupture of the last follicle. The LH surge in gilts and sows is about 20 hours long and peak LH plasma levels immediately preceded or were coincident with the onset of behavioral estrus in 60 to 70 percent of the sows. However in about 20 percent of the sows the LH surge was delayed for 18 to 24 after the onset of estrus. This variability may explain the lowered fertilization and conception rates in certain sows where frequent checks for estrus and services per estrus are limited. Sows should be checked for estrus 2 or more times per day and bred every 18 to 24 hours after the onset of estrus for 2 or more services.^{153b} Ovulations are slightly more frequent, 51 to 55 percent on the left than on the right ovary. The size of the follicles at ovulation is 0.7 to 1 cm. in diameter.¹

Small follicles are present in the porcine ovary during diestrus, but during proestrus and estrus although approximately 15 to 40 follicles approach maturity only about 10 to 20 ovulate. From 7 to 16 days after ovulation the corpora lutea are at their maximum size, about 1 cm. in diameter.¹ The weight of the ovary during diestrus may reach 8 to 10 gm. Degeneration of the corpora lutea is rapid just before and during the next estrus and a few

days before and after parturition.

The symptoms of estrus in the sow are definite and usually marked.^{2,3,7,29,42,58,59,76,142} The sow has a reduced appetite and is restless and nervous, often pacing back and forth by the fence. Salivation, champing of the jaws, and frequent grunting may be pronounced. The sow, if suckling, may ignore her pigs; may try to escape, or if free will seek out the boar and stand for service. During estrus the vulvar lips become swollen and congested and the mucous membrane is pinkish-red in color. Some mucus may be present at the vulva. The most noticeable feature of estrus in the sow is her grunting and standing motionless for long periods in a position for service. This peculiar, immobilizing reflex or stance can be produced in over half of the estrous sows by the pressure of the hands on the sow's back or by straddling the sow. In the presence of the boar with his characteristic odor, his grunts or acoustic signals, and his pushing and lifting of the rear parts of the sow by placing his snout between her rear legs, this sawhorse-like immobile stance and acceptance of the boar will be induced in nearly 100 percent of estrous sows. In late estrus or early metestrus, a whitish mucous discharge composed of mucus, cellular debris and leucocytes may be seen on the vulva.⁷ The vaginal smear or the body temperature do not produce an accurate indication of the stage of the estrous cycle.⁸⁵ As in the other domestic animals changes in the conductivity of vaginal mucus will predict the time of estrus but will not pinpoint the time of ovulation in gilts.³⁹ The vaginal epithelium in the sow undergoes cyclic thickening during estrus when it has 8 to 15 cell layers. During diestrus this will decrease to 4 to 5 layers and during pregnancy to 2 to 3 layers. This permits vaginal biopsies to be utilized for the diagnosis of pregnancy in swine.^{33a} The musculature of the uterus and oviduct is most active during estrus. The endometrium and especially the region where the uterine tube enters the uterus is quite edematous. In healthy sows and gilts 90 to 100 percent of ova are fertilized and 80 to 90 percent of sows farrow after service to a fertile boar.

Plasma hormone concentrations or levels during the estrous cycle have been determined by radioimmunoassays (RIA).⁷⁶ Estrogens are fairly low, 8 to 12 pg/ml except during estrus, days 18 through day 1 of the next cycle when they peak at about 30 pg/ml. Plasma progesterone levels are 1 ng/ml or below during estrus but rise rapidly after ovulation to 20 to 30 ng/ml from days 7 to 16 of the cycle and then decline. Prostaglandin levels in the uterine vein rise to 6 ng/ml between days 14 to 16 of the cycle. Plasma LH has a number of lesser small peaks during the cycle but rises to the highest peak or preovulatory surge of 4 ng/ml at the onset of estrus

between days 20 and 1 of the next cycle. Plasma FSH concentrations are about 6 to 7 ng/ml during the cycle but rise slightly on days 21 to day 4 of the next cycle. Estrus and ovulation are inhibited by estrogens and progesterone. Prostaglandin F_{2a} can induce luteolysis of CL but swine CLs are refractory to prostaglandins until day 12 of the cycle.⁷⁰ So the use of prostaglandins to synchronize estrous cycles in sows or gilts is impractical because they are only effective days 12 through 15 of the cycle. The value of PMSG to increase ovulation rate is negated by the high prenatal loss of embryos so litter size is relatively unaffected.^{42,76} HCG and GnRH if administered late in proestrus or at the onset of estrus will induce ovulation in about 40 hours.⁴² The principal urinary estrogen in sows is estrone. The peak in urinary estrone excretion occurred just before estrus.

Estrous signs can be induced by estrogen injection in ovariectomized sows or in sows without functional corpora lutea. However, if estrogens are injected into sows with mature corpora lutea during the luteal phase of the cycle, estrus does not occur. In fact, even a single injection of estrogen into sows at this period will prolong the life of the corpus luteum causing anestrus that may persist for a number of weeks. Thus, indiscriminate use of stilbestrol or estradiol in sows to promote estrus is to be avoided.^{33a,60}

About 60 to 90 percent of sows will exhibit signs of estrus 2 to 3 days, range 1 to 5 days, after farrowing and will accept the boar.^{2,42} If sows are bred at this estrus they do not conceive because ovulation rarely occurs.^{8,160} Furthermore if a few ova are shed and fertilized they do not develop. This estrus might be due to estrogens from the ingestion of the placenta at parturition.⁵ The older usual or traditional lactation period in sows was 56 days (8 weeks). This period is being shortened to improve sow productivity. The uterus of the sow is completely involuted within 21 to 28 days after parturition. The uterine weight decreased from 2.8 kg on the day after farrowing to 0.2 or 0.3 kg at 21 to 28 days.¹¹³ Most sows that are suckled go into a lactational anestrus that lasts for 6 weeks or longer or until the pigs are weaned. Sows whose litters were weaned at 10 days after parturition came into estrum more than 9.4 days later, 2 sows developed cystic ovaries, and only 12.8 ova were released at the first estrum. Sows whose litters were weaned at 21 days came into estrum at an average of 6.2 days later, and ovulated an average of 15.2 ova. Sows whose litters were weaned at an average time of 56 days, came into estrum an average of 4 days later and ovulated an average of 16.6 ova.⁶⁶ The earlier after farrowing piglets were weaned to produce early cycling and concep-

tion the longer the time from weaning to estrus and the lower the conception rates and smaller the litter size. However if pigs were weaned at 21 to 28 days,^{81b} or possibly 35 days³⁹ sow productivity for the year was maximized. Sows came into estrus sooner after weaning than gilts and white breeds sooner than black breeds.⁷⁶ About 60 percent of primiparous sows returned to estrus the first week after weaning compared to 85 percent of multiparous sows. During the summer, postweaning anestrus, up to 4 months, in the former is increased; only 65 to 75 percent of sows were in estrus the first week after weaning. This delay was more apparent in primipara. Shade and evaporative cooling had little effect. Weaning to estrus interval was shorter because of reduced stress in crossbred sows and in crated sows than in sows penned in groups.^{80,81a,b}

Synchronization of Estrus—During lactation and suckling estrum does not occur. But after the pigs are weaned estrum usually develops in about 4 to 9 days or an average of 5 to 7 days.^{33a,42,76,85,139} Under some circumstances, when it is desirable to synchronize the breeding and farrowing dates, estrum may be produced in a lactating sow by removing her pigs each night for 4 to 5 nights and allowing the pigs to nurse during the day,¹³³ or by weaning the pigs at 3 to 5 weeks of age. Lactation may be suppressed by the former practice. Some sows, if fed well and with a boar nearby come into estrum 5 to 7 weeks after farrowing even with pigs still suckling.¹⁶⁴

Synchronization of estrus in gilts and sows can most practically be accomplished by management procedures. Introduction of boars into close contact with gilts along with transport or a change in the environment to produce stress will usually initiate estrus within a week in puberal gilts. In sows synchronization can also be accomplished readily by weaning pigs after 3 to 5 weeks of lactation and the introduction or close contact with boars. Increasing the nutritive level or "flushing" for 4 to 8 days with 3 to 4 kg/day of a well-balanced ration may slightly improve the ovulation rate.⁷⁶ Vasectomy for heat-check boars has been described where artificial insemination is desired.⁶² Teaser-gilts to be used for detecting sows in estrus could be produced by long-time injection of testosterone propionate¹³⁵ as has been demonstrated in cows and ewes.

Over the past twenty years much research has been conducted with progestins, the gonadotropic hormones, PMSG and HCG, methallibure and recently GnRH alone and in various combinations to induce synchronized estrus in gilts and sows to aid in artificial insemination at a specific time to progeny-tested boars. The results have

varied widely.^{74,131,162} The routine use of PMSG in the U.S. is negligible because of its limited availability even though it has been shown to induce ovulation in lactating sows. Recent studies indicate that estrus synchronization in the future might be possible.^{74,127,146a} Altrenogest (allyl-trenbolone) fed orally at a dose level of 15 to 40 mg./day for 14 or 18 days to gilts effectively synchronized estrus. Low doses of this progestin caused cystic follicles.^{90a,146a}

Ovulation, Fertilization and Ova Transport—The rate of ovulation is 10 to 15 ova and 12 to 20 ova for gilts and sows, respectively. A slightly higher rate of ovulation may occur in certain breeds, in crossbred gilts and in sows 2 to 4 years of age. Very low ovulation rates, 4 or below or very high ovulation rates as in superovulation may result in the loss of the entire litter.¹⁶⁶ Markedly restricting the energy intake will decrease the ovulation rate but this can usually be promptly restored by feeding a high level of TDN, or "flushing" for a week or more depending on the condition of the sow. High rates of ovulation result in larger litter size at 25 days of gestation. But at farrowing the litter size is not increased by higher than normal ovulation rates.^{33a}

In Wrathall's review it was shown that the greater the ovulation rate the lower the prenatal survival rate. Losses of embryos in the pre-attachment stages, before days 15 to 17 of gestation, are mainly due to inherent limitations within the embryos themselves. While in the post-attachment stages losses are due mainly to limitations imposed on the conceptuses by the uterus basically involving uterine length or capacity and the evenness of distribution and spacing of the blastocysts. Those conceptuses with inadequate attachment areas for the diffuse porcine placenta either die or are growth retarded. About 10 percent fetal loss from 30 to 40 days to term is due to uterine space limitations.¹⁶⁶ Thus even though ovulation rates might be elevated by various means, litter size remains fairly constant for the breed and age of the sow or gilt.^{33a,76,166} If large litters of over 12 pigs are born the death losses in these litters prior to weaning are higher. Most embryonic or prenatal losses occur before 25 to 30 days of gestation when the blastocyst begin to elongate rapidly at 11 to 18 days and when attachment is occurring at 18 to 40 days. Thus there is about a 65 to 75 percent embryo survival in most porcine pregnancies based upon ovulation rates of 10 to 22 ova and 8 to 12 pigs born per litter.⁷⁶ Included in these losses are lethal genetic factors causing up to 50 percent of the losses in the blastocyst stage^{95,96} and losses due to possible maternal effects including abnormal uterine secretions ("milk") between days 9 to 16 of gestation. The admin-

istration of progesterone or progesterone and estrogens to augment early embryo survival has not resulted in a conclusive or consistent beneficial response.^{33b,76} High levels of energy or TDN during gestation is not necessary or desirable as early in gestation it may increase embryo loss and late in gestation cause increased size of the fetus, and birth and postpartum problems.

The best time to breed or inseminate sows or gilts is 24 hours apart on the first and second day of estrus or about 12 hours before ovulation which occurs about 40 hours after the onset of estrus.^{42,78} Sows bred the day before heat, the first day of heat, the second day of heat and the third day of heat had 9.8, 68.8, 98.2 and 15.2 percent fertilized ova, respectively.⁷² The average number of fertilized ova in sows mated at the proper time was 95.5 percent. Factors affecting the fertilization and conception rate are boar fertility, timing of service and seasonal conditions, or heat stress.⁷⁶ Sperm cells were present in the uterine tubes of sows within 15 minutes of breeding. Thirty minutes after breeding, although 30 to 60 billions of spermatozoa were in the uterus, only about 90 to a few hundred spermatozoa were in the uterine tubes.^{53-56,76} Seminal plasma and spermatozoa were rapidly lost from the uterus and phagocytosis of sperm cells began within a few hours after mating. Although both live and dead cells may enter the uterine tube, the live sperm cells remain motile in the tube for 24 hours while those in the uterus showed a greatly reduced motility after 2 hours. A mass of live sperm cells accumulate at the uterotubal junction in the apices of the uterine horns for 24 hours and then decline during the next 24 hours thus providing a steady flow of sperm cells through the junction into the uterine tube. The fertilizing ability of swine spermatozoa lasts only 25 to 30 hours in the sow.⁸⁵ The best time to breed sows was 10 to 25 hours after the onset of estrus. If the sow is bred the first day of estrus she should be rebred the second if she is still in standing estrus.

When ovulation time was controlled by an injection of HCG during proestrus and gilts were inseminated 2 hours before ovulation and 2, 6, 10 and 14 hours after ovulation, the proportion of CL represented by normal embryos at 25 days of gestation were 73, 61, 53, 28 and 32 percent, respectively. In control gilts bred 6 hours before ovulation, 88 percent of the CL were represented by normal embryos at 25 days of gestation.^{77a} Aging of ova and spermatozoa significantly affected the number of surviving embryos at 25 days.⁵⁶ Twenty-six percent of sows bred 44 hours after the onset of estrus had heteroploid embryos 17 days later probably due to polyspermy. Four percent of heteroploid embryos were observed.

Fertilization in female swine must take place in the ampullae before 60 hours after the onset of estrus to cause conception and before 50 hours to produce cytologically normal embryos.¹⁵ The block or zona reaction in the vitelline membrane in the ova to polyspermy is highly effective when the sow is mated the first half of estrus.^{33a,76,78}

Thus, it would appear from the above data that capacitation of spermatozoa must occur before fertilization. Fertilization can occur within 2 to 3 hours after insemination. The corpus luteum develops steadily requiring a full week for development.⁵ Fertilized ova in swine pass through the first half of the uterine tube very rapidly and remain near the ampullary-isthmic junction for 24 to 39 hours or until 60 to 75 hours after the onset of estrus. The fertilized ova at the 4-cell stage of development pass into the uterus about 44 to 54 hours after ovulation or 66 to 90 hours after the onset of estrus.^{42,112} Thus swine ova enter the uterus sooner than in the other domestic animals. The morula stage develops and the zona pellucida is shed in the apices of the uterine horns 6 to 8 days after the onset of estrus.^{33a} The blastocyst grows very rapidly from 4 mm. in diameter on the 9th day of gestation to 110 cm. in length on the 16th day.¹¹⁷

Intrauterine migration of fertilized zygotes occur during days 9 through 12 just before the rapid elongation of the blastocyst or blastodermic vesicle^{42,78,159} in sows and has been confirmed by comparing the number of CL in each ovary with the number of embryos in the corresponding horn. Although 55 percent of the CL were on the left ovary, each horn contained 50 percent of the fetuses.⁹² In sows that are unilaterally ovariectomized before mating or sows in which one uterine tube is ligated, equal numbers of embryos implant in each horn.¹⁵⁹ It has been estimated that 40 percent of the zygotes migrate from one horn to the other. This was also shown by ova transplantation.^{41,44} This is apparently accomplished by the motility and activity of the uterine musculature to assure both efficient distribution and equidistant spacing of each embryo. The pig blastocyst synthesizes estrogens from about day 12 of pregnancy. This is apparently responsible for the maternal recognition of pregnancy in this species as estrogens increase blood flow to the uterus and have a luteotropic effect on the corpus luteum. This increased blood flow may explain why luteolysis is not produced by the uterine prostaglandin in early pregnant sows.^{57b}

Litter size—Much study has been conducted on causes of reduced litter size. The prenatal mortality in swine has been estimated to be about 45 percent.¹⁴³ Most of these losses of zygotes occur during the first 25 days of gestation. About 6 percent of these losses occur in late ges-

tation and at parturition resulting in stillbirths. Gilts bred the first, second and third estrus after puberty have 6.9, 8.0 and 9.4 pigs per litter, respectively. In another trial this difference was not significant in well-grown gilts.¹⁶⁸ Farrowing rates also increased from 83 to 94 percent from the first to third estrus after puberty.^{80,81,168} There is an increase in prenatal mortality with increased age of the sow and parity because the increased ovulation rate in sows is not associated with a similar increase in litter size. The peak in litter size occurs about the 5th to 7th litter or 2 to 4 years of age.^{5,33a,137,138} The decline in litter size in older sows is due to an increase in embryonic death rate.

Heritability of litter size is low, 10 to 15 percent.^{16,33a} Litter size will differ between breeds by an average of 3 to 4 pigs per litter. This difference in litter size between breeds may be associated with an increased ovulation rate in certain breeds.⁴⁷ Inbreeding of the dam causes a decrease in litter size and crossbreeding an increase in litter size due to heterotropic effects.^{13,33a,80,81} Embryonic mortality may also be a characteristic of the individual sow. The sire of the sow is also an influencing factor.¹¹⁵

Each of 27 boars in two studies^{141,147b} were mated with about 10 gilts and it was found that boars exerted a significant effect on conception rate ranging from 30 to 100 percent. The number of live embryos at 25 to 30 days of gestation ranged from 3 to 17 with an embryonic survival rate of 24 to 84 percent. If a boar had a conception rate below 65 percent this could be an important cause of reduced litter size.¹¹⁴ Thus culling boars with low conception rates would improve fertility in the herd and increase litter size.^{141,147b} Chromosomal abnormalities have been described in a significant percentage of embryos from normal sows as a cause of infertility or reduced litter size.⁹⁵ One boar was reported that had normal semen volume, sperm cell numbers and progressively motile spermatozoa but had a zero impregnation rate when mated to 12 sows.^{147b} In this instance nuclear or sperm head defects or chromosomal abnormalities might be suspected.

Litter size is usually larger in spring farrowings than in fall farrowings. One disadvantage to multiple farrowing in sows is the lowered fertility in the summer months. Hurtgen reported that farrowing rates are 15 percent, range 2 to 40 percent, lower in the summer, July through September, than in the winter months. Many infertile matings had a delayed interval or return to estrus indicating possible early embryonic death or abortion and mimicking viral reproduction failure.^{80,81} Sows stressed by exposure to 85 to 100°F. heat from days 1 to 5 or 15 of gestation had an increase in embryonic death rates.^{45,80,81,154}

If the sows were stressed by heat before breeding or from 15 to 30 days of gestation, there was no effect on embryonic death rates. Thus, cooling sows with sprinklers on hot days may be indicated the first week or two after breeding. Severe cold stress did not affect litter size.^{147a} Stress due to transportation or change or environment has not been reported to effect fetal mortality.

Confinement of gilts had no effect on the farrowing rate compared to those bred and maintained in outside lots. Furthermore mated gilts maintained in gestation crates in one study had a 13.8 percent higher farrowing rate.⁸¹ There is no evidence that exposure to light over a range of 6 to 18 hours has any effect on ovulation or conception rates in female swine.

Mating on 2 consecutive days of estrus by the same boar improves farrowing rates by 10 to 25 percent in sows and 10 to 13 percent in gilts. When a different boar is used for the second mating farrowing rates increased an additional 4 to 8 percent, respectively, but litter size only increased 0.2 pigs/sow.^{28,80} Sows bred once during an estrum had a 68 percent conception rate and sows bred twice had a 78 percent conception rate. Two services produced 0.5 to 0.7 more pigs per litter than once service.¹⁴⁷ There was no significant difference in the number of ovulations and litter size in sows bred the first or second estrus after weaning their pigs.^{137,138}

The quantity of uterus affected the uterine capacity to maintain fetuses. When one horn and ovary was removed from 59 gilts the litter size at 25 days of gestation was similar to the intact control gilts, but at 105 days of gestation the treated gilts had 5.5 fetuses in the single horn compared to 9.4 fetuses in the intact gilts. In a large number of gilts it was demonstrated^{41,42,44} that intrauterine crowding was not important in early embryo survival at 25 days or 30 days and only when a gilt had 14 or more oversized embryos did it appear likely that uterine crowding was a possible limiting factor in embryonic survival. After transferring 16 to 28 fertilized embryos to gilts, the litter size was similar to control gilts, 8 to 10 pigs.¹⁰ Thus, uterine capacity is an effective factor in limiting litter size. This effect apparently occurs after day 40 of gestation.

A high level of nutrition or energy intake in gilts and sows for several weeks prior to breeding and during the breeding period results in slightly higher ovulation rates.⁸⁹ The level of feeding has no effect on fertilization but a high level of energy intake for four weeks after conception results in a variable but greater embryonic mortality depending upon the amount of energy given. This may possibly be related to heat or other stresses. Limited feeding of female swine is indicated following breeding.⁷³ The number of pigs born is not affected by the

plane of nutrition as long as it is adequate during the latter two-thirds of gestation. The level or quantity of protein is not as critical as energy in its effect on reproduction. Most swine nutritionists recommend 5 to 10 percent alfalfa in the ration during gestation to promote normal farrowing of healthy well-grown pigs. Sows should be kept in lean or moderate condition during gestation for economic reasons and to avoid dystocia or farrowing problems common in fat sows or gilts.

Although both progesterone and estrogen are needed to produce a proper intrauterine environment for the growing embryo, there has been no evidence that implants or daily injections of progesterone and estrogen at a ratio of 2000:1, or single injections of either hormone have any beneficial effect on embryonic mortality.^{33b,34}

It has been suggested that uterine infections during the breeding period and shortly after conception may account for a reduction in litter size. The evidence supporting such a factor limiting litter size is present but not conclusive.^{35,100,131,140} Feeding chlortetracycline and tetracycline continually or only during the breeding period produced no significant benefits.^{35,140} The author and others²⁹ recognize the contradictory reports on the effects of antibiotics fed at the time of breeding on reproduction, but recognize that in a herd acutely-infected with leptospirosis or a similar bacterial infection, antibiotic treatment during the gestation period may be beneficial in reducing fetal mortality and stillbirths. (See Chapter V).

The 30 to 40 percent deaths of fertilized ova or early embryos characteristic of pregnancy in swine, and the other species, may well be nature's way of eliminating some unfit or abnormal genotypes at a low biologic cost. The incidence of genetic or congenital abnormalities in the newborn is low because most are eliminated early in pregnancy.

The utero-ovarian relationship in swine is similar to cattle and sheep. Hysterectomies performed in sows the first half of the estrous cycle caused prolonged anestrus and the maintenance of corpora lutea for the approximate duration of gestation, about 110 days. If the operation is performed late in the cycle, ovulation occurs and the subsequent corpora lutea produced persist for a similar period. If nearly all of the uterus is removed from non-pregnant sows leaving only a portion that is less than one-fourth the length of the horn, then the CL will regress only on the side of the retained small portion of the horn; the CL on the opposite side will persist. If the portion of the uterine horn left in place is one-fourth the length of the uterine horn or longer then the CL will regress on both sides because sufficient amount of prostaglandin is released from the endometrium to cause in-

volution or regression of the corpora lutea. Thus in swine if there is a blind horn due to a localized segmental aplasia involving only a portion of the horn so that zygotes are present only in one horn, then prostaglandin released in the nonpregnant horn or segment of that horn will cause CL regression and prevent implantation and pregnancy. If one horn is ligated near its base, and the sow is bred at estrum, the developing zygotes will not be present in that horn and the prostaglandin will be released resulting in a regression of the CL and the onset of estrum terminating the early, unicornual, pregnant state. If one horn and its corresponding ovary are completely removed then pregnancy can occur in the remaining horn. Thus an intact, but nonpregnant horn will cause CL regression on both ovaries in swine but not in cattle.^{4,36-38,61,97}

Once pregnancy is established with zygotes throughout the uterus the prostaglandin release is suppressed and cycling ceases and corpora lutea persist.¹²¹ By day 14 to 15 at least 4 viable embryos or more are necessary in gilts to suppress prostaglandin and maintain luteal function during early pregnancy.^{78,122} When all the fetuses or embryos in one horn were killed between 4 and 50 days of gestation, that pregnancy was maintained in gilts so treated between 12 and 50 days, but was not maintained in gilts so treated from 4 to 10 days of gestation.^{37,38,110} In these latter gilts the CL regressed on both ovaries. Thus after day 13, pregnancy will continue even if all of the fetuses in one horn die or become mummified. The author has observed a sow with all of the fetuses mummified except one and pregnancy was maintained. (See Figure 74.)

Anatomical, Congenital, and Possibly Genetic Abnormalities of the genital tracts of female swine are occasional causes of failure of conception which can be explained by the close utero-ovarian relationship previously described that results in early regression of the CL induced by the release of prostaglandins before day 12 of gestation in the uterine horns not containing developing embryos. Of 19 "repeat breeding" sows and 44 "repeat breeding" gilts 5, or 11.4 percent of the gilts had a unilateral missing segment of the uterine horn, or uterus unicornis.¹⁶¹ Nineteen, or 43.2 percent, of the gilts and 2, or 10.5 percent, of the sows had bilateral tubal abnormalities; 2, or 4.5 percent, of the gilts had bilateral missing segments such as a missing vagina, cervix, or body of the uterus. Animals with bilateral tubal abnormalities were included with those having hydrosalpinx, "pyosalpinx", and bursitis. Present in the broad ligaments of some of the gilts were structures that appeared to be rudimentary ducts or remnants of the mesonephric or Wolffian duct system. With so many abnormalities affecting gilts, the logical conclusion was that they were developmental defects or arrests. Of 79 female swine that

had been bred an average of 2.8 services without conception,^{105,107,165} a unilateral missing segment was found in 1 gilt and 1 sow, or 2 percent and 3.6 percent, respectively. A unilateral blind segment was present in 4, or 7.8 percent of the gilts, and 1, or 3.6 percent, of the sows. A blind uterine body was found in 1, or 2.0 percent, of the gilts, in many cases the blind horn was distended with mucus. One gilt had a missing cervix. Another 354 day-old gilt had infantile reproductive organs with a complete lack of estrous periods. In several cases one uterine horn, uterine tube and ovary were missing. In cases in which one horn, usually the left horn, and the adjacent ovary were missing, pregnancy occurred normally in the other horn but the litter size was reduced by about one-half. A partial doubling of the uterine horns was observed in 5 of 500 gilts.³⁶ Some of these became pregnant and farrowed. This might be genetic in nature. In Belgium it was reported that 2.2 percent of 1000 female swine examined had missing segments of the uterine horn; 3 percent of the gilts had hydrometra; there were 4 cases of a uterus didelphys (double cervix); and 1 had a missing uterine body.⁶³ A case of uterus didelphys and other cases of a double cervix and median septums of varying lengths in the vagina located most commonly near the hymen and extending cranially were described.^{102,150,158} After examining 2967 gilts and 1288 sows, the following incidence in slaughter house material of missing and double parts of the genital tract was reported.¹⁶³

	Percent
Missing uterine horn	0.3
Missing segment of uterine horn	0.3
Missing vagina, cervix, and uterine horns (with male ducts in broad ligaments)	0.02
Missing cervix	0.02
All reproductive organs missing except vulva	0.04
Double cervix	0.04
Double uterine horn	0.02
Total	0.74

There were 1.8 percent of the open gilts, 0.6 percent of the pregnant gilts, and 1.2 percent of the open sows—or a total of 1.5 percent of 5088 sows and gilts—with tubal abnormalities. None of these abnormalities, except possibly a missing vagina or cervix, could be diagnosed in the living animal by practical methods. Thus it was emphasized by the above figures that anatomic arrests in development were not uncommon.¹⁶³

Of these anomalies hydrosalpinx was the cause of the greatest amount of sterility. Anatomic defects were found in 21.5 percent of the sterile female swine examined.^{105,107,165} Thirty three percent of "repeat breeding"

swine had bilateral tubal abnormalities.¹⁶¹ The incidence of defects in sterile gilts in these reports was 31.3 percent and 43.2 percent, respectively. In sows the incidence was much lower, only 3.6 percent and 10.5 percent, respectively. Of 142 or 3.3 percent genital tract anomalies in 9250 gilts and 9 or 1.8 percent anomalies of the genital tract in 476 sows, about one half were either segmental or total aplasia of the paramesonephric ducts.¹⁵⁰ Thus in swine, especially gilts, anomalies of the genital tract are not uncommon. The incidence is definitely higher than in other species of farm animals. Hermaphroditism in swine is seen occasionally and the affected animals are usually male pseudohermaphrodites, (See Chapter III).

Tubal abnormalities are common in swine in the U.S. as noted above but uncommon in Europe.^{105,107,150} They are usually bilateral and probably genetic in origin and result in hydrosalpinx or "pyosalpinx." In sterile female swine, usually gilts, 35 percent had obstruction of the uterine tubes. In hydrosalpinx, which was by far the most common lesion, there appeared to be an obstruction in the lumen of the uterine tube about two-thirds of the distance from the ovary to the horn, causing an accumulation of fluid.^{161,165} They reported that bursitis, or adhesions between the fimbria and ovary occur commonly in cases of hydrosalpinx. These adhesions were probably secondary to mycoplasmosis, polyserositis, peritonitis or intraperitoneal injection of an irritating substance in piglets.¹¹ Twenty or 2 percent of the 1000 female swine examined had bursal adhesions. These apparently are not so common or serious as the hydrosalpinx that may be associated with them.⁶³ Occasionally "cysts" of the bursa developed secondary to severe adhesions. In hydrosalpinx, which was very common, 97 percent of the cases were bilateral and usually the uterine third of the tube was involved or obstructed.¹⁶⁵ In some cases the uterine tube was patent and a light yellow bacteriologically-negative material was flushed with some force from the lumen. This would effectively prevent the passage of spermatozoa and ova. In most cases of hydrosalpinx or "pyosalpinx," adhesions of the fimbriae to the ovaries were present. There was some evidence that these hydrosalpinges and "pyosalpinges" might have been caused by the obstruction of the uterine tube by embryonal rests of the Wolffian duct system.^{105,107} The condition was invariably bilateral and showed some tendency to be inherited. It appeared almost entirely in nulliparous gilts. Attempts were unsuccessful to reproduce this condition experimentally in normal females by inoculating their uterine tubes with contents from affected tubes. Whether hydrosalpinx and adhesions are due to disease, to congenital lesions, or to some other factors is not definitely known. More work is needed on this problem.

Pathological Lesions or Diseases of the Reproductive System in swine, besides those mentioned, are cystic ovaries and inflammations of the genital tract. The former will be discussed later under hormonal causes of sterility. Nonspecific postpartum or postservice metritis is not considered as common in the sow as in the cow and mare; retained placenta is of less frequent occurrence; delayed involution of the uterus with endometritis, a common cause of postpartum sterility in cattle, is not common in sows. Only two cases of pyometra have been described.^{63,165} On examination of 5088 sows and gilts, no gross uterine infections were reported.¹⁶³

In Chapter XI the mastitis-metritis-agalactia (MMA) syndrome or "milk fever" in sows was discussed. This acute condition occurs soon after parturition and has been the subject of much recent intensive research. The disease MMA has largely been described as a clinical entity characterized by a degree of lactational failure oragalactia also associated with signs of anorexia, stiffness, fever, swollen mammary glands and the usual postpartum mucoid vaginal discharge. Infertility has not been described following this MMA syndrome.^{5,130} The postpartum vaginal discharge is usually not associated with a uterine infection.

Specific Infections of the Genital Tract causing sterility in swine include brucellosis caused by **Brucella suis**. The uterine lesions of brucellosis in swine are well described.¹⁵¹ Often the only recognized symptom of brucellosis in swine is an increased incidence of infertility.⁸³ In one brucella-infected herd 37 of the first 100 sows bred failed to conceive. Eight naturally infected sows studied over a 2-year period farrowed only 14 litters, even though bred for 2 litters a year. Of the 129 pigs born in these 14 litters, 44 were stillborn and 17 were weak and died within 2 days of birth, a loss of nearly 50 percent. In another herd, having 80 percent reactors to the brucellosis test and much sterility, 3 gilts were slaughtered; all had a purulent cervicitis and metritis from which **Br. suis** was recovered. In "repeat breeding," brucella-positive, female swine the incidence of embryonic death was 87.5 percent as compared with an incidence of 46.5 percent in brucella-negative females.¹⁶¹ When sows infected with *Brucella* were serviced by a fertile boar the pregnancy rate was only 35 percent compared to 90 percent in uninfected gilts.¹⁵⁷ This infertility was due to macroscopic and microscopic lesions of the endometrium causing early embryonic deaths with prolonged periods between heats. When infertility is a problem in a herd of swine, the brucellosis status of the herd should be determined.

A boar with **Staph. aureus** infection of the vesicular glands bred 18 females and only 4 conceived, 3 conceived subsequently to another boar, 3 were sold as ster-

ile, and the remaining 8 sows developed an acute metritis with a vaginal discharge. Two of these 8 sows were rebred later and aborted.⁵¹ On postmortem all showed a chronic metritis resembling that due to brucellosis. During a 3-week period 8 of 209 7-month old virgin gilts developed an acute severe metritis due to *Staph. aureus* with an elevated body temperature and copious vaginal discharge.⁴⁹ There is no evidence that leptospirosis causes sterility in swine, even though there is much evidence that it may cause abortions. A high incidence of defective pigs and early embryos and mummified fetuses were reported in non-immune sows vaccinated against hog cholera with the modified virus vaccines 10 to 16 days after conception.^{40,167} Other viruses described in Chapter V including picorna viruses, Aujeszky's disease (Herpes) virus, parvovirus ("SMEDI") and several other viruses described in Japan will cause heavy pre-natal mortality.⁴⁰

Coital vesicular exanthema, or vesicular venereal disease, may in rare cases affect the caudal portion of the genital tract of sows and gilts.^{8,84} This has not been described, and if present is probably rare, in the United States.

Several cases of a **ruptured cul-de-sac** of the cranial and lateral portion of the vulva after copulation were described.¹⁶⁵ These lesions were apparently caused by penetration of the vulvar mucosa by the penis. They were inflamed bulb-like structures containing coagulated blood. Intromission was apparently painful and was resented. In many instances the affected females, even though in estrus would often refuse to accept the boar. Sometimes the female would have a normal service followed by evidence of pain at subsequent services. These lesions did not cause permanent sterility and did not affect the more cranial portions of the genital tract.

Vulvovaginitis, characterized by swelling of the vulva with a mucous discharge, enlarged mammary glands and occasional prolapse of the rectum has been described in Chapter V. This condition is due to the feeding of moldy corn or barley in which estrogenic compounds, zearalenone, were present. Zearalenone (F-2) is an anabolic estrogen-like mycotoxin produced naturally by *Fusarium* growing in grains stored under high moisture conditions. Feeding of this mycotoxin caused infertility with small ovaries and atretic follicles and no corpus lutea and squamous metaplasia of the epithelium of the genital organs. It also caused nymphomania, pseudopregnant sows with persistent corpora lutea, juvenile hyperestrogenism in nursing piglets, malformations and possibly fetal resorption.²¹ Swollen reddened vulvas were reported in pigs consuming a poultry feed containing dienestrol. These animals exhibited estrous behavior. The isolation of a

mycotoxin from *F. graminearum* (*Gibberella zeae*) that caused vulvovaginitis, vaginal prolapse, perineal relaxation and ovarian atrophy in young gilts was described.^{91,146} The action of the mycotoxin was identical to estradiol. When the estrogenic metabolite, zearalenone, of *Fusarium roseum* (*Gibberella zeae*), a common mold of corn is present at high enough levels in grain this mycotoxin causes testicular atrophy and rectal prolapse in boars, vulvar reddening, swelling and vaginal prolapse in gilts and nipple enlargement in both sexes. In some nonpregnant gilts zearalenone will cause persistence of the CL, pseudopregnancy and anestrus with edematous uterine horns. Moderate doses fed to pregnant gilts caused decreased weights of the uterus, placental membranes and fetuses.^{48b} High levels of moldy feed fed 3 to 34 days of gestation caused inhibition of fetal development and decreased numbers of fetuses.^{92b,168b} Other trichothecene mycotoxins such as deoxynivalenol produced by *F. roseum* have also been associated with reproductive disorders, infertility and abortion in sows.^{92b}

Hormonal or Endocrine Disturbances are described as being responsible for about 4 percent of the infertility in female swine or 20 to 50 percent of infertile sows. This is the second most common cause of infertility in swine. A 24 percent incidence of cystic ovaries in 821 sows was described and 83 or 10 percent of these sows were sterile.¹¹⁶ Occasional follicular or luteal ovarian cysts were found in all stages of pregnancy, as well as in nonpregnant sows and gilts.^{105,106} In pregnant sows, cysts apparently developed or persisted after conception inasmuch as ovulation in nonpregnant, cystic females rarely if ever, occurred. The presence of these cysts in pregnant sows was not related to litter size and did not interfere with gestation. Estrus and service may occur during pregnancy in sows possibly associated with the development of follicles or the presence of high levels of estrogen. Cystic ovaries in pregnant female swine could invariably be produced by a single injection of a small dose of 200 to 400 IU of PMS. Cysts on ovaries in pregnant sows was not observed.¹¹⁶ About twice as many cysts, 35 percent were noted during the spring months as in the fall months, 15 percent.

The incidence of cystic follicles in ovaries with corpora lutea was 1.1 percent and cystic follicles alone was 0.6 percent of 5088 female swine.¹⁶³ Cystic ovaries were reported with corpora lutea in 7.6 percent and with no corpora lutea in 2.5 percent of 79 infertile or sterile sows.¹⁶⁵ Six percent cystic ovaries with corpora lutea and 3.2 percent cystic ovaries with no corpora lutea were observed in 63 "repeat breeding" sows.¹⁶¹

Cystic ovaries in nonpregnant swine were of 3 types—

single cysts, multiple, large cysts, and multiple, small cysts.¹⁰⁴⁻¹⁰⁶ Single cysts were found in 2 percent of 1751 pairs of ovaries. In these cases only 1 or 2 cysts were present on the ovary. They were 2 to 3 cm. in diameter, whereas a normal follicle is only .7 to 1.1 cm. in diameter. The reproductive tract and behavior of these female swine were normal. These single cysts were found during the luteal phase of the cycle with normal corpora lutea present. These were probably atretic follicles that failed to rupture when ovulation occurred and were not associated with sterility.^{104-106,116}

Multiple cysts were always associated with permanent or temporary sterility. Three to 4 percent of non-pregnant females were affected. It is usually impossible to differentiate clinically between sows with large or small multiple cysts as estrous cycles in both are irregular and characterized by anestrus periods of varying length.

Large multiple luteal cysts were most common. These measured 2 to 10 cm. in diameter and an average of 5.6 cysts were present on each ovary. Thus the number of these cysts was nearly the same as the normal number of follicles. The walls of these large cysts were either heavily luteinized or contained lutein patches. The uterine endometrium in these cases showed progestational changes. The external symptoms manifested by these sows were extreme irregularity of the estrual cycle with intervals of 2 to 90 days between estrous periods. The heats were of greater intensity but of the same duration as those in normal noncystic females. In 60 percent of the affected female swine the clitoris was larger and longer, up to 1 to 2 cm. in length, than the clitoris of normal females, 1 to 2 mm. in length. The amount of estrogen present in these large cysts was less than in normal ovarian follicles. Androgens were not present. Although progesterone was present, the amount could not be measured. It was believed that progesterone, or progesterone converted into androgens, was the probable cause of the enlarged clitoris. There was no significant difference between the gonadotropic activity of the hypophysis in cystic and noncystic sows. In sows with large cysts given injections of LH, neither ovulation or further luteinization of the cysts resulted. This does not mean that LH deficiency might not be the cause of the condition, as the animals treated had been affected for a long period.^{104-106,116}

Small multiple follicular cysts were observed only occasionally. They resembled a cluster of grapes and were always present in numbers exceeding the number of follicles found normally. These cysts were about 1 cm. in diameter. An average of 22.5 small cysts per ovary was reported.¹⁰⁴⁻¹⁰⁶ The walls of these small cysts were lined by normal granulosa cells. The uterus showed an estro-

genic type of endometrium and the clitoris was not enlarged. These animals showed marked irregularities in the length of the estrual cycle. Symptoms of estrus were intense, similar to the symptoms produced by the larger cysts. In neither large nor small multiple cysts was nymphomania, or continuous estrus, observed. These small cysts were found to be as rich in estrogen per unit weight as the normal follicles, but because of the large number of small cysts the total concentration of estrogen was 4 to 5 times that of the normal ovary just before ovulation and several hundred times that of sows affected with large luteal cysts. The pituitary assays showed no increase in gonadotropic hormones over that seen in normal sows. A single small dose of 250 to 400 PMS always produced cystic ovaries in nonpregnant swine but the cysts never reached the size of large luteal cysts.

Thus it appeared that multiple cysts may be due to lack of luteinizing hormone necessary to cause ovulation and normal corpus luteum formation. It is doubtful that sows once they develop cystic ovaries recover spontaneously.¹¹⁶ Whether there is a genetic basis or cause for cysts in sows as in cows is not known. Further work is required to determine the actual cause and possible therapy of cystic ovaries in swine.

Porcine ovarian abnormalities other than cysts include: ovotestes in hermaphrodites, ovarian abscesses, rare parovarian cysts, and aplastic or missing ovaries.¹¹⁶

Anestrus is common in prepuberal gilts and post-weaning sows.^{24,46,79,81a,b,82,86} The incidence of anestrus is most common in the summer months but varies from 20 to 40 percent in both gilts and sows.⁸²

In 54 anestrus gilts 10 to 11 months of age examined at slaughter 19 gilts or 35.2 percent had no luteal tissue in the ovaries and were prepuberal. Forty two percent of the gilts had ovaries with active corpora lutea indicating cyclic activity but the external heat signs either were missed or were too weak to be observed. The remaining 10 gilts, 18.5 percent, had normal corpora lutea and/or luteinized cysts.⁴⁶ In another study of anestrus gilts 7 to 9 months of age, 50 percent exhibited behavioral anestrus and would not mate even when exposed continuously to a boar. These were confinement-reared gilts and estrous cycling was occurring based on plasma progesterone levels at frequent sampling periods. This study also showed that exogenous ACTH and glucocorticoids inhibited estrous behavior and shortened the duration of estrus. Further studies on confinement-rearing stress and managerial practices to reduce this stress is indicated.²⁴ In a third report from Japan⁸⁶ 192 sows or 70 percent of 274 sows with ovarian "disease" were anestrus or failed to exhibit estrus based on rectal palpation of the ovaries under thiamylal sodium anesthesia, 20 ml IV. Thirty

percent of these 274 sows had corpora lutea and 30 percent had cystic ovaries.

The factors contributing to anestrus in swine are prepuberal status or delayed estrus in gilts and sows due to the breed, age, nutrition, season, especially summer, lack of boar exposure, confinement-rearing or management problems, and failure to check frequently several times daily and observe estrus, preservice or postservice.^{79-81a,b} To minimize to problem of anestrus and infertility in a swine herd, it is essential that all non-pregnant sows and gilts of breeding age be adequately "teased" daily by boars that have demonstrated their estrus detection ability and libido. Postweaning anestrus in sows is most common in the summer months, especially in primiparous young sows. During the summer months 40 percent of the fertile matings was followed by a return to estrus in a 25 to 35-day interval. This interval is suggestive of a pregnancy that was present for 12 or more days followed by early embryonic death.⁸⁰ Pregnant sows are anestrus. Boars lacking libido may be a cause of missed estrous periods. Too many sows in a pen for a boar to check efficiently may also be a cause of apparent anestrus. Excessive stress on prepuberal or postweaning females causes anestrus and short estrous cycles. Cystic ovaries, either follicular or luteal cysts may cause anestrus but these are not as common as the other factors. Lactating sows and gilts are usually anestrus. Other causes of anestrus include: delayed puberty is seen more often in Durocs and Yorkshires; first litter gilts are more frequently anestrus than multiparous sows, 35 vs 15 percent; gilts and sows whose pigs are weaned during the summer are more frequently anestrus than those whose pigs are weaned in the winter, 40 vs 10 percent; the larger the number of sows penned together the greater the incidence of anestrus due to the loss of condition and lack of feed intake in some sows; cystic ovaries and lameness also contribute to the anestrus condition as well as inefficient management and failure to detect estrus.^{81b}

Since anestrus is a symptom, an accurate diagnosis is desirable but may be difficult to achieve. Progesterone levels above 1.5 ng/ml on a number, 6 to 18, of affected animals would indicate estrous cycling is occurring, the sow is pregnant or a luteal cyst is present. Serial samples 5 to 10 days apart would aid in diagnosing whether cycling is occurring. Slaughter house or abattoir examination of a selected sample of females in a herd would also be most informative.^{81b} Costly rectal examinations of the ovaries of anesthetized sows, although difficult, could be very helpful.^{86,99}

Treatment of anestrus in gilts and sows, as in cattle, requires as accurate and correct a diagnosis of the cause as possible.⁷⁹ The history, records, physical examination

of the females for pregnancy by ultrasonography at 30 to 35 days of gestation or other means, nutritional status, age, season, managerial practices, disease factors, and other tests as noted above should be carefully reviewed. The use of PMSG for treating anestrus sows was reported in 1953.¹²⁵ Estrogens and HCG gave poor results. Later trials with PMSG also proved promising.^{43,90} In gilts stressing by trucking, movement or mixing of females, introduction of a boar and giving PMSG (500 IU) or PMSG and HCG (250 IU) if no corpora lutea are on the ovaries frequently induces estrus within 3 to 5 days at which time breeding should take place.^{81b}

If corpora lutea are present prostaglandins 5 to 10 mg of PGF_{2a} or 1 mg (100 ug) of a prostaglandin analogue might be used.⁸⁶ They are ineffective except between days 12 and 15 of the estrous cycle or in cases of persistence of the corpus luteum or luteal cysts and could cause abortion in early gestation.^{17,87b}

Prevention of seasonal postweaning anestrus in sows during August through October was accomplished by administering 500 IU of PMSG at weaning. This study reported 52.8 percent of controls and 91.3 percent of the treated sows in estrus within 7 days after weaning during the months of August through October.^{81b,82} Estrus occurred 3 days later about a day earlier than controls. Presently PMSG is not available commercially in the U.S. Further trials with other FSH products are indicated. Ovine pituitary gonadotropin showed promise for the treatment of cystic ovaries in sows.⁸⁶ Repeated daily doses of 5 to 10 mg of estradiol for 5 to 20 days to age the luteal tissue followed 5 days later by prostaglandin to involute the CL and induce estrus has been reported.¹⁷

It was recommended that gilts not in estrus by 8 or 9 months of age and sows anestrus for more than 40 days after weaning should be culled.⁷⁹ A high incidence of anestrus after weaning in one herd was associated with a low packed-red-cell volume of about 20 percent and many sows serologically positive for *Eperythrozoon suis*.¹⁸

In a study of 63 anestrus gilts over 7 months of age and 28 sows that failed to show estrus within 5 weeks of weaning less than 10 percent of the gilts and more than 40 percent of the sows had corpora lutea indicating the presence of an estrous cycle.¹¹⁴ After the stress of transporting the gilts to the study center and changing their environment 68 percent of the gilts and 25 percent of the sows came into estrus within 10 days. Daughters of late maturing gilts were also late maturing so a genetic factor was involved in this type of anestrus that might be susceptible to improvement by selection for early puberty. Rare cases of infantile or hypoplastic ovaries and genital tracts in well-grown gilts have been described.¹⁶⁵

Repeat Breeders in female swine, as in other ani-

mals, are caused by high embryonic death rates and low fertilization rates. These are also causes for reduced litter size. Embryonic death was of more importance than was the ovulation rate in controlling litter size in swine.⁸ Between 10 to 25 percent of sows and gilts fail to conceive.^{104-107,163} In these sterile swine, gross abnormalities of the reproductive tract were the cause of sterility in 25 to 50 percent of the gilts and 25 percent of the sows. In the rest of the sterile females there was no apparent cause for the failure of fertilization or early embryonic deaths. Failure of reproduction due to embryonic deaths appeared less common in gilts than in sows.

In an experiment modeled after those made on "repeat breeding" cattle, 63 "repeat breeding" female swine were assembled.¹⁶¹ These had previously been bred 2 to 4 times without conceiving. They represented 5 breeds and included both gilts and sows. Part of the 63 were killed 4 days after service to a fertile boar and the rest were killed at 25 days. Those that came in estrus again before 25 days were rebred and killed 4 days later. Gross abnormalities were found in 63.7 percent of the gilts and 31.6 percent of the sows. Some of these were unilateral and permitted conception. In the percentage of reactors to the blood test for brucellosis there was no significant difference between either the gilts and the sows, or between those with gross abnormalities and those with no gross abnormalities. The difference in percentage of fertilized ova between brucella-positive and brucella-negative animals was not significant but the incidence of embryonic death was 87.5 percent in the positive animals, and 46.5 percent in the negative animals. This experiment showed the importance of the role of brucellosis in infertility in swine. These workers¹⁶¹ concluded that "repeat breeding" was due to failure of fertilization in 53.4 percent of the gilts and 32.6 percent of the sows. Gross abnormalities accounted for failure of fertilization in 50 percent of the gilts and 16.8 percent of the sows. Thus accountable failures of fertilization occurred in 3.4 percent of the gilts and 16.8 percent of the sows. Embryonic death caused "repeat breeding" in 23.9 percent of the gilts and 67.4 percent of the sows. "Repeat breeding" swine with normal embryos 25 days after the one additional breeding included 22.7 percent of the gilts and none of the sows. Therefore, the major cause of "repeat breeding" in gilts was genital abnormalities causing failure of fertilization. In sows the major cause of "repeat breeding" was embryonic deaths.

In another study 79 "repeat breeding" sows and gilts that had been bred 3 to 10 times previously were assembled.¹⁶⁵ All brucella-positive females were eliminated from the experiment. After being bred to a fertile boar on the first estrus, 53.2 percent conceived. They considered that this high conception rate in infertile females may

have been due to breeding an average of 3.9 times per estrus as compared to only 1.4 times per estrus previously. There was some indication that these animals might have ovulated early. Only 5 to 10 percent of these animals could be considered to have experienced embryonic deaths.¹⁶⁵ This is in marked contrast to the 20- to 70-percent rate of embryonic deaths reported in the previous study.¹⁶¹ The 5 to 10 percent of the animals exhibiting extreme embryonic mortality were apparently fertile but a reduction in litter size occurred soon after implantation. Some of these losses were probably due to segmental aplasia and defects of the uterine horns and genital tract resulting in early and complete loss of embryos.

Repeat breeders could also be due to poor management and infertile boars.¹¹⁴ Of 75 female "repeat breeding" swine brought to the study center and bred the next estrus to a fertile boar, 49 females conceived. The conception rate experienced by "travelling" boars on first service was 62 percent for gilts and 56 percent for sows; in herds using their own breeding boars the respective percentages were 82 and 77. The lower conception rate in "travelling" boars may have been due to overuse, the presence of genital infections, or poorly timed services.

Tumors of the genital tract in female swine are rare, possibly because most swine are slaughtered at a relatively young age. Leiomyomas and a fibroma of the uterus in sows and one case in which a lymphoblastoma involved one ovary have been described.⁵⁰ The author has observed a 12 × 7 × 4 cm. hamartoma on the ovary of a sow. A rare teratoma of the porcine ovary was reported.¹⁰³ Embryonal nephromas and sarcomas of the vagina and cervix have been described.¹⁰¹ Two hemangiomas, a papillary cystadenoma and a granulosa cell tumor of swine ovaries were found.¹⁰⁹ Other reports on ovarian cystadenomas, sarcomas, teratomas and a fibroma have been cited.¹⁰⁹

Nutrition may have a definite effect on fertility in female swine.²⁹ Except for a few important differences, the same general principles apply to swine as to the other farm animals. As in all animals, inanition due to a low plane of nutrition in swine results in a delay in the onset of puberty, and failure of estrus, or irregular estrus after weaning. The detrimental effects on embryonic survival of overfeeding and a high energy intake immediately after breeding have been discussed. The beneficial effects of a temporary high plane of nutrition to promote early puberty and a higher ovulation rate have also been described. Gilts on a protein-free diet failed to cycle normally or conceive.¹ A protein deficiency acute enough to cause severe retardation of growth in sows did not affect the incidence of fetal atrophy.³¹

The presence in newborn swine of embryonic defects

and abnormalities caused by a vitamin A deficiency in sows during early pregnancy has been reported.^{12,69} These anomalies included eye defects or the absence of eyes. Evidence was cited to indicate that deficiencies of vitamin E, C, B, complex and D are seldom, if ever, the cause of infertility in the sow or other farm animals.^{128,129} Evidence of severe deficiencies in phosphorus, calcium or other minerals affecting reproduction in swine have not been reported in recent years.

Reproductive management in swine herds, as in cattle herds, requires close cooperation between the owner and/or the manager and the veterinarian. The success of a reproductive program lies in its day to day efficiency and effectiveness which is primarily the responsibility of the manager and/or owner.^{29,81a,b} The results of several recent large surveys of swine fertility in the U.S. revealed that overall farrowing rates were only 72 percent in over 50,000 sows and gilts. Some well-managed herds achieve an 85 percent farrowing rate. Infertility, sterility and small litter size may be due to a variety of infectious agents and boar infertility discussed in this chapter and in Chapter XVIII, respectively. Other factors contribute to low fertility and should be recognized. Farrowing rates during the summer months, June through September, average about 15 percent lower than in the winter months of November through March in the northern hemisphere. This high seasonal loss of pregnancies is apparently not due to failure of fertilization, boar fertility or infectious agents. The nature or cause of this apparent loss of pregnancies is not known.^{81b} The farrowing rate of gilts is lower than first-litter gilts which is lower than multiparous sows. Crossbred females are more fertile than purebreds. Although high ambient temperatures reduce conception rates and embryonic survival its role in the summer infertility problem is equivocal.^{81b} As the number of females in a pen increases, fertility decreases due to heat detection, nutritional, infectious disease and stress problems. Sows and gilts should be bred twice during estrus at a 24 hour interval and to two different boars for highest fertility. Females should be tested for estrus starting 17 days after mating and checked for pregnancy at 30 to 40 days of gestation with an ultrasonic detection instrument.

In diagnosing or preventing reproductive failures or inefficiencies a number of requirements are essential including:

- 1) Breeding records, necessary to monitor and analyze the monthly (seasonal) and yearly programs and results including the inventory, costs and net income.
- 2) An evaluation and understanding of the standard of management including training and capability of

personnel and herd management procedures, including buildings, animal comfort, degree of stress and techniques for estrous observations and breeding both females and males, and pregnancy testing.

- 3) An evaluation and understanding of the nutritional program including adequacy of TDN, protein, minerals and the delivery of the rations to the herd.
- 4) A good preventive disease control program is essential including vaccinations, parasite control, feed additives, quarantine and isolation facilities and practices, supervision of farrowing and vector control.
- 5) The genetic program and goals of the owner and/or manager should be understood and integrated effectively to improve herd productivity.

To further these goals the veterinarian and owner and/or manager should have a good veterinary diagnostic laboratory and consulting service that also includes a nutritionist, a geneticist, an accountant, and if the herd is large a computer would be desirable. If artificial insemination is to be used in a swine herd excellent management of the female herd, very competent estrous detection, careful control of the boar, semen collection and insemination and complete records are essential.

Standards of production that are recognized as necessary for a successful swine herd operation are:²⁹

Litters/sow/year	2 to 2.25
Pigs/sow/year	20 to 21
Stillbirths (%)	5
Farrowings (%)	88-90
No. of live pigs/litter	10-11
Weaning to service interval (days)	7
Repeat breedings (%)	6-8
Abortions (%)	1.0
No. of pigs weaned/litter	9.5
No. pigs marketed/sow/year	18.0

If these standards or goals are not closely approached or met then it is necessary for all concerned to properly assess their deficiencies, correct the problems and work toward achieving these standards in order to insure the success of the enterprise.

Chapter XVI

INFERTILITY IN EWES AND DOES

Infertility or sterility in ewes and does is uncommon when compared with the incidence of these conditions in other domestic animals. This is probably true for two reasons: first, there has been less study of the infertility or sterility occurring in these animals; and second, the incidence of disease or infertility apparently is much lower in these species because of their lower economic value and prompt elimination if they are infertile. Fertile members of the species have been selected and perpetuated over many years. In examining the genital tracts of 90 ewes, no structural defects or other abnormalities that would be a barrier to fertilization were found.^{37b} There are many similarities between the genital tracts, the ovaries, the reproductive hormones and other facets of reproduction between ewes, does and cows. The structure and functions of the various portions of the genital tracts of ewes and does are similar to that of the cow, and treatment of pathologic conditions is similar to that used in the cow except for the fact that the smaller size of the ewe and doe renders impossible the use of certain procedures and types of therapy employed in the cow. Because of the differences between the ovine and caprine species in reproductive physiology and to avoid confusion, the author is separating the discussion in this Chapter into two sections—Infertility in Ewes and Infertility in Does.

INFERTILITY IN EWES

Reproductive Physiology

Puberty occurred in spring lambs at a mean age of 249 to 293 days, 8 to 9 months; Rambouillet or crossbred lambs born in the fall had their first estrus at 316 days range 199 to 577 days.^{43,54,159} About 90 percent of the lambs had ovulated before the first standing estrus, as noted by laparotomy and the presence of a corpus luteum. In lambs that were not bred, it was noted that over 53 percent ovulated after the last standing estrus of the breeding season. Many lambs only exhibit one or a few estrous periods their first breeding season. Sexual maturity varies with the breed and rate of growth. The fine-wool or Merino type sheep are slow to mature and often

fail to reach puberty the first breeding season. Early maturing breeds such as the Finn-sheep may reach puberty as early as four months of age.^{3,83} Merino sheep mature more slowly than the Hampshire or Suffolk breeds. Crossbred lambs generally mature earlier than purebred lambs. A high plane of nutrition may hasten the onset of puberty and a low plane of nutrition will delay it as in cattle.¹⁴³ Most ewes are bred at the first breeding season after they reach one year of age. Under good conditions of feeding and management 60 percent or more of spring lambs of the early-maturing breeds will become pregnant if placed with rams in the fall. Virgin ewes were still fertile after reaching 4 years of age¹⁵⁸ this is different from 4 to 5-year-old virgin cattle. (See DeLange.)

The estrous cycle—The common coarse-wool breeds are seasonally polyestrous. The fine-wool breeds like the Merinos, Rambouillet and the coarse-wool horned Dorset and crossbreds of these breeds may be polyestrous the year around, depending upon climatic and feed conditions. The coarse-wool breeds in the northern hemisphere usually come into estrum about September 1. If they are not bred or do not conceive they continue to come into estrum until about January 1 or slightly later. Rambouillets tend to come into estrum the earliest in the breeding season; followed by the Hampshire, South-downs and Shropshires.¹

About 12 to 48 hours after parturition about 10 percent of ewes exhibited estrus.^{61,157} After this brief estrous period probably due to the high plasma levels of estrogen and the low progesterone levels postpartum¹²⁸ lactational anestrus lasting 5 to 7 weeks usually develops. After this period some ewes suckling lambs will exhibit estrus but most heats are not observed until about 2 weeks after the lambs are weaned. As determined by the fern pattern of cervical mucus, lactating ewes have one or more quiet or silent ovulations before the first estrus after lambing. It is very difficult to induce estrus unless an involuting corpus luteum is present or exogenous progesterone is given.^{54,55,105} In sheep, as in cattle, progesterone apparently is necessary to potentiate the effect of estrogen to produce signs of estrus.

When rams were introduced into a flock of ewes at

the beginning of the breeding season, 40 to 90 percent of the noncycling ewes ovulated within 65 to 72 hours. These ovulations were preceded by LH peaks about 35 hours after ram introduction.⁸⁹ This study confirms prior reports that ewes ovulated within 6 days of the introduction of rams early in the breeding season. This first ovulation is not accompanied by signs of estrus. But the next estrus period 17 to 24 days after ram introduction is associated with estrus and fertile copulations. Thus the presence of rams at this time of the breeding season triggers the release of GnRH or LH causing a "silent" estrus with ovulation and CL formation. Although the duration and intensity of estrous signs were similar to ovulating puberal ewes in the same flock, 6 to 33 percent of the first estrus periods of puberal ewes were anovulatory as determined by endoscopy. The following inter-estrous period was of normal length, 16 days.⁴⁸

In a recent study it was shown there are usually two peaks of estrous activity after rams are placed with ewes early in the breeding season, the first at 18 to 19 days and the second at 22 to 24 days.⁹⁰ Frequent laparoscopic examinations revealed that 85 percent of ewes that were previously anovular, had ovulated within 4 days of ram introduction. Premature regression of the CL occurred in 50 percent of the ewes between days 4 and 8 and the first estrus in these ewes occurred at about 23 days after the rams were introduced. The remainder of the ewes ovulating within 4 days of ram introduction had no regression of the CL and they showed their first estrus at 19 days.⁹⁰

In fall-lambing Rambouillet ewes the average interval from lambing to the start of regular estrous cycles was 72 days, range 12 to 212 days; this varied from 46 days for ewes lambing in August to 98 days for ewes lambing in January.⁷ The onset of estrous cycles is hastened by early weaning of lambs. The interval from lambing to breeding had a significant effect on conception but had no effect on the induction of estrus.¹⁵⁴ Apparently, as in cattle, a 40 to 60 day interval postpartum was necessary for an optimal conception rate. Uterine involution is largely completed by 24 days postpartum.⁵² Thus, with the Dorset, Rambouillet, or Merino breeds or their crosses, it is possible, but very difficult on a flock basis, to obtain two lamb crops or a 200 percent or greater lamb crop each year. By alternating breeding in the spring and fall, it would be possible to get 3 lamb crops in two years.⁷⁶ Over a two-year-period 539 Rambouillet ewes were mated for six weeks beginning the 21st of March, the 21st of June the 21st of September and the 21st of December in the northern hemisphere. The incidence of estrus in open ewes for the four mating periods was 84.5, 96.4, 97.2 and 99.1 percent, respectively; the ovulation rates were

105.6 140.8; 175.4 and 151.9, respectively, and the lambing rates were 83.9, 96.5, 126.8 and 135.2, respectively.¹³⁵ The higher ovulation rates in June and September were not reflected in higher lambing rates because the higher environmental temperatures during the breeding season had a detrimental or modifying effect on embryonic survival.

The factors limiting the achievement of the goal of two lamb crops or a 200 percent lambing rate per year in the coarse-wool breeds was reviewed.⁸⁰ The manipulation of light and temperature was not practical because of the long latency period required to induce results.⁸⁰ Although ovulation rates could be increased by: (1) breeding during the middle of the breeding season instead of late in the season, (2) "flushing" the ewes by increasing the TDN or energy intake for several weeks prior to breeding, or (3) by the injection of PMSG, preceded by progestin, 3 to 4 days before the next estrus, or on days 12 or 13 of the cycle, only 20 percent of the ewes with 3 CLs were carrying 3 fetuses while 75 percent of the ewes with 2 CL were carrying two fetuses. Thus although a combination of breeding management, including controlled lighting, and hormonal therapy makes 2 lamb crops per year feasible, much more research is needed to make it practical and a routine procedure for most breeds of sheep.^{91b}

The presence of a ram stimulates the breeding activity or the onset of estrus in ewes in the transitional period between the anestrous period and the breeding season.^{77,78,139,164} As noted previously the first ovulation thus induced is often silent and the next period associated with a regressing corpus luteum that provides some progesterone is manifested by signs of estrus. This technique can be used to obtain a degree of synchronization of estrus in a flock. When rams were introduced from July 1 to August 8th, the maximum conception period occurred 17 to 32 days later.¹³⁹ When rams were introduced after August 8th conception rates for the first and second 16-day periods of the breeding season were similar. If a vaginal pessary containing a progestogen was placed in the vagina of the ewes for 12 days during this transitional period before the breeding season and then removed the day the ram was placed with the flock, over 90 percent of the ewes were in estrus within 4 days and 62.5 percent lambled to first service.^{164,165} Thus combining a progestational agent and the introduction of a ram resulted in a higher level of synchronization. As with boars, the presence of a ram, the senses of smell, sight and contact all combine to produce a stimulation of the onset of the estrous cycle and ovulation in the ewe. This effect was not produced when the ram ran continuously with the ewes.^{77,78}

Photoperiodism is a characteristic of the reproductive cycle or the sexual activity in sheep and goats, and horses.^{3,66,67,101,102,142} The onset of the estrous cycle and the breeding season in most breeds of sheep is principally influenced by the reduction in the length of daylight in the late summer and fall in the northern hemisphere. A reduction in daylight to about 10 or 11 hours, whether it occurs naturally or whether it is induced artificially by penning the ewes in a darkened area during part of the day, will induce the onset of the estrous cycle in anestrus ewes. The seasonal nature of the breeding season permits the birth of lambs at the most favorable time or in the late spring months when feed supply and ambient temperatures are nearly optimal. The breeding season of sheep tends to become shorter at latitudes near the poles.^{3,67} Near the equator ewes tend to have estrous cycles throughout the year and not exhibit a restricted breeding season. However irregular and prolonged intervals between estrous periods due to a persistence of the corpus luteum, especially in June, was reported in Niger Peulh ewes in Africa.^{166a} In the northern latitudes there are year to year minor variations in the onset of the breeding season as in horses. A reduction in ambient temperature occurring naturally or induced artificially also has an effect on promoting the onset of the reproductive cycle and the breeding season.^{39,66}

There is a wide breed difference in the number of estrous periods per year from 2 to 3 periods in a short breeding season in some breeds to estrous periods in other breeds in regions near the equator occurring all the year around.^{3,67} The ram, similar to the stallion, does not show a restricted breeding season as does the female but there are seasonal variations in semen production and characteristics.^{3,67} (See Male Infertility.) Rams are sexually more active and produce better quality semen during the breeding season. The onset of the breeding season could be somewhat advanced by a higher energy intake before the season.^{123,124}

Most breeds of sheep have an average cycle length of 16.5 days, with a range of 14 to 19 days.¹ Most of the breeds are in estrus for a period of 20 to 40 hours, with an average of about 28 to 36 hours and ovulation occurs in estrus about 24 to 27 hours after its onset. If AI is used it is best performed about 10 hours, 2 to 15 hours, after the onset of estrus.¹²⁸ The Texel ewe has two follicular growth waves. The first wave began on days 1 and 2 and ended on days 11 to 12 but atretic changes were evident beginning on days 5 to 6. The second growth wave began on days 9 and 10 and resulted in mature follicles at the next estrus.³³ Thus these changes were similar to those reported in bovine ovaries during the estrous cycle. The follicle size varied from 0.5 to 1.0

cm. and the corpora lutea were about 1 cm. in diameter. "Silent" heat or ovulation without estrus occurs frequently at the beginning and after the end of the breeding season. The estrual cycles tend to be longer or shorter in duration than the average at the beginning or end of the breeding season. Short cycles are more frequent in older ewes. Cycle length does not affect fertility.¹⁶² There was no tendency for individual ewes to have an early or late onset of the breeding season, so selection on this basis is not possible.

Sexual activity and signs in ewes, as in the mare, are nearly lacking in the absence of the male.^{2,3,67,78} Proestrus is rather indefinite and the onset of estrus is abrupt. Cessation of estrus is gradual. The symptoms of estrus in the ewe include restlessness, seeking out the ram, frequent switching of the tail as if the vulva itched, teasing the ram and standing immobile to be mounted and bred. In estrus the Dorset ewe has a characteristic stance. During an average heat period a ewe penned with a ram was teased 18 times, mounted 25 times and mated 6 times.^{77,78} Anorexia and swelling of the vulva are usual symptoms of estrus in the ewe. Most owners allow the ram to run with the ewes during the breeding season. Painting the brisket of the rams or having them wear a harness containing a marking device, in which various colors can be placed, is a common practice. Thus by observation of the rumps of the ewes, service can be noted and the date recorded. After 17 to 20 days a different color may be used to determine which ewes return to estrus. If many return, the fertility of the ram is probably questionable. Vasectomized rams can be used as teasers and "heat detectors" for ewes that are to be bred artificially. Administration of 50 to 100 mg. of testosterone propionate every other day for 20 days and then every 10 days or using testosterone implants resulted in producing normal male sexual behavior in treated ewes and others that could be used for estrus detection.^{28,97,132a} Rams can be operated upon similarly to bulls, to produce a lateral deviation of the penis at the time of erection. These surgically prepared rams were satisfactory as estrus detectors in ewes and semen could be collected from them.⁶

The ewe secretes mucus from the cervical glands but not in large amounts like the cow. Smearing the estrous mucus on a slide and allowing it to dry results in a fern or arborization pattern, similar to that in the cow, due to the high salt content in the mucus of estrus.³¹ The vaginal smear in the ewe is of limited diagnostic value in determining the stages of the estrous cycle.³ As in the cow, increased activity of the uterine muscle and edema of the endometrium occur during proestrus and estrus. The endometrium in some ewes may be black due to the

presence of melanoblastic pigment. This is not associated with stages of the cycle. The cervix is somewhat dilated and relaxed during estrus. Often ewes may attract rams by the odor of the vaginal mucus before the ewe is ready to accept coitus.¹ Ewes may occasionally show estrus during pregnancy. Eleven of 50 pregnant ewes had 1 to 3 "heats" during pregnancy.¹⁶²

The time of mating or artificial insemination during estrus in sheep is not as critical as in other animals.¹ The optimum time to breed is about 12 to 18 hours after the onset of estrus. Ovulation is spontaneous and usually occurs from 18 to 24 hours after the onset of estrus or from 12 to 24 hours before the end of estrus. In rare cases ovulation may occur after the end of estrus. In twin ovulation several hours or more may separate the time of ovulation of each follicle. Usually 1 to 3 ovulations take place and the rest of the follicles become atretic.

Ovulation Rate—Placing ewes on a high plane of nutrition or flushing for 2 weeks before mating increased the lamb crop by about 20 percent and flushing ewes for 3 to 5 weeks increased the rate of twinning to 40 percent or higher, compared to a 4 to 6 percent twinning rate in control, non-flushed ewes. Increasing the length of time of flushing beyond 4 to 5 weeks did not give a further ovulatory response.^{49,123,124} Breeding ewes fed a high plane of nutrition for 6 to 8 months before flushing resulted in a higher rate of twin ovulation than ewes fed a low plane of nutrition before flushing.⁵³ The lamb crop of range ewes was increased from 80 to 135 percent for a 6-year period by continuously feeding on a high plane of nutrition.¹⁰⁴ There is no evidence that high condition predisposes the ewe to sterility. Ewes on a high nutritional level had a higher ovulation rate, possibly a higher fertilization rate, and a slightly lower embryonic survival rate than ewes on a low nutritional level.⁴⁹ It was suggested that higher feeding levels caused an elevated plasma glucose, greater hypothalamic stimulation and release of larger amounts of gonadotropin causing greater ovarian activity and twin ovulations.^{76,103} The evidence that a high plane of energy intake was detrimental to embryo survival in the weeks following conception was not observed in ewes as in sows.^{53,123,124} In flushing ewes a high energy or TDN intake is needed; an increased intake of protein is not necessary.¹⁰³ The lambs, especially twins, of the ewes on a high plane of nutrition, were heavier, larger and stronger.^{123,124} When ewes had a severe diet restriction during the period from weaning to breeding, about a 4 month dry period, lambing percent was 22 percent lower the first year and 52 percent lower the second year than in control ewes even when a 20 day flushing period preceded the breeding season.¹⁵ Sim-

ilarly thin ewes affected with a chronic debilitating condition such as progressive pneumonia or visceral caseous lymphadenitis had a reduced reproductive efficiency when compared with normal ewes. The fertility and percentage of lambs born alive was 76 vs. 91–93 percent and 61 vs. 86 percent, respectively.⁶⁰

Other factors also influence the ovulation rate and the subsequent lamb crop. Ewe lambs, yearlings and young ewes as well as old ewes produce fewer twins and have lower lamb liveability.¹⁵⁵ The peak percent of lambs weaned was in 4-year-old ewes, range 3 to 6 years. However, a higher percentage of single lambs are viable at birth and are weaned than are twins or triplets.^{3,137} Crossbred ewes produced 9 to 23 percent larger lamb crop than purebred ewes when bred as ewe lambs. Older crossbred ewes produced 10 to 16 percent larger lamb crops.^{134,135} Ovulation rates are higher in the early to middle portions of the breeding season and decline later in the season.^{3,6} When ewes were given a 10 hour daily light period for 9 weeks starting late in the anestrus or transition period ovulation rates and lambs born per ewe increased about 25 percent from 1.2 to 1.65 lambs/ewe.³⁶ Certain ewes tend to have higher ovulation rates than other ewes. Thus selection of ewes born as twins or greater multiples from young mothers, large sheep of certain breeds, and those with open faces, free of wool, can be used to increase the lambing rate to 150 percent or greater in a flock.³ The mature ewes of the Finnish Landrace and Romanov breeds or their crosses frequently produce triplet or greater numbers of lambs.^{134,155}

Ovulation rates in Merino, Scottish Blackface and Finnish Landrace was 1.09, 1.36 and 3.37, respectively.¹⁵⁵ The breeding season midpoints for these three breeds were November 25th, December 20th and January 23rd, respectively and the incidence of "silent" ovulation for the three breeds was 35.6 percent, 16.2 percent and 7.3 percent. This strongly emphasizes the genetic differences between widely different breeds of sheep studied at one location.

Ovulations were slightly more frequent on the right ovary of ewes than on the left, 53 to 55 percent and 44 to 47 percent, respectively.^{24,80} In single ovulations 62 percent were on the right ovary. Twenty-six to 32 percent of embryos migrated from one horn to the other when twin ovulations occurred on one ovary; while only 0 to 10 percent migration occurred when a single ovulation occurred from one ovary.²⁴ As in cattle, an increased embryonic loss occurred in twin ovulations especially with twin ovulations from one ovary.

The LH content of the anterior pituitary gland started to be discharged at the onset of estrus and was completed 6 hours later when 52 percent of the LH in the

pituitary gland had been released.¹²⁹ The plasma surge in estradiol from maturing Graafian follicles stimulated by FSH preceded the LH release or surge. Small amounts of estrogen injected into sheep stimulated LH release.¹²⁹ A recent review of ovulation reported the maturing Graafian follicle is about 0.5 cm. in diameter and the plasma progesterone level is below 0.2 ng/ml. 1 to 2 days before estrus. The estradiol produced by the follicle reaches a peak of 15 pg/ml. in the peripheral plasma 24 hours before the onset of behavioral estrus that induces the release of GnRH and LH surge about 4 to 6 hours after the onset of estrus. The ovulatory follicle enlarges rapidly to about 1 cm. in diameter at the time of ovulation.¹²⁸

Gonadotropin levels in the anterior pituitary gland were high and constant during the nonbreeding season as were the presence of small follicles on the ovaries.^{1,88} Thus the onset of the estrous cycle in the late summer months associated with declining daylight may be triggered by a greater release of FSH and/or LH associated with an increased estrogen production. The ewe's pituitary gland is about 10 times as potent as the cow's in LH content and 5 times as potent in FSH content.¹

In the ewe progesterone is needed as well as estrogen to produce psychic estrus.² This probably accounts for some silent heats accompanying ovulations at the outset of the breeding season. Sixty-four ug. of estradiol was necessary to induce psychic estrus in ovariectomized ewes; if the injection was preceded by progesterone administration only 20 to 25 ug. of estradiol was needed to produce psychic estrus.¹ During the estrous cycle 10 to 15 mg. of progesterone in oil daily inhibited estrus. After ovulation, progesterone levels in blood plasma increased from 22.2 ng/ml. to 37.6 ng. by 9 or 10 days of the cycle and then decreased to 21.8 ng/ml. about 13 to 15 days after estrus or 2 to 3 days before the next estrus.¹¹⁹ The highest rate of estrogen excretion in the urine occurred at estrus with the lowest rate of excretion two days after estrus. No estrogens were found in the urine in sheep in the anestrus season. The principal estrogen excreted was estrone but some estradiol was also present in the urine.¹¹⁸ If conception occurred the level of progesterone in the peripheral plasma generally rose from 2 to 4 ng/ml. the first few weeks of gestation until day 60. After day 60 progesterone levels rose to 12 to 20 ng/ml. by day 110 due to increased progesterone production by the conceptus.¹²⁸ Ovariectomy after 55 days of gestation in the ewe is not generally followed by abortion because progesterone is produced by the placenta.

Following copulation and ejaculation of sperm into the vagina of the ewe, **sperm cell transport** is very rapid with spermatozoa appearing in the uterine tube within

15 minutes. Dead spermatozoa were also transported at a similar rate. Although about 800 million spermatozoa are in an ejaculate of a ram, some hours after copulation less than 100,000 sperm cells were in the uterus and several thousand or less were in the uterine tube. Spermatozoa retain viability and fertility for about 24 hours in the genital tract of the ewe.² The capacitation time for spermatozoa in ewes was 1.5 hours. Fertilization occurs in the uterine tube with sperm penetration of the ovum beginning about 3 hours after ovulation, pronuclei formed about 3 to 9 hours after ovulation, and the first cleavage of the ovum occurred about 20 to 30 hours after ovulation in the ewe.² The fertilized ovum enters the ovine uterus 3 to 4 days after ovulation.^{79,80} The low rate, 9 to 10 percent, of embryo migration from one horn to the other after single ovulations and the high rate, up to 60 percent or greater, after double ovulations has been discussed previously.²⁵

As in cows, estrogens injected into ewes cause a regression of the corpus luteum.^{14,64} Exogenous gonadotropins (HCG or LH) protected the C.L. of the ewe from regressing after an injection of exogenous estradiol. Developing follicles play a role in the regression of the C.L. in ewes.⁶³ Small doses of estradiol, 39 to 150 ug, given to ewes immediately before mating did not adversely affect sperm transport, ovum fertilization or embryo survival.⁷² Large doses of estradiol may hasten or delay ova transport and prevent conception.

Because ewes experience about 20 percent early embryonic deaths, especially those mated early in the breeding season, 0.4 mg per lb. of body weight of progesterone in oil was given daily subcutaneously to ewes for varying periods after breeding. This had no beneficial or harmful effects on fertility or embryonic deaths. Injections day 1 through 5 did tend to cause smaller C.L., but all ewes carried normal embryos.¹⁶⁷ Ovulation could be induced experimentally in both the luteal and follicular stages of the estrous cycle of ewes but ova produced during the luteal phase had a very low rate of fertilization.¹¹⁰ When natural C.L. were removed by laparotomy on day 5, 9 or 13, ewes came into estrus at 2 to 3.5 days after removal.^{86,87}

Transportation stress induced follicular growth and ovulation in anestrus ewes but since no declining C.L. were present no estrus was exhibited.^{152a} When hydrocortisone acetate was given to ovariectomized sheep, a marked increase in FSH occurred. In intact goats hydrocortisone stimulated the growth of luteal phase follicles and reduced the size and progesterone concentration of corpora lutea. The effect of hydrocortisone on inducing parturition in late pregnancy in ewes, cows and rabbits has been discussed previously. Parturitions in sheep late

in gestation were induced within 48 hours by the injection of 10 to 20 mg of dexamethasone.²

Utero-ovarian relationships in the ewe are similar to those observed in cows. Hysterectomy from early to mid-cycle in the ewe results in the maintenance or persistence of the C.L. for about 150 days or for the approximate length of gestation.^{64b,86,136} Unilateral hysterectomy regularly prolonged the life span of the C.L. about 17 days on the adjacent or ipsilateral ovary, but had no effect on the opposite or contralateral ovary. In one ewe with a C.L. on each ovary, unilateral hysterectomy prolonged the life of the ipsilateral C.L., while normal regression of the C.L. on the opposite ovary occurred. As in the cow the regression of the C.L. in a nonpregnant intact ewe is caused by prostaglandin released from the endometrium after the middle of the estrous cycle. The presence of an embryo in the uterus at 13 days of the cycle prevents the normal involution of the C.L. and the initiation of another estrous cycle by inhibiting the release or formation of prostaglandin and allowing pregnancy to proceed.¹³⁶ A single embryo in one horn can maintain a C.L. in both ovaries in intact ewes because the blastocyst extends into both horns.⁶⁷ Removal of the hypophysis of the pregnant ewe on day 30 of gestation caused abortion due to luteal regression because of the removal of the source of luteotrophin or prolactin.¹³⁶ If the hypophysis is removed from a pregnant ewe after day 60 of gestation, no abortion occurs because progesterone and possibly a luteotrophin are secreted by the placenta.

The presence of intrauterine plastic spirals or coils, an intrauterine device or I.U.D. causes a variety of effects in ewes that are somewhat similar to cows. A plastic coil in one horn of the ovine uterus inhibits sperm cell transport into the uterine tube and fertilization on both sides of the reproductive tract, and promotes spermicidal conditions in the uterine lumen.⁷⁰ The presence of an I.U.D. in the ewe's uterus caused more than 75 percent of the uterine contractions to be propagated toward the cervix; while in control ewes over 60 percent of contractions were propagated toward the uterine tube.⁹⁶

An I.U.D. introduced into a ewe's uterus within the first 3 days after estrus would prevent the normal development of the C.L. and hasten its regression and shorten the estrous cycle.⁶² If the I.U.D. was inserted on the 8th day of the cycle, the cycle length was normal or slightly prolonged.^{62,156} In I.U.D.-treated ewes about 25 percent of the ovulations were quiet or silent apparently due to a lack of enough progesterone from the regressing C.L. to cause the normal manifestations of estrus.⁶² When a uterine infection was produced by injecting *E. coli* into a ligated horn with an adjacent C.L. on day 3, C.L. growth was suppressed and early regression of the C.L. and a

shortened cycle occurred; infection at day 11 of the cycle caused a prolonged cycle. Thus infection acted in a manner similar to an I.U.D.¹⁸

Synchronization of estrus in ewes during the breeding season is possible using prostaglandins and long term suppression of estrus, 12 to 16 days, with progestogens alone, usually as vaginal pessaries impregnated with 60 mg. MAP or 30 to 40 mg. of flugestone (**Cronolone**), or combined with 500 I.U. PMSG on the day the pessary is removed as in anestrus ewes.^{87,91b,93b} A variety of treatments utilizing the prostaglandins have been proposed.¹⁴⁴ Ewes are observed carefully for estrus for 5 days since prostaglandin is ineffective if given before 4 days after estrus. Those not in estrus during this period are given 5 to 15 mg. P.G.F._{2a} or 100 to 125 ug. cloprostenol and usually 50 to 80 percent of the ewes will show estrus in 2 to 5 days after the injection and accept service by the buck for a period of 31 to 52 hours. Ovulation rates are normal. If random injection of the flock is used then all the does are given prostaglandin and the second dose is given 9 to 11 days later with up to 90 percent or more of the flock coming into estrus within 1-1/2 to 5 days. Giving 500 IU PMSG 2 days before the second dose of prostaglandin induces an earlier onset of estrus.¹⁴⁴ Although the evidence is somewhat contradictory, there is a lower fertility or conception rate, seldom exceeding 56 percent, on breeding the first estrus after the use of prostaglandins. This is apparently due to inhibition of spermatozoal transport in the cervix and uterus due to loss of motility and death of sperm similar to the effects of the persistence of a level of progesterone.^{72a,73} This reduction in fertility is variable and apparently not as noticeable as that following long term injectable progesterone therapy to synchronize ovine estrus. A recent study of double injection of P.G.F._{2a} at a 10 mg. dose at an 11 day interval in ewes in the breeding season compared to MAP vaginal sponges for 8 days with 10 mg. P.G.F._{2a} given at the time of withdrawal of the sponge resulted in 82 to 93 percent of the ewes showing estrus in 1-1/2 to 5 days, (1-1/2 to 3-1/2 days for the latter group) and a 60 to 80 percent conception rate, average 71.7 percent, after AI service 12 and 24 hours after the onset of estrus.⁹⁴ Worldwide the vaginal pessaries or sponges and PMSG are most preferred for estrus synchronization in cycling and anestrus ewes.⁸⁷

Synchronization of estrus in anestrus ewes has received much study over the past 20 years. Results of studies utilizing progestogens given orally, intramuscularly, intravaginally or subcutaneously as implants alone or combined with PMSG up to 1971 have been reviewed.¹²⁷ Although many of these studies were encouraging, at present approval by the Federal officials

for use of progestogens has not been forthcoming. PMSG in a standardized form is not readily available in the U.S. The estrogens have been proven to be of no value for synchronizing or inducing estrus in ewes. Fertility of ewes following the use of long-term progestogen therapy is reduced at the first estrous period due to poor sperm transport in the ewes' genital tract.^{73,128} Use of vaginal pessaries containing progesterone have shown the most promise because the exogenous source of progesterone can be rapidly removed allowing the prompt development of the estrous cycle. However problems of vaginitis, adhesion of the pessary to the vaginal wall and loss of pessaries have complicated this procedure. Prostaglandins are ineffective during the anestrus period because functional corpora lutea are not present. All of the above chemical procedures for estrus synchronization were most effective during the transitional period between the anestrus period and early in the normal breeding season. Synchronization of estrus or establishing the estrous cycle in the anestrus period of late spring and early summer has been less successful and impractical because of a great variation in response and results.

Furthermore inducing estrus in ewes out of the regular breeding season creates additional problems with rams as at this time libido and production of spermatozoa are at a low level.¹²⁸ This can be alleviated to some extent by maintaining and introducing a large number of rams. Artificial insemination of ewes is costly because of the time and labor involved in estrus detection, inseminating at the correct stage of estrus, and the collection and extension of fresh ram semen. Frozen ram semen has a reduced survival time in the ewe's genital tract so timing of insemination is important. It is usually recommended that ewes be serviced 12 to 14 hours after estrus is first observed or 48 to 55 hours after progestogen withdrawal in synchronized ewes.¹²⁸

Ewes synchronized during the anestrus season and the breeding season with progestins and PMSG had an increased ovulation rate but had markedly higher reproductive losses, 58 and 49 percent respectively, compared to untreated ewes bred during the breeding season, 25 percent.⁹⁵ These losses were due to both increased fertilization failure and increased embryonic mortality. The increased fertilization failure was due to both decreased tubal numbers of spermatozoa and a decrease in number of accessory spermatozoa/ovum possibly related to poorer out-of-season semen quality and abnormal sperm transport.⁷³ The increased embryonic mortality in treated ewes was associated with an increased variation in stage of embryo development within the ewes indicating asynchronies of timing of onset of estrus, ovulation and fertilization.⁹⁵ The use of artificial insemination with fresh

semen produced better conception rates than the much lower conception rates with frozen semen.⁵⁸ Further studies on estrus synchronization and induction during the anestrus season are continuing. (See ewe productivity at the end of this chapter.)

Pathological Changes in the Reproductive System of the Ewe

Anatomic defects of the genital tract of female sheep are uncommon. Intersexes may occasionally be observed in sheep. Freemartins, such as occur in twin births in cattle, are rare in sheep.⁹³ Since other anatomic defects or arrests in development such as uterus unicornis, uterus didelphys, persistence of the median wall of the Mullerian duct with a fleshy pillar caudal to the cervix, other arrests in development of the Mullerian duct, and persistence of the hymen occur in other species, they probably occur in sheep but are rarely recorded. Undoubtedly they are highly unusual. One ewe was reported with a bifurcation of the cranial part of the vagina.³⁸

Pathological lesions or diseases of the reproductive system in sheep and goats are similar in most respects to those in cattle. Vulvitis, vaginitis, cervicitis, metritis, pyometra, perimetritis, and salpingitis may occur in sheep usually as sequelae to dystocia, difficult parturition, retained placenta, and delayed involution of the uterus.⁹³ These acute or chronic infections in the ewe are handled in a manner similar to the treatment for these infections in cattle. In retained placenta, which is much less common in ewes than cattle, the uterus may be treated locally, preferably with a broad-range antibiotic, and the placenta is allowed to drop away. For a valuable ewe a

Figure 151. Parovarian Cysts Adjacent to the Left Ovary in a Ewe. (Courtesy K. McEntee.)

better treatment is to give parenteral antibiotics for 3 to 5 days and not to place any drug in the uterus or to attempt to remove the afterbirth. Manual removal of a retained placenta is not indicated due to the small size of the genital tract.

A group of 25 ewes that had failed to breed for two consecutive seasons were mated a third season.¹¹¹ Eleven ewes lambled after only one service. Five ewes were bred and apparently conceived, but on postmortem examination showed evidence of interruption of pregnancy before term, and 8 ewes were bred at several estrous periods but failed to conceive. On postmortem examination 6 of these sterile ewes were found to have occluded or cystic uterine tubes and one ewe had a mummified fetus. An incidence of 8.7 percent of abnormalities in the reproductive tracts of 276 ewes was described.⁹³ These included parovarian cysts, hydrosalpinx, bursal adhesions, and adhesions of the uterus to the abdominal viscera. These lesions apparently account for only a small percentage of the infertility in ewes.⁴⁶ Extensive and severe changes could be produced in the genital tract in the ewe by feeding chlorinated naphthalenes.⁹⁹ These changes were characterized by an enlarged uterine horn and cervix due to marked squamous metaplasia with profuse keratinization of the endometrial glands as well as keratinization and ulceration of the vulva. Naturally-occurring cases of hyperkeratosis or X disease have not been seen in sheep.

Tumors of the ovaries and genital tract of the ewe are rare. Several leiomyomas affecting the uterus of sheep have been recorded.⁵⁰ Rare granulosa cell tumors of the ovaries and leiomyomas of the uterus of sheep have also been reported.^{27,109} An adenoma of the pituitary gland of a ewe has been observed.²⁷ Rare cases of lymphosarcoma or reticulum-cell sarcoma, myeloma and squamous cell carcinoma of the vulva of ewes have been described.¹⁰⁶

Infections of the genital tract other than postpartum infections apparently are seldom a cause for infertility in ewes. This may be explained in part by the long period between breeding seasons, in which recovery can take place. Vibriosis and brucellosis, the latter usually due to *Br. melitensis* or *Br. abortus* are characterized by abortion. Infertility in ewes associated with vibriosis and brucellosis has not been described. The incidence of embryonic deaths in ewes bred early in the breeding season was about 20 percent. There was no indication of an infection associated with the condition.^{38,41} In observing and examining rams with various degrees of infertility, an enzootic venereal type of infertility spread by the ram to the ewe, as is observed in cattle has not been reported.^{66b,160} The infectious causes of abortion, such as

listeria, rickettsial agents, and others have not been associated with infertility.

Ulcerative dermatosis, lip and leg ulceration or ulcerative venereal disease due to a virus can be spread by an infected ram or buck to a susceptible ewe or doe through breaks in the skin, causing a necrotic, swollen, bleeding lesion on the cutaneous and mucous surfaces of the vulvar lips.^{4a,4b,13,146,147} The lesion usually starts at the inferior commissure of the vulva and spreads upward. Only rarely is the vagina involved. The lesion is an ulcer covered by a scab. Removal of the scab reveals a shallow, bleeding crater containing a small amount of creamy pus. The disease is usually spread to the ewe at the time of coitus by an infected ram that has similar lesion on its penis and sheath. Occasionally the disease may spread to wethers and to ewes that have not been bred.^{4b} This venereal disease of the external genitals should not be confused with contagious ecthyma which is due to a different virus and the lesions are proliferative. In a recent report it was indicated that the viral agents causing these two diseases might be related since there was cross neutralization between the two viruses in serologic studies.¹⁴⁵ The symptoms of ulcerative dermatosis usually subside within a week or 10 days. No successful specific treatment is available. Five percent copper sulphate has been advised for use in treating these lesions but should only be applied externally. No vaccine is available. Rams with lesions on the prepuce causing posthitis should not be purchased or placed with ewes during the breeding season. This disease, although a cause for cessation of breeding until the lesions are healed, is not characterized by infertility. However in the acute phase the ewe may refuse to copulate due to irritation and pain.

Ureaplasma have been isolated from the genital tracts of ewes with granular vulvitis³⁴ and from the uterus of a few ewes that apparently suffered early fetal losses.^{92b} A recent report indicated that in sheep, ureaplasmosis appears to be a venereal disease possibly capable of causing infertility, low birth weight of fetuses,^{92a} and acute vulvitis.^{6b} The significance of infertility from this common organism in the genital tract of ewes and cows must be further evaluated.

Mules' operation has been described^{108,166} for the **prevention of blowfly strike** (myiasis) caused by folds of skin on either side and below the vulva becoming moist with urine or soft fecal material resulting in an inflammation, bacterial growth, and an odor that attracts the blow flies to lay their eggs in the site. The moist fleece provides the hatching maggots with food, warmth and protection. Since clipping the wool in the area or applying insecticides to prevent blowfly strike are short-lived practices, Mules' operation has been used extensively in

Australia to increase the area of smooth skin around the vulva and anus in Merino or other heavily-fleeced breeds. Also, the tail should be docked short so that no long wool lies against the vulva. Mules' operation is performed on recently clipped sheep during the cold season in the spring or fall when there are no flies. The folds of skin ventral and lateral to the vulva are removed and healing is allowed to occur without suturing.¹⁶⁶ The resulting healing and scarring eliminates the skin folds and long wool lateral and ventral to the vulva and prevents blowfly strike.

A vulvitis that occurred in ewes on clover pasture similar to the noncontagious posthitis that was seen in wethers on lush clover pasture has been described in Australia.¹³⁸ There was no evidence that estrogens in the clover were a factor in this disease. The ulceration, scabbing and scarring of the ventral commissure of the vulva in this disease led to its disfigurement or loss with a resulting soiling of the rear parts with urine predisposing to flystrike even in ewes on which Mules' operation had been performed.

Nutritional deficiencies in sheep and their effect on fertility have been extensively studied. The same general nutritive deficiencies affecting reproduction and fertility in cattle also affect sheep. Most deficiency diseases affecting reproduction in ewes on range are multiple and involve a lack of protein, and a lack of vitamin A. The effects of inanition on fertility are more pronounced in immature than in adult animals and they are characterized by failure of estrum and delayed puberty. A low plane of nutrition in ewes resulted in subestrus with undetected estrus, with cycles 26 to 42 days in length.⁸⁵

A low protein diet is to be avoided if a high percentage of lambs is to be produced.¹⁰⁴ The symptoms of vitamin A deficiency are similar in the ewe and cow.^{74,123,124} Pregnancy in vitamin A deficient ewes usually terminates in abortion or the birth of dead or weak young. The female is more susceptible to vitamin A deficiency than is the male. The estrous cycle, ovulation, and early fetal development are not noticeably affected in sheep even when partial night blindness due to Vitamin A deficiency is exhibited.^{123,124} In drouth years feed low in vitamin A is often also low in energy, protein, and phosphorus. Vitamins E, C, B complex, and D are not necessary for reproduction in the ewe. It is possible, however, that a lack of cobalt, an essential part of vitamin B₁₂ would cause a deficiency of rumen bacteria, and anorexia with secondary inanition. Severe deficiencies of cobalt may result in debility, failure of estrum, and the birth of weak lambs. Estrum in ewes was regular on a cobalt-deficient diet but only 48 percent of the lambs born to cobalt-deficient ewes were strong, as compared

to 92 percent of the lambs from ewes fed a cobalt supplement.¹⁶ Postnatal losses of lambs from ewes fed low levels of cobalt were 58 percent as compared to 17 percent for the lambs nursing the ewes receiving cobalt in their diet. Copper deficiency in sheep characterized by infertility and irregular estrous periods has been reported in certain areas of South Africa.

Reproduction is not affected by a low phosphorus diet until the usual symptoms of phosphorus deficiency develop.^{123,124} Symptoms of phosphorus deficiency in sheep are the same as in cattle. A low protein diet was not as severe as one low in both protein and phosphorus.¹⁰⁴ The reproductive symptoms of a phosphorus deficiency, which is usually complicated by low protein and vitamin A level, are: delay in onset of puberty and estrum, irregular estrous periods, and a tendency to produce only one lamb every two years. Abortions are uncommon but weak or dead young may be expelled at term. Impaired fertility is unlikely when the ewe or doe is receiving protein supplements or minerals containing phosphorus. Other trace mineral elements such as iron and iodine may also be lacking. In several mineral and protein deficiencies, ewes may pull and eat the wool of other ewes in the flock.

Ewes but not rams, require Vitamin E and selenium to have satisfactory reproduction.^{20,35,69} Not only could selenium deficiency in ewes in New Zealand cause neonatal death losses due to several myocardial lesions but in selenium deficient areas, farms would experience an incidence of 10 to 30 percent barren or open ewes after service and apparent conception.⁶⁹ Giving ewes 5 mg. of selenium monthly during pregnancy or 25 mg. in one dose after mating reduced the number of barren or open ewes to 2 to 4 percent compared to 30 percent open ewes in the control or untreated ewes. Although evidence would indicate that a selenium deficiency occurred in New Zealand, it should be noted the diseases corrected by selenium therapy were referred to as "selenium responsive" diseases. It is possible that some other factor(s) may cause the primary or basic disease.

Ewes fed kale had a short duration of estrus of about 22 hours and a slight increase in embryonic deaths.¹⁶¹ Kale feeding also resulted in anemia and produced a goiterogenic effect.

In Australia a specific type of infertility in sheep due to pasturing on subterranean clover rich in estrogens is observed. In this condition, the incidence of sterility in ewes may be 30 percent or even greater.¹⁰ Dystocia due to uterine inertia may have accounted for 30 to 40 percent of the fetuses being expelled or removed dead and for the death of 15 to 20 percent of the ewes. Prolapse of the vagina was seen in approximately 10 to 12 percent of the ewes. The sterile ewes failed to conceive on re-

peated services and on postmortem examination of the genital tract a cystic degeneration of the endometrium was observed that varied in severity from microscopic to gross lesions. The estrous cycles were normal and cystic ovaries did not occur. The infertility persisted and was irreversible even when the affected ewes were changed to pastures free of the subterranean clover.^{132,150,151} Ovulation occurred regularly but fertilization or implantation were prevented by the pathologic "Swiss cheese" type of endometrium. In a recent study of 49 ewes with a permanent phytoestrogenic sterility it was demonstrated that only 57 percent of the affected ewes showed estrus accompanied by ovulation vs. 90.5 percent of the control ewes, and 21 percent of the ovulations in affected ewes were not accompanied by behavioral estrus vs. only 4 percent in control ewes.¹ Progesterone assays were normal in 7 of 12 affected ewes that had normal length estrous cycles. Four of 5 other ewes had prolonged estrous cycles of 21 to more than 23 days with prolonged high levels of progesterone. In 43 affected ewes with a C.L., the C.L. failed to regress in 5 of 7 ewes with hydrops uteri and 3 of 36 ewes without hydrops uteri. These abnormal life spans of C.L. in affected ewes were considered to be caused by endometrial changes in the uteri of affected ewes.¹

The "toxic" principle in the Dwalganup strain of subterranean clover was an isoflavone derivative, genistein or 5:7:4 trihydroxyisoflavone, that was one-fifth as potent as estrone in estrogenic activity.^{30,46} Genistein may be found in amounts of 100 mg. per 100 gm. of fresh subterranean clover. Reducing the amount of subterranean clover in a pasture by increasing the amount of grasses controlled the disease. Possibly since the pasture season coincides with the anestrus season in sheep, when the ewe is not cycling and progesterone is not produced, the ingested estrogens may cause more severe lesions and disease in sheep than in cattle which are generally not affected by the level of estrogen in the clover pastures. Ewes in Australia, grazing red clover pastures were similarly affected as ewes on subterranean clover pastures.^{9,149} Estrogens have also been found but in lower quantities in other legumes such as ladino clover and birdsfoot trefoil.^{11,120,131} Injection of 0.03 to 0.09 mg. of stilbestrol per ewe 3 days a week for 6 months to 2 years caused a high incidence of sterility, persistent and permanent cystic change in the endometrium.¹⁵¹ A few ewes with cystic endometritis developed pyometra in a manner resembling that seen in dogs. The estrous cycle remained normal. Cystic ovaries have not been described in ewes.

Fertilization Rates and Prenatal or Embryonic Death Rates in Ewes. In 80 pregnant ewes there were normal

fetuses equal to only 87 percent of the corpora lutea present. The numbers of atrophic fetuses and missing eggs were about equal.^{68a} The incidence of fetal death was estimated in a similar manner and it was reported that 16 percent of the corpora lutea were not accounted for by live fetuses but early embryonic death with complete resorption could not be detected.^{71b} Increased fetal deaths occurred with an increase in number of ova released, 8 percent with 1 ovum, 26 percent with 2, and 43 percent with 3 ova. This fetal mortality may be more apparent than actual when these figures are interpreted to indicate that with a large number of eggs more embryos must die before the pregnancy is terminated.^{22,23} Fertilization rates and embryonic death rates in Western ewes bred throughout the breeding season showed the overall embryonic death rate on the basis of 18-day nonreturns was 20 percent but that on the basis of the lambing rate the embryonic death rate was nearly 30 percent.^{22,23} A much higher embryonic death loss developed in ewes with 3 C.L. compared to ewes with 1 or 2 C.L.⁸⁰⁻⁸² A 20 to 24 percent loss of fertilized eggs is normal in the ewe.¹³⁰ A prenatal death loss in Merino sheep in Australia of about 25 to 30 percent from 3 weeks after conception to term was noted.^{107b} Ewes bred once early in the breeding season showed an embryonic death rate of 20 percent and a failure of fertilization in 38.9 percent of the ewes.^{38,41} Failure of fertilization was the most important factor accounting for the low lambing rate. Fifty-four of these ewes bred artificially with semen having a 20 to 50 percent spermatozoan motility rate had about a 31 percent conception rate, while 100 ewes bred with semen having a 60 percent or better motility rate had a 62 percent conception rate. The embryonic death rate in both groups was about equal. When rams from high and low prolificacy lines of breeding were used on unrelated ewes there was no difference in ovulation or fertilization rates. However pregnancy rates and lambing rates were higher in ewes bred to rams selected from the high prolificacy lines than rams from the low prolificacy lines.²¹

Ewes bred early, August 1 to September 15, had a fertilization failure of 64.3 percent, 16.7 percent due to defective ova and 47.6 percent due to poor sperm, with a conception rate of 25.5 percent.⁷⁷ In ewes bred from September 16 to October 25, the respective figures were 34.3 percent, 29 and 31.4 percent, and a conception rate of 59.2 percent. The deaths of the embryo were high early and late in the breeding season.⁵ In asynchronous heats and ovulation, the eggs failed to fertilize. The high figure of 40 percent early embryonic deaths by 24 days of gestation in 65 ewes was reported.⁵

High ambient temperatures, especially during and

shortly after estrus, have an adverse effect on fertilization and the survival of the zygote. Ewes exposed to an ambient temperature of 90° F on the 12th day of the cycle through estrus had a fertilization rate of 51.9 percent, as determined 3 days after breeding, compared to a 92.6 percent rate for control ewes kept in a cool environment.^{38,41} Only 3.7 percent of ova from the control ewes were grossly abnormal compared to 44.2 percent of the ova from the ewes kept at 90° F. Embryo loss based on fertilized ova that died was 91.7 percent compared to 4 percent loss in control ewes at 24 days after breeding. In sheared ewes there were 32 percent abnormal ova and the rise in body temperature was 1.8° F. In unsheared ewes there were 55.6 percent abnormal ova and the rise in average body temperature was 2.6° F. Ewes kept at an ambient temperature of 90° F for 24 hours during estrum had only a 10 percent lamb crop from service at that estrum. If the 90° F temperature was maintained for 24 hours at 3 or 5 days of gestation the lamb crop in each group of ewes was 35 and 40 percent. The control ewes produced an 85 percent lamb crop. The early ovum during the initial stage of cleavage is most sensitive to heat.⁴² This effect on the early zygote in ewes is similar to the effect of high ambient temperatures on cattle shortly after service (See Infertility in Cows) After reviewing the adverse effects of thermal stress in ewes on fertilization rates early embryonic death rates and lambing rates, one study⁷⁵ showed that maintaining ewes at high ambient temperatures, 36° C, resulting in a rise of 1.4° C in body temperature caused significant decreases in the incidence of behavioral estrus, the preovulatory L.H. surge and in the plasma progesterone level between days 7 and 13 of the cycle. These endocrine imbalances may contribute to the decreased reproductive efficiency of heat-stressed ewes.⁷⁵ Rams exposed to high ambient temperatures, especially with much wool on the scrotum also have greatly lowered semen quality due to degeneration of the seminiferous tubules. Another study^{3,4} confirmed the above effects of high ambient temperatures on the early ova by ova transfer. A recent study indicated that the greatest embryonic death loss in heat-stressed ewes conducted during early pregnancy occurred from days 10 to 23 of gestation.⁴² Thus 90° F ambient temperatures are harmful to fertilization and early embryo survival and may be a cause of seasonal infertility in ewes. Ewes to be bred early in the season should be kept sheared and cool. Possibly early breeding in the summer months should be avoided. Ewes that were heat-stressed during the last two-thirds of the gestation period when compared to ewes kept cool, had fewer lambs, 81 vs. 100 percent, the lambs were lighter and smaller and fewer lambs survived, 57 vs. 81 percent.¹³³ A high plane of feeding had no effect

on embryonic or fetal death rates. Ewes giving birth in a hot environment had a significantly shorter gestation period. This is interesting in the light of the influence of the glucocorticoids and stress on the initiation of parturition.

Ewe Productivity—Because ewes can produce twins or triplets and have a 145-day gestation period it should be feasible to produce 3 lamb crops in 2 years. This goal has been sought by many investigators and sheep farmers but currently a practical way to achieve it has not been formulated.¹²¹ It is recognized that if such a goal is to be reached management of the flock must be excellent. Some of the factors mitigating against such a goal is the photoperiodicity of the breeding season in sheep. Although excellent lamb crops can be obtained from fall and winter breeding seasons, the lamb crop from late spring breedings, whether produced by “chemical” or light manipulation methods has generally been low.^{43,153} Even with the best of control and management it is difficult to produce more than 2 lambs/ewe/year.^{91b} Of the “chemical” methods for inducing estrus and conception the prostaglandin and progestogen treatments alone can not be recommended. However, even the progestogen-PMSG controlled breeding is best in the fall breeding season.¹²¹ Progestogens and prostaglandins have not been approved by Federal agencies for use in ewes and PMSG is not readily available in the U.S. Yearling or younger ewes do not do well in controlled breeding regimens. Possibly certain breeds might be more suited to this intensified production scheme.

Currently the best or most easily accomplished practice to increase ewe productivity is to crossbreed using the Finnish Landrace on the standard breeds in the U.S.^{43,113} Half-bred Finn ewes gave birth to 42 percent more lambs and weaned 24 percent more kilograms of lambs than 1/4-Finns and 52 percent more lambs and 38 percent more kilograms of lamb than did Suffolk-Rambouillet cross ewes.¹¹³

INFERTILITY IN DOES

Reproductive Physiology

Puberty—Depending upon breed, season of birth, latitude and level of nutrition, puberty usually occurs about 6 to 8 months of age in the Swiss breeds of goats in the temperate latitudes. Young bucks and does should be separated before 5 months of age. Certain pygmy does may reach puberty by 3 months of age.^{22,25} Does should not be bred until they reach 60 to 70 percent of their adult weight, about 80 to 90 pounds, to assure higher

conception rates and safer parturitions. Delaying breeding until they reach this weight often results in breeding does after they reach a year of age. Twin births are common in young well-grown primiparous does. In later parities twin or triplet births are more common and quadruplet births are not rare.

The estrous cycle—Does and bucks in northern temperate climates are photoperiodic with a breeding season extending from late summer (August) to early spring (February and March) with the peak of the breeding season in late fall (October) through early winter (December). During this breeding season brought on by shorter daylight hours, the does are polyestrous with most cycles being 20 to 21 days in length.^{22,25} In the tropical regions near the equator the breeding season is not dependent on photoperiods and extends throughout the year.^{13,25} Short cycles of 5 to 12 days in length are not uncommon in young does at puberty or older does at the beginning of the breeding season. Long cycles 40 to 50 days, at the end of the breeding season are also fairly common.^{6b,22,25} Further studies on the cause of these abnormal cycles are indicated. Estrus may occasionally, 1 to 5 percent, be observed during pregnancy.^{6b} Between early March through May, nonpregnant does in the temperate zones are anestrous. Between May and July is the transition period from anestrous to ovarian activity and cycling. Bucks like rams and stallions do not have a restricted breeding season as do females of those species. But during the breeding season bucks are sexually more active, have a stronger “buck odor,” and produce better quality semen. Like sheep and swine placing bucks in a group of does early in the breeding season often induces estrus in many of the does within 7 to 10 days,^{22,25} probably due to the release of GnRH or LH (see ewes).

The estrous period is variable in length depending on the interpretation of behavioral signs indicating the onset and termination of this period. It is generally given as 32 to 40 hours with ovulation occurring about 30 to 36 hours after the onset of estrus.^{19,22,25} In the Angora breed estrus is about 22 hours in duration.²² Another study²⁵ indicated proestrus lasts about 24 hours during which time the buck follows the doe but she will not stand for service. Once standing estrus occurs it only lasts 12 to 24 hours. When does are observed in estrus they should be bred then and again 12 hours later.^{13,26b}

Signs of estrus in does is detected by a teaser or breeding buck because does, like mares and ewes, rarely mount other females or stand to be mounted by other does as do cows.²⁵ If a rag is rubbed over an older buck's scent glands located caudomedially to his horns and stored in a tightly-covered jar, this “buck jar” is warmed, opened and presented daily to each doe in a small flock.²⁵ If the

doe is in estrus she will be very interested in the jar. In the presence of a buck a doe in estrus will stay close to him. Her external genitalia may be more swollen, reddened and moist during estrus. Rapid up and down or side to side movements of the doe's tail, flagging, is a good sign of heat along with restlessness, increased frequency of urination, increased bleating and decreased milk production and appetite. Vaginal smears are of limited value to identify the stage of the cycle.²⁵ As in other domestic species a speculum examination of the vagina and cervix will show an increased reddening of the mucosa, a variable amount of clear mucus in the cervix and on the floor of the vagina early in the estrogenic stage of the cycle. The mucus becomes more cloudy together with a more relaxed cervix in midestrus. Metestrous bleeding, as occurs in cows, is not present in does.²⁵ Sexual behavior in the buck usually consists of nuzzling the doe's perineum, pushing or butting her rear parts, flehmen and flicking out the tongue, striking out with a forefoot and emitting a low-pitched sound.^{26b} Mounting and copulation is rapid and quick.

As in sheep the introduction of bucks into a flock of does at the beginning of the breeding season produces a prompt stimulation of the onset of the estrous cycle. This effect is probably caused by the combined senses of sight, smell and contact. In one study 66 percent of the does kidded between the 8th and 12th day of the kidding season. This indicated that most does come into estrum about 10 days after the bucks were introduced.^{20,21,24a} Recent reports^{17,27} have demonstrated rather conclusively that introduction of bucks into flocks of does in the early breeding season or late anestrus season and observing and monitoring the latter with progesterone assays of blood plasma, that a synchrony of estrus was obtainable. Sixteen of 17 does were in estrus at an average of 5.5 ± 1.3 days after the bucks were introduced, with 31 of the does showing a subsequent progesterone profile, with concentrations of 3 to 4 ng/ml., characteristic of a normal diestrous period. When the bucks were introduced into the control does 15 of the 17 exhibited estrus within 7 ± 1.5 days. Short six-day estrous cycles were seen in 4 does but the progesterone concentrations between the estrous periods never rose above 1.0 ng/ml indicating the first period was anovulatory. Thus it appears that at the onset of the breeding season in goats the first estrus is usually clinically observable and ovulatory.²⁷ This is probably related to a small, brief but significant rise in plasma progesterone levels occurring just before this first estrus.⁴ Occasionally a short anovulatory cycle has been reported.²⁷ This general pattern in does of a standing estrus and ovulation at the first estrus of the breeding season apparently differs from that in ewes in which the

first estrus and ovulation is "silent" or without signs of estrus.

Following copulation and ejaculation of sperm into the vagina of the doe, sperm cell transport is very rapid with spermatozoa appearing in the uterine tubes within minutes with fertilization occurring in the ampullae of the uterine tubes. Does usually ovulate 2 ova with 3 being quite common. So they are generally more prolific than most breeds of sheep or cattle.¹⁹ After ovulation it normally requires about 4 days for the fertilized ova or embryo to reach the uterus. As with ewes, the plane of nutrition, degree of growth and development, and freedom from disease influences the ovulation rate.²²

The corpus luteum in the doe persists throughout pregnancy as in the cow. Thus ovariectomy at any time during pregnancy will result in abortion unless progesterone replacement is instituted. The conceptus, placenta and fetus, does not produce sufficient progesterone like they do in ewes, to maintain pregnancy in the absence of the CL in the middle or latter half of gestation.¹⁹ Twice daily doses of 50 units of oxytocin given to does on days 3 to 6 of the estrous cycle shortened the cycle to 6 to 7 days. The next cycle was normal in length. This oxytocin stimulated uterine prostaglandin F_{2a} release in does to cause luteolysis in the same manner as occurs in cows given oxytocin several days after estrus to cause failure of normal CL development.

Synchronization of estrus in the doe has been studied outside the breeding season (during the anestrus period) and during the breeding season. In the former period plasma progesterone levels are very low, below 1 ng/ml. and there is little or no ovarian activity. Thus prostaglandins are ineffective during this anestrus period. PMSG at doses of 400 to 750 IU, depending on the season, month of lactation and lactation rate, given intramuscularly, or combined with HCG, have been reported to induce estrus in 2 to 3 days with about 40 to 50 percent conceptions.^{6b,13,25} Progesterone impregnated vaginal pessaries have been inserted for 17 to 21 days with PMSG given 48 hours before removal. By using large numbers of spermatozoa by artificial insemination, this procedure has been reported to be highly successful. The use of 100 ug GnRH daily for 4 or 5 days may produce estrus.²⁵ During the transition period between anestrus and the breeding season synchronization is promoted, as mentioned previously by the introduction of bucks into the herd. Manipulation of the photoperiod to advance the breeding season by keeping both does and bucks under daylight or artificial light for 14 to 18 hours a day for 3 months or 19 hours a day for 70 days in midwinter and then reducing the amount of daylight to 6 to 10 hours per day in the spring.^{4,25} This will usually successfully

synchronize the herd and result in conception in over 50 percent of the does.

A practical procedure to alter the photoperiod and breeding season of does so that a uniform supply of milk could be maintained throughout the year was described.³ Since most does under natural conditions freshen from January through May in the northern hemisphere, September through November freshenings are desired. To accomplish this 40 watt fluorescent bulbs, 1 foot (12 inches) of bulb for 10.5 square feet of floor space, 9 feet above the floor were turned on by a timer for twenty hour days starting on January 1. The lights were turned off from 1 to 5 am. Continuous 24 hour lighting did not produce the desired results. From one hour after sunrise to one hour before sunset the barn light may be turned off to save energy. This regimen was continued for 60 days for both does and bucks or until between March 1 and 15. At this time normal daylight of 14 to 15 hours exists and this shortened day length initiates estrus cycling 7 to 10 weeks later or late in April or May and cycling continues into June with 80 to 90 percent conceptions during that period. Putting yearling does and bucks on a 19 hr./day-light regimen for 70 days starting in January and then introducing the bucks to the flock 42 days after the 70 day light period resulted in 79 percent of the does coming into estrus and ovulating within 21 to 30 days.⁴ Sixty three percent of all the does or 80 percent of the does ovulating conceived at this estrus. Thus the breeding season was advanced to 60 to 80 days and a degree of synchronization achieved without hormones.

Breeding bucks need to be light-stimulated like does or their libido may be poor. If bucks are to be used in both breeding seasons their feeding and management should be excellent.³ Standing heat in light-treated does is shorter, often only 8 to 10 hours, during the artificially established breeding season and often occurs during the night hours so clinical signs of estrus are often not observed. Therefore handmating of all does is not possible and opportunity for pen mating is necessary. When the latter practice is used the attendant should check the does every other day for the discharge that mats the tail following service. Often a pen of light-treated does may come into estrus at the same time. To obtain maximal milk production during November and December 16 hours of daylight should be provided by the supplemental use of lights. If the above regimen for light stimulation during January and February is provided the entire herd, it has no effect on does or bucks not bred until the natural fall breeding season.³

During the breeding season synchronization is best achieved by the injection of 1.25 to 2.5 mg. of prosta-

glandin F_{2a} or its equivalent of prostaglandin analogue, 125 to 150 ug. of cloprostenol, to produce luteolysis or involution of the CL.^{5,13,25} If estrous cycling is occurring a single dose should result in estrus within 2 to 3 days in about 60 percent or more of the does. Another method is to inject PGF_{2a} in 2 doses four hours apart. In cycling does PGF_{2a} was luteolytic as early as day 5 of the cycle and does were in estrus 50 to 57 hours after the second injection with a preovulatory peak of LH observed at 55 hours after injection.¹⁸ Similar posttreatment results were observed with 2 treatments, 11 days apart and 100 percent of 20 does were synchronized compared to 85 percent with a single treatment.¹⁶ The estrous period was normal and 30 of 32 does, 93 percent, conceived by natural service. Although doses of 5 to 15 mg of PGF_{2a} were originally recommended to produce luteolysis in does, smaller doses of 1.25 to 2.5 mg, were found to be equally as effective.⁵

Another procedure for synchronizing estrus in does during the breeding season is administering progestogens to suppress estrus and cycling in does for 20 to 22 days^{6b} alone or usually with 300 to 700 IU PMSG at the time of progestogen withdrawal. Progestogens may be given either orally, intramuscularly, subcutaneously or as implants or intravaginally as an impregnated pessary or sponge. The latter method is most preferred because of the ease of administration and the rapid withdrawal of progesterone on removal of the sponge that favors a higher conception rate.^{25,28} In France about 45,000 does were synchronized in 1981.^{6b} Does may be inseminated with large numbers of spermatozoa 31 and 48 hours after pessary or sponge withdrawal and PMSG injection. Further large scale field trials with various combinations of progestogens, PMSG and prostaglandins are indicated. Vaginal progestogen pessaries and PMSG are neither approved nor available in the U.S. for synchronizing does. Furthermore, fertility at the first estrus after certain types of progesterone administration, oral and intramuscular, is reduced even if larger numbers of spermatozoa are inseminated.²²

Pathological Changes in the Reproductive System of the Doe

Anatomic defects of the genital tract of female goats are rare except for a high incidence of intersexes, or pseudohermaphrodites. This was discussed in Chapter III. Hermaphroditism was noted most commonly in polled goats of Swiss origin.^{2,3,78} In one Saanen herd the incidence of pseudohermaphrodites, was as high as 11 percent; in a Toggenburg herd the incidence reached 6 per-

cent. The intersexes are usually male pseudohermaphrodites. The condition appears to be inherited as a simple recessive character associated with hornlessness. Horned hermaphrodites are extremely rare, if they occur at all. To eliminate hermaphroditism in a flock, the polled goats that were normal should be mated to horned goats. Freemartins, such as occur in twin births in cattle, are rare in goats.²⁶ Since other anatomic defects or arrests in development such as uterus unicornis, uterus didelphys, persistence of the median wall of the Mullerian duct with a fleshy pillar caudal to the cervix, other arrests in development of the Mullerian duct, and persistence of the hymen may occur in goats they are rarely recorded. Undoubtedly they are highly unusual.

Pathological lesions or diseases of the reproductive system in goats are similar in most respects to those in cattle. Vulvitis, vaginitis, cervicitis, metritis, pyometra, perimetritis, and salpingitis may occur in goats usually as sequelae to dystocia, difficult parturition, retained placenta, and delayed involution of the uterus. These acute or chronic infections in the doe are handled in a manner similar to the treatment for these infections in cattle. In retained placenta, which is much less common in does than cattle, the uterus may be treated locally, preferably with a broad-range antibiotic, and the placenta is allowed to drop away. For a valuable doe a better treatment is to give parenteral antibiotics for 3 to 5 days and not to place any drug in the uterus or to attempt to remove the afterbirth. Manual removal of a retained placenta is not indicated due to the small size of the genital tract.

Infections of the genital tract other than postpartum infections apparently are seldom a cause for infertility in ewes and goats. This may be explained in part by the long period between breeding seasons, in which recovery can take place. Brucellosis, usually due to *Br. melitensis*, is characterized by abortion. Infertility in goats associated with brucellosis is not described. A granular vulvovaginitis in does has been described due to *Mycoplasma agalactiae*.¹⁴ After an incubation period of 7 days, the lesions in the vulva which are similar to those in granular venereal disease of cattle, are observed for several months. The granular papules are accompanied by edema and a mucopurulent exudate. The granular lymphoid lesions were also noticed in the anterior vagina and on the cervix.

Anestrus in does during the breeding season is occasionally observed and may be due to:

1. the intersex condition in naturally-polled does.
2. pregnancy or rarely pseudopregnancy with a persistent CL.

3. hydrometra or mucometra, probably with a persistent CL.
4. severe nutritional deficiencies especially in TDN and protein, or a chronic debilitating disease including external and internal parasitisms resulting in cachexia often with anemia.
5. prepuberal anestrus, usually due to restricted feed intake and anestrus in old does due to inability to chew properly, a restricted diet and heavy lactation.
6. anestrus due to pyometra or cystic ovaries is possible but seldom reported.
7. severe heat stress may shorten estrous periods and reduce the observable signs of estrus.
8. mineral deficiencies of copper, cobalt, phosphorus, and selenium may have a minor role in infertility, delayed puberty and reduced signs of estrus.
9. failure to observe estrus particularly in small flocks without a buck is not uncommon.

Hydrometra or mucometra has been described as a cause of anestrus, infertility and abdominal distention in does. The uterus is distended with up to several liters or gallons of a thin clear fluid but no membranes or fetus are present. The doe usually has a history of mating normally and the owners consider her pregnant. This fluid is often expelled spontaneously about 150 days after service.^{24b,25} The laymen often speak of this as a "cloud-burst" condition. A corpus luteum remains in the ovary during this condition and pregnancy examination with ultrasonography, not the Doppler instrument, will often erroneously indicate the doe is pregnant. There is no association in hydrometra with evidence of a fetus, cystic ovaries or an obstructed cervix. The report of a hydrops condition in ewes with permanent sterility caused by phytoestrogens and a persistent CL after mating¹ would lead one to speculate that this condition in does is due to a failure of the production of prostaglandin, the uterine luteolytic substance, and a persistence of the CL. A plasma progesterone assay is probably indicated. If this is the case and a high progesterone plasma level is present, the administration of prostaglandins, 2 to 3 mg. of PGF_{2α} or 100 to 150 ug. of cloprostenol should cause luteolysis and expulsion of the fluid. The prognosis for the future reproductive life of the doe is good. One doe was cited that had alternate normal and false pregnancies for 6 years.^{26b}

Cystic follicles or ovaries have not been described in does. The normal Graafian follicle is about 1 cm. in diameter. Larger "follicles" up to 3.7 cm. in diameter have been reported in abattoir specimens.²⁵ These may be parovarian cysts, cystic ovarian tumors, bursal cysts, or

larger than normal follicles. Short cycles in does especially early or late in the breeding season are common and not an indication of a pathological endocrine problem. Treatment is not indicated.

Intersexes or hermaphrodites are commonly observed in naturally polled does. These intersexes are genetic females and although the polled condition is dominant the hermaphroditic defect is recessive, sex-limited and incompletely penetrant. (See Chapter III.)^{2,3,22,25} Prevention of this condition is assured if either the sire or dam is horned. Most of these hermaphrodites are phenotypic females most with ootestes and many exhibit a projecting vulva and enlarged clitoris. The more masculine phenotypes have a penile-like clitoris, hypospadias and hypoplastic testes often in the inguinal region. Variable development or lack of development of the mesonephric and paramesonephric ducts are seen at autopsy. The vagina in these hermaphrodites is very hypoplastic and a small glass rod will only penetrate about an inch past the vulva.¹¹

A **caprine freemartin** with XX-XY chimerism was described.²⁶ It resembled a male pseudohermaphrodite with an enlarged clitoris and inguinal testis-like gonads. Goat X sheep **hybrids** have been produced. Does (60 chromosomes) bred to rams have greater fertility than ewes (54 chromosomes) bred to bucks. Early development of the embryo is normal but at the time of placentation a possible immunorejection response may occur resulting in early fetal deaths from 40 to 60 days of gestation.²⁵

Reproductive efficiency in Angora goats is very low under range conditions compared to the other caprine breeds and the net kid crop per year in the U.S. is about 50 percent vs. 100 to 200 percent for the other breeds. This low rate is possibly due to poor nutrition but most likely due to selection practices and the stress of high mohair production. In range flocks predators and cold stress also reduce the kid crop.^{22,23,25} This condition in Angora goats has been intensively studied in South Africa.²⁹⁻³¹ It is characterized by the selection of larger kids with finer hair coats that produce more high quality mohair until 3 to 5 years of age. This was also associated with a better breeding potential of both does and bucks the first breeding season. These selected animals usually had small adrenal glands and low plasma cortisol levels. Such selective practices would make these animals with adrenocortical hypoplasia more susceptible to nutritional, physical, climatic and gestational stresses.

After about the fourth or fifth year of life the incidence of abortion increased markedly. Most abortions occur from 90 to 110 days of gestation and were associated with

evidence of growth retardation and anemia of the fetuses and fetal adenocortical hyperplasia with excessive estrogen secretion. This was usually preceded 10 or more days by a severe reduction in maternal plasma cortisol levels along with maternal adrenocortical atrophy. High nutritional levels during this period protected most habitual aborters from losing their fetuses. With our present knowledge an hypothesis might be proposed that this triggers prostaglandin release, involution of the corpus luteum and abortion similar to the sequence of events at parturition. Older habitual "aborters" tended to develop adaptive changes of enlarged pituitary glands, adrenal hyperplasia, high plasma cortisol levels and hyperadrenocorticism, with poor hair growth, and abdominal distention. In Angora goat flocks a minor peak of early abortions was noted at 34 to 46 days of gestation and in these does fetal mummification or maceration occasionally followed fetal death and delayed evacuation of the uterus. Controlling this problem in Angora goats requires careful genetic selection by eliminating aborting does and their progeny. Bucks should be selected from nonaffected strains or families. Abortion, although common, was not identified as the major cause of low reproductive efficiency in Angora goats in Texas. Adequate nutrition including supplemental feeding, parasite and infectious disease control, shelter in inclement weather and predator control are further required management practices.²³

Tumors of the genital organs of goats are rare.^{9,25} Granulosa cell tumor and dysgerminoma of the ovary have been reported. Uterine tumors include adenocarcinoma, leiomyomas and fibromas. Rare adenomas and fibromas of the vagina and vulva have been described. As in cows, squamous cell carcinoma of the vulva and perineum is not uncommon in white-haired does exposed long periods to sunlight. Although lymphosarcomas are reported in goats the genital tract is apparently seldom involved. Warts and melanomas are occasionally seen on the perineum.²⁵

Ectopic mammary tissue in the vulva of does is characterized by a firmness and swelling of the vulvar lips prior to parturition that regresses in several months. Aspiration of milk or a biopsy confirms the diagnosis. Rarely these swellings at parturition may interfere with defecation and urination.²⁵

Chapter XVII

INFERTILITY AND REPRODUCTIVE DISEASES IN BITCHS AND QUEENS

by Donald H. Lein, DVM, PhD*

In the last ten years, significant studies in reproductive physiology in the bitch and queen have taken place. Learning the normal female reproductive physiology and endocrinology of both these domestic small animal species has helped understand the infertility problems that may be due to misinterpretation and lack of knowledge of the normal reproductive cycle, as well as those irregular cycles that are abnormal physiological patterns. Still more research in the pituitary gonadotrophins, gonadotrophic releasing hormones, endogenous prostaglandins, influence of higher brain centers on reproductive hormones as well as the influence of other endocrine hormones on the reproductive cycle is needed. This decade has certainly noted the influence of hypothyroidism on the cycle and reproductive performance of both the female and male dog and to a certain extent the queen. The genetic effect of certain breeds in both species also plays a significant role in their reproductive performance since selection, small gene pools of certain breeds, close line breeding or inbreeding are all frequently potentiated by breeders.

New hormone products to treat infertility problems, especially prostaglandin F_{2a} (PGF_{2a}), analogues of PGF_{2a} , gonadotrophic releasing hormone, (GnRH), and the bromoergocryptine drugs have just recently began to be used in these two species to treat infertility problems. Use of hormone products to influence the cycle in both species is still largely empirical and controlled by observed or expected clinical effects. Use of hormones, antihormones, immunological measures and other unique methods for cycle and reproductive control and widespread inexpensive sterilization of pet populations still needs in depth research and field trials.

The clinical study of infertility in the bitch and queen have been enhanced by careful methodical examinations over a period of the reproductive cycle time, with good

adequate histories and clinical records. Use of veterinary diagnostic endocrinology laboratories for hormone profiles, vaginal cytology and good veterinary clinical practices including vaginoscopic examinations, sexual behavior records, deep vaginal cultures, laparoscopic examination, hysterosalpinography, ultrasound and good client education has greatly enhanced the success of diagnoses and treatments of infertility in these two species. The veterinary profession and several veterinary colleges and private clinics have made small animal theriogenology a specific service or entity much like that for our large domestic animal theriogenology services.

Infections of the reproductive tract are common in both species and in recent years have been studied and characterized further, leading to the successful treatment of selected cases to restore fertility. Tumors of reproductive organs and mammary glands, hyperplastic and degenerative reproductive tract lesions and their association with both exogenous and endogenous sex steroid levels have been further elucidated. Several recent excellent review articles on small animal reproductive physiology, endocrinology, pathology and infertility have been published and the reader is encouraged to review this list at the end of this Chapter.

Canine Reproductive Physiology

Puberty in the bitch occurs as early as 6 months of age and rarely as late as 22 months of age with most bitches showing their first estrus between 8 to 12 months of age. The plane of nutrition and other stress or disease factors may influence the onset of puberty as in other species. In general, small breeds of dogs exhibit earlier puberty than large breeds. Confined dogs reach puberty later than free-roaming dogs and single confined dogs may reach puberty later than groups confined together. (See pages 409-411.)

Onset of puberty is gradual with interrelated changes in hormone levels and reproductive development. Some bitches apparently have several abortive attempts at estrous expression. Endocrine studies show that individual

*Associate Professor of Pathology, Assistant Director Veterinary Diagnostic Laboratory, Department of Pathology, Department of Clinical Sciences, New York State College of Veterinary Medicine, Cornell University, Ithaca, N.Y., 14853.

pubertal bitches have inadequate or sporadic elevations in estradiol-17B blood levels during the preovulatory phase of the cycle that are associated with reduced or abbreviated LH surge blood levels and this leads to an absence or only minor preovulatory rise in serum progesterone which is also associated with a lack of sexual receptivity.^{27,139} Bitches may show vulvar swelling, bleeding and attract males because of brief elevated blood estrogen levels from early follicular activity prior to a full estrous cycle. In studies on the Beagle bitch by Anderson and Simpson, a few showed false estrus at 6 and 9 months of age with short periods of proestrus (2 to 5 days) during which time the female attracted but would not accept the male.³ These bitches usually showed estrus in the next few weeks. Puberty in these Beagle bitches occurred at approximately 12 months of age with the youngest being at 8 months. In one study, the mean duration of proestrus and estrus was significantly shorter in bitches experiencing the first reproductive cycle than in those experiencing the second. The ability of bitches to demonstrate normal sexual behavior at the first estrus appears to be a function of age and not size.¹³⁹

Asdell cited Schotterer in reporting that ovaries of female pups at birth contain 700,000 oocytes; at puberty there are 355,000, at 5 years of age nearly 40,000 and at 10 years of age only about 500 follicles remain.⁵ In another report, the ovary of a 2 month old Beagle contains approximately 100,000 follicles and thereafter the number progressively decreases so that at 8 years of age only about 2000 follicles are present.³

The genital ridge is first recognized in Beagle embryos of 7 to 9 mm in crown-rump (C-R) length.³ Histologic evidence of the testis and ovary are recognized in 20 mm and 30 mm embryos, respectively. By late gestation, oogonia and pregranulosa cells are present in the cortex of the ovary with no evidence of prophase meiosis until after birth. Primary follicles become more abundant as prophase meiosis wanes and ceases in Beagle pups between 33 and 54 days of age. Any oogenic foci found after this time appear to be presumptive and abortive centers of oogenesis. Polyovular primary follicles, that is follicles with 2 or more oocytes surrounded by a common granulosa, are first observed at 81 days of age and become a prominent feature of the dog ovary.³ Most primordial germ cells, primary or vesicular follicles undergo atresia with only relatively few reaching maturity, ovulation and formation of corpora lutea. As the bitch ages the ovary develops surface crypts which increase and may be used to distinguish prepuberty, maturity, middle and old age.³

If a bitch is well grown, there is no reason not to breed on the first estrus. Full sexual maturity, the attainment

of maximum capacity, may not be fully attained until the second or third estrus.¹⁰⁹ Beagle bitches in one study reached a reproductive peak at 3 years of age.³ By 8 years of age, reproductive senility was present, with longer interestrous periods, increased infertility and increased preweaning mortality.

The estrous cycle—The dog is considered a monestrous animal with only one estrous cycle occurring during the breeding season. In a review by Shille and Stabenfeldt, an even distribution of estrous cycles throughout the year was shown, although there is definite pattern of increased incidence of estrus from January through May.¹⁰³ There are some reported breed differences, with the Basenji bitch having the highest birth rate from November through January although pregnancies and estrous cycles occur throughout the year in this breed.¹⁰³ Greyhounds and other large breeds may have only one estrous period a year.¹⁸ (See pages 411–415.)

The interestrous interval is affected by breed differences, but not necessarily by breed size. There appears to be less variability within animals than within the breed. Studies on several breeds showed interestrous interval differences for the Toy Poodle of 239 days, Cocker Spaniel, 186 days, Basset Hound, 175 days, German Shepherd, 149 days, and Rough Coat Collie, 255 days.^{103,115} Differences for the same breed but in different localities have also been reported: Great Britain versus the United States, Cocker Spaniels, 224 vs. 186 days, Miniature Poodle 189 vs. 239 days, respectively.¹⁰³

In some studies, the interestrous period appears to be lengthened following pregnancy versus a nonpregnant cycle, while other studies have shown no significant differences.^{27,103,115} Further studies on the interestrous period are needed on the effect of pregnancy versus nonpregnant cycles and the effect of breed, husbandry, nutrition and environment. Latitude and photoperiodicity had no effect on the reproductive activity in dogs in Great Britain.²³ Age does affect the interestral period with increased interval time and more irregular cycles.

Bums and Fraser quoted Frost in reporting that in nearly 500 bitches, 338 had an estrous interval of 5 to 7 months, over 100 had an interval of over 7 months and only 16 had an interval of less than 5 months.¹⁸ In other studies, the interval averaged between 7 to 8 months and 4 to 13 months (over 7 mo.) in a Beagle colony.^{27,103} Intervals longer than 13 months always had an intervening ovulatory and luteal phase for which no sexual behavior was observed, a silent heat, but was detected by serial progesterone blood levels.^{27,34} In the author's experience, interestral periods less than 4 months are usually irregular or abnormal cycles with no ovulations, luteinized cystic follicles or very short luteal function. The interval

between estrous cycles is rarely 6 months, so most bitches have the ability to be in estrus or whelp in any month of the year.

The estrous cycle of the dog as originally described using the four terms, anestrus, proestrus, estrus and metestrus are still used and accepted.^{3,27,34,62} Metestrus was used to designate the full luteal phase. The terminology used in other domestic animals; metestrus, the period of luteal formation to maximal size or maximal progesterone production, and diestrus, the period of maintenance of the mature corpora lutea, is difficult to use in the bitch, since these stages may be looked at differently by sex behavior, estrogen and progesterone blood levels, and vaginal cytology. Concannon, et al., has shown that progesterone is produced by the mature graafian follicle prior to ovulation and is responsible for initiating sexual receptivity in the bitch.³³ Also, the bitch is sexually responsive to the male well after ovulation and into early formation of the corpora lutea with high progesterone levels. Thus, metestrus and estrus in the strictest sense overlap or occur within each other. Maximal blood progesterone levels do not occur until 15 to 25 days after the LH peak and the nonpregnant bitch may continue to secrete progesterone above basal anestrus blood progesterone levels for 120 to 150 days after the LH peak.

Holst and Phemister observed a sharp decline in vaginal cornified cells about 3 days before the end of behavioral estrus and suggested that this be considered the first day of diestrus.^{55,56} They also found in a later study that vaginal cornification was complete in 12.1 days (S.E., 0.2) from the beginning of estrus and 8 days (S.E., 0.3) from the LH peak. They considered this stage of the cycle should be diestrus. Behavioral-wise the bitch may still be in estrus, the corpora lutea are still developing, progesterone levels are still rising for some days and in the strict scientific sense this stage is metestrus.

Stabenfeldt and Shille suggested that the simplest approach is to recognize that metestrus occurs during the latter part of estrus in the dog and to use the term diestrus for the luteal phase of cycle which begins with the loss of sexual receptivity.⁴⁷ A nomenclature committee of small animal theriogenologists, endocrinologists and physiologists must finally decide on an acceptable terminology for all to use.

The estrous cycle of the dog is considerably longer and more variable compared to our large domestic animals. In general, the four accepted phases or time periods are: 9 days for proestrus (range 3–16), 9–10 days for estrus (range 4–12), 75 days for metestrus-diestrus (range 51–82), and 125 days for anestrus (range 15–265).¹¹⁷ The less variable portion of the estrous cycle is proestrus-estrus which is frequently quoted as 21 days

of attraction followed by loss of receptivity to the male. The most variable are metestrus-diestrus and anestrus.

Vaginal cytology, If used on a routine basis in a cycling bitch can accurately reveal the stages of the estrous cycle. Vaginal smears examined at one- to two-day intervals during proestrus, estrus and early metestrus/diestrus can be a very valuable clinical test to predict when a bitch will ovulate, when to inseminate or send to a stud for breeding, or when an irregular cycle is taking place. Couple the vaginal cytology with sexual behavior, teasing with a sexually active male, changes in the size and consistency of the vulva, changes in the vaginal and cervical mucosal folds and possible sex steroid hormone serum profiles and the strength of clinical diagnostic and management at breeding for optimum reproduction greatly increases. (Chart III) The above tests and changes are all under the influence of estrogen and its mitogenic

Chart III. A schematic summary of temporal relationships between periovulatory endocrine level changes, behavioral, vaginal exfoliated cytology, vulval and vaginal mucosal changes associated with the estrous cycle in the bitch. (Courtesy and with permission of P. W. Concannon and publisher, W. D. Saunders, Co.²⁷)

influence especially on target tissues. Several excellent reports have been published on the obtaining of specimens, stains and techniques for staining, interpretation and correlation of vaginal cytology to the estrous cycle, reproductive hormone changes, sexual behavior, reproductive tract changes and diagnostic use for infertility conditions in the bitch.^{2,8,22,27,42,55,64,68,87,88,98,100,102,117,122}

Specimens must be collected from the vagina and not the vestibule since cells from this area do not readily reflect sex steroid hormone changes and are always cornified.^{42,98} Thus, the use of a speculum is important to bypass the vestibule. No lubrication for the speculum or collecting instrument should be used since most cause artifacts on the smear. Specimen collection can be done with a moist clean cotton swab, metal or wood spatula, glass rod, pipette and saline flush; the author prefers a moist (saline) clean cotton swab which is rotated in the anterior vagina. Cells are less distorted if the swab is rolled on the clean glass slide instead of pulling across the slide. Several stains are available; Wright's, Leishman's, Giemsa, Wright's-Giemsa, Trichrome stains such as Sano-Pollack Trichrome,⁹⁸ Shorr's trichrome, New Methylene Blue, Toluidine Blue and Diff Quick, a modified Wright's-Giemsa stain.^{27,87} The author prefers to use Diff Quick because it is simple, rapid and adequate and the slides can be stored for reference and studied throughout a bitch's cycle. A drop of New Methylene Blue on a cover slip, applied to an air-dried vaginal smear can be read immediately and shows good detail, but it will not stain red blood cells and cannot be stored for reference.^{68,87} It is advisable to stay with one stain throughout a study of an estrous cycle because of the difference in staining detail between stains.²⁷

An excellent study on the changes of cells and cell types with percent of changes throughout the cycles is reported by Christie, et al.²² Increasing estrogens from the developing follicles during proestrus and estrus cause the target tissue of the vagina to progress rapidly from a two cell thick epithelium in anestrus, made up of basal and parabasal cells that are small round cells containing a large distinct nucleus, to a very rapid growing epithelium that will become several cell layers thick as estrogen levels increase in late proestrus. Cells as they mature from basal and parabasal cells will become larger, lose their round shape and become polyhedral or angular, still contain a nucleus (called intermediate cells) and eventually become larger, more polyhedral and degenerate so that the nucleus now becomes pyknotic, eventually lysing (karyolysis) and disappears. These cells are classified as superficial cells, containing a pyknotic nucleus, partly cornified, or anuclear, fully cornified. The completely cornified superficial cells are seen with the full effect of high estrogen levels and are predominant in the

smear when the height (number of cell layers) of epithelium is maximum. These cells are polyhedral, frequently "wrinkled" or "curled" and appear like "corn-flakes."^{130a} The cytological change, day by day, through the early cycle (proestrus, estrus, early metestrus) is always a percentage of change in types of cells. Late in anestrus, mainly scant parabasal and early intermediate cells are present. Occasionally in the last 40 or 50 days of anestrus, erythrocytes will be seen in the smears before any vulvar bleeding at proestrus is noted indicating early follicular activity and estrogen production.¹²² Proestrus is characterized by mixtures of parabasal, intermediate and superficial cells (cornified cells) that progress towards a higher percentage of mature or completely cornified cells in late proestrus to early estrus. Erythrocytes, from uterine diapedesis are quite numerous in proestrus, tend to decrease in estrus, but in some bitches, may be present through estrus and into metestrus/diestrus. The presence or absence of erythrocytes in estrus or diestrus is the most variable of all cell types. Leucocytes, polymorphonuclear leucocytes, are present in proestrus, but are not present in full estrus. If they are present, it indicates an inflammatory process in the reproductive tract and they are usually degenerate leucocytes filled with phagocytized bacteria. Epithelial cell changes and height (number of cells thick) of epithelial layers in the vagina during proestrus and estrus follow estrogen secretion levels by approximately 1–2 days, thus maximum cornification (95–100%) follows the preovulatory LH surge by 1–2 days.^{27,102,103} Near the time of the LH peak, a clearing of the background on the glass slide (lack of debris) takes place and is possibly related to a decrease in mucoprotein content of the vaginal mucus.^{27,68} This is usually an optimal time to start breeding a bitch or to send the bitch to a breeder, since LH release has taken place and destined ovulation is eminent. Shipping and changing of the environment of bitches prior to destined ovulation may cause a bitch not to ovulate because of inadequate LH-RH, LH release, possibly controlled and blocked by the higher brain centers. The "clearing" effect is best noticed when following a series of daily or every other day vaginal smears. By 3 or 4 days after the LH peak, fully cornified superficial cells (anuclear) almost completely replace partially cornified superficial cells (contain pyknotic nuclei). About 7 to 8 days after the LH peak, an abrupt decrease in cornified epithelial cells takes place, confirming retrospectively that ovulation has taken place. There is a rapid loss of fully cornified epithelial cells and reappearance of intermediate and parabasal cells indicating the start of metestrus or the onset of diestrus as described by Phemister, et al.⁹¹ This is probably the last day that an unmated bitch is likely to be fertile since it coincides with the

fertile lifespan of oviductal oocytes.²⁷ The reappearance of leucocytes in the vaginal smear in early metestrus/diestrus indicates the end of the fertile period and the increase of progesterone blood levels. The reappearance of leucocytes may coincide with the metestrus/diestrus shift of epithelial cells, but frequently their entrance are more variable and may be one or two days earlier or in the author's experience, two to four days later and in many cases may not be that abrupt in appearance. If a bitch is presented at this time with no prior history of stage of cycle, by either behavior or vaginal cytology, this stage (early metestrus) may be confused with proestrus. Study of further daily smears will determine the stage of the cycle. As the bitch proceeds into late metestrus/diestrus, the cell thickness (number of layers of cells in vagina) returns to 5 to 8 cells thick and eventually to two or three cells thick at anestrus. In a study during metestrus and anestrus, Dore described the great increase in parabasal and intermediate cells after 30 days postovulation which increased in late metestrus/diestrus and early anestrus to mainly parabasal cells. Recognition of this stage is important when a bitch of unknown cycle status is presented for contraceptives or for estrus induction (Chart III).

Vaginal smears for cytologic diagnosis of inflammatory processes of the genital tract; vaginitis, endometritis, pyometritis, or subinvolution of placental sites versus postpartum metritis or endometritis, neoplasia, etc. are well described by Rozzel and a recent report by Olsen, et al.^{88,98}

Vaginocopy or endoscopy of the vagina of the bitch has been a very valuable procedure for pinpointing the changes from proestrus to estrus and finally metestrus/diestrus. This procedure is also useful for breeding soundness examinations and the diagnosis of anatomical abnormalities, inflammation, neoplasia, obstetrical and postpartum difficulties.^{27,68,69,70} Lindsay has described the method used for postuterine endoscopy and the estrous cycle changes. Visualization of the vaginal mucosa can best be accomplished with a fiberoptic proctoscope or sigmoidoscope (Welch-Allen) in both noninflated and insufflated states. These instruments can easily be passed with sterile lubricant to the anterior vagina and a complete examination performed with minimal restraint of the bitch. The true cervix cannot be easily viewed because of the anterior dorsal median vaginal fold which occupies the anterior 2 or 3 cm. of the vagina and narrows this portion of the vaginal cavity to a ventral slit, making it difficult to pass instrumentation in this area unless it is 4 mm in diameter. The true cervix opens on the anterior ventral portion of this dorsal fold. A paracervix, which is the caudal portion of this dorsal vaginal fold and contains

the narrowed ventral lumen leading to the true cervix, is frequently mistaken for the external cervical os.^{27,68,69,70,93}

The cervix can be seen easily in full estrus or at late pregnancy, at whelping or early postpartum when the area is under the influence of estrogen, is edematous and quite dilated. As estrogen increases during proestrus, the vaginal mucosal folds become progressively more edematous, rounded, puffy and turgid in appearance. At the time of the preovulatory LH peak, estrogens are falling, progesterone is rising, the blanched, rounded, smooth mucosal folds and prominences that completely fill the vaginal lumen quickly change and rapidly develop a wrinkled, angular, peaked or crenulated appearance that are less edematous and do not fill the vaginal lumen. It is felt that these gross changes probably reflect an abrupt withdrawal of the water retention effects of estrogen during the preovulatory decline in estrogens and the triggering of the LH peak. This is the start of estrus and coincides with acceptance of the male and complete cornification of vaginal cytology. The angular or crenated vaginal mucosal folds will continue to be present for 5 to 6 days and then are lost about the time of the metestrus/diestrus shift in the vaginal cytology and are replaced by flaccid vaginal folds with the paracervix area appearing as a soft "rosette." These changes can easily be followed through proestrus, estrus and early metestrus/diestrus by every other day examinations (Chart III).

Progressive swelling and edema with turgidity of the vulva, perineum and the ventral floor of the caudal vagina takes place with increasing estrogen levels in proestrus. Frequently this edema is ascertained prior to vulvar bleeding in early proestrus. Since these are target tissues for estrogen and easily visualized and palpated, daily examination of the vulva will give a good indication of the progression of proestrus and the change to estrus because the rapid decline in estrogen levels will cause a rapid softening of the vulva and vaginal floor at estrus. This is an ideal time to breed the bitch. Some bitches could not be naturally bred in late proestrus because the vulva and hypertrophied caudal vaginal floor are so edematous and enlarged. In some bitches, severe edema and hypertrophy of the vaginal floor will lead to prolapse of the hypertrophied caudal vaginal floor between the vulvar lips.

Endocrinology of the estrous cycle and pregnancy—Excellent studies and reviews on the endocrinology and physiology of the estrous cycle and pregnancy of the bitch have been reported.^{3,20,24,26,27,30,31,33,34,35,36,37,38,40,47,}

^{53,54,62,70,74,75,77,79,82,84,85,91,94,95,102,103,106,108,109,116,117,119,}

^{120,121,123,124,125,127,128,136,137,139} The follicular phase, mainly proestrus and early estrus was considered an abrupt occurrence following a quiescent anestrus. Olson, et al. has shown that in late anestrus (at least 45 days before proes-

trus) concentrations of follicle stimulating hormone (FSH) in serum are high (240 to 294 ng/ml) and again at the time of the preovulatory surge of luteinizing hormone LH (297 ng/ml). During proestrus, FSH was lowest (131 to 200 ng/ml). There is sufficient FSH present during anestrus for follicular growth.⁸² Serum estradiol 17-B was high in late anestrus (20 to 46 pg/ml), decreased prior to proestrus (8 to 46 pg/ml), and increased through proestrus and then dropped just prior to estrus. Inhibition of FSH may be caused by elevated estrogen levels (negative feedback) or, as proposed for other species, elevated serum levels of inhibin a follicular peptide that selectively inhibits FSH secretion.²⁷ The serum LH levels were inverse to the estrogen levels, low early, higher just prior to proestrus, possibly inducing a new follicular phase, lower during proestrus, and then surging to a high level at estrus. Similar findings for LH and estrogen were found in prepuberal bitches prior to their first estrus.¹³⁹ Concannon has also noted that in nonpregnant bitches in anestrus (150–180 days from last estrus) ovarian follicular activity, uterine and oviductal hyperemia, including enlarged fimbria and a congested red endometrium are present. He believes this represents the transition from late luteal phase of one cycle to the early follicular phase of the next cycle.²⁷ Others have also reported this phenomena in pubertal and anestrus bitches.^{3,116} From the above reports, anestrus cannot be considered strictly a quiescent state.

At the onset of proestrus, several follicles, 1.0 to 1.5 mm in diameter are present on the ovaries of Beagle bitches. They increase to 2 mm by mid proestrus, 3 to 4 mm by late proestrus and 3 to 5 mm by the onset of estrus.³ Several of these follicles degenerate at any of these stages, while a few, up to 20 or more, increase to 8 to 10 mm in diameter at ovulation.¹³⁷ Mature follicles are amber in color, contain several infolds of the granulosa cell lined wall and coiled blood vessels can be seen in the walls. Just prior to ovulation, the oocyte becomes free-floating in the follicular fluid. The rupture site of a follicle can be recognized by a pinpoint area with very scant hemorrhage and no appreciable collapse of the walls.³ The released oocytes promptly pass to the ampullary region of the oviducts. The turgid fimbria effectively close the ovarian bursa (ventral slit) at ovulation to prevent the loss of ova.

During the follicular phase, estrogens cause the increasing evidence of external signs of proestrus: edema, hyperemia and enlargement of the vulva, vaginal discharge of uterine blood (endometrial diapedesis), edema and hypertrophy of the caudal vaginal floor, secretion of sex pheromones from the vaginal or vestibule secretions and attraction of males. Urine from bitches in proestrus

and estrus will attract males at this time.⁴³ One vaginal sexual attractant was analyzed as methyl-p-hydroxybenzoate.⁵¹ Methyl-p-hydroxybenzoate and to a lesser extent, propyl-p-hydroxybenzoate, when applied by cotton swab applicators to the vulva and vestibule of anestrus or ovariectomized bitches caused intense anogenital interest and attempts at mounting by teaser males. The use of oral administration of chlorophyll in some bitches at the first sign of proestrus appears to mask the sexual attractive odors of bitches in proestrus/estrus.¹⁰³

During proestrus, the bitch will usually not permit mounting and intromission. The behavioral change from proestrus to estrus is when the bitch will stand for the male, with tail deviated laterally and the back in a lordosis position. This is also the time when vaginal cytology has changed to mostly cornified epithelial cells with no leukocytes and lack of debris and variable amounts of red blood cells. At this time the vulva has come from a full swollen, turgid, edematous estrogen-primed tissue to a more flaccid, soft tissue with a rapid decrease in estrogen blood levels and increasing progesterone blood levels. The tumescence of the vulva of most bitches during proestrus would make intromission by the male almost impossible even if the bitch would stand. Daily vaginoscopic examination at this time also shows a change in the anterior vaginal longitudinal and transverse folds and the paracervical areas from a smooth edematous rounded swollen, "pillow" type appearance to an angular, sharp edged or crenulated, wrinkled appearance. These changes take place when serum estrogen levels are falling and early progesterone levels are increasing and indicate the luteinizing hormone (LH) surge that will cause ovulation in the next 2 days.^{69,70} This abrupt change is one of the best clinical signs to indicate the LH surge and ovulation (Chart III).

The endocrine and reproductive patterns during proestrus and early estrus have been well defined by several investigators.^{3,20,24,27,31,33,34,38,47,53,62,74,75,77,82,84,91,94,95,102,103,106,107,109,136,139} The serum estradiol 17-B levels increased from basal levels of 2 to 10 pg/ml to peak levels of 50 to 120 pg/ml in late proestrus.²⁷ Concurrent increases in estrone also take place with these levels being elevated during the 6 day interval both before and after the LH peak, while average estradiol-17-B levels remain elevated only during the 6 day interval preceding the LH peak.¹³⁹ The release of LH to cause ovulation is initiated by the drop of blood estradiol-17B and that is facilitated by the low, but rising blood progesterone levels.^{27,31,33,34,38} Sexual receptivity in the bitch is the result of a slight preovulatory rise of serum progesterone in association with a preovulatory serum LH surge and a rapidly declining serum estradiol-17B level.^{27,38} The source

of the progesterone appears to be the preovulatory luteinizing granulosa cells of the mature follicles (Chart IV).

Further work with ovariectomized Beagle bitches showed that the best combination of sex steroid hormones for inducing estrus was to administer estradiol-17B for 8 days followed by progesterone and removal of estradiol-17B.^{31,33,38} The mechanism of regulating LH release in the dog appears similar to that of other species, mainly gonadotrophin releasing hormone (GnRH) from the hypothalamus which releases both LH and FSH. Exogenous GnRH causes LH release in the bitch within minutes.¹⁹

Atypical reproductive behavior and patterns are observed in certain bitches at estrus. These atypical responses include lack of sexual receptivity and reduced or inconsistent patterns of circulating concentrations of estradiol-17B, luteinizing hormone (LH) or progesterone. It appears that inadequate or sporadic elevation in levels of estradiol-17B during the preovulatory phase of

the cycle were associated with reduced or abbreviated LH surge concentration which resulted in a minor preovulatory rise in serum progesterone causing a lack of sexual receptivity.¹³⁹

Olson, et al. has reported that during proestrus, mean serum testosterone levels range from 106 ± 29 to 239 ± 3 pg/ml with a high concentration of 526 ± 225 pg/ml occurring the day of the preovulatory surge of LH. During late anestrus, levels of serum testosterone ranged from 31 ± 11 to 141 ± 63 pg/ml. The physiological or endocrinologic function of testosterone in the bitch has not been studied.⁸⁴

Ovulation is spontaneous in the bitch and occurs about 24–48 hours after the LH peak with a range of 24 to 72 hours.^{27,34,91,136} In relation to estrus or acceptance of the male, ovulation has been reported by laparoscopic examination to occur from the first to the seventh day of estrus with one bitch ovulating on the ninth day.^{119,136} Studies on the preovulatory LH peak and the onset of estrus indicate that the latter occurs between 7 to 8 hours

Chart IV. A schematic representation of typical endocrine changes reported, or presumed to occur, during the nonpregnant canine ovarian cycle and their relation to observable stages and functional phases of the cycle.

(Courtesy and with permission of P. W. Concannon and publisher W. D. Saunders, Co.²⁷)

after the LH peak with a range of 3 to 5 days before the LH peak to as late as 4 to 5 days after the LH peak.²⁷ One bitch was reported to have been in estrus 9 days before the LH peak.¹³⁶ "Early estrus" may be caused by a slight or transient drop in estrogen levels or a rise in progesterone during the follicular phase prior to the final estrogen peak. The later estrus, following the LH peak, may occur in an insensitive bitch and is seen particularly in the pubertal bitch. Occasional bitches never show estrus, or even proestrus, and still ovulate. Some of these conditions may be the degree of knowledge, talent and time spent by the observer on canine sex behavior or the number of mating attempts, compatibility of the dog and preference or experience of the pairs. Estrus in the bitch is typically 6 to 12 days, but it may be short, 2 to 3 days in those showing late after the LH peak, or it may be protracted up to 3 weeks or longer in a few females.

The luteal phase of the canine estrous cycle begins before ovulation with preovulatory luteinization of the granulosa cells and theca interna. Complete transformation of granulosa cells into lutein cells is not observed until 4 to 5 hours after ovulation.³ The serum progesterone level continues to rise during estrus and reaches peak levels of 15 to 80 ng/ml or higher between 15 and 25 days after the LH peak.²⁷ Progesterone levels will gradually decline after reaching a peak and are quite variable in concentration between bitches and in duration in the nonpregnant bitch. This may vary in the nonpregnant bitch from 55 to 110 days before reaching serum levels of 1 ng/ml, but may not reach basal levels of 0.3 to 0.4 ng/ml, until 120 to 150 days after the LH peak (Chart IV). Depending on the definition of metestrus and/or diestrus, the duration can be considered to last about 2 months, as in pregnancy; 2 to 3 months until mammary development associated with physiological pseudopregnancy subsides or near the mean of 80 days, when mean serum progesterone levels are 1 ng/ml or lower, or when serum progesterone levels reach anestrus basal values of 0.3 to 0.4 ng/ml, or at 120 to 140 days, when the effect of progesterone on histologically examined endometrium is no longer evident. In the pregnant bitch, desquamation of the endometrial lining is more extensive and repair occurs about 2 weeks later, 140–155 days post coitus.³ One other steroid, estriol, has been found during metestrus and may play a role in the cycle. Estriol is a weak estrogen and may act as a competitive metabolite, displacing estradiol-17B endometrial receptors.

Throughout the non-pregnant cycle, LH and FSH levels appear to remain at basal levels. FSH rises again late in anestrus, as described earlier in this Chapter, and stimulates late anestrus follicular development. LH and prolactin (PRL) are both pituitary luteotrophic hormones

for corpora lutea maintenance in the dog. Studies show that removal of the pregnant or nonpregnant uterus did not alter maintenance of luteal function in the bitch. Also that serum LH concentration appears to increase as progesterone levels decline indicating that cessation of luteal function does not appear to result from a lack of LH.⁸⁵

Prolactin also is inversely proportional to progesterone secretion. Thus serum prolactin levels rise as progesterone levels decline, which may result in overt behavioral signs of pseudopregnancy in some bitches.^{27,64}

Pseudopregnancy—All nonpregnant bitches will undergo a pseudopregnancy in late metestrus/diestrus which may be covert or overt. The covert type will show no behavioral signs of pregnancy, but will still have endometrial and mammary gland hyperplasia. The overt bitch will have varying degrees of pregnancy signs from milk secretion, enlarged uterus and abdomen, nest making, restlessness and false labor, anorexia, vomiting and the caring for toys, inanimate objects or other animals' young. In some bitches and possibly some breeds, either higher levels of prolactin are released or the dogs are more sensitive to expression of pseudopregnancy.²⁷ Some dogs are triggered into overt pseudopregnancy when blood levels of exogenous progesterone or progestins, or possibly similar blood steroids drop.

A homologous radioimmunoassay for canine prolactin has been developed. Throughout the estrous cycle, basal plasma prolactin (PRL) levels of 2–4 ng/ml remain fairly constant until the end of metestrus/diestrus in non-pregnant bitches, when a rise to 9 ng/ml was noted.⁴⁰ Prolactin is highly lactogenic in the bitch and exogenous administration can maintain lactation indefinitely (Chart IV).⁶²

Prolactin and thyroid-stimulating hormone (TSH) are both released following an injection of thyrotropin-releasing hormone (TRH). Prolactin secretion is controlled by hypothalamic prolactin releasing inhibitory factor (PIF) which may be dopamine. Dopamine agonists, such as bromoergocryptine, can reduce prolactin secretion in dogs as in other species and can reduce the severity of overt pseudopregnancy.²⁷ Bromoergocryptine is not used clinically because of its unfavorable side effects, but new analogues show great promise in treating overt pseudopregnancy.

Growth hormone (GH) is primarily a metabolic hormone, but is also lactogenic in some species. Hypothalamic somatostatin, an inhibitor of GH secretion, and GH releasing factor from the hypothalamus, regulate the secretion of GH. Growth hormone secretion can be elevated by progesterone secretion endogenously, and also exogenously, leading to acromegaly-like changes in

bitches, and alterations in glucose and insulin levels.^{27,29}

The most fertile period in the bitch appears to be associated with the time of the LH peak to 4 days after ovulation.^{27,91,103} Bitches have conceived with single breedings as early as 3 days before and up to 7 to 8 days after the LH peak thus leading to gestation periods of 57 to 72 days.^{27,128} It is usually recommended to breed early followed by services every 2 to 4 days.^{27,87} The best method is to utilize daily teasing with a sexually responsive male and breed when the bitch shows the first good stance, with lordosis and lateral deviation of the tail (so called "flagging"). To increase the knowledge of timing or in lieu of a teasing stud, the use of vulvar changes from tumescence of proestrus to relaxation and detumescence of estrus, daily vaginal cytology and vaginoscopic examination can be used to pinpoint the changes from proestrus to estrus, ovulation and on to metestrus.

Ovulation, fertilization and implantation—Canine ova are ovulated from follicles as primary oocytes about 36 to 48 hours (24–72) after the LH peak. Maturation of oocytes take place in the oviduct and may take as long as 2 to 3 days, so fertilization probably occurs no earlier than 3 days after the LH peak.²⁷ For this reason the immature ova shed by the dog, and fox, remain viable for several days after ovulation before the male and female pronuclei join and cell division begins. Thus in canine ova, sperm penetration occurs while the egg is still a primary oocyte but the sperm head remains quiescent in the vitellus until the second polar body is extruded. In one study, using laparoscopy for determining ovulation, the first polar body was extruded at 48–72 hours post-ovulation, the germinal vesicle (follicular cells) were retained until 24 to 48 hours and no follicular cells were seen at 68 hours. Cleavage began from 72 hours on, in the middle or distal part of the oviduct and ova were in the 2 cell stage at 96 hours, 3–6 cell stage at 120 hours, 8 cell at 144 hours, 8–16 cell stage at 168 hours and 16 cell at 192 hours in the distal oviduct. At 204 to 216 hours postovulation the ova in the morula stage were transferred into the uterus.¹²⁰ (See pages 419–422.)

After ova maturation, the fertile life span is not known, but may be two to three days; since in some bitches, fertilization and pregnancy occurred as late as seven days after the LH peak. Mahi and Yanagimachi found that canine oocytes mature to the stage of germinal vesicle breakdown within 48 to 72 hours of in vitro incubation following removal from follicles. Thus, this process may take as long in vivo. They also reported that dog sperm can penetrate canine oocytes after 7 hours of incubation in vitro and that they can penetrate immature or degenerate oocytes as well as mature oocytes.⁷¹ Dog sper-

matozoa can remain viable in the lumen of the uterus for 5 to 6 days and even to 11 days after copulation.^{27,41} Disappearance of spermatozoa coincided with the onset of metestrus.

Free floating blastocysts have been observed in the uterus between 8 and 20 days postcoitum. Implantation occurs 21–22 days after first acceptance, but may have a range of 17 to 18 days (late estrus mating) to 26 days after mating (early mating, 3 days prior to LH peak).^{27,62}

In a series of 21 bitches studied by TsuTsui, the blastocyst on the 16th day after ovulation (determined by laparoscope) has shed the zona pellucida and was free floating in the uterine lumen. Implantation took place 20.5 to 23.0 days postovulation in bitches allowed to mate from 54 hours preovulation to 108 hours postovulation, respectively. Thus the time interval between mating and implantation was 18.5 to 24.0 days and if dated from the time of fertilization, 18.5 to 19 days post fertilization.¹²³ Future implantation sites are noted as edematous areas of the endometrium (Chart V).³

The number of follicles that mature and rupture may vary from 4 or fewer, especially in small breeds, to 20 or more in the larger breeds. As the bitch ages, the number of follicles maturing and ovulating, as well as litter size will decrease. In a study of 135 mongrel bitches the rate of ovulation was 6.0 ± 1.7 ova (2–12), 2.9 ± 1.4 (0–8) in the right ovary, and 3.1 ± 1.4 (0–6) in the left ovary. There was no statistical seasonal affect. The fertilization rate of all bitches was 88.8%. Transuterine migration showed a tendency for distribution to be equal between both uterine horns.¹²¹

Diagnosis of pregnancy via abdominal palpation is usually possible by day 25 of pregnancy following the last mating, but may be possible by 17 or 18 days when mating occurs late in estrus or not until 26 days after a mating occurring 3 days before the LH peak. The uterine horns are like a "corkscrew" from endometrial hyperplasia and hypertrophy during early metestrus and may be difficult to differentiate from implantation sites or swellings of pregnancy.¹¹⁶ The uterine swellings are about 1.0 cm in diameter at 19 to 20 days after the LH peak, 1.5 cm at 23 to 24 days and 2.0 cm at 27 to 28 days and 3.0 cm at 31 to 32 days. The uterine swellings become more confluent and oblong by day 30 to 35 and are difficult to palpate as individual entities from this time on.²⁷ The amnionic vesicle and developing embryo can be viewed by ultrasound by 20 to 22 days postmating with evidence of fetal heart movement by day 22. In the author's experience, biweekly studies with ultrasound can be used to detect, confirm and record by photography early embryonic and fetal death and resorption. Rendano, et al. demonstrated that fetal skeletons do not

Chart V. Events of Canine Pregnancy Timed in Relation to the Preovulatory LH Peak and to Potential Times of Fertile Matings

Event	Days After the Preovulatory LH Peak*	Potential Range of Days After a Fertile Mating†
Onset of proestrus	-20 to -3	-25 to -2
Full vaginal cornification	-4 to +2	
Onset of estrus	-3 to +5	
Estradiol peak	-3 to -1	
Decreased vaginal edema	-1 to 0	
LH surge and sharp rise in progesterone	-1 to 0	
LH peak	0	-7 to +3
First mating	-5 to +10	
First fertile mating	-3 to +7	
Crenation of vaginal mucosa	0 to 1	
Ovulation of primary oocyte	2	-5 to +5
Oviductal oocytes		
Resumption of meiosis	3(?)	
Extrusion of first polar body	4(?)	
Sperm penetration	3 to 7	0 to 7
Fertilization/pronucleus formation	5 to 7	1 to 8
Degeneration of unfertilized ova	6 to 8(?)	
Two-cell embryo	6 to 8	
Loss of vaginal crenulation	6 to 8	0 to 9
End of complete vaginal cornification	6 to 9	
Return of leukocytes to vaginal smear	7 to 12	
Morulae (8 to 16 cells) in oviduct	8 to 10	
Blastocyst (32 to 64 cells) entry into uterus	9 to 11	3 to 14
Intracornual migration (1-mm blastocysts)	10 to 13	
Transcornual migration (2-mm blastocysts)	12 to 15	
Attachment sites established, zona pellucidae shed	16 to 17	
Swelling of implantation sites, primitive streak formation	18 to 19	
Palpable uterine swellings of 1-cm diameter	20 to 25	17 to 27
Onset of pregnancy anemia	30	
Reduced palpability of 3-cm swellings	32	26 to 38
Hematocrit below 40 % PCV	40	
Hematocrit below 35 % PCV	50	
Fetal skeleton becomes radiopaque	43 to 46	
Radiographic diagnosis of pregnancy	45 to 48	39 to 50
Prepartum luteolysis and hypothermia	63 to 65	
Parturition	64 to 66	58 to 70

*Conservative estimates based on literature reports and unpublished observations.

†Based on fertile single matings from three days before to seven days after the LH peak.

become sufficiently mineralized and radiopaque for a pregnancy diagnosis until approximately 46 days after the LH peak or 19 to 20 days prior to parturition.⁹⁷ Uterine enlargement is detectable 35 days prior to parturition. Mineralization of fetuses progresses rapidly with the proximal extremities; forelegs/hindlegs/pelvis, caudal vertebrae/paws, and finally teeth becoming visible at approximately 17, 11, 5 and 4 days prior to parturition, respectively.^{36,97} (See pages 32, 33.) Fetal death late in gestation or at parturition can be diagnosed if the radiographs show the following: (1) alteration of fetal skull bone alignment: overriding of the fetal skull plate bones or extreme deformity of the fetal skull; (2) intra-fetal or perifetal gas collections; (3) abnormal fetal posture, "ball sign" or increased fetal flexion or straightening of the hind limbs.⁹⁷

The endocrine patterns have been studied for the pregnant bitch but not to quite the extent of those at estrus (Chart VI).²⁷ The sex steroid hormones, estradiol-17B and progesterone are similar in the nonpregnant and pregnant bitch up to the time of implantation (18 to 19 days post LH surge). Secondary elevations in proges-

terone levels are seen in the fourth and fifth week of pregnancy. This difference over the nonpregnant bitch cannot be used diagnostically because of the great individual variations encountered. Whether the increased progesterone is caused by increased luteal progesterone secretion or by placental gonadotropic activity is unknown at this time. Hemodilution that probably accompanies the rather dramatic anemia of pregnancy in the bitch from implantation to the end of gestation, probably effects the concentration of hormones, and if corrected, the higher progesterone levels of pregnancy versus nonpregnancy may be significant. The mean hematocrit (PCV) falls below 40% following implantation and by the end of gestation reaches 30 to 35 percent.^{27,35}

Serum estrogen levels rise during the latter third of pregnancy but do not reach levels as high as those observed during proestrus. Follicle stimulating hormone (FSH) increase in pregnant bitches has also been reported following implantation. The two-fold increase in FSH was observed as early as 28 days of pregnancy and was present to one week prepartum. This may account for the increased ovarian follicular activity and increased

Chart VI. A schematic representation of typical endocrine changes reported, or presumed to occur, during the course of a fertile canine ovarian cycle including pregnancy and lactation, and their relation to events critical to breeding protocols, pregnancy diagnosis and estimation of gestation length.

estrogen levels in the second half of pregnancy.²⁷

Luteal progesterone is needed to maintain pregnancy in the bitch. This has been substantiated by several researchers. Removal of ovaries, hypophysectomies causing loss of LH and prolactin support of the corpora lutea, anti LH serum, suppression of prolactin with bromocryptine, prostaglandin F2a induced luteolysis in the last 30 days of pregnancy, all cause reduced serum progesterone levels to baseline and abortion.^{3,27,112,126}

Progesterone levels begin to drop between 30 to 35 days and 60 days of pregnancy from peak levels of 15 to 80 ng/ml to a prepartum plateau of 4 to 16 ng/ml, which is maintained for one or two weeks prior to parturition. Formation, full development, and progressive retrogression of the corpora lutea in the dog have been fully described and each phase occupies approximately one-third of pregnancy (0–21, 22–43, and 44–63 days postcoitum).³ The corpora lutea decrease in size after 37 days of pregnancy, but not until after 45 days is there histologic evidence of retrogression. Retrogression is progressive and remnants of corpora lutea can be detected for 2 or 3 subsequent estrous cycles.^{3,62} In non-bred bitches, degenerative signs are seen about the same time (42 days) as pregnant corpora lutea, but retrogression becomes more extensive at this time than in the pregnant bitch. By 5 to 6 months after the onset of estrus, corpora lutea in both bred and non-bred bitches are approximately 2 mm in size, are located deeper in the medulla of the ovary and have similar histological features.³

A pregnant specific two to five fold increase in serum prolactin (50 ng/ml) takes place with a rapid decline in progesterone the last few prepartum days.^{27,30,40} Prolactin levels remain high during lactation because of the suckling stimulus and decline to basal levels following weaning. Levels fall rapidly in bitches not nursing pups. In one study, PRL increased very rapidly during the 16 to 56 hours prepartum and reached peak levels (117 ± 24 ng/ml) at 8–32 (21 ± 3) hours prepartum in 6 bitches and at 24 hours postpartum in one bitch. By 36 hours after this peak, PRL levels were reduced to 37 ± 8 ng/ml before again increasing in response to suckling. Mean PRL levels increased during the first week of lactation, peaked at 86 ± 19 ng/ml at 1.5 weeks of lactation, fell slowly to 43 ± 6 ng/ml at 5 weeks, shortly before weaning, and then fell abruptly to 13 ± 2 ng/ml following weaning (Chart VI).³⁰

In the week prior to parturition maternal cortisol levels increase and are considerably increased 24 hours prepartum at the time that progesterone levels are falling. Concannon, et al. reported that on Days –3, –2, –1, 0 and 1 from parturition, mean plasma progestins were 4.2,

4.3, 1.6, 0.9, and 0.8 (± 0.2) ng/ml while the mean corticoids were 19, 19, 37, 15, and 14 (± 3) ng/ml.³⁵ In another study, mean serum progestin levels at approximately 120, 36, 20 and 10 h prepartum were 4.5 ± 0.6 , 3.1 ± 0.4 , 1.2 ± 0.4 , and 0.6 ± 0.1 ng/ml respectively. In 6 of 7 bitches, serum cortisol was elevated above mean prepartum levels of 23 ± 1 ng/ml during the day prior to the start of parturition, reached peak levels of 63 ± 7 ng/ml at 8–24 hours prepartum and fell to 19 ± 4 ng/ml at 8–12 hours postpartum. Mean serum cortisol levels remained between 22 ± 1 and 27 ± 5 ng/ml during lactation and weaning.³⁰ Dexamethasone treatment (2×5 mg daily for 10 days) from Day 30 of pregnancy caused, fetal death and fetal resorption, while treatment about Day 45 caused abortion or birth of dead fetuses at Days 55–59. A very accelerated decline of serum progesterone occurred after treatment in midpregnancy.⁶

By recording rectal temperature twice daily a transient hypothermia will parallel the decline in serum progesterone prior to parturition with a delay of approximately 12 hours. Rectal temperature falls about one to two degrees centigrade between 12 and 36 hours prepartum. During or following parturition, a rise in rectal temperature to slightly above normal takes place which will persist for several days.^{27,35} Further studies have shown that administration of prostaglandins F2 α (60 ug/kg divided bid or tid) can cause luteolysis, serum progesterone levels to fall rapidly, and some abortions in the last half of pregnancy. Rectal temperature also dropped within 15 minutes of PGF2 α administration, but only in luteal phase bitches and not in ovariectomized bitches, which suggested that the temperature drop depends on rapid drop in progesterone levels.^{32,35} Three bitches in this study did not abort, because progesterone levels remained at 2.1 ng/ml and after treatment of PGF2 α was stopped, progesterone levels returned to 5–10 ng/ml until normal prepartum decline. Progesterone serum levels must drop to baseline for parturition to take place. Exogenous progesterone given prior to Day 60 caused prolonged gestation, with either death of pups and the bitch if caesarian sections were not done.³⁵ What role prostaglandins play in natural luteolysis and parturition are not known. It has been shown that the canine pregnant uterus does produce PGE2 and PGI2 but no PGF2 α . Thus the PGE2; PGF2 α ratio may present a protective mechanism as it does in other species for the corpora lutea and maintenance of myometrial vascular tone during late pregnancy. Possibly PGF2 α is increased at the very end of gestation.^{27,83}

Parturition—The bitch at parturition is responsive to exogenous oxytocin, but measurements of endogenous

oxytocin have not been reported. Clinically the bitch appears like other species, that the neural reflex release of oxytocin occurs in response to cervical and vaginal distention during delivery of pups, digital "feathering" or stroking of the vaginal wall and suckling during lactation. The relaxation and dilation is probably caused by progesterone decline and estrogen increase at this time. The sharp prepartum prolactin rise may play a role in the anxiety, panting, scratching, chewing, nesting behavior, milk secretion, and seclusion that are usually observed 12 to 24 hours prior to whelping. It may also be responsible for other maternal activities such as removal of fetal membranes from pups, separation of the umbilical cord, eating of the placenta and licking and cleaning each pup as it is born. These same maternal behavioral signs and lactation may be seen in bitches with overt pseudopregnancy. (See pages 107-110.)

It appears that relaxin or a relaxin-like hormone is also present in the bitch, since along with increased estrogens the bitch shows great relaxation and softening of the sacroscopic ligaments, pubic symphysis, relaxation and dilatation of the vulva, vestibule and vagina.

The sequence of parturition in the bitch includes the three recognizable stages of labor. The first stage involves the anxiety, restlessness, nesting behavior, anorexia, seeking seclusion, and temperature drop of 1-2°C, 12 to 36 hours prior to whelping. The pelvic ligaments are softened with the tail head and tuber ischii becoming more prominent and the vulva lengthened, becoming flaccid and moist. Mild uterine contractions during this time can cause some of the restlessness. The second stage of labor is the true delivery of the pup or pups with usually one or two delivered at a time period and may consist of tenesmus and a few forceful strains similar to defecation resulting in the delivery of a pup in the non-complicated case. Over half are delivered in the anterior dorsal position, 40% in the posterior position. Usually extremities are extended, but birth in many can take place with a retained limb. Most bitches will deliver one or two pups every 30 minutes to 2 or 3 hours with the interval usually the longest following the first pup or pups delivered. Most bitches deliver their litter in 3 to 6 hours but can take up to 24 hours. Placentas are usually passed between the delivery of one or two pups since pups usually come alternately from each uterine horn. The third stage of labor, delivery of the placenta, is blended with the second stage. Most bitches will ingest the fetal membranes.

Suppression of estrus or control of estrus, contraception or complete sterility in the bitch are subjects of great interest and research in recent years. Different populations of dogs need different forms of control. The

most difficult group is the control of the stray, ownerless or homeless dogs (and cats) which require permanent sterilization of both sexes, instead of suppression or reversible control of fertility. These are usually dogs (and cats) owned originally by irresponsible persons. Animal shelters would like to provide sterile male and female pups, (kittens) or adults with a minimum of expense. A method or methods are needed that are effective, humane, permanent with one application, easily obtained by consumers, and easily provided by the health delivery system involved. Several studies and conferences have been held to provide measures to meet these needs, such as the National Conference on Dog and Cat Control, held in 1976 and sponsored by the American Humane Association, American Kennel Club, AVMA, Humane Society of the U.S. and Pet Food Institute.⁸¹ Several state and local societies have also studied the problem. A large part of their studies have been organizational, defining who is responsible, educational and informative to the public, setting control measures and the most difficult, finding finances for research and field trials to conduct studies on control of fertility or permanent sterilization.

Studies on the pet population in the United States are interesting and appalling. In nearly two decades of effort to raise public awareness and to educate conscientious pet owners, there appears to be little improvement.⁶¹ A report by APHIS-USDA in 1981 showed that 20 million dogs and cats are annually not wanted; 5 million are abandoned and 15 million are given to animal pounds and shelters.⁸⁰ Of those, 2 million are adopted and 13 million are destroyed. Faulkner's paper on pet population problems claimed that in 1973, 4.5 billion dollars were spent on combined care and feeding of pets, 18 million neglected pets were impounded costing society nearly 125 million dollars. To maintain a zero growth in the population, 72,000 dogs and cats must be destroyed each day. He also brought out the public health hazards, zoonotic diseases, waste problems of feces in highly populated areas and the trauma and fear of bites and stray dog packs.⁴⁹

Two studies in pet population control in a midwest U.S.A. college town showed that the dog population stayed stationary from 1968 to 1979 with 66% of all bitches spayed; with a people to dog ratio of 4.14:1 and a 12% population of roaming dogs with 36% of them, actually stray dogs. The cat population though was increasing by 18% annually. Only 59% of the females were spayed and it was calculated that 88% should be spayed to obtain zero population growth. The people to cat ratio was 5.2:1, household average was 0.508; 28% of all households had cats with 1.74 cats per household, whereas 43% of the households had dogs with 1.36 dogs per

household.⁷⁸ An excellent study by Schneider on the pet population in two areas of California from 1970 to 1975 showed an increase in pet owners, a reduction in the numbers of unwanted pets, increased life expectancies of pets and increased neutering of pets.⁹⁹

The only procedure available to the humane shelters is the spay or castration clinics which are expensive and time consuming. However, Faulkner stated that surgical sterilization or any alternative contraceptive technology deals with the consequence of the problem and not with its cause, which are irresponsible owners and inadequate control of irresponsible ownership.⁴⁹ Other methods currently being investigated are immunological control, especially with gonadotrophins, gonadotrophic releasing hormones, the ova, zona pellucida, fertilized eggs, spermatozoa, testicular tissue; the destruction of specific cells of the pituitary or hypothalamic area with cytotoxic substances, the formation of acyclic pets by testosterone sensitization of the perinatal hypothalamus and quicker methods of sterilization, utilizing laparoscopic techniques, electrocautery, lasers and injection of sclerotic or caustic agents for castration.^{1,13,28,48,50,59,72,73,92,104,138}

Probably no one method will answer all needs. Population control of other wild carnivores; coyotes and foxes are being studied for possible control of the stray dog. The second population of dogs to provide estrus control are those that are owned by conscientious persons that want to produce litters, but need estrus suppression or control to avoid the nuisance of estrus while using the bitch for performance, show, work and also to avoid the problem of confinement, attraction of males and possible unwanted pregnancies. When unwanted breedings do take place, then mismating, "day after" or pregnancy termination methods are needed.

Options for preventing estrous cycles or pregnancy in the bitch still remain limited to veterinary practitioners in the United States compared to other countries in the world. If permanent sterility is desired, then the best method available is ovariectomy. This is not without postoperative complications. In one study of 109 bitches, referred to a University clinic over a 30 month period, 28 bitches had a persistent vulvar discharge, 37 attracted male dogs, 28 showed periods of estrus, 14 had postoperative pseudopregnancy. Pseudopregnancy may occur post surgically when bitches are spayed in the luteal phase causing a rapid fall in blood progesterone levels and a release of prolactin which may simulate the same hormone sequence as parturition.²⁷ Forty seven of these bitches had remnants of ovaries left on exploratory surgery (41 right side, 22 left side); 70% had elevated progesterone levels, 39% had cyclic vaginal smears; 19 bitches had uterine stumps infected and inflamed.^{81a} One

case report involved a bitch with a partial hysterectomy; ovarian cycles continued; three years post surgery a vaginal discharge was discovered and on surgery the remaining uterus and cervix contained abscesses and granulomas from which *B. canis* was recovered. A high *B. canis* titer was maintained for at least one year after removal of ovaries, remaining uterus and cervix and therapy with tetracycline.^{40a} These reports indicate that good techniques are required and that complete ovariohysterectomies are much preferred over tubal ligations, ovariectomy, salpingectomies or subtotal hysterectomy which frequently lead to uterine, cervical and/or ovarian disease. There is a move to encourage spaying prepubertal or pubertal bitches for several reasons; the infantile tract is located and removed with minimal time and trauma. There is little or no chance of developing mammary gland tumors and there is no chance of several unwanted litters before accomplishing ovariohysterectomy. Post complications of prepubertal spayings may result in a higher incidence of juvenile vulvas, perivulval dermatitis and hypoenestrogenism with bilateral miliary dermatoses. Increased obesity may be seen in some bitches, but frequently the young bitch will have a greater tendency to exercise well and exercise and diet control will control the obesity problem. To what extent bone development, epiphyseal closure, or adult body conformation will change is not known and further studies are needed.²⁸

For control of estrus, reversible contraception by pharmacologic means is available with synthetic progestins or androgens.^{16,28,135} One of each for use in the dog are approved for use in the United States ("Ovaban," Schering Corp, Kenilworth, N.J. and "Cheques," Upjohn Co, Kalamazoo, Mich.). With either of these two steroids, estrus can be prevented and pregnancies postponed. Manufacturers recommendations should be followed. They are not the answer for life control for estrus nor are they meant to replace ovariohysterectomy. They are products to be used in young bitches prior to uterine or ovarian disease. Bitches that were not planned to be bred or have finished their reproductive use should be neutered.

Megestrol acetate ("Ovaban") is marketed in the United States as a canine contraceptive in 5 and 20 mg tablets for oral use. It is distributed as "Ovarid," Glaxovet Ltd., Greenford, Middlesex, in the United Kingdom and Europe. It is a potent oral progestin with a very short half life, with total elimination from the bitch in about 8 days.¹⁶ It can be administered at two times of the cycle to control estrus, either in anestrus or the first 3 days of proestrus. The recommended dose for anestrus bitches is 0.25 mg/lb (0.55 mg/kg) body weight for 32 days. The time for anestrus treatment must be selected on the basis of

the bitches' history of interestrous intervals and be at least one or two weeks prior to the next expected proestrus. The return to estrus averages 4–6 months (1–7 mo. range).

The proestrus dose is 1 mg/lb (2.2 mg/kg) for 8 days, which is the same total dose for the 32 day treatment. The occurrence of proestrus should be verified by examination of vaginal cytology. The bitch should be confined for 3–8 days or until cessation of bleeding and loss of attraction for males. Usually proestrus subsides in 3 to 8 days. Again, most bitches return to estrus in 4 to 6 months (1–7 mo. range). If treatment is started too early in proestrus, the bitch may return to proestrus, if too late in proestrus, a fertile estrus may occur.²⁸

British work on "Ovarid" reported that return to estrus can be delayed by administering megestrol acetate at 1 mg/lb, (2.2 mg/kg) for 4 days, beginning during the first 3 days of proestrus, followed by 0.25 mg/per lb (0.55 mg/kg) for 16 days which again is the same total dosage as the other two regimes. They also recommend that if mating occurs during the first three days of treatment, megestrol acetate therapy should be stopped and the bitch treated for mismating. If mating occurs after 3 days of treatment, therapy should be continued at 3 to 4 mg/kg since the drug will prevent pregnancy in most cases. British work also prescribed megestrol acetate for up to 4 months following a postponement course of therapy for extended suppression, but these bitches should be allowed a normal cycle before being retreated.¹⁶

Precautions indicated by the manufacturer for "Ovaban" are; not to administer for more than 2 consecutive treatment periods; do not use in bitches with reproductive tract disease, pregnant bitches, or bitches with mammary tumors; do not use in first estrus or pubertal dogs. A report has shown that it is safe and effective in first-heat or pubertal bitches when the onset of proestrus is accurately determined and treatment administered as prescribed for proestrus.⁹ Clinical trials reveal suppression of estrus in 92% of 387 bitches in early proestrus and 97% of 117 in anestrus with minimal adverse effects.¹⁷ Treatment did not affect subsequent cyclicity and fertility.

Temporary minor side effects include increased appetite, decrease of activity, calming effect, less aggressive behavior, weight gain, water retention and rarely lactation. Therapy during either the first or second half of pregnancy did not result in fetal abnormalities. Overdosage or prolonged therapy may cause cystic endometritis or Cushingoid syndrome.^{14,15,16,28}

"Mibolerone" is a synthetic androgen-derived steroid and is approved for long-term estrus prevention in dogs as "Cheque" drops to be added to food daily in the United

States and as "Matenon" in the United Kingdom. Approval has been obtained in the United States to market mibolerone in canned dog food as a prescription diet. It is androgenic, anabolic, antigonadotrophic and does not possess progestational or estrogenic activity. Inhibition of estrus was over 95% successful in dogs treated for periods up to 5 years and possibly it may prove capable for life-time use.^{16,111} Manufacturers recommended treatment for up to 2 years, starting in early or mid anestrus. Treatment should start at least 30 days prior to the onset of the next proestrus to completely suppress estrus. It will not arrest proestrus or estrus like megestrol acetate, and will not interfere with conception or gestation, however, female puppies were masculinized.^{16,110,113}

Dosage ranged from 30 µg/day for dogs weighing 1 to 12 kg. up to 180 µg/day for dogs over 45 lbs, German Shepherd Dogs and any German Shepherd cross-breed which for unknown reasons require the high dosage. Undesirable side effects include: mild clitoral hypertrophy which is worse in prepubertal bitches to the point of os penis formation; vaginal or vulval discharge, especially in those with an enlarged clitoris; masculinized deeper voice, masculinized hair coat, especially over the neck region; anabolic effects; overdose leads to anal gland inspissation and resulting odor; increase severity of preexisting seborrheic dermatitis; and occasional elevation of liver function test which returns to normal when the compound is removed from the diet.^{16,28,111}

Bitches that show estrus while on therapy are either receiving too low a dose, started with less than 30 days to estrus, or therapy was not reliably administered. Return to estrus following cessation of administration is usually 2 to 3 months but may be as short as 7 days and up to 7 months.^{16,28} Bitches that are on higher doses than recommended may also have a decrease in the post treatment size of the first litter.¹¹¹

Several other non-approved steroid hormones have been shown to suppress or inhibit normal ovarian cyclicity in the bitch. Excellent reviews on their use and side effects have been reported.^{16,28,60,103} The steroids used include natural steroids, progesterone and testosterone, and synthetic steroids including medroxyprogesterone acetate, melengestrol acetate, proligestone, norethisterone acetate. It is felt that all of these work by mimicking the normal feedback effects of endogenous ovarian steroids or in the case of androgens, testicular steroids, on the hypothalamus (releasing hormone and/or pituitary gonadotrophins, FSH and LH). All of the above steroids are effective in controlling ovarian cycles in the bitch, but have undesirable side effects: progestins promote uterine disease, mammary gland hyperplasia, and other effects on pituitary and adrenal cortical functions, whereas

androgens have masculinizing effects. Both progestins and androgens can cause fetal reproductive abnormalities if given during pregnancy.^{39,132}

Medroxyprogesterone acetate, MAP or also known as α -methyl 17 α acetoxy progesterone, MPA ("Promone," Upjohn) was marketed as an injectable canine contraceptive in the U.S. until 1969. It was removed at that time because of the high incidence of cystic endometrial hyperplasia, endometritis and pyometra.^{4,11} This effect may be related to overdosing or administering during stages of the cycle other than anestrus since the importance of a synergism between progesterone and estrogen to cause increased uterine disease was confirmed earlier.¹⁰³ High doses of MAP (MPA) also cause mammary gland tumors, adrenal suppression and acromegaly.^{29,45,101} With reduced amounts, (50 mg/dog) estrus was prevented and normal fertility followed,¹² but later studies using this dose, either single or multiple injection schedules, caused uterine disease.¹⁰³ However MAP/MPA is still used widely in other countries as a contraceptive ("Depopromone," "Perlutex," "Anovulin") and is marketed in the U.S. for human use other than contraception as "Depo-Provera" (Upjohn Co.) The minimal effective contraceptive dose is approximately 2 mg/kg every 3 months.

Melengestrol acetate, MGA, another progesterone, effectively prevented estrus in dogs at 200 μ g/day, but levels of 4 or 8 μ g/kg produced abnormal uterine changes, dystocia and pyometra.^{52,114}

Proligestone (14 α 17 α propylidene-dioxyprogesterone), a progestin, is an injectable canine contraceptive marketed in Europe as "Delvosterone" (Mycofarms, Ltd. and Gist-Brookades).¹³¹ Doses of 10 to 30 mg/kg depending on the weight of animals, are injected subcutaneously at zero, three and four months followed by others at 5 month intervals thereafter. Administration during proestrus resulted in signs disappearing within 5 days and retreatment of these animals within 3 months resulted in continuing persistence of anestrus in 97% of animals treated. Clinical trials showed no formation of mammary gland tumors, only 0.3% of uterine disease and none of these were in proestrus treated cases (1685 cases). There appears to be little or no restrictions on usage at any stage of the cycle.^{28,103,131}

Silastic implants containing 169 μ g/kg of testosterone controlled estrus for as long as 840 days with normal estrus cycles and litters after removal.¹⁰⁵ Androstenedione, at a dose of 400 μ g/day/dog was not effective in preventing estrus. No uterine disease was observed, but mammary gland development with milk secretion (4/13), clitoral enlargement of all treated and one pregnant bitch with testosterone implants in situ produced two female pseudohermaphrodites.

Progesterone implants placed subcutaneously in bitches inhibited cycles for 15 to 20 months with no objectionable side effects. These implants, although effective, will probably not be made available commercially because they are not biodegradable and must be inserted and removed surgically.²⁸

A 19-norandrogen, norethisterone called "Norlutin A" (Parke Davis) was used orally to suppress estrus in Greyhound bitches. A 4 week treatment regime starting at proestrus delayed the return of estrus for 132.9 days average. Four bitches had normal litters following treatment.¹⁰³

A synthetic 19 norsteroid, 6,6, spiroethylene, 19-nor-estrioxenone, effectively suppressed the occurrence of estrus in dogs when administered orally once daily for 90 days at a dosage of 0.9 mg/kg body weight. There was no evidence of mammary gland or uterine disease during the period of treatment.⁷⁶

Testosterone propionate has been used to prevent estrus, especially in racing Greyhounds, for up to 5 years at an oral dosage of 25 mg per week. Many of these have returned to normal reproductive status. Clitoral hypertrophy and vaginitis are frequent side effects with clitoral hypertrophy being so prominent in some Greyhound bitches that they are referred to as "tail-lighters."¹⁶ Other side effects such as premature epiphyseal closure if immature bitches are treated and urogenital anomalies, hermaphroditism in female pups born to treated pregnant bitches, makes testosterone objectionable.

The oral administration of 2 to 4 drops of a 1% solution of pilocarpine has been reported to suppress estrus in bitches, but the action and method of control has not been reported or investigated.^{16,28}

Vaginal devices ("Option I") have been marketed and used as a contraceptive but since have been discontinued because of expense, various sizes needed, problems with fitting, poor retention, vaginal discharges, rejection and loss, unacceptable failure rates and dissatisfaction on the part of owners and veterinarians.

Immunization as described for population control and use in either bitches or studs may have value for temporary estrus suppression and control of spermatogenesis through LH or GnRH control, but a great deal of research is needed to find the right antigens, protocols for repeatability of effect, evidence of any deleterious effects and overcome the disadvantage of the need for irritating adjuvants for antibody production.

Luteinizing hormone, LH, given during proestrus has been reported as a possible antifertility drug for that cycle (20 units/kg-IV). This is repeated once again 2-3 days after the first injection if proestrus has not subsided. The effect is supposed to cause premature luteinization of follicles instead of stimulating further follicular growth

and maturation. The effect would depend on timing of administration so that follicles are young enough to ensure premature luteinization and not ovulation. This would be similar to reports of premature luteinization of follicles when too early attempts are made to induce estrus in bitches using PMSG or FSH and following with LH or HCG resulting in preovulatory luteinization instead of ovulation.²⁸

For years estrogens have been used as post-breeding, "day after," misalliance and antinidatory treatment in bitches that were mismated. A variety of estrogens have been used with little scientific and experimental evidence of their effectiveness and side effects. Diethylstilbesterol, before it was removed from use in the United States, was the hormone of choice and continues to be used in many countries where it is still legal. Since then, several of the longer acting available estrogens are being used, especially estradiol cypionate (ECP) followed by estradiol valerate or benzoate and finally estrone. Few statistics are quoted for their success and/or for failure. One report revealed, that 1–2 mg of ECP given intramuscularly the first 5 days following mating had prevented conception in 537 consecutive cases.⁶⁵ Several failures had resulted when ECP was given later than 5 days after mating. It was indicated that these animals should receive a second injection of ECP five days after the first or receive oral diethylstilbesterol tablets at the rate of 1 to 2 mg daily for five days. Estrogens usually delay the transit of zygotes in the oviduct and may affect the development of zygotes directly (zygototoxic).¹⁰³

Holst and Phemister have shown that oocytes remain in the oviduct until one to three days after the vaginal smear is no longer fully cornified or the beginning of metestrus/diestrus.^{55,56} Since a bitch can accept a male over a long period of time, late proestrus to early metestrus/diestrus, it is very important that vaginal smears be made and the cytology studied for stage of cycle when the bitch had coitus and judge the most appropriate time for "mismating" with estrogen therapy. Concannon has given excellent guidelines on the use of ECP until more scientific evidence is presented for its use in misalliance. If the smear is still of estrous type, only a most conservative dose of ECP should be considered (0.1 mg/10 lbs, max. of 0.5 mg); if the smear is not fully cornified or late proestrus, a delay of 1 to 3 days before estrogen administration should be considered because the bitch probably has not ovulated. Remember, semen in the uterus can be fertile for 5–6 days or possibly to 11 days or at least until metestrus.⁴¹ If the vaginal smear is very late estrus or early metestrus, then an intermediate or less conservative dose can be given (0.2 mg/lb for a total of 1.0 mg). These doses are based on clinical impressions and published reports.^{28,58} Estrogen will lengthen the es-

trus or attractiveness and if given in proestrus may do little but delay the LH surge and the bitch eventually reaches estrus and may become pregnant. Bitches must be confined during this prolonged acceptance period. Bitches that have received the long acting estrogens are more prone to developing pyometra in 2 to 6 weeks, which is frequently an "open" pyometra with a mucopurulent or mucosanguinous vulval discharge. Excessive estrogens can cause aplastic anemia, thrombocytopenia and a hemorrhagic syndrome with a rapid course and death.^{10,66} Concannon has reported on the several forms of estrogens used for mismating bitches with no scientific data on safety, side effects or effectiveness (Chart VII).²⁸

An antiestrogenic compound, 3-4-trans-2,2-dimethyl-3-phenyl-3-4-p-(B-pyrolidinoethoxy)-phenyl-7-methoxychroman, devoid of progestational, androgenic, or antiandrogenic activity, was reported to be effective when given 24 hours after mating to prevent pregnancy. It can be given orally or parentally in a single dose to interfere with ovum development.¹⁰³

Administration of two compounds, (L10492) and (L10503) prevented pregnancy in bitches most effectively when administered at 20 days postbreeding, about the time of nidation. A single dose of 100–150 mg/kg was administered. When given at 45–48 days, they caused resorption in 2 bitches and expulsion of macerated fetuses 1 week past the due date. Undesirable side effects include loss of appetite and diarrhea for 3–8 days beginning 1–3 days after the start of treatment.¹⁰³ These drugs seem to work on the utero-placental complex directly and do not influence pituitary or ovarian function since plasma progesterone levels remain normal post treatment.

Termination of pregnancy after diagnosis has also become an alternative choice after an undesirable mating. Several drugs have been used including estrogen implants, prostaglandins, bromoergocryptine (an ergot alkaloid) and dexamethasone.

At midpregnancy, silastic capsules containing crystalline estradiol, sufficient to maintain blood levels of estradiol of proestrous level, were inserted subcutaneously. All bitches treated either resorbed or aborted their litters.²⁸

Adrenal corticosteroids have the potential to terminate established pregnancies in the bitch. One study reported on the use of dexamethasone at 5 mg twice a day for 10 days with intrauterine death and resorption when started at 30 days; and birth of dead fetuses at days 55 to 59 when treatment started at day 45.⁶

Bromoergocryptine, an ergot alkaloid, reduces prolactin secretion as a dopamine agonist, is luteolytic and when administered to bitches at 0.1 mg/kg/day for 6–10 days

(1) Mann, 1971; (2) Jochle, 1975; (3) The Merck Veterinary Manual, 5th ed., 1980; (4) Jackson and Johnston, 1980; (5) Okin et al., 1976. (Courtesy and with permission of P. W. Concannon and publisher, W. D. Saunders, Co.²⁸)

it terminated pregnancy in 60% of bitches studied. Nausea, depression, anorexia are some of the deleterious side effects reported.²⁷

Prostaglandins of the F series, PGF_{2a} are used in the bitch for their luteolytic and smooth muscle effect, resulting in cervical dilatation and uterine contraction. This effect causes luteolysis and abortion in midpregnancy; approximately from 30 days to parturition in the bitch. The current popular clinical use of PGF_{2a} is to treat pyometra—endometritis in the bitch and queen. Prostaglandin analogues have also been studied in the bitch to cause luteolysis and abortion. The right analogue could become a very important drug for small animal use because they usually are much more potent and long acting with lower dosage, and less side reactions.

The median subcutaneous lethal dosage for PGF_{2a} in the bitch was determined to be 5.13 mg/kg.¹¹² Clinical signs of side reactions and toxicosis include excessive salivation, vomiting, diarrhea, hypernea, ataxia, urination, anxiety, and pupillary dilatation, then constriction. Severity of side effects are dose dependent. At low dosages, defecation is more frequent, while at intermediate dosages, hypernea, anxiety, hypersalivation, vomiting and defecation have been observed. Higher doses have

caused ataxia and slight depression.⁹⁰ The clinical dose range in the bitch has been from 0.02 to 1.0 mg/kg or 20 ug to 1000 ug/kg administered usually intramuscular or subcutaneously.^{32,90}

Side reactions are seen in 20 to 120 minutes post injection. Death in animals given lethal doses range from 2 to 12 hours post injection.¹¹² Bitches seem to adapt to PGF_{2a} with side effects diminishing by the fourth or fifth treatment. Prostaglandin F_{2a} or analogues should not be used in dogs with asthma, liver, kidney or cardiac problems.

Early researchers thought that PGF_{2a} was not luteolytic in the dog but did cause temporary lowering of serum progesterone levels for a brief time.^{3,7,63} Concannon was the first to show that 20 ug/kg every 8 hours or 30 ug/kg every 12 hours for 3 days caused abortion in 4 of 7 bitches started on treatment on days 33 to 53 of gestation, with abortion occurring 56 to 80 hours after initial treatment.³² Progesterone plasma levels were 0.6 to 1.4 ng/ml when abortion occurred. The 3 bitches that did not abort had a mean low value of 2.1 ng/ml of plasma progesterone during PGF_{2a} treatment beginning on day 31 to 40 of gestation. Their plasma progesterone recovered to 5–10 ng/ml and were maintained until nor-

mal prepartum decline. In this study, 8 nonpregnant bitches in mid or late luteal phase were also treated and all 8 had complete luteolysis with low anestrus baseline plasma progesterone levels afterwards. Two nonpregnant bitches in early luteal phase (days 5 and 20) were also treated and plasma progesterone levels were not drastically altered.

Concannon also found a transient fall in rectal temperature within 15 minutes and maximal at 45–60 minutes postinoculation that averaged 1.39 °C. No change in temperature was seen in ovariectomized bitches treated with PGF_{2a}. It was concluded that hypothermia was due to the 20 to 45 percent fall in plasma progesterone levels within the 15 minute period postinoculation of PGF_{2a}.

Ten mated bitches were given 250 ug/kg of PGF_{2a} bid; 5 between the first and fifth days of metestrus and 5 between 31 and 35 days of metestrus.⁹⁰ Early metestrus dogs were not affected and appeared the same as the 5 nontreated controls, whereas all 5 in midgestation had complete luteolysis, hypothermia following the initial injection of PGF_{2a} and abortion following the fourth to eighth injection.

Prostaglandin analogues, fluprostenol and cloprostenol ("Equimate" and "Estrumate," respectively, Imperial Chemical Industries, U.K.) were administered to 42 Beagle bitches at gestational periods of 4 to 35 days at doses from 10–40 ug/kg.⁵⁷ A slow releasing formula of both analogues (48 to 72 hours) and a 24 hour release intravaginal device of both analogues showed minimal acceptable side effects compared to the aqueous marketed form of cloprostenol. Sustained depression of plasma progesterone levels and pregnancy termination were seen in 6 of 22 bitches (27%) treated before day 25 of gestation and 16 of 20 bitches (80%) treated on or after day 25. An interesting effect was that 2 bitches whose pregnancies or corpora lutea were terminated at 14 days by the 40 ug/kg cloprostenol injection showed clinical estrus 10 to 14 days after treatment with normal mature ovarian follicles at necropsy. This suggests that a bitch could possibly be remated in a few weeks after correction of a misalliance in the first 2 weeks instead of having to wait until the next cycle at 4 to 12 months.

Eleven pregnant bitches were treated with a single subcutaneous injection of 20 ug/kg of synthetic prostaglandin analogue (TPT) in an aqueous buffer.¹³³ Five bitches treated between days 30–43 of pregnancy aborted 5.4 ± 1.4 days following treatment. Two of 4 bitches treated on days 20–22 of gestation continued to normal term, while the other 2 appeared to resorb their fetuses following diagnosis by palpation on day 28. Two others treated on day 9 had normal pregnancies.

Further work by this group utilized bitches on days 20–22 of pregnancy and administered TPT subcutane-

ously in different treatments: minipump at a rate of 10 ug per hour for either 24 or 48 hours, single injection of 200 ug in either aqueous, or polyethylene glycol 400 or the methyl ester of TPT in polyethylene glycol 400.¹³⁴ All treatments caused abortion or resorption with the best treatments being those that had the longest administration of analogue; 48 hours minipump, 5/6 aborted and the methyl ester of TPT, 3/4 aborted.

Eight bitches were given 5 to 30 mg of PGF_{2a} on day 5–17 of pregnancy which resulted in a marked temporary decrease in progesterone levels and in those given 20 mg or more deaths occurred in some or all of the embryos after implantation. Seven bitches given 5–50 mg of PGF_{2a} in 25–51 days of pregnancy resulted in only one animal given 20 mg of PGF₂ having a premature birth at day 51. All others were normal. Bitches given 5–10 mg of PGF_{2a} on days 55–58 of pregnancy resulted in induced parturition in 38.1 hours. In this study, side effects of PGF_{2a} were intense in bitches given 10 mg or more of PGF_{2a} and those treated during pregnancy returned to estrus about 40 days earlier than untreated control bitches.¹³⁰

The above research indicates that the early corpora lutea are quite resistant to exogenous prostaglandin until midgestation, 25 to 30 days to term. The author has aborted 6 mismated bitches. Their ages ranged from 8 months to 5 years, gestations ranged from 31 to 60 days, and a range of 2 to 8.5 days of PGF_{2a} therapy was needed to cause abortion. Treatment consisted of 25 to 50 ug/kg of PGF_{2a} (Upjohn Co., Kalamazoo, MI) intramuscularly, given twice a day. The lower dose was given the first day or two to observe the severity of side effects and to relax the cervix. These bitches showed nesting signs 24–48 hours prior to abortion. Vaginoscopic examination of 3/6 bitches revealed daily changes in the anterior vagina with increasing edema of the vaginal and cervical folds, fluid, and dilation of the cervix 24 to 48 hours prior to abortion. The two late gestation bitches, 57 to 60 days of gestation, aborted at 2 and 4.5 days of treatment, respectively, and both had live pups. The bitch at 31 days of gestation aborted 3 pups 6 days post initial treatment and abortion appeared to be complete. She was given 10 i.u. of oxytocin intramuscular the following day to enhance uterine involution. Two weeks later, two retained viable fetuses were noted on palpation and radiographs. The bitch whelped 2 normal live pups and has had 3 normal litters since. All bitches returned to estrus at normal intervals. One bitch had prolonged postpartum hemorrhage for 6 weeks that was diagnosed as subinvolution of placental sites. All bitches showed varying individual slight side effects the first 15 to 60 minutes post injection including increased salivation, diarrhea, emesis, and panting.

The above work shows that $\text{PGF}_{2\alpha}$ can be used to cause abortion in healthy bitches from midgestation to term. A dose range of 25–250 $\mu\text{g}/\text{kg}$, given intramuscular, BID to effect can be used. Hospitalization and close observation are necessary and the later the stage of gestation the quicker the effect. More research is needed on the analogues, different routes of administration such as the intravaginal route, possible early gestation luteolysis and early return to estrus.

Induction of estrus and ovulation with successful breeding is desired at times for convenience of a timed whelping for companion dogs, show or performance bitches, research dogs, infertile bitches with a history of never expressing estrus or having an abnormal long interestrus period (usually >12 months). The infertile bitch with this history should have a physical and reproductive tract examination, thyroid function test for hypothyroidism, vaginal cytology and a blood serum progesterone test to determine true anestrus or a possible missed cycle.

Gonadotrophins, follicle stimulating hormone, (FSH), pregnant mare serum gonadotrophin, (PMSG), luteinizing hormone, (LH), and human chorionic gonadotrophin (HCG) and gonadotrophin releasing hormone, (GnRH), estrogens and some human fertility drugs have all been used, in different regimes, combinations and dosages with varying success. Several have induced estrus with or without ovulation, normal or degenerate ova, and few have been highly successful in producing normal pregnancies or having repeatable results. The induction of estrus in the queen is much more predictable than in the bitch.^{21,43,44,46,60,64,67,68,86,89,102,103,118,129,140,141}

The use of PMSG daily, utilizing either 250 IU/day, 500 IU/day or 20 IU/kg/day for 10 days with 500 IU of HCG combined on the last day of PMSG treatment resulted in successful induction of estrus and ovulation in 14/25 bitches.¹¹⁸ Another researcher, used these same regimes for 8 days, with successful induction of estrus and ovulation in 6/6 bitches.¹⁰³ The undesirability of causing premature luteinization of follicles with HCG is important to consider. The 10 day interval from the start of treatment is about the normal interval for follicular growth in the dog prior to the preovulatory LH surge.¹⁰³ Another group reported on the use of 20–50 IU/kg/day, IM for 9 days or 500 to 1000 IU/day, I.M., of PMSG, two treatments, six days apart, followed by either 500–1000 IU/day, I.M. on the first and second day of estrus or 2 treatments of GnRH, 50 μg , IM, each six hours apart on the first day of estrus. Bitches treated with these regimes ovulated 60% of the time. Ovulation was determined by serum progesterone increase or pregnancies following artificial insemination.^{19,21} This group found PMSG more effective than FSH-P. These treatments appear to work in the truly anestrus bitch and appear to

be more effective when administered intramuscular instead of subcutaneously. If the bitch is in metestrus/diestrus with progesterone levels above basal levels, then pretreatment with either estrone or estradiol is recommended. Pretreatment with 100 to 300 μg of estrone per day for 5 to 6 days produced vulval bleeding. This was followed by the regime of PMSG and HCG previously mentioned and resulted in normal pregnancies. Either PMSG or FSH-P if used indiscriminately can cause cystic follicular degeneration. Induced bitches should be bred every other day for three matings starting with the first day of acceptance. In another study, 4/8 bitches had fertilized ova or pregnancies when 200 IU of PMSG and 500 IU of HCG IM was followed by 500 IU of HCG 3 days after the vaginal smear was fully cornified.¹²⁹ Wright induced estrus in eleven anestrus bitches with 110 IU/kg of PMSG given once weekly until estrus occurred or until 3 treatments had been given. Estrus occurred in 8 of 11 bitches. Three of 8 received 500 IU of HCG on the first day of estrus resulting in 7/8 bitches ovulating with those receiving HCG having a better ovulation rate (88.6% vs 46.1%). In a later study, 8 anestrus bitches were given 250 IU of PMSG per day until estrus occurred, or till 20 days of treatment. Then 500 IU of HCG was given on the first day of estrus or on day 21. Six of 8 ovulated, 3 with 100% ovulation rates; two showed estrus at 14 days, the rest went to day 20.^{140,141} Several regimes using either PMSG and HCG, sheep pituitary gonadotrophin ("Vetrophin") or equine pituitary gonadotrophin ("Pitropin") are reported with about 85% normal dogs induced at the proper time and 65% of bitches with prolonged anestrus showing good standing estrus after treatment with expectation of normal conception and litter rates.⁴⁶

One FSH and LH scheme was reported to cause follicular growth but not ovulation.⁸⁹ Another method, utilized 1 mg diethylstilbesterol oral tablets daily for 4 days and on day 8 twice daily injections of 2 mg FSH subcutaneously, until the vaginal epithelium was 90% cornified (about 8 days of FSH) followed by 500 IU of HCG I.V. Most bitches accepted the male 48 to 72 hours post HCG. This regime has produced small litters in bitches with prolonged anestrus but not in normal anestrus bitches.⁸⁵ The author prefers a method of weekly 25 mg FSH injections, I.M., in truly anestrus bitches, until vulvar enlargement or a bloody vulval discharge occurs.⁶⁷ The author only gives FSH for up to 5 treatments. If estrus does not occur then one month's rest and repeat the regime for another five weekly treatments. Most bitches will show estrus after the second and third FSH injection. At each injection day, vaginal cytology is performed for evidence of increased estrogens and follicular development. Once proestrus is determined, then every

day vaginal cytology is taken and the bitch is bred at estrus every 48 hours for 3 or 4 times. If proestrus occurs but doesn't proceed to estrus by daily increasing superficial cells or cornified cells on daily vaginal smears then daily FSH injections starting with 25 mg on day 1, 10–15 mg on day 2 and 5 mg on day 3 will usually cause complete cornification and estrus. This bitch is then given 500–1000 IU of HCG, IM, when fully cornified and bred as described above. Approximately 60% of bitches treated in this manner will ovulate, conceive, have normal pregnancies and litters.

Reproductive Physiology of the Queen

Puberty in queens usually occurs between 7 and 12 months of age depending upon their nutritive state, breed, freedom from disease and season of the year that they are born. Queens may have their first estrus as early as 4 months of age if they obtain the minimal body weight of 2.3 to 2.5 kg or they may be as late as 21 months of

age. If the normal pubertal age and weight are attained during the anestrus period of October to December, cycling usually begins in January or February following birth. If pubertal weight is attained in early or late summer then an early pubertal estrus may take place.⁴⁸ Males usually reach puberty at a minimal body weight of 3.5 kg which is attainable at 9 months of age. (See pages 409–411.)

Purebred cats may reach puberty later than non-purebred cats. Cats that are housebound versus a free-roaming environment, especially those that are housed without other cats, may reach puberty later.¹⁸ A British study of several breeds showed that puberty on the average was seen between 9–10 months of age, with considerable breed difference; Himalayans or colorpoints were the oldest, average 13 months (9–18 mo.), while Burmese were the youngest, average 7.7 months (4.5–15 mo). They noted that puberty was affected by age of kittens at weaning, time of year litter is born, natural or artificial increase of daylight and the breed of cat.³⁰

The reproductive life of the cat is long, with both toms and queens known to continue breeding for 14 or more years, with a period of 8 to 10 years most common for continuous breeding of a queen. (See page 110, 111) **Litter size** is reduced with age. Most queens will have two litters of 2 to 6 kittens with an average of 4 each per year. Some will produce 3 litters per year. Siamese cats or their crosses have slightly larger litters (average 6). First litters of pubertal breedings are usually small and rearing is less successful.^{34,38}

The estrous cycle—The queen is seasonably polyestrous, a long day breeder, similar to the mare.²⁹ Breeding season in temperate zones usually begins 20 to 60 days after the winter solstice and may end any time after the summer solstice. In the northern temperate zone, breeding usually begins in January or February and extends through the early part of September with a range of August to October or early November.^{18,22} The first cycle usually will occur between January and March, the second from April to early July, and the last during late July through early September.¹⁸ The author has frequently noted the first cycles of the year will be during a January or February thaw in free-ranging cats. Again, like the mare, kittens can be born in any month of the year.³⁰

In conditions of artificial light or combinations of natural and artificial light, where queens receive 12L:12D, 14L:10D, or 16L:8D, many will cycle throughout the year. Fourteen to 16 hours of light versus 12 hours will increase the percentage of cycles. Even in colonies with artificial light, some queens will experience a winter anestrus.²² Winter anestrus was reported

in 90% of long-haired cats (aver. 4 mo., 2–9 mo.) from September to January, whereas 60.8% of shorthairs remained cyclic throughout the year. More queens of all breeds confined indoors remained cyclic, while those allowed or confined outside, usually become anestrus.³⁰ Tom cats will show depressed sexual activity during the winter period.⁴⁸

The vomeronasal organ, which is a blind pouch dorsal to the hard palate and communicates with the nasal and oral cavities via the nasopalatine duct that opens behind the incisors, is thought to be used to perceive sexual pheromones from urine and glands, possibly vaginal and vulvar secretions and the scent marks in the environment.²⁴ Odor produced by intact tomcats and valeric acid, or a mixture of fatty acids, produced by the estrous queen act as sexual pheromones. Tomcat odor released during urine spraying for territorial marking is androgen-dependent and disappears after castration. Its source is uncertain, but may be part of a lipid component of the urine and/or it may be produced by the anal glands. During estrus, valeric acid is present in vaginal secretions. Tomcats may show an open-mouth flehmen response when sniffing urine, but anosmic sexually experienced males continue to mate. In tomcats, the odor of valeric acid induces a restless and lively searching reaction, but no sexual connotations, while sexually mature intact queens respond by exhibiting typical estrous behavior, thus it may induce or facilitate estrus in other queens.⁴

Catnip leaves contain nepetalactone which produced a characteristic behavior response simulating the antics of estrous queens. This is an olfactory response via the vomeronasal organ but is considered not a feline sex pheromone or pheromone-mimic but a hallucinogen which induces pleasurable behavior in cats, independent of sex or the presence of gonads. This response appears to be inherited as an autosomal dominant trait.⁴

Cats utilize 3 methods of territorial marking including scratching; leaving visual marks and odor marks from foot gland secretion; the cat's human family and familiar objects are marked by cheek or head rubbing with secretions from glands at the cheek corners and in the supraorbital region; and tomcat urine spraying to mark territorial boundaries.²⁴ The author has observed tomcats spraying parked car wheels, a trait frequently displayed by male dogs.

Sexual behavior of the queen is considered the most stimulatory to attracting tomcats. Proestrous signs are usually minimal, with increased affection or occasionally aggression and a desire to be petted. Frequent urination is usually seen.⁶⁰ In proestrus or early estrus, a slight amount of clear watery vaginal discharge may be present. In one study, 20% of cycling queens showed a

0.5 to 2 day proestrus in which many queens have behavioral characteristics of estrus, attract tomcats, roll in front of them, meow, but will not allow mounting or copulation.^{22,35}

Estrous behavior in the queen in the absence of a tomcat usually includes persistent vocalization, rolling, rubbing, extreme affection, and with variable incidence and intensity, treading the hind legs, lordosis, and tail deviation. A slight anterior and lateral set to the ears is common, and an intense facial expression simulates that seen with aggression or fright. A repeated monotone howling for as long as 3 minutes at a time is common and may accompany treading and rolling. The estrous cry is given by the queen to indicate that she is in estrus and in presence of the male, an "appeasement" cry to stimulate the tomcat to mount. Restlessness, general uneasiness, pacing back and forth, may accompany any of these behavioral patterns. A general loss of appetite of both the queen and tomcat is common during the breeding season. Some queens may not exhibit typical behavioral signs at every estrus except for increased affection, but will when properly handled or exposed to a tomcat. Treading, lordosis and the typical copulatory stance with lateral deviation of the tail can be induced by flank stimulation, stroking the back, alternate strokes over the thigh or stroking the perineum. Rubbing or scratching the back of the neck or shoulders induce treading, but usually not the precoital stance. The ear and facial expression may be induced by all of these manipulations. Handling and stroking an estrous queen may cause enough neural stimulation to induce ovulation.^{3,22,37,49,57,58}

Once the female shows good copulatory signs, the waiting and watchful male will approach usually from the side and grasp the skin of the neck in his teeth. This usually takes 5 to 50 seconds. He next will place his forelegs over her shoulders and mount, and for 0.3 to 8 minutes he will position himself by straddling her pelvic area and treading along her flanks with his legs and possibly stroke or strum the queen's thorax with his front feet. The queen at this time reflexly varies her perineal area by lordosis until her perineum and vulva are almost horizontal. Her tail will be deviated laterally. When positioning is right the tomcat will start pelvic thrusting with his exposed penis and on contact, intromission and ejaculation and the queen's coital "cry" or "scream" usually takes 1 to 17 seconds followed by the queen quickly rolling or twisting out of the male's grasp and aggressively attacking the male if he doesn't move away quickly; this takes 0 to 1 seconds for dismounting. Immediately the queen displays a postcoital "after action" consisting of disoriented rolling, stretching and genital

licking and twisting, taking 1 to 7 minutes and a variable period, 0 to 5 hours of refusing attempts by the tomcat to remount. Usually the tomcat stays at some distance watching and protecting his territory. Freeroaming, other tomcats may challenge him and indeed other males may mate with this queen and if they are successful, resulting in a litter from different tomcats or superfecundation.^{22,34,60} In one study, copulations numbered 20 to 36 during 36 hours of observation and were more frequent during the first 2 hours (3 to 6 copulations) than any subsequent 2-hour period.²² In one study, estrus averaged 7.1 ± 0.8 days, even though a significant level of plasma progestins were present.⁴⁴ The average range of estrus is considered to be 5 to 8 days with a range of 3 to 20 days. Ten days or longer periods is considered prolonged. Duration of estrus is not greatly influenced by mating and induced ovulation, although some feel estrus may be one or 2 days shorter in average duration in mated queens.²² Other researchers have reported the opposite effect, with mated queens in estrus for 8.3 to 8.6 days and non-mated queens in estrus for an average of 6.2 days.⁵³ Occasionally a timid queen, low on the social scale in a colony of females and checked with an experienced breeding male, will express poor estrous behavior, have good estradiol-17B serum levels indicating active mature follicles, but not allow interested males to mount and breed.⁵³

Relative size of the male and female may influence the success of mating. Females that are too large or too small may make it difficult for a successful rapid coital act resulting in a frustrated and unsuccessful breeding male. This is especially a problem with young males or timid males that are hand bred. The activity of the male attempting to breed a female may be enough to induce ovulation although the lack of intromission and ejaculation has failed to deposit semen for fertilization.¹⁸

The coital "scream" or "cry" was at some time thought to be pain caused by the penile spines, but this reaction can be elicited in queens in or out of estrus, intact or spayed, with any instrument that invades the vaginal and cervical area.^{18,34,48}

The cat is an induced or reflex-ovulator. Either natural mating, mechanical stimulation of the cervix/vaginal wall with probes, exogenous luteinizing hormone (LH) or gonadotrophic releasing-hormone (GnRH), or in a few queens, other stimulation, such as handling, or rubbing against objects during estrus, petting or stroking, may be enough neural response to cause GnRH and LH release which then appears as spontaneous ovulation.^{22,37,53}

Experiments on the effect of genital desensitization on mating behavior and ovulation in the queen revealed that sensations from the vagina cause the appropriate behav-

ioral responses of queens to intromission. Ovulation in queens can be triggered by impulses from the vagina, as well as the cervix, received during intromission.²³

Most queens in the absence of coitus will have non-ovulatory estrous cycles throughout the breeding season (Chart VIII). The cycle then consists of waves of follicles producing estrogen followed by atresia of these follicles and an interestrus period with no luteal or metestrus period. The mean and duration ranges of proestrus, estrus and the interestrus periods and cycle interval are quite variable. Proestrus can really only be characterized early by the presence of a male or possibly with vaginal cytology. A length of 0 to 3 days has been reported for proestrus. Estrus may last 3 to 20 days, but most will average 7 to 8 days. The interestrus period will last usually 3 to 14 days during the breeding season, but may be as long as 30 days. The mean interestrus time ranged from 9 to 13 days. Thus the length of nonbred queens' cycles can range from 7 to 40 days with most cycles being 12 to 22 days long with a mean of 16 to 20 days.^{18,22}

In non-fertile or induced ovulation by instruments or

exogenous LH or GnRH, pseudopregnancy occurs with corpora lutea persisting for 3 to 7 weeks, with a mean of about 40 days followed by 4 to 10 days of anestrus. Thus the duration of pseudopregnancy from mating to the next estrus is usually from 35 to 70 days, the average is around 45 days.²²

Pregnancy in the queen lasts 64 to 69 days with an average of 66 days. Some reports have an average of 63 days with a range of 58–65 days which is probably based on timing from the last of multiple breedings.^{22,53} Successful litters have recorded gestation periods of 59 to 71 days. (See pages 104–107) Variations may also be due to breed difference, colony differences, litter size and possibly time of year.^{18,22} Occasional queens will show estrus during pregnancy and estimates of 10% of pregnant queens, typically around 21 and 42 days of pregnancy, may show sexual behavior. Possible superfetation can occur at this time.^{34,48,60} Some queens will be in estrus within 7–10 days following parturition and may conceive if bred at this time while caring for the litter they just queened. Most will show lactational anes-

DOMESTIC CAT

Chart VIII. A schematic representation of endocrine changes typically observed during polyestrous cyclic activity in unmated queens and during pregnancy or pseudopregnancy (Psp.) following fertile matings or vaginal stimulation resulting in ovulation. Solid bars indicate potential proestrus periods.

(Courtesy and with permission of P. W. Concannon and D. H. Lein, publisher, W. D. Saunders Co.²²)

trus and not return to estrus until 15 to 60 days (aver. 2–3 wks), while queens that have kittens that are removed from them within 3 days postpartum will return to estrus in 6 to 8 days. Post abortion estrus can occur within one week.²²

Sexual behavior and **vaginal cytology** of the queen are the two clinical signs best characterizing the estrous cycle. Several excellent articles on vaginal cytology in the queen have been reported.^{14,18,21,26,36,39,40,48,50,53} Vaginal cells are collected with a moistened sterile cotton swab (3 mm dia. Caliswab; Type 1, Inolex, subs. of American Can Company, Glenwood, Ill.), a 3 mm diameter smooth glass rod or by a clean glass eyedropper containing about 0.25 ml of sterile physiological saline solution. The collecting instrument is passed into the vagina about 1 to 1.5 cm by first inserting it into the vestibule in a dorsally directed manner and when resistance is met then redirect the instrument horizontally and place in the vagina. That way the clitoris and clitoral fossa are not entered or irritated. The moistened swab or glass rod are rotated and the fluid in the eyedropper is flushed 2 or 3 times in the vagina. The sample is placed on a clean glass slide and stained. Roll swab or glass rod on a glass slide for the best cytology or place fluid from eyedropper on a glass slide and either fix in alcohol immediately or air dry. Any good cytologic or hematologic stain can be used (See vaginal cytology for the bitch, p. 677). Keep the slides for reference of changes throughout the estrous cycle. Smears of vaginal cytology should be prepared every day or two when looking for changing ratios of cell types to determine the changes from proestrus to estrus to metestrus. The vaginal swabbing or flushing of some queens in estrus may induce ovulation.

No diapedesis of red blood cells is seen in the queen's vaginal cytology during any stage of the estrous cycle as seen in the bitch unless the vaginal cavity is traumatized when taking the sample, a genital tract infection is present, or slides are taken in the early postpartum period. Three basic epithelial cells are present. Parabasal cells are the smallest of the three. The cells are round to oval, and each contain a large clearly defined nucleus. Intermediate cells are larger than parabasal cells, the cytoplasmic borders are slightly angular and the nucleus is defined. Cornified cells show various signs of degeneration. The cytoplasmic borders are irregular or the cell is polyhedral. The cell may be folded or wrinkled; they look like "cornflakes." Vacuoles may be present in the cytoplasm. Nuclei may be pyknotic or absent or undergoing karyolysis.

In anestrus or prepuberty, scant parabasal cells, frequently in groups with tight intercellular bridges, are present. Debris may or may not be present and occasionally polymorphonuclear leukocytes will be present.

In proestrus, more mature cells will be seen as the vaginal epithelium responds to estradiol-17B with multiple layers of cells that become more mature at the surface. Few parabasal cells are seen, the number of intermediate cells are increasing and cornified cells are beginning to appear with more frequency as estrus approaches. Leukocytes are generally absent. At estrus the smear is dominated by cornified cells. Copious vaginal fluid and cells are present, but the fluid is watery and will wash instead of fix to the slide so that the background will be "clear" and lack the debris seen in the other stages of cycle. This is one of the earliest signs of the follicular stage of the cycle, or estrus.⁵⁰ In full estrus, 80% or more of the cells will be cornified.²⁶ Shille, et al. showed that the appearance of a relative increase in fully cornified (anuclear) polyhedral cells ("corn flakes") followed the rise in plasma estrogen levels in a majority of queens by 3 or 4 days and is in concert with the onset of estrous behavior.⁵⁰ These researchers also found that fully cornified cells (no nucleus) increased from 5% to 40% of the total cell population and intermediate cells (partially cornified with nucleus) decreased from 45% to 6% progressively for the 1 to 4 days of the follicular phase or estrus. Parabasal cells, generally low preceding estrus (1–6%) were absent on follicular phase days, 4 to 7 and the following days, cornified cells with pyknotic nuclei did not change much (40–50%) except for a slight increase during the follicular phase (50–60%). The author notices that the queen, unlike the bitch, may have good polyhedral large epithelial cells predominantly at estrus with most containing pyknotic nuclei, whereas in the bitch most of the cells will be anuclear at this stage.

If the queen does not ovulate, the cytology will regress back to proestrus and an anestrus type of cell appears. In early pregnancy or pseudopregnancy there are numerous cells and the reappearance of increasing numbers of intermediate and parabasal cells with a rapid decline in cornified cells. Leukocytes reappear, debris and mucus are present again. As pregnancy or pseudopregnancy progresses the smear will resemble that seen in anestrus with intermediate and parabasal cells predominant and less cells present although the background may contain a great deal of mucus. Queens that exhibit estrogen surges during pregnancy or at the end of gestation may reflect this in their vaginal cytology. If leukocytes are numerous in any smear and show indications of clumping in masses and advanced degeneration or toxicity, contain large numbers of bacteria and/or red blood cells are present, one should consider an inflammatory process and examine further.

The endocrinology and physiology of the estrous cycle, pseudopregnancy and pregnancy has been partially characterized and reported by a number of re-

searchers. 1,2,6,10,17,18,20,21,22,27,32,33,34,37,43,44,46,47,48,49,50,51,52,53,55,56,59,61,67

In proestrus, follicular growth and development associated with increased secretion of estradiol-17B occurs rapidly over a 2 to 3 day period just prior to the onset of estrus. The onset of estrus usually occurs as estradiol levels attain peak levels or during subsequent rapid decline. Levels from 5 to 20 pg/ml at basal serum measurement will peak to 40 to 100 pg/ml by or before the onset of estrus (Chart VIII). Levels usually greater than 20 pg/ml are closely associated with sexual attraction and receptivity.^{50,61} Levels decline during estrus as the fully mature follicles begin to undergo atresia. For the first 4 to 5 days of estrus, follicles retain the capacity to ovulate if sufficient copulatory stimulus is present, but how fertile these follicles are in protracted periods of estrus is unknown. Estradiol-17B levels rise and fall in sequential non-overlapping waves suggesting that follicles grow and degenerate as a group in nonbred queens although a few cats have shown overlapping follicular waves, more like that seen in the rabbit, another induced ovulator.^{50,53} Serum progesterone levels remain low (-0.5 ng/ml) throughout the non-breeding estrous cycle. Follicle stimulating hormone (FSH) is probably important in stimulating follicular waves, but no studies of levels in the cat have been reported.

Ovulation in the queen depends on the release of sufficient amounts of luteinizing hormone (LH) from the anterior pituitary, as in other species. Since the queen is a reflex-ovulator, LH is released on a neural reflex initiated by vaginal-cervical stimulation during coitus. Probably luteinizing hormone-releasing hormone (LH-RH) is first released from the hypothalamus following copulation which in time causes release of LH from the anterior pituitary gland. Exogenous LH-RH (25 ug) caused LH release from both anestrus and estrus cats and resulted in ovulation in the estrus cats.¹⁰ Luteinizing hormone (LH) in the cat fluctuates episodically with increases occurring every 20–30 minutes, probably under the influence of episodic release of LHRH. In castrated cats of either sex, the LH basal levels increased. Restoration of negative feedback was accomplished by administration of estradiol-17B, reducing LH concentrations to precastration levels.³² Concentrations of LH increased within 5 minutes after mating and usually reached a maximum within 20 minutes if a queen was limited to a single copulation.³³ This was similar to a single injection of LH-RH.¹⁰ A second mating one hour after the first resulted in a second similar increase in LH levels without evidence of a priming effect of the first mating on the LH release mechanism. Females allowed to mate at their own pace with several copulations during the first 2 hours showed LH release being evident during the first 90 minutes but copulations were ineffective in increasing the

peak levels of LH when mating continued beyond this point. There is no correlation between plasma levels of estradiol or progesterone. Repeated matings in the first 2 to 4 hours appear to be important in controlling the magnitude of the preovulatory LH surge.³³ In another study, less than 50% of fully estrous queens ovulated after a single copulation because of inadequate LH release, but most queens ovulated after 4 or more copulations.²⁰ Additional LH release became negligible after the first 1.5 to 4 hours.^{20,67} Following 30 copulations in 24 hours and 36 copulations in 36 hours, maximum LH release became negligible after the first 2 to 4 hours. The refractory LH release after 4 hours appears to be at the hypothalamic LH-RH release level, since exogenous LH-RH after these periods of multiple copulations and low LH levels after 2 to 4 hours will result in another immediate LH peak.^{21,22} Another study did show that LH release could be enhanced when coital inputs were repeated at 4 hour intervals indicating that the refractory period may be relatively short in cats.⁶¹ This occurred mainly in the 1st day and again at much lower levels of LH output on the second day (less than half the 1st day's peak) and no response on the third or fourth day.

Levels of plasma LH have been quite variable depending on the type of standard used in the test. Rat LH and cat LH standards have much higher levels than ovine LH standard (10% of cat or rat LH standards). Basal levels of 1.6 ± 0.4 ng/ml to high peak levels of 121 ± 24 ng/ml after multiple copulations are reported for the ovine LH standard compared to basal levels of 49 ± 19 ng/ml to high peak levels of 941 ± 154 ng/ml are reported for the cat LH standards.^{22,51}

Ovulation occurs within 25 to 30 hours after matings that cause release of sufficient LH; others reported up to 50 hours after mating. The differences in time and in some instances, no ovulations occur, may be the individual threshold levels of LH-RH and LH needed, days in estrus when mated, immaturity of follicles, and number of copulations required per individual for adequate release of LH; all may be quite different for individual cats. It appears that some cats will not release an ovulatory amount of LH until the second, third, or even fourth day of estrus.¹ Thus it appears that the best time to breed queens may be on the second or third day of estrus and to observe at least 4 or more coital acts to obtain adequate LH release and maximal ovulation.²²

Ovulation can also be induced in queens in estrus by stimulating the vaginal walls and/or cervix with a probe and just like multiple breedings, multiple repeated probings at 5 to 15 minute intervals will enhance adequate LH release.²² Ovulation can also be accomplished by injection of 25 to 50 I.U. of human chorionic gonadotrophin (HCG) with ovulation occurring in 26 to 27 hours.

Fertilization rates were nearly 100% for a natural service from the time of treatment through 27 hours, but declined to 35 to 80% from 30 hours to 49 hours after treatment. Conceptions occurred 52 or more hours after treatment, indicating the fertile life of the feline ovum after ovulation was about 24 hours.⁵⁴ Another study showed that a single injection of 500 IU of HCG produced a significant increase in mean percent ovulation rates in comparison to single injections of 0, 50 and 100 IU of HCG. Also administration of either 250 or 500 IU of HCG daily for 2 days of estrus resulted in a greater percent of ovulation than the 2 day injection of 50 I.U.⁶⁵ Administration of 25 ug of LHRH also caused ovulation in estrous queens.¹¹

Wildt, et al. by laparoscopic study have described the formation of the mature follicles, ovulation and corpora lutea.^{62,66} The ovary at proestrus will contain clear grayish areas with distinct borders that are 0.5 to 1.5 mm in diameter and at estrus become distinct fluid filled pre-ovulatory follicles. Mature follicles measure 2.5 to 3.5 mm in diameter and develop to this state in 24 to 48 hours. Non-ovulated follicles will regress to a nondetectable state in 3 to 7 days. As ovulation approaches the follicle dome becomes clear in appearance while the base at the surface of the ovary becomes heavily vascular. Ovulation is gradual, culminating in the release of a yellowish-gray mound-like mass that often adheres to the surface of the ovary. Hemorrhage at the site takes place and a cratering of the follicle's dome appears. Within 24 to 36 hours postovulation, luteinization and maturation of the corpus luteum takes place. It changes from a dark red to an orange-yellow color. The mature corpora lutea are raised above the surface of the ovary and contain a flattened dome. Corpora lutea reach a maximum diameter of 4.5 mm. Regressing corpora lutea are small yellowish flat luteal scars that may remain visible on the ovarian surface for up to 6 weeks.

Sterile matings, exogenous LH or LH-RH, and occasional "spontaneous" ovulation result in **pseudopregnancy**. Corpora lutea are formed within 1 to 3 days and persist for 3 to 7 weeks postovulation. Progesterone levels rise over 1 ng/ml by day 3 after ovulation and reach peak levels of 15 to 90 ng/ml by day 15 to 25 and thereafter decline (Chart VIII). Progesterone levels return to 1 ng/ml within 30 to 50 days, although reports of duration of pseudopregnancy as the interval from mating to the next estrus range from 35 to 70 days with the average being 45 days.^{22,44,52,61} Following a fertile mating and ovulation 25 to 30 hours after sufficient release of LH, oocytes are fertilized by the ejaculated sperm that requires about 1 to 2 hours for capacitation in the female reproductive tract. Sperm recovered from the ductus def-

erens of male cats were capable of fertilizing recently ovulated feline ova in vitro without in vivo capacitation. This may indicate that epididymal or ductus deferens sperm are different from ejaculated sperm or indeed capacitation is not required.⁵ Oocytes remain fertile for up to 48 hours. **Oviduct transport of fertilized oocytes** takes 4 to 5 days. Migration of blastocysts in the uterine horn takes place for 6 to 8 days and implantation occurs around day 12 to 14.^{18,22,55}

Endocrinology of pregnancy—The progesterone plasma levels in early pregnancy are similar to those seen in pseudopregnancy until implantation takes place at about day 12 to 14 (Chart VIII).⁵⁹ Progesterone plasma levels were 13 ng/ml on day 50 versus 2 ng/ml and 4–5 ng/ml on day 62 versus 1 ng/ml in pregnant and pseudopregnant queens, respectively. Elevated progesterone blood levels in pseudopregnancy coincides with implantation in the pregnant cat and again on about day 28 when the first appearance of regressive luteal changes in the pseudopregnant cat are seen.⁵³ At this time, blood progesterone levels increase in the pregnant queen, while levels in the pseudopregnant queen decline. At 28 days the progesterone levels in the pregnant queen are also enhanced by an increase in placental progesterone.^{18,38} Corpora lutea of pregnant queens persist and produce progesterone until 40 to 50 days when placental production of progesterone is adequate to maintain pregnancy.³⁸ Ovariectomy performed between 45 and 49 days or later will not effect pregnancy and normal kittens will be born at term.^{22,48,53}

Parturition is accompanied by a decline in progesterone to basal levels, but detailed studies are needed to determine if the serum progesterone levels fall to basal levels preceding or following placental expulsion.²² Estradiol-17B is elevated above the base level of 9 pg/ml between Days 58 and 62 and declines sharply just before parturition.⁵⁹ Pregnant queens treated with FSH on Days 33–37 and HCG on Days 38 and 39 developed follicles (av. 9.3 follicles/cat), ovulated (av 3.4 corpora lutea/cat), and exhibited behavioral estrus (5/7 cats). Estradiol-17B levels gradually increased but serum progesterone levels remained constant in the treated cats while in control cats levels gradually declined as expected. Gestation periods and litter size were not significantly different between treated and control queens.¹²

Prolactin (PRL) levels were measured using canine PRL antisera by Banks, et al.² PRL blood levels were elevated the last third of pregnancy (31.2 ± 5.1 ng/ml.). The last 3 days of gestation, levels increased to 43.5 ± 4.5 ng/ml. Suckling stimulus maintained PRL levels at 40.6 ± 7.2 ng/ml for the first 4 weeks postpartum, and 27.8 ± 3.1 ng/ml during the last 2 weeks of lactation.

Following weaning, levels decreased to approximately 15 ng/ml with basal levels of 7.3 ± 0.6 ng/ml maintained after the second week. Pseudopregnancy had no effect on PRL levels in the queen.

Induced abortion—Feline corpora lutea are very resistant to the luteolytic effect of prostaglandins and bromoergocryptine, both of which cause luteolysis in the dog after 30 days of pregnancy or pseudopregnancy.²² Queens one and two weeks pseudopregnant were treated with 0.5 to 5.0 ug/kg of PGF₂ with no significant effect on progesterone levels.⁶⁴ Repeated administration of PGF₂ every 12 hours with either 220 or 440 ug/kg on days 11 to 15 or 21 to 23 postcoitus did not cause a significant drop in progesterone during the second week. During the fourth week, significant reduction took place, but did not cause complete luteolysis and did not reduce the length of pseudopregnancy.⁵² PGF_{2a} (500 to 1000 ug) given twice subcutaneously, 24 hours apart, caused abortion in queens after day 40, but not before. Abortion occurred within 24 hours after the initial injections in 9 cats and after the second injection in 4 cats.⁴¹ Pregnancy was also terminated in cats by administration of a combination of ACTH and PGF_{2a}.⁶⁸

Pregnancy diagnosis is best accomplished by careful palpation of the uterus per abdomen from days 17 to 25 when the conceptuses are in a round segmented condition. After days 30–35 the elongated fetus and fetal membranes become confluent and it is difficult to ascertain pregnancies from an enlarged uterus.^{18,22} Radiographs will show the mineralized opaque fetal skeleton from 40–45 days of gestation to term. Approximate gestation age can be made by radiographic appearance of mineralized bone in the fetus, ie. 41 days, the radius and ulna, 43 days, tibia, fibula, ilium and ischium and occipital bones of the skull, at 55 days, the axial skeleton can be visualized.¹⁸ Breeders often depend on the physical change of nipples from light pink to rosy pink in the second and third weeks following copulation as indicative of pregnancy.²⁷ (See pages 14–33)

The endocrinology and physiology of parturition in the queen has not been fully studied. Certainly there is a decrease in progesterone to basal levels and an increase in estradiol 17-B a few days just prior to queening and a drop the day of queening and an increase in PRL levels. The endogenous effects and levels of prostaglandins, relaxin, cortisol and oxytocin are not known. Clinically, oxytocin is very effective in causing uterine contractions for uterine inertia, retained kittens or placentas and milk let-down. Probably endogenous oxytocin is present. The queen will react to "feathering" the vagina during parturition resulting in uterine contractions. Rectal temperature does fall in the first stage of

labor, similar to the bitch.⁴⁸ The queen will search for a warm, dark, secluded place and nest. The last 2 weeks, gland development and the last day, milk secretion are present. The second stage of labor is usually quite rapid with a few abdominal strains, similar to defecation, and a kitten will be delivered. One or two may be born, are cleaned vigorously by the queen and the cord severed by biting. Placental expulsion, the third stage of labor, follows the fetal delivery quite closely and the placenta is consumed by the queen. Usually the next kitten is presented in less than an hour. If the queen is disturbed, especially if not confined or even if confined, labor may cease, kittens may be moved, nursed and then continuation of queening, hours or days later. The longer intervals between births may be superfetation.

To sex kittens on the day of birth the anogenital distance is measured with a soft, pliable plastic millimeter ruler. Males ranged from 11 to 16 mm and females, 6 to 9 mm at birth, 14 to 21 and 8 to 13 at 21 days of age, 16 to 23 and 10 to 15 at 42 days of age, respectively.⁷

Induction of estrus in queens can be accomplished in several ways; lengthening of the light cycle 14 to 18 hours per day, socializing of queen with other cycling queens and/or exposure to a tomcat, use of sex steroid hormones and gonadotrophins. Induction of queens with gonadotrophins may lead to large numbers of follicles which may not contain mature ova, or may lead to cystic follicular degeneration. Excessively long periods of estrus may be encountered with the use of either gonadotrophins or sex steroid hormones.¹⁹ Induction of estrus has been followed by successful matings when using a daily intramuscular injection scheme of pregnant mares serum gonadotrophin (PMSG) for eight days, the dosage depending on time of the year (Chart IX) as reported by Colby.^{16,19} The dosage may be reduced to 25 IU. as estrus behavior becomes apparent to prevent overdose problems. Estrous behavior should be judged daily by a handler or by placing the queen with an experienced tomcat. This regimen should not be used in queens under 1 year of age because of production of cystic ovarian follicles. The best age group is probably from 1 to 5 years. Litter size decreases with older queens. The results are reported by Colby to be 80% efficient. The guidelines given above are important to follow with any of the hormone regimens used for induction of estrus.

Another method has been described using a single injection of 100 IU of PMSG followed in 7 days by 50 IU of HCG which produced results comparable to natural breeding.¹⁵ Follicle stimulating hormone-pituitary (FSH-P) has also been used to induce estrus. Administration of 2 mg of FSH-P intramuscularly daily for 5 days unless

Calendar Months	Day							
	1	2	3	4	5	6	7	8
	PMSG (IU)							
December–January	100	50	50	50	50	50	50	50
February–August	100	50	50	50	50	25*	25*	25*
September–November	100	50	50	50	50	50	50	50

*In cats near estrus (behavior), dose decreased until bred.

Chart IX. Induction of Estrus in Cats by PMSG

(E. D. Colby,^{16,19} and courtesy and with permission of P. W. Concannon and D. H. Lein and publisher, W. D. Saunders Co.²²)

the queen shows estrus before 5 days; results in most showing estrus in 4 or 5 days. On day 1 and 2 of estrus, 250 IU of HCG are given intramuscular to enhance ovulation. Queens should be bred at least 4 times on each day of estrus for a period of up to 4 days. Mean litter size was normal.^{45,63} This regimen was used successfully to produce litters by using frozen cat semen.

Estrogens (50 mcg of estradiol benzoate or 0.25 mg of estradiol cypionate (ECP), given IM and repeated in 48 hours) will induce estrus in most queens.^{18,22} No more than 8 mg of estrogen should be administered within any continuous 4 month period to avoid toxicity or extreme bone marrow suppression.⁵⁶ Testosterone can also be used at 20 mg/day, intramuscular, to induce estrus in the queen.¹⁸ Either excessive use of estrogens or testosterone in the queen may initiate estrus that will last for 2 to 4 weeks unless natural or artificial coitus is provided.

Estrus control in the queen using progestins has been successful in Europe and Australia; medroxy-progesterone acetate ("Perlutex," Leo Laboratories, Ltd., Middlesex, England and "Anobulin," Berk Pharmaceutical Ltd., Surrey, England) has been used successfully in both oral and injectable forms. These are not approved or available in the United States. Megestrol acetate ("Ovaban," Schering Corp., Kenilworth, N.J.), is marketed for dogs to control estrus, but has been experimentally and clinically used to control estrus in cats. Progestins when administered are believed to mimic the corpora lutea and have a negative feedback on gonadotrophic-releasing hormones. Megestrol acetate, 5 mg daily for three days will control signs of estrus within 5 days. Queens were then given 2.5 to 5 mg once weekly which kept them in anestrus for up to 2 years with successful estrus and pregnancies following. This regimen should be used only in young queens that have experienced estrus. It can also be used in nonestrous queens to maintain an anestrus state.^{22,28} This drug has also been used to control urine spraying in tomcats and queens (5 mg/day until spraying is controlled, then 5 mg/week) and in the treatment of miliary dermatitis and control of eosinophilic

granuloma. Progestin therapy may cause increased appetite, increased body weight, a calming effect, and increased affection. Prolonged and indiscriminate use may produce a Cushingoid syndrome.^{13,22} Cats with genital tract infections should not be administered progesterone or progestins. Indiscriminate use of progestins can lead also to cystic endometrial hyperplasia-pyometra complex, hypertrophy and hyperplasia of mammary glands and possible mammary gland neoplasia.²² It appears that progestin compounds result in much less uterine disease in the cat compared to the dog. In a small field trial it was reported that either 5 mg of megestrol acetate (MA) or chlormadinone acetate (CAP) given orally once at early estrus completely prevented gestation and that this was accomplished for 15 estrous periods. This queen did have successful pregnancies during and after the use of these progestins. Two tomcats received either 5 mg of MA or CAP or 2.5 to 5 mg of delmadinone acetate (DMA) orally on a weekly basis to control sexual behavior with no side effects and the return to sexual activity within 8 to 10 days after discontinuing the progestins.³¹

"Mibolerone," a synthetic anabolic steroid ("Cheque," Upjohn Co., Kalamazoo, MI) is an approved contraceptive used to control estrus in young bitches. Estrus was prevented in queens when administered at a daily dose of 50 ug for a 180 day period. There was no apparent effects on subsequent estrus, mating, queening, litter size, or developmental defects in neonates. The mechanism of actions of this androgen, like progestin, is to suppress release of pituitary LH. Side effects consisted of increased thyroid weight, decreased thyroid function, increased serum cholesterol levels, slight masculinization of neck skin and clitoral hypertrophy in some cats. Formation of a cartilaginous or osseous penile baculum and central retinal degeneration and chorioretinitis were seen in a few cats.⁹

An extensive review by Colby described other non-approved drugs that may or may not be available in the United States for estrus suppression in the queen such as "Provera" (medroxyprogesterone acetate), "Orgaster-

one" (methylloestrene), and DMA (delmadinone acetate).¹⁹ Burke cited the use by Europeans of 1% pilocarpine solution for 2 to 4 days to stop estrus in queens within 2 days. No mechanism was given.⁸

Mismatched queens can be successfully treated with as little as 0.125 to 0.25 mg of estradiol cypionate (ECP) given 40 hours after coitus or within the first 5 days post coitus. The ova are retarded in transport through the oviduct for at least 6 days instead of 4 to 5 days, resulting in degeneration in the late proliferative state instead of the secretory phase.^{22,25}

Repositol diethylstilbesterol, a product not available in the United States has been used for mismatching at the level of 2 mg on day 2 and repeated on day 10 following coitus. All estrogen therapies will extend the period of estrus and will cause accumulative effects to cause toxicity and myelosuppression if overdosed.^{19,25}

Abortion may be induced in cats over 40 days of gestation or live newborn after 55 days with PGF_{2a} at doses of 0.5 to 1.0 mg/kg of body weight given twice at 24 hour intervals.⁴¹

The control of free-ranging cats in the United States has become an important issue in the last 20 years. Few accurate studies or estimates of this population and means of control have been studied. One study in Manhattan, Kansas estimated that the population in that city increased by 18% annually and that 59% of the females were spayed. It was calculated that 88% should be spayed to maintain a zero population growth.⁴²

Anatomic and Congenital Defects, Intersexes

Anatomic or congenital defects or abnormalities of the reproductive system in bitches and queens are rare but have been reported.^{23,109,239} Hare in his report considered intersexuality rare in the dog. His review reported on 48 spontaneous and 52 drug-induced cases.¹⁰⁹ Of the 48 spontaneous cases, 16 were Cocker Spaniels and 5 Beagles.^{73,109,110,162,179}

The differentiation of sex occurs prenatally and is expressed finally by events that occur at puberty. In normal development, an XY genotype will cause induction of primary medullary sex cords and a normal functioning testis will form. In the XX genotype, or more likely, the absence of a Y chromosome, the medullary sex cords regress and the secondary or cortical sex cords are induced and an ovary develops. A number of abnormalities have been observed to occur with both normal XX and XY genotypes and especially with abnormal genotypes (XO, XX/XY, XO/XY, XX/XXY or XXY).

The development of either a Wolffian (male) or a mesonephric duct system or Mullerian (female) or paramesonephric duct system, although both are present in the prenatal state, takes place resulting in either epididymis and vas deferens in the male, or oviducts, uterus and the cranial one-third of the vagina in the female. This development depends on the secretion of hormones by the fetal testis, an inhibitory hormone now called Mullerian inhibiting factor (MIF), a nonsteroid macromolecular factor is produced by the fetal Sertoli cells. MIF inhibits development of the paramesonephric duct and an androgen-like hormone from the fetal testis stimulates the development of the mesonephric system. The ovary has little influence, but the total aplasia of gonadal tissue results in a rudimentary paramesonephric (female) duct system.²⁵¹

The phenotypic sex involves the organogenesis of the urogenital sinus and external genitalia, probably the descent of the testis is under the influence of an androgenic-like hormone from the fetal testis which results in male external genitalia, whereas, the lack of this androgenic-like hormone results in a female external genitalium. Excess circulating androgens, exogenous or adrenal gland source, will cause masculinization of the urogenital sinus but has little influence on prior developed mesonephric or paramesonephric duct systems.

Hermaphroditism or intersexuality occurs because of faulty differentiation and/or function of the fetal gonads and results in a deficiency of male-stimulating or female-inhibiting hormones, or there is a loss or reduction of sensitivity to a hormone on the part of a receptor organ. Induction can also take place if an excess of androgen-

like hormone is produced either endogenous (congenital adrenogenital syndrome) or given exogenously.¹⁰⁹

Hermaphrodites are classified as true hermaphrodites if both male and female gonads are present in any of 3 forms; bilateral, ovotestes present on both sides, unilateral, ovotestes on one side, and either testes or ovary on the other and bilateral, with ovary on one side and testes on the other. A male pseudohermaphrodite has testicular gonadal tissue and genital organs with some female characteristics. A female pseudohermaphrodite has ovarian gonadal tissue and genital organs with some male characteristics.

In Hare's review of 48 cases, 25 of the 48 were male pseudohermaphrodites, with 13 having an enlarged clitoris, 10 an underdeveloped penis and the testes usually were abdominal, but occasionally one was found in the inguinal canal or scrotum. All but 2 of 25 had some development of Mullerian duct systems. Thirteen of 48 were true hermaphrodites. All had clitoral enlargement with or without an os or underdeveloped penis, with Mullerian duct development. Seven cases had some Wolffian duct development. Two of 48 cases were female pseudohermaphrodites with masculinization of the external genitalia and development of a penis and prepuce. The genetic sex determination showed that 7 of 25 male pseudohermaphrodites were XY and 5 were XX. While 5 of the true hermaphrodites were studied and 3 were XX, one a possible XX/XXY and another a possible XX/XY. All female pseudohermaphrodites studied were XX including the 52 drug-induced cases.¹⁰⁹

Exposure of female fetuses to exogenous androgens between the 4th and 7th week of gestation results in masculinization of the genital ducts and urogenital sinuses. Early exposure may lead to almost complete formation of an epididymis, vas deferens, male urethra, prostate and penis. Exposure after 50 days of gestation results in clitoral enlargement only. These latter animals have normal ovaries, Fallopian tubes, a uterus and may be fertile.²⁵¹ Forty-five female pseudohermaphrodite pups of 87 offspring were produced by feeding 14 bitches methyl testosterone throughout pregnancy.²³¹

Exposure of female fetuses to exogenous estrogens during the sensitive period of sexual differentiation can lead to incomplete fusion of the caudal Mullerian ducts, incomplete fusion of the urogenital sinus, incomplete formation of the vagina and induction of prostate development. Exposure after sexual differentiation results only in hypertrophy of the uterus.²⁵¹

Female fetuses subjected to exogenous progesterone may result in limited masculinization. Various synthetic progestogens are quite androgenic and can produce virilization of female fetuses. The first sign of

virilization in newborn pups is the displacement of the orifice of the urogenital sinus, resulting in the vulva assuming a ventrocranial direction. This usually occurs when the fetus is exposed between the 30 and 50 days of gestation. Clitoral enlargement may also be seen.^{72,251}

Exposure of male fetuses to excessive exogenous estrogens in-utero may lead to feminization of the genital tract resulting in partial regression of the Mullerian ducts and insufficient gubernaculum outgrowth and hypospadias. Hypospadias may also be seen with excessive progesterone, especially synthetic progesterone and also with antiandrogens (megestrol acetate, chlormadinone acetate and cyproterone acetate). The antiandrogens may also cause complete inhibition of the Wolffian ducts and a female type of development of the urogenital sinus. No genital duct systems may be found since Mullerian duct regression is normal.²⁵¹

A history of difficulty in determining sex, urinary incontinence, abnormal or bloody discharges from the urogenital opening, abnormal external genitalia and position, a complaint of the males or females assuming the stance of the opposite sex when voiding are all common in intersexes. Intersexes should be examined systematically. A detailed history of therapies during pregnancy, examination and/or history of siblings with similar problems and a complete physical examination usually reveals a female with an enlarged clitoris or a male with an underdeveloped prepuce and penis or a degree of hypospadias and a lack of scrotal development.

A definitive diagnosis of pseudohermaphroditism or true hermaphroditism requires exploratory surgery or removal of the gonads and genital tract for histological section, sex determination by karyotyping and sex chromatin determination.⁷³ Removal of an enlarged clitoris may be esthetically desirable and corrective surgery if possible of urethrovaginal fistulae may be necessary. Retrograde contrast urethrography or pneumocystography may be needed to define urethrogenital tract abnormalities.¹³⁴

Neoplasia of retained testis, especially with the formation of Sertoli cell tumors in male pseudohermaphrodites, development of feminizing syndromes, attraction of males and cystic endometrial hyperplasia-endometritis-pyometra in remaining Mullerian systems requires surgery for correction of these problems.^{40,155,191}

Ovarian agenesis, hypoplasia and aplasia of portions of the Mullerian duct system in the bitch have been described.¹⁷⁵ Uterus unicornis is occasionally seen in the bitch and has been reported. Partial fusion and unequal length of uterine horns may occur in the bitch.¹⁷⁵ Remnants of mesonephric or paramesonephric ducts may be found parovarian, parametrial or in the fimbriated end

of the oviduct where they are called hydatids of Morgagni. Cysts of Gartner's ducts in the bitch are rare.^{25,26} A persistent postcervical band caused a dystocia in one bitch.¹²⁰

Hypoplasia of the vulva, persistent hymen, vaginal/vestibular strictures, congenital vestibulovaginal stenoses, segmental vaginal aplasia, vulvovaginal clefts, double vaginas have all been reported in the bitch.^{22,127,143,200} Vestibulovaginal stenosis was reported in 22 maiden bitches of various breeds with clinical signs of vulvar pruritus, incontinence, and vaginal inflammation, perivulvar dermatitis, and/or difficult mating. Thirteen of these bitches had vestibulovaginal strictures and 9 had a persistent perforated hymen.¹²⁷ Diagnosis is frequently made by digital palpation. Vaginoscopic examination or radiography with contrast media or pneumocystography may be needed to diagnose cranial vaginal tract strictures or stenoses. Digital dilatation, vestibulo-vaginoplasty, vaginectomy or vaginotomy may be needed to correct these conditions.

The author has seen cases of vestibulovaginal strictures or dorsal perivaginal folds with an inverted deep-set vulva in many bitches. Most are found at mating with bitches refusing copulation or males not successfully penetrating and "tying." Others have been found on routine prebreeding examination which should always include a digital exam of the vestibular-vaginal area when a hypoplastic vulva or a single or multiple fibrous strictures are found in the vestibulovaginal area.

In the author's experience, this condition is best treated with digital expansion or dilatation, or if this is not possible, artificial breeding. At parturition only an occasional bitch will require an episiotomy or caesarian section. Most will dilate with the hormones of parturition and be normal postpartum.

The author has seen this condition most frequently in German Shepherd bitches. Wadsworth and coworkers described a mid-vaginal imperforation in 3 Beagle bitches with mucoid material distending the vagina cranially and multiple fluid-filled submucosal cysts of possible Gartner's duct origin in one bitch.²⁴⁸ The author has also seen 2 similar cases. Hematocolpos or hematometra may occur secondary to congenital atresia of the Mullerian duct system.

In the queen, rare cases of intersexuality are reported.²³⁹ Cystic rete tubules in queens of any age are quite common.^{175,239} Uterus unicornis has been reported with a 1 in 1000 incidence and this may be associated with renal agenesis on the same side.^{216,232} Gartner's duct cysts, Bartholin's gland cysts, paraovarian and parametrial cysts, and cysts of the fimbriated end of the oviduct in the cat are rare.^{25,26} Segmental aplasia of the uterus

has been seen in the queen by the author. Cystic rete ovarii tubules in queens of any age may be seen.^{175,239}

Tortoise-shell or black and orange cats are invariably female and when male are usually sterile since the orange coat color and its alternate black, are determined by genes within the X chromosome and are sex-linked.^{150,167,239}

Nutritional Aspects

Nutritional causes of infertility in the bitch were reported by Mosier.¹⁸⁵ Several commercial dog food companies have completed research on the requirements for breeding, pregnancy and lactation in bitches and the results of deficiencies in proteins, calories, fats, minerals and vitamins. A 5 to 10% increase in the total maintenance diet will result in "flushing" a bitch during proestrus leading to a larger-sized litter. Researchers reported that protein deficiency in the dog leads to a reduction in blood levels of gonadotropic hormones.¹⁶¹ The additional 5–10% increase in dietary intake must be discontinued during estrus and the first 2 or 3 weeks of gestation or the rate of embryonal death will increase.

Vitamin K deficiency in puppies is characterized by hemorrhage around the mouth and nose and is seen when dog food is improperly stored for long time periods. Puppies with poor muscle strength, myodegeneration and/or anemia may need Vitamin E supplementation, while puppies that are not content, cry frequently but come from healthy bitches may have Vitamin B-complex deficiencies and may have come from bitches fed a low thiamine diet. Liver in the diet of pregnant bitches, 2 or 3 times weekly, is an excellent source of B-complex vitamins, vitamin K, phosphorous, high quality protein and causes increased lactation and increased placental size resulting in increased fetal nourishment.

Excess supplementation of calcium can cause zinc deficiency, resulting in uterine inertia and subinvolution. A ratio of calcium to phosphorus should be maintained at 2:1. Zinc can be increased by giving zinc sulfate or gluconate tablets or feeding liver. Excess Vitamin D leads to tissue calcinosis, premature closure of the cranial vault, calcium deposits on the tongue and liver surface, and kidney disease and death of pups before 1 year of age. National Research Council, (NRC) recommends a Vitamin D intake of 8 to 9 units per pound daily.

The NRC nutritional requirement for a pregnant bitch recommends a protein requirement of 25% of food on a dry weight basis, but some commercial dog foods contain 20 to 22% protein and usually contain higher cereal content which causes lysine deficiency resulting in increased puppy mortality at birth and an abnormal liver-

brain ratio (normal 2 to 1). A 25 to 30% protein level should be recommended for pregnant dogs, toy breeds should be about 30% and animal protein is favored over plant protein for puppy survival rate. Again, liver is an excellent source of protein and 1/2 to 1-1/2 ounces can be given 2 or 3 times a week. Cottage cheese and fish meal are two other good protein sources. Fat content should range from 7 to 9%. Insufficient fat results in linoleic acid deficiency, which can be supplied by adding corn oil or vegetable oils, but greater than 5% of caloric intake causes excess linoleic acid resulting in hemorrhage, anemia and muscle degeneration in puppies. Even though caloric requirements are increased by adding fat, no more than 4% above the 7–9% recommended should be added since puppy weight decreases and puppy mortality may increase by up to 30%. Carbohydrate should not be more than 57% of a pregnant dog's diet. During lactation, diets containing 28 to 30% protein, and 20 to 25% fat are very effective in stimulating lactation and puppy growth.

The puppies condition at birth will reflect the nutrition of the bitch. Three factors are measured: weight at birth for the breed, liver-brain ratio and fat at the kidney hilus. Puppies that are underweight for the breed at birth are usually undernourished. The bitch may have been under-nourished or inadequately fed too much fat, carbohydrate, or inadequate quantity or quality of protein. The liver-brain ratio by weight should be 2 to 1 with the liver being at least 1-1/2 times heavier than the brain. Fat should be present in the kidney hilus of the puppy if the bitch received adequate caloric intake. If the bitch has poor labor at whelping, an imbalance of calcium-phosphorus-zinc ratio may be present. During pregnancy a bitch should show a 5–10% weight gain. If a bitch loses weight during the gestation period, puppies will be poor growers and have an increased mortality rate. If a bitch receives marginal feed early in pregnancy, then supplemented later, the puppies will usually show increased obesity.¹⁸⁵ As in other animals, bitches with severe emaciation will have delayed puberty and anestrus. Obese infertile animals should be checked for hypothyroidism.

In a study of preferences for diets containing sucrose over a bland diet, both female and male dogs preferred the sucrose diets over bland diets, but bitches had a greater preference for the 1% sucrose diet than males with no difference noted at concentrations of up to 20%. Daily caloric intake was lowest in bitches during estrus, higher during metestrus and highest at anestrus. Ovariectomized bitches had higher food intake and weight gain than sham-operated bitches for the first 10 days post-operatively.¹³⁰

Another study showed that Beagle bitches fed two different diets from 3 weeks post conception, one containing 44% metabolizable energy from carbohydrate and another containing 0%, had similar numbers of pups at whelping, but fewer pups from the carbohydrate free diet were alive at birth (63% vs 96%) and only 35% of the pups were alive at 3 days of age. Plasma glucose levels, as well as alanine and lactate were depressed, while free fatty acids and B-hydroxybutyrate were elevated in bitches in late gestation on the carbohydrate-free diet. Milk from these bitches was low in lactose and high in fat.²¹⁷

Hormonal Disturbances—Anestrus, Ovarian Cysts, Hypothyroidism and Others

Hormonal disturbances, imbalances or abnormal expression of estrus, either exaggerated, prolonged, split, short, shallow or silent, **or anestrus in the bitch and queen** have been noted by clinicians and observed by the author. These cases have not been well-documented by clinical and/or research studies since repeated examination, hormonal assays of gonadotrophins and sex steroid hormone levels, daily recording of sex behavioral and vaginal smear changes are time consuming, expensive and may not be practical for the average pet or kennel owner. Most of these studies have been carried out by reproductive physiologists studying normal bitches and queens throughout their reproductive cycles. The association of infertility and hypothyroidism in both the female and male dog has been well-documented and this can be diagnosed and documented with a single blood test and treated with thyroid supplementation.^{212,219}

It is well-known that reproductive changes are seen with increased age in dogs of both sexes. In the male, increased testosterone levels or constant testosterone secretion over the years will lead to cystic prostatitis, perianal or circumanal gland adenomas. Castration will alleviate these conditions if neoplasia has not occurred. Examination of the testes may reveal single or multiple functional Leydig cell tumors and increased testosterone levels. Temporary relief can be achieved with exogenous estrogen therapy. The aging intact tom cat appears to have less reproductive tract pathology than the stud dog.

In the bitch and queen, either prolonged repetitive secretion of estrogens followed by progesterone from multiple non-pregnant cycles, cystic follicular degeneration, luteal cysts, or granulosa cell tumors, can all cause cystic endometrial hyperplasia, hydrometra, pyometra, mammary gland hyperplasia and tumors, inguinal hernias and possible alopecia of the ventral portion of the body. **Cystic endometrial hyperplasia and its associ-**

ated complications of endometritis and pyometritis can be seen in bitches following several non-pregnant cycles at 3 years of age with an increased incidence with advanced age. Dow has shown that either prolonged estrogen and/or progesterone administration in the bitch and queen will cause cystic endometrial hyperplasia and pyometritis.^{81,82,83,84,87} (See later section) Therefore, it is a good practice to breed bitches and queens at an early age or probably use steroid contraceptives to delay pregnancy but maintain a normal uterus. Once litters are produced, and others are desired, several non-pregnant cycles should not be permitted since the same syndrome may develop. As soon as a bitch or queen are finished with producing litters, an ovariohysterectomy should be performed to alleviate the potential threat of pyometritis and ovarian cysts or tumors.

Ovarian cysts, commonly observed in dogs and cats, increase in incidence with age. One study reported nearly 90% of older female dogs having ovarian cysts.^{24,25} Frequently these are not functional follicular cysts but are expressions of hyperplasia of remnants of rete ovarii, mesonephric or Wolffian duct (parovarian cysts), paramesonephric or Mullerian duct or invasion or downgrowth of surface epithelium called epithelial tubules, causing sub-epithelial structures (SES) or sex, egg or granulosa cell cord hyperplasia. All of these cysts in the bitch increase with age and are probably due to sex steroid stimulation. Only 3% of older Beagle bitches had functional follicular cysts in one study.⁶ Functional cysts, such as follicular cystic degeneration and luteal cysts reported in cattle are seen in the older intact bitch and queen and may lead to hyperestrogenism or prolonged low levels of blood progesterone. Sex steroid levels, sexual behavior, vaginal cytology, vaginoscopic and laparoscopic examinations are all useful in the clinical diagnosis of these conditions.

Anestrus in the puberal bitch may be observed after 1 to 1-1/2 years of age. In some larger breeds, puberal estrus may not occur until nearly 2 years of age. If these bitches are truly anestrus, the ovaries and reproductive tract are small, hypoplastic and juvenile. Delayed puberal estrus may be due to nutritional deficiencies, stress of disease and environmental and husbandry conditions. Failure to observe puberal estrus can also be due to a "silent" estrus or shallow estrus. These are characterized by minimal to no vulval discharge and/or vulvar size change and poor attraction of males, but ovulation and mestestrus/diestrus are followed by normal anestrus and normal behavior and expression of estrus in the second heat.

Vaginal cytology and blood progesterone levels are helpful in detecting the metestrus/diestrus period fol-

lowing an undetected estrus. Failure to cycle is also associated with hypothyroidism, primary ovarian or adrenal dysfunction, intersexuality, or a previous unreported ovariectomy. These conditions should be ruled out by blood tests for hypothyroidism, adrenal cortical function and sex steroid levels, physical examination, evidence of clitoral enlargement, vaginal abnormalities and scars of a possible previous ovariectomy. Sex chromosome or karyotypic analysis in suspected intersexes is also diagnostic.^{143,148,160,206,212}

Anestrus can be seen in bitches that have had previous estrous cycles or pregnancies, and currently have an abnormal long interestrus interval. Most breeds will recycle in 8 months. Some breeds, such as the Basenji, wolf and coyote crosses, usually have only one cycle a year. It is the author's experience that frequently "so called" anestrus bitches have been missed and can be in metestrus. Many are hypothyroid. Vaginal cytology, progesterone determination for the metestrus/diestrus state and a TSH response test for hypothyroidism are used to determine these conditions. It is also important to know the use of these bitches. If their environment and handling are stressful, such as intensive training, performances, working, showing, endurance racing, and Greyhound racing, it will cause certain individuals to delay or interrupt cycles. These animals need to be changed into a less stressful handling and a more stable environment before cycles will return.

True anestrus bitches with no obvious reason for delay of treatment can be induced into estrus (See section on induced estrus in canine physiology). The author's best clinical results follow the administration of 25 mg of FSH-P subcutaneously every 7th day for 5 weeks, and weekly vaginal cytology examinations prior to the next injection to detect proestrus changes.¹⁵ Many bitches will show proestrus between the second and third injections. When signs of proestrus are seen, a daily vaginal cytology examination is performed with breeding taking place during maximum cornification. The bitch should be bred at least 2 or 3 times at 48 hour intervals. If vaginal cornification is not complete and progressive and vaginal cytology indicates a return to anestrus, daily injections of FSH-P starting with 25 mg, 15 mg and 5 mg on successive days, and monitored daily with vaginal cytology are instituted. Usually 75 to 100 percent of the vaginal cells will be cornified and anuclear on the 3rd day of this therapy. At this time, 250 to 1000 units of HCG is administered intramuscularly and the bitch is bred. Ten days following the last breeding, blood progesterone levels are checked. Levels over 20 ng/ml are normal and indicate adequate ovulation and luteal formation. Levels between 10 to 20 ng/ml indicate ovu-

lation, but less luteal tissue, a lower number of ovulations, decreased luteal function, or delayed ovulation. Levels lower than 5 ng/ml or at the baseline of anestrus indicate no ovulations with atresia of follicles, luteal cysts or delayed ovulation. When low levels are encountered, another progesterone blood level should be determined at the time of pregnancy palpation or ultrasound pregnancy check at 25 to 30 days to determine if levels have reached maximum indicating delayed ovulation or no ovulation if progesterone levels are still low and pregnancy has not occurred. If after 5 weeks of FSH, no proestrus signs are evident, the bitch should be given no treatments for 4 to 6 weeks, but watched carefully for proestrus and if still anestrus following this period FSH therapy should be repeated weekly for another 5 weeks.

Short interestrus intervals are those seen in bitches that have less than 4 to 4-1/2 month intervals from one proestrus to the next. In the Beagle, approximately 150 days is needed for completion of endometrial desquamation and repair after the onset of estrus. Bitches with short interestrus intervals are frequently infertile. Possibly this infertility is caused by implantation failure, failure to ovulate or poor luteal formation and longevity. Progesterone blood levels should be performed during metestrus to determine if maximal ovulation and luteal formation have taken place. A suggested treatment is to place the bitch on a contraceptive such as mibolerone (Cheques, Upjohn Co.) and suppress the next several estrous cycles until breeding is desired and then breed on the next estrus after removal of the daily oral contraceptives.^{143,148}

Occasionally a bitch may have "split" or "false" estrus which will be characterized by vulvar swelling, blood-tinged proestrual discharges, attraction of males, a proestrus vaginal cytology followed by a return to anestrus and a quiescence of 2 to 6 weeks or longer until the bitch has another false or a full estrous cycle. This is seen in the puberal as well as later estrous cycles and can be seen when environmental changes are upsetting, e.g., shipping to breeders, infectious disease outbreak, training, endurance racing, etc. These bitches are usually fertile once they accomplish a normal estrus.

Some bitches fail to show standing behavioral estrus, but undergo full vaginal epithelial cornification with ovulation. This occurs in bitches with vaginal/vestibular strictures or with bitches that object to a particular male or any male. Breeding with restraint and muzzling or artificial insemination and use of vaginal cytology and/or vaginal mucosal changes to determine the onset of estrus usually results in pregnancy. This type of bitch can be the highly cuddled household dog that is socialized to humans but not other dogs, shy bitches, or a bitch

with a vicious attitude towards any other dog.

Occasionally a bitch will display a **prolonged estrous standing behavior** for any male, usually longer than 10 days and possibly into mid-metestrus/diestrus and pregnancy. Delayed ovulation, failure to ovulate or cystic follicular degeneration are possible causes of this behavior. Vaginal cytology and progesterone blood levels should be used to determine if the bitch is still in a proestrous or estrous stage. Many bitches will have normal metestrus/diestrus vaginal cytology, adequate progesterone blood serum levels (over 20 ng/ml) and be pregnant, but still accept the stud dog. Once the vaginal cytology changes from maximum cornification to less cornification, breeding should be stopped.

The queen is a seasonal breeder and responds to an increase in daylight or artificial light. Puberal estrus may be seen as early as 4 months of age in the early spring-born kitten that is well-grown, disease-free or may not occur for 12 months in the late spring, summer or fall-born kittens. **Anestrus**, like in the bitch, is associated with nutritional and disease states, gonadal hypoplasia, intersexuality, environmental stresses and also in the queen, the effect of insufficient light.^{121,167,239} Secluded house queens that select dark areas may never come into estrus. Also, single housed queens are less likely to show estrus compared to socialized queens housed with other cycling queens or tom cats.^{43,121,167} True anestrus queens are successfully induced with PMSG or FSH regimens (see section on estrus induction in feline physiology). Hypothyroidism is uncommon in the cat and is seldom a cause of anestrus.

Nymphomania in the bitch is characterized by excessive sexual desire and hyperestrogenism. Occasionally a bitch will mount and ride males, but not permit copulation. This condition may be caused by single or multiple follicular cysts or by functional granulosa cell tumors producing estrogens. These bitches are usually infertile with endometrial cystic hyperplasia caused by prolonged estrogen or estrogen/progesterone stimulation. Several early workers reported follicular and luteal cysts in older dogs and cats.^{25,86,175,176,177} Anderson and Simpson identified only 7 (3%) follicular cysts in ovaries in their aging Beagle study.⁶ None of these bitches showed clinical signs of nymphomania. Epithelial tubule proliferation or subepithelial structures, granulosa cell and rete ovarii derived cysts were most frequently found in their study.

The pathogenesis of follicular cystic degeneration in the dog is not known, but is probably similar to cattle. Hyperestrogenism is characterized by vulvar swelling, vulvar discharge, cystic endometrial hyperplasia, mammary gland hyperplasia, endometritis and pyometritis and

genital tract fibroleiomyomas or fibroids. Functional luteal cysts may cause increased progesterone blood levels which frequently lead to cystic endometrial hyperplasia-endometritis-pyometritis complex. These individual cases need more clinical documentation, e.g., vaginal cytology, vaginoscopic and laparoscopic studies, sex steroid hormone blood levels, and sex behavioral studies.

Queens with cystic follicular degeneration usually show signs of nymphomania, attract tom cats and show signs of proestrus but will not allow mating. Many are ill-tempered and unsuitable for pets during this time. The most frequent ovarian cyst in the cat at any age is cystic rete ovarii. These queens do not show nymphomania. These are found in queens at any age and can cause complete destruction of the ovary resulting in a cystadenoma. Nymphomania in the queen should not be misdiagnosed in cats with regular cycles that are not mated or receive only a single mating with insufficient vaginal stimulation to cause ovulation. These queens may remain in estrus for 10 to 20 days or longer and return in a few days to a few weeks with a similar cycle. Queens that have a sterile mating and ovulate will have a pseudopregnancy of 20 to 45 days and again return to proestrus and estrus within 7 to 14 days during the breeding season. These queens will respond to breeding and are usually fertile. Exogenous HCG, 25 to 200 units, intramuscularly given once or adequate pseudocopulation will cause the queen to ovulate and become pseudopregnant.

Treatment for bitches and queens with cystic follicular degeneration is designed to attempt luteinization of the cyst or ovulation with exogenous HCG given intramuscularly at a dose of 100 to 1000 units or the use of progestins to counteract hyperestrogenism. Progestins may result in further endometrial hyperplasia, endometritis and pyometritis. Once a regular cycle is produced, these animals should be bred. If litters are not desired, these animals are best treated by ovariohysterectomy.

Hyperestrogenism and nymphomania can be seen in spayed bitches and queens. This is usually due to an ovarian remnant or possibly accessory ovarian tissue between the removed ovary and the attachment of the ovarian ligament to the body wall.²⁰⁹ A laparoscopic examination, identification and removal of the remnant is best accomplished when the animal is showing signs of estrus and the vaginal cytology is cornified. At this time the follicles or cysts are present making the remnant easier to identify. Injection of HCG, 100 to 1000 units, once, intramuscularly, may cause ovulation and/or lutenization with increased progesterone blood levels, but in time these animals will recycle. Removed ovarian remnants should be checked by histopathology to identify ovarian structures. Hyperestrogenism in either queens or bitches

may lead to estrogen toxicity, bone marrow depression, thrombocytopenia, and rapid hemorrhagic shock and death.²⁴⁰

Spayed or intact bitches may attract males because of vaginitis, vestibulitis, or clitoritis but not accept copulation. Metritis, endometritis, uterine tumors, even in spayed bitches that did not receive a total hysterectomy, and possibly infected anal glands, may be other causes of "constant" attraction of males. It appears that these conditions cause the release of the sex pheromones from the vulva and vestibule. In spayed bitches, uterine stump infections or abscesses will cause vaginitis, vaginal discharge and attraction of males. Removal of these conditions by surgery or medical treatment will resolve the problem. Any vulvar discharge must be diagnosed by vaginal and vulvar culture, cytology, vaginoscopic and possibly laparoscopic examination. Intersexes with active ovarian tissue or abdominal testicles with Sertoli cell tumors producing estrogens will cause hyperestrogenism and attraction of males. Diagnosis of intersexes followed by gonadectomy will correct this condition.

Sterility caused by insufficient secretion of progesterone or hypoluteoidism in either queens or bitches must be well-documented by repeated embryo or fetal loss or abortion at the same stage of pregnancy. All other causes such as infectious diseases, low grade reproductive tract infections or degenerative endometrial conditions, and genetic causes must be differentiated. Blood progesterone levels taken bi-weekly are helpful in diagnosing hypoluteoidism. Repositol progesterone, 0.25 to 0.5 mg/kg, intramuscularly, at weekly intervals, starting 7 to 10 days before the expected abortion and terminated 7 to 10 days before expected parturition has been used successfully in the queen.¹²¹ Progesterone administered to the bitch during pregnancy can lead to intersexuality in female pups resulting in female pseudohermaphrodites.²⁵¹

Pseudopregnancy or pseudocyesis (false pregnancy) in bred or unbred bitches produces typical maternal behavior and signs at the approximate time of normal parturition along with mammary gland development and even the production of milk. Lactation may persist for 2 or more weeks and is encouraged by nursing or adoption of unrelated neonates and inanimate objects. The bitch may show nesting, mothering activity, restlessness, irritability, anorexia, and false labor. The abdomen may be distended and the uterus is palpable and shows endometrial hyperplasia grossly and/or microscopically. Vomiting, diarrhea, polyuria, polydipsia, and polyphagia have all been reported. Pseudopregnancy can be both "overt" or "covert." All dogs that ovulate undergo a physiological pseudopregnancy, but some individuals

will show behavioral signs.^{144,146,247} There is no correlation between expression of pseudopregnancy and reproductive disease or fertility.

Pseudopregnancy is caused by the decrease of progesterone following luteolysis and the pituitary release of prolactin as progesterone levels fall. Prolactin release can be enhanced by nursing and the presence of the neonates. In some bitches, ovariohysterectomy during the metestrus/diestrus state of pregnancy will result in prolactin release and "overt" signs of pseudopregnancy. Others, following progestin therapy, such as megestrol acetate (**Ovaban-Schering**) will respond with increased prolactin levels and overt signs of pseudopregnancy.^{144,146}

Pseudopregnant bitches should be treated with supportive therapy such as care of the mammary gland and sedation if needed for psychological and behavioral changes. Treatment with any of the sex steroids will mediate negative feed-back and inhibition effects on the hypothalamic-pituitary axis.⁹ Androgens, such as testosterone at 1 to 2 mg/kg once intramuscularly, or mibolerone (**Cheques-Upjohn Co.**) given orally to effect are preferred. Megestrol acetate, 2 mg/kg, orally, once daily for 8 days is very effective, but relapse following therapy will occur in some bitches. Bromoergocryptine is highly effective in reducing prolactin secretion, but the human drug forms have severe side effects and depressive behavioral actions on the bitch. A new bromoergocryptine product has been developed in Europe for use in the dog and is reported to be very successful but is not available in the United States.^{138,183}

The queen in the absence of coitus usually has no luteal phase. A few queens can be stimulated to ovulate by stroking the perineum or handling and will spontaneously ovulate.⁸⁷ If a sterile mating occurs, or ovulation is induced by exogenous LH, or vaginal stimulation with a probe, corpora lutea are formed and a pseudopregnancy occurs but is less persistent than in the bitch, with luteolysis taking place in 20 to 45 days.

Very few queens show "overt" pseudopregnancy. Occasionally there will be mammary gland engorgement, queens may allow young to suckle or display parturient behavior and maternal behavior towards inanimate objects. Usually no treatment is necessary. If therapy is indicated, repositol testosterone (1 mg/lb) or tranquilization may be provided.²³⁹

Preventing conception in mismating in bitches and queens has been discussed previously in the sections on Canine and Feline Physiology and is usually accomplished with estradiol cypionate injected in the first 5 days following breeding or during true estrus or late estrus. Administration during proestrus may not prevent

conception. Usually .25 mg to 2 mg, intramuscularly are the dose ranges. Several side effects, such as prolonged estrous behavior, pyometritis and estrogen bone marrow depression are undesirable. Other methods include the use of diethylstilbesterol tablets and several abortifacient drugs such as prostaglandins and their analogs, and bromocryptine drugs, which are undergoing experimental studies at this time, but offer potential alternatives (see sections on Canine and Feline Physiology).

Incontinence of urine following ovariohysterectomy in bitches is still poorly understood. There appears to be no age or breed predisposition and in general, for the number of ovariohysterectomies done in this country it is not a common sequela. The condition is infrequently reported in the queen. In one study, in dogs, the mean age of occurrence was 8.3 years (range 1 to 15 years).²⁰³ In some, the condition was seen most frequently when disorders causing polyuria developed. The diagnosis is made after differentiating neurogenic from non-neurogenic incontinence.^{197,203} This condition is usually diagnosed after other causes of urinary incontinence such as ectopic ureters, patent urachus, pseudohermaphroditism, urethrectal fistulas, obstructive incontinence and others are ruled out. Diagnosis is made by remission of urinary incontinence following estrogen therapy. Oral administration of 0.1 to 1.0 mg/day of diethylstilbesterol for 3 to 5 days followed by a maintenance dosage of approximately 1.0 mg/week is needed. Another treatment is 0.1 to 1.0 mg of estradiol cypionate, intramuscularly administered at intervals of weeks to months. These are completely empirical doses. The lowest dosage should be used because of the myelotoxicity of estrogen therapy in dogs. Recent experiments in rabbits show that ovariectomy decreases sensitivity to stimulation of alpha adrenergic receptors in the bladder and urethra that are important in controlling incontinence and that these receptors are estrogen sensitive.²⁰³ Adhesions between the stump of the uterus and the bladder, urethra and ureters following ovariohysterectomy may also result in urinary incontinence.^{25,195,203}

Hyperadrenocorticism in the dog of either sex is occasionally observed and can be caused by tumors of the pituitary gland or hypothalamus.¹²⁹ The most frequent primary pituitary neoplasm in the dog is the chromophobe adenoma.^{150,153} These tumors usually secrete excess adrenocorticotrophic hormone (ACTH) which results in hyperadrenocorticism. Other causes are functional adrenocortical tumors, abnormal negative feedback mechanism and iatrogenic causes.²¹¹ Iatrogenic canine Cushing's syndrome is due to exogenous glucocorticosteroids, which suppress endogenous ACTH secretion, causes atrophy of the zona fasciculata resulting in re-

duced endogenous glucocorticoid production and secretion. The iatrogenic form has been seen both in dogs and cats where prolonged and excessive use of glucocorticosteroids, and progestins such as megestrol acetate (**Ovaban**) administered for skin conditions, urine spraying in tom cats, aggressiveness or prolonged suppression of estrus.

This condition usually develops in dogs 5 years old or older. Purebred dogs, especially Miniature and Toy Poodles, Dachshunds, and Boston Terriers are most commonly affected, although any breed or mixed breeds can develop this condition. Primary hyperadrenocorticism is rare in cats. Clinical signs include bilateral symmetric alopecia, dull, dry and easily epilated hair, dermal atrophy, variable hyperpigmentation, muscle weakness, pendulous abdomen due to muscular weakness and hepatomegaly. Females are usually anestrus and 20 to 30 percent have an enlarged clitoris suggesting excessive androgens. Testicular atrophy is found in approximately 30 percent of the affected male dogs.²¹¹ In dogs with pituitary tumors, there is usually diabetes insipidus with polyuria, polydipsia and polyphagia. These dogs are usually hypothyroid, which also contributes to skin disorders and infertility and results in a lowered basal metabolism. In another study of this condition, clinical signs and prevalence were listed as polyuria and polydipsia in approximately 85 percent of cases, abdominal distension, 75 percent, anestrus, 70 percent, polyphagia 70 percent, muscular weakness and atrophy, 50 percent, bilateral symmetrical alopecia, 40 percent, testicular atrophy, 40 percent, comedones, 35 percent and calcinosis cutis, 10 percent.²⁰⁵

Laboratory tests for diagnosis include increased blood cortisol levels, absolute lymphopenia, eosinopenia, low urine specific gravity, low thyroid function test, hypercholesterolemia, and elevated serum alkaline phosphatase level (liver dysfunction). The more definitive tests are the ACTH response or a dexamethasone-suppression/ACTH-stimulation test.^{205,212} A high-dose (0.1 mg/kg) dexamethasone suppression test can more definitively diagnose either pituitary-dependent Cushing's syndrome with depressed serum cortisol from a functional adrenal tumor which does not depress serum cortisol. Whereas the low-dose (0.015 mg/kg) test is a screening test for a normal dog.²⁰⁵

Treatment consists of administering o,p'-DDD (**Lysodren**, Bristol Laboratories, Syracuse, NY) an analog of DDT, a drug that selectively causes necrosis of the zona fasciculata and reticularis. The initial dose is 50 mg/kg daily for 10 days with glucocorticoid supplementation; prednisolone, 0.2 to 0.4 mg/kg daily or cortisone, 1 to 2 mg/kg daily, to reduce the side-effect of

acute cortisol withdrawal from necrosis of the adrenal cortex.^{205,211} Surgical bilateral adrenalectomy and/or hypophysectomy can also be therapeutic, but skillful surgery, intensive monitoring and lifelong hormone replacement are required.

Pituitary dwarfism in dogs has been described in German Shepherds and Karelian Bear dogs.¹⁵⁰ It is a genetic disease caused by a recessive autosomal gene. Affected puppies are normal at birth but grow at a much slower rate than normal litter mates due to a deficiency of somatomedin, a growth promoting protein which is stimulated by growth hormone or somatotrophin (STH). These dogs keep their puppy hair for months and fail to develop sexually.^{150,229}

Pituitary cysts or other abnormalities may result in loss of sexual function. Cysts or abnormalities of the craniopharyngeal duct or Rathke's cleft are common in dogs. Depending on size, location and number of cysts, pressure on the neurohypophysis resulting in its destruction, may cause dwarfism, diabetes insipidus, genital atrophy, and obesity.^{150,153} Parasitic migration, usually of larval forms, may lead to massive pituitary destruction and inflammation resulting in hypopituitary function.¹⁶⁸

Acromegaly is caused by hypersecretion of growth hormone in the mature animal. It has been reported in dogs associated with injections of anterior pituitary gland extracts, eosinophilic cell hyperplasia of the anterior pituitary gland, administration of progestational compounds and in some intact bitches following the progesterone normally produced during metestrus/diestrus.^{64,89,187,229} Canine acromegaly and mammary gland nodules were reported following the administration of medroxyprogesterone acetate (MPA).⁶⁴ Canine acromegaly is characterized by inspiratory stridor due to diffuse soft tissue increase in the orolingual/oropharyngeal region, thick skin caused by myxedematous skin developing excessive folds, hypertrichosis, abdominal enlargement, diabetes mellitus, polyuria-polydypsia and fatigue. The dog appears to be particularly sensitive to the diabetogenic action of growth hormone which is characterized by hyperinsulinemia followed by hypoinsulinemia and exhaustion or pancreatic B-cells.⁸⁹ Dogs with acromegaly have elevated growth hormone plasma levels (11 to 1476 mg/ml). Dogs with acromegaly and diabetes associated with diestrus or progestational compounds that were administered respond well to ovariectomy or removal of the progesterone therapy, respectively.^{64,229}

Hypoestrogenism as a cause of an estrogen-responsive dermatosis, is a rare bilateral alopecia, seen in spayed female dogs. The cause and pathogenesis is not known. The condition is seen in spayed bitches and believed to

be seen more frequently in prematurely ovariohysterectomized dogs. In affected dogs it is hypothesized that the adrenal cortex may not produce sufficient estrogens.¹⁸⁷ Diagnosis is based on history, physical examination, laboratory elimination of other endocrine skin diseases such as hypothyroidism and hyperadrenocorticism and responsive therapy consisting of 0.1 to 1.0 mg of diethylstilbesterol orally, once daily and continued on a three weeks "on" and one week "off" basis until hair growth is evident. If good response is not seen in three months, the diagnosis is questionable. When good response is seen, a maintenance dose of 0.1 to 1 mg given once or twice weekly is established. If signs of estrus occurs, the dose should be lowered. Estrogen-induced bone marrow depression (thrombocytopenia, leukopenia, anemia) must be monitored by hematological examination.²⁴⁰

Hyperestrogenism caused by follicular cystic degeneration, functional granulosa cell tumor, Sertoli cell tumor in pseudohermaphroditism, or prolonged administration of large doses of estrogen may cause **alopecia**. The alopecia begins in the perineal and genital regions and may eventually involve the ventral abdomen and chest, flanks and neck. The skin can be thin or of normal thickness. The hair is easily epilated. These animals usually attract males, can have gynecomastia, usually have a vulvar discharge, an estrous type of vaginal cytology with cornification and frequently develop cystic endometrial hyperplasia-endometritis-pyometritis complex.⁸⁵

Hypothyroidism is the most common endocrine disorder of the dog. In a study of 2033 T₄ determinations of suspected hypothyroidism cases an incidence of 9.4 to 36.6 percent among 15 breeds of dogs was found;^{23a} Schnauzers, 9.4%, Dachshund, 10.5%, Chihuahua, 16.3%, Poodle, 18.2%, Doberman, 19.4%, Shepherd, 19.6%, Setter, 20.3%, Mixed, 20.5%, Collie, 21.2%, Terrier, 21.9%, Spaniel, 22.6%, Retriever, 23.5%, Labrador, 31.1%, Sled Dog, 33.3%, Beagle, 36.7%. Another study showed a relative risk factor of Chow Chow, 11, Great Dane, 4.1, Irish Wolfhound 4.1, Boxer, 7.8, English Bulldog, 3.2, Dachshund, 2.8, Afghan Hound, 2.7, Newfoundland, 2.6, Malamute, 2.5, Doberman Pinscher, 2.2, Brittany Spaniel, 2.0, Poodle, 2.0, Golden Retriever, 2.0 and Miniature Schnauzer, 2.0. A reduced risk was found for Beagle, Cocker Spaniel, English Springer Spaniel, German Shepherd and the mongrel.¹⁸⁷ These results are conflicting. Genetic studies concerning hereditary hypothyroidism are lacking. The two main causes of hypothyroidism in dogs are lymphocytic thyroiditis, an autoimmune disease, and idiopathic thyroid necrosis and atrophy. Secondary hypothyroidism, seen in about 10% of the cases is associated with pituitary

dwarfism and pituitary neoplasia.¹⁸⁷ There is no sex predilection for canine hypothyroidism and dogs between the age of 6 to 10 years are most often affected. Larger and giant breeds usually are affected at an earlier age of 2–3 years.

Associated reproductive abnormalities in the bitch include general infertility, prolonged interestrual periods, anestrus, prolonged estrous bleeding, shallow estrus, and short cycles.¹⁰⁰ In the male, abnormalities include poor libido, testicular atrophy and oligospermia. Other clinical signs include a wide range of dermatologic signs including a dry and brittle coat, patchy alopecia over points of wear, easy epilated hair, poor hair growth after clipping, poor hair turnover in cheek and temporal regions of short-haired dogs and a fine puppy-like coat in long-coat breeds. The skin is often dry, scaly, thickened and may appear myxedematous, especially facial skin. All forms of seborrhea and pyoderma can occur secondarily.

Other clinical signs can include mental dullness, lethargy, fatigue, obesity, hypothermia with desire to seek warm, heated places, cardiovascular signs including bradycardia, weak apex beat and decreased amplitude of QRS complex in all EKG leads. Cardiac dysrhythmias with congestive heart failure and myocardial changes are seen in largebreed dogs. Musculoskeletal/neurologic symptoms can be seen with severe hypothyroidism and include weakness, limb stiffness and dragging or knuckling of the feet. Clinicopathologic abnormalities include mild to moderate normocytes, normochromic anemia, serum lipid abnormalities, fasting lipemia, hypercholesterolemia and hypertriglyceridemia.^{187,219} In the author's experience, many bitches may be subclinically hypothyroid and show no other clinical signs than infertility.

Diagnosis of hypothyroidism is best performed by the thyroid stimulating hormone (TSH) response test. One procedure is to collect pre-injection baseline blood samples, inject 5 IU of TSH intravenously, and collect a post-injection blood sample 4 hours later. The baseline plasma level of T_4 is between 1.5 and 3.0 ug/dl; T_3 is between 1.0 and 2.0 ng/ml.²¹² Four hours post TSH stimulation, the T_4 and T_3 levels are increased 2 to 3 times. Dogs with primary and secondary hypothyroidism have subnormal or low normal baseline levels of T_4 and very little change after TSH stimulation. Baseline and post TSH; T_3 are more variable and less predictable. Normal levels of T_3 and T_4 and TSH response test can be different from laboratory to laboratory and should be checked for interpretation of results.

Treatment with thyroid replacement therapy is very beneficial and the clinical states usually return to normal. Synthetic products include L-thyroxine (T_4) called **Levothyroxine**, given orally at 20–32 ug/kg daily or

20 ug/kg every 12 hours in smaller dogs; L-triiodothyronine (T_3) called **Liothyronine**, is administered orally at 4.4 ug/kg every 8 hours; or L-thyroxine and L-triiodothyronine combined ($T_4 - T_3$) called **Liotrix**, administered at 20 ug/kg T_4 , 5 ug/kg T_3 every 12 hours and crude desiccated thyroid thyroglobulin, given orally at 15–20 mg/kg, once daily or divided every 12 hours. Post treatment testing after 4 to 6 weeks is indicated about 4–8 hours after an oral treatment to check for adequate replacement levels.²¹⁹

Clinical spontaneous hypothyroidism in the cat is unknown. Hyperestrogenism and hypoestrogenism as seen in the bitch can be seen in the queen.

Pathology of the Genital Tract

The principle pathology of the genital tract in the bitch and queen are developmental anomalies, cystic embryological remnants, hyperplastic and degenerative changes, neoplasia, inflammation and infection.

Developmental Anomalies and Cystic Embryological Remnants

In the study by Anderson and Simpson, ovarian cysts increased with age in the Beagle bitch and originated from follicles, corpora lutea and epithelial tubules (subsurface epithelial structures, SES), granulosa cell cords, rete ovarii and remnants of the mesonephric (Wolffian duct) or paramesonephric (Mullerian duct) ducts (paraovarian cysts).⁶ Follicular cysts, luteal cysts, and cystic corpora lutea were less common than epithelial tubular cysts and were not correlated with endometrial changes or nymphomania.⁶ Luteinized cystic follicles occur more frequently than cystic follicles.¹⁷⁶ Epithelial tubular cysts, also called subsurface epithelial structures (SES) are frequently multiple and are located in the cortex from the downgrowth of surface epithelium. Epithelial cysts may also be seen in the medulla or hilus. They are usually lined by simple epithelium. The epithelium may proliferate and become papillary. This hyperplastic condition may proliferate and eventually result in ovarian cystadenocarcinoma. Surface epithelium of the ovary becomes increasingly more active with advancing age in man, rodent and dog.⁶ In aged bitches the cortex may be replaced by multiple epithelial tubules and cysts resulting in complete destruction of the germinal cortical tissue. These bitches are anestrus. The cysts contain a clear watery secretion with little protein content which will remain fluid when fixed with formalin fixative, com-

Figure 152 Pyometra in a Bitch (Pseudomonas organisms were recovered from the uterus of the ill 8-year-old female)

pared to follicular or luteal cysts which contain an amber fluid rich in protein that will become solid and amorphous with formalin fixation.

In the aging Beagle bitch, granulosa cell cords (sex, egg or ova cords) can equal or exceed the number of epithelial tubules, whereas in the young adult, the ratio of epithelial tubules to granulosa cell cords was 4:1. These tubules develop from atretic follicles and remnants of the original migrating granulosa cell cords.^{6,241} Granulosa cell

Figure 154 Segmental Aplasia of the Right Uterine Horn with Mucometra in a Queen. (Courtesy K. McEntee)

cords are the precursors of the granulosa cell tumors, pseudotesticular tubules, sex cord stromal tumors, androblastoma, arrhenoblastoma or Sertoli-Leydig cell tumors of the ovary of the dog and cat. Granulosa cell cords are most frequently found near the corticomedullary junction but may occur in any region of the ovary.

The rete ovarii located in the hilus of the ovary in 10% of Beagles over 8 years of age contain cysts of variable size, while in another 5%, the structure was greatly enlarged.⁶ Hyperplasia with papillary proliferation occurs with age and in some bitches, the proliferation of epithelial, granulosa cell cords and hyperplastic tubules of the rete are difficult to distinguish apart.⁶ A large parovarian cyst was diagnosed following an ovariohysterectomy in a 7-year old West Highland White terrier.⁹³ A large ovarian cyst (19 × 7 cm) was grossly diagnosed

Figure 155 Uterus Unicornis in a Bitch (Courtesy J. D. Sweet)

as a functional follicular cyst because the 11-year old Labrador Retriever that it was removed from had a persistent estrus for several weeks.^{219a} The cyst and ovaries of this bitch were not examined histologically. Thus it is impossible to classify this cyst. The size would indicate that it possibly was not a follicular cyst but either a parovarian cyst of mesonephric or paramesonephric origin or a cystadenoma of one of the ovarian tubular structures. (See Figures 156–158)

Cystic rete ovarii in the queen become large enough to be confused with cystic follicles. They may be singular and destroy most of the ovary. Frequently they are incidentally found, and may be seen in the young as well as the older queens. The cyst if non-functional, contains clear watery fluid with little protein compared to the amber protein-rich fluid of follicular or luteal cyst. Follicular cystic degeneration has been reported in the queen.^{175,239}

Anderson and Simpson reported in aging Beagles that small cysts occurred in the fimbria and proximal portion of the oviduct, some obtaining the size of 1 cm in diameter. Fibrosis of the middle and distal portion of the oviduct was observed. Beagles between 4 and 8 years of age had uterine abnormalities that could impair their ability to reproduce. At ages between 9 and 17 years, two-thirds of the dogs had prominent uterine pathology. Hyperplasia of the endometrium was characterized by proliferation of glands, cystic formation and formation of variable-sized folds extending into the lumen of the uterus. Fluid accumulation either as hydrometra, mucometra, or pyometra was present in some. Approximately 4% of 216 Beagles developed moderate to severe pyometra. Beagles with cystic hyperplasia-pyometra syndrome usu-

ally had corpora lutea present. Atrophy of the endometrium was characterized by poorly developed uterine glands and a dense lamina propria.⁶ Further discussion on the cystic endometrial hyperplasia, endometritis, pyometra syndrome will occur later in this chapter.

Other complications of endometrial hyperplasia are the formation of pedunculated cystic endometrial polyps that may be singular or multiple and attain the size of a fetus. The author has seen pedunculated endometrial polyps in both aged bitches and queens. The author studied a case of torsion of one uterine horn containing a large endometrial polyp resulting in rapid hemorrhagic shock and death in an 8-year old German Shepherd bitch. Pedunculated endometrial polyps can prolapse through the cervix and result in a constant bloody and fetid vulvar discharge.

Another sequela of endometrial hyperplasia is adenomyosis, a downgrowth of hyperplastic glands into the myometrium. These masses are frequently misdiagnosed as a leiomyoma or fibroids until sectioned and the glandular “swiss cheese” muscle is noted.

Firm vaginal polyps were reported in 25% of Beagles over 10 years of age. These polyps can prolapse through the vulva.⁶

Segmental vaginal aplasia with incomplete development of the Mullerian duct was reported in 3 Beagles.²⁴⁸ Persistence of the mesonephric duct just lateral to the uterus and cervix in the broad ligament or the ventral floor of the vagina may be found as single or multiple cysts, tubules or the entire duct either unilaterally, but more frequently bilaterally. A persistent post-cervical band caused a dystocia in a 19-month old nulliparous Bull Terrier.¹²⁰ Congenital vestibulo-vaginal stenosis has been reported in several bitches. One study reported on

Figure 156 Cystic Ovaries from a Bitch

Figure 158 Granulosa Cell Tumor of a Canine Ovary
(Courtesy K. McEntee)

22 maiden bitches, 13 with strictures and 9 with persistent but perforate hymens. These bitches showed vulvar pruritus, incontinence, increased micturition frequency, vestibulitis and vaginal inflammation and mating difficulties, usually refusing copulation.¹²⁷ Diagnosis is made by digital examination, vaginoscopy, or radiography with pyelography or pneumocystography. Surgical correction is possible and sometimes necessary if constant irritation or chronic inflammation is present. In breeding bitches, artificial insemination with resulting pregnancy usually leads to a normal uncomplicated pregnancy and correction of the condition. If delivery is difficult, then an episiotomy at 11 or 2 o'clock position or a Caesarian section will alleviate the dystocia. In the author's experience, this condition is probably inherited and is seen frequently in the German Shepherd breed. Multiple fibrotic stenotic rings may be present cranially from the vestibulo-vaginal junction. The rings in the mid-vaginal area may create a "dam" that affects the flow of vaginal and uterine discharges resulting in periodic drainage of mucoid, serous or purulent debris and attraction of male dogs. A 3-month old German Shepherd with a congenital mid-perineal vulvo-vaginal cleft was repaired surgically with a good cosmetic effect.⁴⁵ The author has seen this condition in other German Shepherds and other large breeds of dogs. Other defects are the small juvenile vulva or the dorsal vulvar fold that covers a deep-seated, slightly tipped or inverted vulva.

Vaginal prolapse is seen in some dogs during increased endogenous estrogen levels of proestrus and just prior to whelping and is frequently called vaginal eversion or vaginal hypertrophy.²²⁰ This condition is seen frequently in the Bull Mastiff and Boxer breeds and is considered an inherited syndrome. Most bitches in proestrus will display a slight hypertrophy of the floor of the vagina and vestibule, but in some, it is so exaggerated that a protruding symmetrical mass will prolapse over the urethral meatus and occasionally the entire circumference of the vagina will prolapse resulting in a doughnut-shaped mass. The tissue is hypertrophied and edematous. This condition must be differentiated from a vulvo-vaginal leiomyoma, fibroid or polyps or a transmissible venereal tumor. The stage of cycle, symmetry and examination will differentiate vaginal prolapse from the above conditions. Severe cases must be artificially bred to become pregnant. This condition is inherited and the author has seen kennels where every bitch is affected. The condition will disappear following ovulation. Surgical excision and mucosal resection can be accomplished in those cases where severe trauma or urine scald has complicated the condition.²²⁰ The urethra should be catheterized so that the surgeon does not resect through it. The surgical incised free edges are sutured together as the mucosa is resected usually with interrupted suture of 2-0 chrome gut. The area heals very quickly with little complication. In bitches with prolonged estrogen stimulation, such as hyperestrogenism from a granulosa cell tumor, the chronic prolapsed floor of the vagina may become organized with fibrous tissue and remain a large organized fibrous prolapsed mass that has to be removed surgically.

The most common genital tract abnormality of the queen is **uterus unicornis and segmental aplasia of portions of the reproductive tract**. (See Figures 153–155) One horn and possibly the ipsilateral ovary may be missing, or blind segments of the uterus are present that become more fluid filled with each estrous cycle.^{121,239} Stenotic or fibrous adhesions or complete-closure and scarring of the cervix in the queen is occasionally diagnosed as a cause of infertility. This usually results when a young nulliparous queen delivers one or two kittens and tears or traumatizes the cervix. Diagnosis is made following a history of infertility and examination of the cervix in a well-restrained or tranquilized queen with a small otoscope cone and light. The prognosis is poor for further breeding.

Neoplasia

Neoplasms of the genital tract are more common in the bitch than the queen, but increase in prevalence with

age in both. In the study by Andersen and Simpson of the aging Beagle bitches, hyperplasia of epithelial tubules, the so-called subsurface epithelial structures (SES) leads to adenomas, sometimes filling the cortex of the ovary with multiple microadenomas consisting of a complex of simple tubules.⁶ They also can be cystic or papillary. (See Figure 157) This can lead to **papillary cystadenocarcinoma** which can vary in size and can grow through the bursa and beyond the ovary. Surrounding tissue implanted by contact and metastasis via the lymphatics is common resulting in peritoneal ascites. Histologically, these neoplasms contain elaborate branching tubules with variable amounts of vascular connective tissue and cystic formation. In one Beagle bitch, a unilateral tubular adenocarcinoma caused death of this intact bitch at 14.3 years of age. The dog had estrous cycles until 12 years of age, followed by anestrus. At 12.2 years of age, ascites was detected and at death the peritoneal cavity contained 1600 ml of fluid.⁶ These tumors are usually bilateral instead of unilateral as reported in this case. The aging Beagle study listed ovarian adenocarcinoma of tubular origin in 9 of 59 (16%) control Beagles, with an average age of 13.5 years (11.0 to 16.6 years). Among all of the 216 Beagles examined, 42 carcinoma of tubular origin were found and 31 (74%) were composed of papillary and cystic structures. They found that most of them infiltrated or metastasized to other organs or structures in the abdominal cavity causing ascites at terminal illness.⁶

In this latter study, granulosa cell cords were most frequently seen in the corticomedullary junction and hyperplasia of these cords led to benign and malignant neoplasia. Benign granulosa cell tumors usually consist of solid groups of cords with dense cellularity. Granulosa cell carcinomas are composed of variable-sized anaplastic cell cords scattered throughout a highly vascular matrix of loose connective tissue. These tumors can have cells with high mitotic figures and can be quite invasive with spread to adjacent or distant organs. In the above study, 3 of the 59 aged control Beagles had **granulosa cell tumors**, which were malignant. Among 157 irradiated Beagles, 14 granulosa cell tumors were found, 5 of which were malignant. In this study, granulosa cell tumors comprised about one-fourth of the ovarian neoplasms.⁶

The World Health Organization classifies the ovarian tumors of domestic animals as follows; epithelial tumors as papillary adenoma and adenocarcinoma, cystadenoma and undifferentiated carcinoma; germ cell tumors as dysgerminoma and teratoma; sex cord-stromal tumors as granulosa cell tumors, thecoma and luteoma. In their report, epithelial and granulosa cell tumors occur with equal

frequency in the bitch, whereas granulosa cell tumors are more common in the queen.¹⁹² In their study, the canine papillary adenoma and adenocarcinoma share similar features with their counterpart in women with the same histological appearance, frequent bilateral occurrence with peritoneal implantations, ascites and metastasis. Papillary tumors in the bitch have been induced by prolonged administration of diethylstilbesterol.¹³³ The tumors were fairly small, the largest being 7 × 6 × 4 cm. The ovaries were largely replaced by shaggy spongy masses of proliferative tumor tissue that grew through the bursal sac. Peritoneal implants occurred in 5 of the 6 cases and lung metastasis occurred in 2 cases.¹³³ Six papillary cystadenocarcinomas in bitches 6 to 15 years of age were described with marked ascites in 2 and bilateral involvement in 3 cases.¹⁷⁴ Cystic endometrial hyperplasia with a blood-tinged vaginal discharge and irregular cycles was also described. This may not be directly due to the influence of the ovarian neoplasia, but probably more likely was an endometrial hyperplastic degenerative change with age.¹⁵⁴

Sex cord-stromal tumors are also known as gonadostromal or sex cord mesenchymal tumors. Sex cord tumors are of the granulosa cell tumor series and may have luteal, Sertoli, thecal or granulosa cell types and patterns or can have all cell types and patterns co-existing in the same tumor. **Granulosa cell tumors** are able to produce steroid hormones, estrogens and progesterone, that can result in either nymphomania or virilizing effects. Approximately 20 percent of the granulosa cell tumors in dogs are malignant. Luteomas, thecomas and granulosa cell tumors with Sertoli patterns are usually benign.¹⁹² Several case reports of granulosa cell tumors in dogs are in the literature. A 14-month-old female Golden Retriever was reported to have a malignant granulosa cell tumor with widespread metastases to the omentum, mesentery, diaphragm, liver, serosal surface of the urinary bladder and all regional lymph nodes.⁵⁸ A metastatic stromal ovarian tumor with metastasis to the liver, spleen, lung, and kidneys was diagnosed in a 7-year-old Greyhound bitch.²²² Another malignant granulosa cell tumor of the Sertoli cell type with metastasis to the kidney, liver, and uterus was reported in a 6-year-old Airedale bitch.⁵ An 8 × 10 cm thecoma was removed from a 10-year-old Toy Poodle bitch with uneventful recovery. No metastasis was observed at surgery.⁹²

The granulosa cell tumors are usually seen unilaterally, often presenting as a large, lobulated, firm mass with a yellow-white cut surface, maybe solid, but often containing cysts, hemorrhage and/or necrosis.¹⁹² The distinct histological characteristic of the granulosa cell

tumor is the formation of Cal-Exner bodies or rosette formations of cells around an amorphous or proteinaceous central cavity. The largest granulosa cell tumor in a series studied was $11 \times 9 \times 5$ cms. and weighed 213 grams.¹⁷⁴ Most bitches affected with this tumor had a cystic endometrial hyperplasia, endometritis, pyometritis complex and showed signs of hyperestrogenism. The author has observed a case of hyperestrogenism in a 5-year-old Springer Spaniel bitch with attraction of males, a moderate persistent prolapse of the vaginal floor through the vulva and a constantly cornified estrous vaginal epithelium. Ovariohysterectomy revealed a unilateral granulosa cell tumor. The bitch recovered uneventfully. A 10-year-old female dog with endocrine abnormalities and abdominal distention responded to removal of a granulosa cell tumor and a regimen of immunotherapeutics using a mixed bacterial toxin even though multiple metastasis were present. The dog was normal 2 years later.¹¹⁷ Case reports of an 11.5-year-old West Highland White Terrier and a 4-year-old Afghan hound with abnormal prolonged estrous activity were diagnosed as granulosa cell tumors producing estrogen and progesterone. The Afghan hound also showed acute hyperestrogenism toxicity with myeloid depression, thrombocytopenia and hemorrhagic diathesis from endogenous estrogen production. Both returned to normal following ovariohysterectomy.¹⁷³

Cystadenomas, found in bitches and queens appear to originate from the rete ovarii. They are usually multiple, thin-walled cysts containing a clear watery fluid and may replace with time the true ovarian tissue.

Germ cell tumors include **dysgerminomas** and **teratomas**. Dysgerminomas are seen in both bitches and queens and are malignant in 10 to 20 percent of the cases. These are analogous to the seminoma in the testes of the male and consists of a uniform population of large round or polygonal cells, with frequent mitotic figures and giant cells. It is a highly cellular tumor, with little connective tissue. It grows quickly and necrotic and hemorrhagic areas are frequently present.¹⁹²

Teratomas are rare tumors that contain a mixture of normal and neoplastic tissues from two or three germ layers. They may be solid or cystic and contain hair, skin, cartilage, bone, teeth or muscle. The left ovary of a 5-year-old virgin Alsatian bitch contained a large teratoma characterized by large cyst lined with stratified squamous epithelium, dermoid cyst, cartilage, fat, collagen bundles and smooth muscle.⁵⁹ The dermoid cyst is a special form of cystic teratoma with one or more cystic cavities lined by epidermis and epidermal appendages that may produce sebum, sweat, and hair which accumulates in the cystic spaces. The author has diagnosed

a unilateral dermoid cyst as an incidental finding in a routine ovariohysterectomy in a 2-year-old St. Bernard bitch. A malignant ovarian teratoma was diagnosed in a 3-year-old St. Bernard bitch. The left ovary contained a large mineralized mass, 26 cm in diameter, easily discernible on radiology and contained areas of skin, adrenal glands, hair follicles, dermoid cyst, nervous tissue, cartilage, bone, and glandular epithelium and areas of liposarcoma. Peritoneal metastases were composed of tissue resembling liposarcoma.⁷⁰

Metastatic tumors to the ovary of the bitch include pancreatic adenocarcinoma, mammary adenocarcinoma, lymphosarcoma, transmissible venereal tumor and reticulum cell sarcoma.¹⁷ Metastasis to the ovary frequently occurs in the developing corpora lutea if they are present. Lipomas and leiomyomas, fibroleiomyomas (fibroids) can be found in the bursa of the canine ovary.^{176,177}

In a California epidemiologic study of canine mammary and genital neoplasia, ovarian tumors occurred at an incidence rate per 100,000 of 4.6 with 1.9 malignant and 2.7 benign; 2.3 in the uterus, 0.5 malignant and 2.7 benign; 13.1 in external genitalia, 1.0 malignant and 12.1 benign; 319.3 in mammary glands, 92.2 malignant and 227.1 benign. In this study, most ovarian tumors were adeno-types with 33 percent being malignant. Of 44 ovarian tumors, 3 were dysgerminomas. About 75 percent of the uterine tumors were benign leiomyomas. **Vaginal tumors** were mainly either leiomyomas or fibromas. Vaginal tumors were approximately 12 times greater in intact versus neutered bitches.²²⁷

Tumors of the oviduct are considered to be rare or absent in the dog and cat.⁶ Only one irradiated Beagle had a uterine adenocarcinoma in the study of aging Beagles.⁶ Forty uterine adenomas were studied but they were benign and characterized by vascular connective tissue, scattered uterine glands and cystic cavities. Grossly, these adenomas protruded into the uterine lumen as a pink mass and were either spongy or firm. Two leiomyomas were reported in the wall of the uterus among the 216 aging Beagles. **Tumors of the uterus** in the bitch are rare, but include adenocarcinoma, fibroma, fibrosarcoma, leiomyoma, leiomyosarcoma, lymphosarcoma, and lipomas in the broad ligament.¹⁹² A uterine adenocarcinoma with metastasis to the myocardium was reported in a 7-year-old Beagle-Terrier cross.²⁴⁹

Leiomyomas and fibroleiomyomas are most frequently found in the vagina and vulva.^{38,66,67,69,175,176,177} Other tumors, lipomas, fibromas, neurofibromas, fibrosarcomas, transmissible venereal tumor (TVT), adenomas, and lymphosarcomas can also be found as vaginal and vulvar tumors.^{17,175} A vulvar leiomyosarcoma with metastasis to the spinal cord, lung, and external iliac

lymph node was reported in a 13-year-old Standard Poodle.¹¹⁹ Any of the skin tumors; squamous cell carcinoma, melanoma, histiocytoma, mast cell tumors, etc. can be seen on the vulva since embryologically it is of cutaneous origin.

Rare cases of chorioepithelioma of the placenta of the bitch were reported by early workers, but recent studies of the post-partum period in the bitch reveal longterm subinvolution of placental sites that would fit the description given by the early workers of chorioepithelioma.^{3,186,215}

Granulosa cell tumors in the queen are seen more frequently than papillary cystadenocarcinoma. More than half of the granulosa cell tumors in the queen are malignant and metastasize.¹⁹² A sex cord stromal tumor, androblastoma with Sertoli-Leydig cell pattern, or a granulosa cell tumor, was reported in a 6-year-old queen. The right ovary measured $7.5 \times 5.4 \times 3.6$ cm and was cystic in areas. The left ovary was inactive. The uterus had adenomatous hyperplasia indicating an estrogenic effect, although none was clinically recorded.¹²⁵ Prolonged estrus and alopecia has been attributed to granulosa cell tumors in cats.²³⁹ The right ovary of a 15-year-old thin, depressed female Persian had a large lobulated mass which contained granulosa cells in solid areas and lining cystic spaces. Metastases were present in the pelvic areas, dorsal abdominal wall, liver, lungs and right kidney. The cat was lethargic, anorexic with pale mucus membranes. A hemogram indicted hypochromic anemia with moderate erythropoiesis. These signs and findings indicate a hyperestrogenic state prior to euthanasia.⁴ An extra-ovarian granulosa cell tumor was diagnosed in a 5-year-old Siamese queen exhibiting estrus for 3–4 months together with weight loss. A $4 \times 3 \times 3$ cm mass on the distal left uterine horn, not connected to the ovary, was diagnosed as a primary granulosa cell tumor. Response with weight gain following ovariohysterectomy but later a relapse with metastases were found in the liver, kidney and spleen.¹⁰ Cystadenomas are quite common in the queen's ovary. Dysgerminomas accounted for 15 percent of feline ovarian tumors in one study.¹⁷ These can be malignant. Both malignant and benign teratomas in the ovary of the queen have been reported.²³⁹ Uterine adenocarcinoma and lymphosarcoma have been reported as metastases to the queen's ovary. Carcinomas, adenocarcinomas, adenomas, leiomyomas, fibroleiomyomas, lymphosarcoma have all been described in the uterus of the cat.^{17,182,226,239} A vaginal leiomyoma was reported to cause constipation in a cat.²⁵⁴

Canine transmissible venereal tumor (TVT) has been well-described by a number of workers.^{17,24,25,27,46,150,175,178,250} It is known by a variety of names;

Sticker tumor, infectious transmissible venereal tumor, transmissible sarcoma, transmissible lymphosarcoma or histiocytoma. It is easily transmitted by transplantation of cells by contact during coition, or by licking of the genitalia or extragenital tumor masses.¹⁹

In the United States, the incidence was formerly high around the large city areas such as New York City and Chicago. This miraculously has disappeared, probably because of better dog control programs and immune status of the population. More recently, areas of southern United States and the Caribbean Islands have higher prevalence.

This tumor can implant in any epithelial tissue. On a mucosal surface, the tumor appears as a glistening, nodular, cauliflower-like elevation that becomes larger and in many cases reseeds itself in the surrounding tissue. Although usually the genitalia are affected, it may also occur on the face, shoulders and other locations and may metastasize to lymph nodes and other organs including the spleen, liver, lung, tonsils, nasal cavity, brain and eye.¹⁷ Occasionally extragenital tumors are found with no primary genital tumors; although initial infection may have been the genitalia with regression by the time of clinical diagnosis.²⁵⁰ In advanced cases, a bloody, purulent fetid discharge usually is present from the vagina of the affected bitch. The tumor may protrude through the vulva of the bitch or involve the vulva itself. Large cauliflower-like masses may be seen on the prepuce and penis of the male dog. Occasionally the tumor can be pedunculated, nodular or papillary. They are often ulcerated and inflamed on the surface.

Histologically, the tumor is very cellular, consisting of large round cells which bear resemblance to lymphoid cells, histiocytic, or mast cell tumors, but the cells are usually larger.^{17,150} Mitotic figures are quite numerous even though the infiltrative and metastatic characteristics are low.¹⁵⁰ The cells of the venereal tumor usually contain only 59 chromosomes (58 to 60), 17 of them metacentric and 42 acrocentric.^{1,150} Normal cells of the dog at metaphase contain 76 autosomal chromosomes, all of them acrocentric. The sex pair are metacentric, the X is largest of the complement and the Y near the smallest in size.

C-type virus particles have been detected in TVT by electron microscopy, but attempts to transmit with cell-free filtrates have failed.²²⁴ Older dogs are susceptible, while young dogs seem refractory to experimental infection. Tumors grow to maximum size in 5 to 7 weeks and usually spontaneously regress in about 6 months.^{186,208} Treatment is often not necessary because of regression. Recovered dogs remain immune for long periods.¹⁸¹ Persistence and recurrence following surgery is due to a de-

iciency in cell-mediated immunity.^{39,250} This has been measured by a mixed lymphocyte culture test in which those dogs with tumor regression had a high lymphocyte blastogenic response to TVT cells compared to those that did not regress or had persistence with metastases.³⁹ Surgical removal is often curative. Persistent local lesions can be treated with X-radiation therapy with either single or divided courses totalling 2000–2400 rads.^{17,250} If metastasis occurs, chemotherapy with a combination regimen consisting of vincristine, cyclophosphamide, and methotrexate is highly effective.³⁹ Vincristine alone appears to be comparable to the above combination chemotherapeutically, with less side effects and easier management and therapy.⁴⁷

Mammary tumors in the bitch and queen are common compared to other domestic animals. In the bitch, tumors of the mammary gland are second in frequency only to tumors of the skin.^{150,175} An epidemiological study of canine mammary gland neoplasia in California revealed several interesting facts.²²⁷ Mammary gland tumors are seen in approximately one male case to every 100 female in the cat, and two male cases to every 100 female in the dog. Bitches spayed prior to any estrous cycle had 200 times less mammary cancer. Those spayed after one cycle had 12 times less risk and those spayed after maturity had no reduced risk. Regardless of age when spayed, overall reduction in risk is 5 to 7 times for most populations. Castrated males have the same rate as non-castrated.²²⁷ The lowest breed incidence was noted in Chihuahuas.^{79,227} If the incidence in Chihuahuas is equal to 1.00, then all other breeds are 1.75 to 4 times higher with the following rates reported: Pekingese, 1.15; Labrador Retriever, 1.74; Beagle, 1.75; Poodle (all sizes), 2.31; German Shepherd dog, 2.14; German Shorthaired Pointer, 2.60; Dachshund, 2.67; Cocker Spaniel, 4.03.²²⁷ Death rate the first year following malignant mammary tumor removal from bitches was 2.5 times the rate of bitches not having mammary cancer. The younger the dog, the longer the period before additional tumors or complications developed. Over 70 percent of dogs studied developed additional tumors.²²⁷ Within 42 months of the first diagnosis of mammary cancer, 50 percent of bitches 6 years or younger developed additional mammary cancer, whereas 75 percent of bitches 10 years and over developed such cancer.²²⁷ Others have reported similar findings.⁹¹ Spaying bitches after cancer development did not prolong life.²²⁷ In another epidemiological study, the incidence rate was 198.8 in 100,000 females. Tumor rate increased after 5 years of age.⁷⁹

Progesterone, endogenous secretion and exogenous therapy causes mammary gland hyperplasia and neoplasia in the bitch and queen. Researchers have found that

exogenous progestins, such as medroxyprogesterone (MPA), and cyproterone acetate (CPA) cause an increase in growth hormone (GH) or somatotrophin, and resulting mammary gland nodules and tumors. Prolactin (PRL) levels remain normal.^{64,101,102} Acromegaly following progesterone and GH increase was described earlier in this chapter. Both GH and PRL receptor sites are found in canine mammary gland tumors. It is believed that GH, stimulates growth of the gland and PRL mammary secretion.^{90,101,102} Antiprolactin drugs, such as the bromocriptine drugs, when administered to bitches with mammary gland nodules and tumors, or lactating bitches will cause a drastic reduction in size and secretion.^{138,183} The amount of progesterone influence of synthetic progesterone used for therapy will have different effects on the mammary gland. In one study of estrus control in 1011 bitches with progestin there was no increase in mammary tumor nodules among 331 given proligestone whereas 341 given medroxyprogesterone acetate (MPA) had increased nodule incidence over the 339 untreated controls (age groups 4–6 and 6–9 years of age, 19 and 39% for MPA and 5 and 13% for controls, respectively).²⁴⁵

In the California study, 67 percent of 4000 mammary tumors studied were mixed mammary types, whereas 32 percent were various adenomas and adenocarcinomas. Most mixed types were benign (6.5 to 1) while most adeno-types were malignant (2 to 1). The probability of malignancy increased with age. Spayed females over 3 years of age in the California study had a 5 to 10 percent increase of probability of having a malignancy over non-neutered females, therefore early neutering appears to spare benign development, but not malignancy.²²⁷

In another study of 226 canine mammary tumors, it was reported that both benign and malignant tumors increased in frequency from the anterior to posterior glands.⁹¹ Approximately 57 percent of all canine mammary gland tumors arise in the posterior glands.¹⁷⁵ In the previous study, where pseudopregnancy had been marked, there was a significantly increased chance of the tumor being malignant.⁹¹ Others have reported that the incidence of dogs with mammary tumors and normal dogs were similar with regard to normal and irregular estrous cycles, signs of pseudopregnancy, and pregnancy.^{37,94} Bloom noted that the mammary tumor was apt to grow rapidly during proestrus, estrus, and metestrus and tended to become smaller and firmer with retardation in growth during anestrus and after ovariectomy.^{24,25} In the study by Else and Hannant, 50 percent of malignant tumors were cured by surgery, metastases in 52 percent of cases caused death within one year.⁹¹ Metastases were most frequently to lungs (38%), liver (18%), regional lymph

nodes (12%), kidney (12.7%), spleen (10%) and peritoneal/pelvic fascia (5%). Similar incidences have been reported by other workers.¹⁸⁸ Mortality with well-circumscribed carcinomas was lower and median survival longer following surgery than those with tumors having irregular infiltrating borders; as 86 percent of the latter died in less than 6 months post surgical removal.⁹¹ In a study of 120 cases of mammary cancer, 117 females, 2 males and a 1 dog of undetermined sex, 8 were duct carcinomas, 38 lobular carcinomas from alveoli with 8 dogs having 2 primary tumors.¹⁸⁸ Another study revealed that 65 percent of mammary tumors were benign mixed tumors and 25 percent were adenocarcinomas with the remainder being a variety of benign or malignant tumors.¹⁸⁶ Cotchin described 424 mammary tumors from bitches: 249 were benign and 187 malignant. Metastases were present in only 41 bitches.⁶⁸

Classification of canine mammary gland tumors are varied. Most prefer to use a histological descriptive classification. Adenoma, either intraductal or acinar (secretory tissue), or fibroadenoma. Adenocarcinoma is either simple (epithelial only) or complex (both epithelial and myoepithelial) and consists of papillary (ductal), tubular (ductal), lobular (acinar), scirrhous, or adenocanthoma (portion containing squamous cell carcinoma within the adenomatous epithelium). There also are medullary or solid carcinomas, either simple or complex, or undifferentiated (anaplastic) carcinoma. Mammary adenocarcinoma in the dog comprises approximately one-half of all mammary gland tumors.¹⁷⁵ Mixed mammary gland tumors with both epithelial and mesenchymal tissue involvement, is usually the most common mammary tumors of the dog.^{150,175} This tumor contains glandular tissue, myoepithelium, myxomatous connective tissue, cartilage and bone. Mixed tumors are slow growing and less likely to metastasize. Sarcomas, usually less than 2%, are of the osteosarcoma, chondrosarcoma, fibrosarcoma or combined types. The so-called spindle cell carcinoma, rare in the dog, is of myoepithelial origin.¹⁵⁰ Frequently the malignant mammary gland carcinoma will ulcerate the overlying skin and exude a bloody discharge and a foul decaying flesh odor will be present.

Nodular hyperplasia of the mammary gland of the bitch is seen following progesterone therapy for estrous cycle control or during the luteal phase of the cycle.^{64,101,102} This is classified as cystic glandular hyperplasia and lobular hyperplasia or papillary cystic lobular hyperplasia and nodular papillary cystic myxodysplasia, respectively. Both types have ductal hyperplasia and sometimes myoepithelial cell formation, while the nodular or lobular form is the transitional form between hyperplasia and benign mixed tumors.^{150,175}

Ductal ectasia with accumulated milk secretion resulting in a periductal granulomatosis infiltration created by the accumulated secretion or stasis of milk in the gland called galactostasis will also cause a nodular mammary gland lesion.¹⁴⁷ These mammary gland dysplasias are fluctuant depending on stage of cycle. It is important when examining the bitch for breeding soundness or general physical examination to record the location, size and appearance of any mammary gland abnormality. The stage of estrous cycle and any exogenous progesterone therapy should also be recorded. On reexamination the mammary gland abnormalities can again be reevaluated and decisions made on treatment. The inguinal lymph nodes or fat pads in this area should not be confused with mammary gland nodules or tumors.

Mastitis does occur in the mammary gland of the bitch and queen and is caused by bacterial infection of the lactating gland postpartum or during pseudopregnancy. Enterobacterium, streptococci and staphylococci are commonly cultured. Broad spectrum antibiotics are given immediately, followed by specific antibiotics following culture and antibiotic sensitivity tests. Acute mastitis may progress to abscessation or gangrenous mastitis.^{104,147}

Feline mammary hypertrophy, also called juvenile fibroadenomatous hyperplasia is characterized by hyperplasia of both epithelial and stromal components. It can be seen in single glands or the entire chain.^{116,150,167} It is most frequently seen in young sexually intact females of 1 year of age or less following estrus and resulting during pseudopregnancy or during pregnancy and appears to be progesterone dependent. Progesterone receptors, but no estrogen receptors were found in hypertrophied mammary gland tissue.¹¹⁶ Spontaneous remission occurs and recurrence during following pregnancies or pseudopregnancy is usually not noted or with less involvement and appears to be a normal physiological hypertrophy.⁵⁶ Many of these affected queens have difficulty walking due to the extremely hypertrophied glands and are lethargic. Ulceration and excoriation of the skin over the enlarged glands is common. Secondary mastitis may occur. Antibiotic therapy is advocated when this happens as well as the use of warm water soaks.⁵⁶ Feline mammary hypertrophy has been shown to regress following ovariectomy. The clinical condition in young queen should not be misdiagnosed as a rapid growing mammary gland carcinoma with radical surgery of the complete mammary chain. Regression is usually noted in 2 to 3 weeks to 1 month after reaching maximal size. Treatment with bromocriptine drugs has not been reported, but the success in dogs with mammary gland hyperplasia and neoplasia in decreasing the size of the tumor masses should be studied in the queen. Mam-

mammary hypertrophy in older cats of both sexes following progesterone treatment with compounds such as megestrol acetate (**Ovaban**-Schering) for skin conditions or the control of tom cat behavior or urine spraying is progesterone-related. Removal of progestin therapy results in alleviating the nodular hypertrophy.¹¹⁶

Mammary tumor development in the cat comprises between 6 and 11 percent of all feline tumors. This incidence is much lower than that of the dog. Feline mammary tumors tend to occur at an older age than in dogs with an average of 11.5 years given by Cotchin.^{67,69} Mammary tumors in the cat arise more frequently in the anterior glands. The neoplasms are nearly always malignant, fast growing and between 75 and 86 percent being simple adenocarcinomas mostly of the papillary type, although the solid type is found. Recurrence following surgery is common. The most common sites of metastases are the regional lymph nodes and lung, but they can be found in the liver, adrenal, kidney, spleen and myocardium. A study involving 132 cats, including 2 males with mammary neoplasia revealed a ratio of 9:1, malignant to benign tumors.¹¹⁸ Adenocarcinomas were the predominant type.^{118,175,186} The Siamese breed had twice the risk of developing mammary carcinoma with an increased prevalence at a younger age, 7 to 9 years compared to the peak age incidence in other breeds at 10 to 14 years of age.¹¹⁸

Non-metastatic ovarian and uterine tumors can successfully be removed by ovariectomy. Mastectomy is indicated for mammary gland neoplasia. Regional lymph nodes and radiographs of the lung should be examined for metastases. Vaginal and vulvar tumors are frequently benign and pedunculated and can be removed easily after ligating the pedicle. When the base of the tumor is broad, a dorsal episiotomy may be indicated in order to obtain adequate exposure of the vagina and tumor so that complete excision can be accomplished.

When **malignant reproductive tract or mammary gland tumors** have metastasized to other organs, the prognosis is grave. New methods of treatment including radiation therapy, chemotherapy, immunotherapy and antihormone therapy can increase life span or in some cases cure the animal.

A bilateral ovarian papillary cystadenocarcinoma in a 5-1/2-year-old Coonhound bitch with ascites and several peritoneal and visceral tumor nodules was reported and treated with chemotherapy consisting of a combination of cyclophosphamide (**Cytoxan**: Mead Johnson) and chlorambacil and nitrosurea (**Cee Nu**: Bristol) following ovariectomy and removal of 4L of peritoneal fluid.¹⁰³ Four months post-operative, hydrothorax due to

malignant pleural effusion was diagnosed. The thorax was drained and infused with bleomycin (**Blenoxcine**: Bristol) which was removed 24 hours later. Ten months after diagnosis, the dog appeared in excellent health.¹⁰³

Crow gave an excellent summary on the treatment of malignant neoplasms of the reproductive organs and mammary glands of the dog. Radiation therapy can be used either as a primary therapy or as an adjunct to surgery or cryosurgery. Superficial single tumors such as transmissible venereal tumor or squamous cell carcinoma can be treated with up to 4000 to 6000 rads of external beam irradiation administered in 500 rad fractions three times weekly. Cobalt therapy can be used for deeper lesions.⁷¹

Chemotherapy is most often used in treating disseminated malignancies seen in ovarian and mammary gland metastatic malignancies. Use of anticancer agents are dosed on basic surface area and monitored daily for the following: weekly examination including packed cell volume (PCV), total white blood count (WBC) and differential and platelet quantitation. Cytotoxic agents are discontinued if PCV is less than 25 percent, WBC less than 3000/ul, neutrophils less than 1000/ul, and platelets less than 50,000/ul. A list of commonly used chemotherapeutic drugs by Crow included: chlorambucil (**Leukeran**), cyclophosphamide (**Cytoxan**), cytosine arabinoside (**Cytosan**), 5-fluorouracil (**Fluorouracil**), **Methotrexate**, Prednisone, vinblastine (**Velban**), vincristine (**Oncovin**). The reader is referred to the article by Crow for further information on dosage and use.⁷¹

Increased levels of circulating immune complexes were demonstrated and reported in the sera of bitches with both benign and malignant mammary gland neoplasia by a group of workers using a modified Raji cell technique.¹⁷² Dogs with persistent increases of circulating immune complexes were found to be at greater risk of developing metastatic cancer post-mastectomy. Significant anti-tumor response was found following immunoadsorption with staphylococcus whole organisms and treatment with saline supernatant staphylococcus preparation, incubated with plasma from solid tumor bearing bitches. The workers felt that tumor regression following staphylococcus reaction with plasma may be related to the release of a non-protein A bacterial product.¹⁷² A 10-year-old bitch with endocrine abnormalities and abdominal distention caused by a granulosa cell tumor was reported to have tumor metastases on the liver and partial peritoneum.¹¹⁷ Following an ovariectomy and removal of fluid from the peritoneal cavity, the bitch was given 4 months of immunotherapy consisting of a mixed bacterial toxin (MBT). This treatment has been used to successfully treat malignant ovarian and uterine neoplasia.

sia in women.¹¹⁷ Radiography 5 months post-surgery and 1 month post-immunotherapy revealed no metastatic disease with an apparent cure lasting two or more years. The use of bacillus Calmette-Guerin (BCC) to cause regression of experimentally-induced transmissible venereal tumor in dogs has been reported.⁴⁷ Bromoergocryptine drugs are antiprolactin in activity and when administered to bitches with mammary gland neoplasia cause noticeable regression in the size of the gland which has been beneficial in surgical removal of the tumorous masses.^{138,183} Combinations of surgery with radiation therapy, chemotherapy, immunotherapy or antihormone therapy appear to be highly beneficial in increasing the life span or curing dogs of malignant metastatic reproductive tract and mammary gland neoplasia.

Specific Infections of the Genital Tract

Specific infections of the genital tract of the dog causing infertility are *Brucella canis*, canine herpes and transmissible venereal tumor (TVT) (discussed previously in this chapter under neoplasia). Tuberculosis of the uterus in the dog has been reported, but is rare.²⁵

Brucella canis was first reported in 1966 as causing abortion in Beagle bitches.^{54,55} It is known now to be an established disease of dogs, occurring in all breeds of dogs with worldwide distribution and manifesting many clinical syndromes as well as a nonclinical carrier state.^{30,35,122,189,196,207,242,243} Human infections have also been reported. A literature review of 18 human cases revealed that this disease was of public health significance but that man was relatively resistant to ***B. canis***. Signs included headache, fatigue, enlarged regional lymph nodes, without splenomegaly, and mild fever.⁵³ Infected individuals responded well to tetracycline therapy.

Dogs are the only known natural host, although experimentally foxes and cats are highly susceptible.⁵³ Canine infections can also be caused by ***Brucella abortus***, ***B. melitensis***, and ***B. suis***, following contact with infected material, but the disease is usually self-limiting and the organisms do not persist.^{49,50}

A case was reported of a clinically normal pregnant bitch shedding ***B. abortus*** in urine, vaginal secretions and following euthanasia, isolates were made from the brain, mammary gland, and all lymph nodes. The bitch had been exposed to a ***B. abortus*** seven-month-aborted bovine fetus, 5 weeks prior to sampling and 3 weeks before whelping clinically normal pups. The pups were negative for ***B. canis***.²¹

Several excellent reviews on canine brucellosis have been published by Carmichael and other workers.^{49,50,51,53,54,55,131,184,214} In the bitch, clinical signs in-

clude abortion after 13 days but most commonly between 45 and 55 days of gestation. Some pups may be expelled dead and others alive, if after 55 days of gestation. Early embryonic death which appears as a failure to conceive is infrequently associated with ***B. canis*** infection. In the male, epididymitis and orchitis followed by testicular atrophy are common. A draining fistulous track can occur between the epididymis and the scrotal skin.^{99,228} General lymphadenopathy with enlargement of all lymph nodes is common in the infected dog. ***Brucella canis*** is readily isolated for several weeks from the aborted pups, placentas, and vaginal discharges post abortion. In the male, ***B. canis*** is easily isolated from the draining scrotal fistulous track and from semen and prostatic fluid of the clinically-affected stud dogs with prolonged carrier states and intermittent recurring acute infections occurring in the prostate gland. Infertility with poor semen quality, pus in the ejaculate and agglutination of sperm are common clinical signs in the effected stud dog.⁹⁹ Prolonged bacteremia lasting more than 2 years is characteristic of this disease. After several months the bacteremia may be intermittent.⁵³ Experimentally infected dogs have remained blood culture positive for as long as 5-1/2 years.

The most common non-reproductive disorder associated with seropositive status for canine brucellosis is discospondylitis and osteomyelitis.¹³¹ This is similar to ***B. suis*** infections in swine. Joint involvement may occasionally be seen. ***Brucella canis*** was also reported from a uterine stump abscess in a spayed bitch.⁷⁶

Many infected carrier animals may appear clinically normal, even though they are bacteremic and may shed organisms in the semen or possibly intermittent vaginal secretions. Clinically normal appearing males may shed the bacteria in semen and infect susceptible bitches venereally at breeding. It appears that the male is most likely infected via the oral route. It requires a minimum of approximately 2 million ***B. canis*** organisms to establish infection by the oral route.⁵⁰ Organisms can be isolated from the urine and vaginal secretions of affected bitches, but usually in insufficient numbers to infect others, although experimental infection can occur via all mucosal membrane surfaces such as the eye, nose, mouth and vagina. Contaminated needles used to draw blood or as a transfusion may cause disease in susceptible dogs.⁵⁰

Diagnosis of ***B. canis*** in an individual dog or kennel depends on an adequate clinical history, serology and bacterial isolation. Isolation of the organism from blood, semen, aborted fetuses and placentas and vaginal secretions is the definitive diagnosis. A rapid slide agglutination test that produces a presumptive diagnosis if positive is available (Pitman-Moore, Inc.). This test is highly accurate for the negative status since false negatives have

not been observed. Thus all dogs examined for breeding soundness or infertility should routinely be tested for *B. canis* using the rapid slide test. Positive reactions should be tested further since cross-reactivity to other antigens, such as some of the mucoid strains of *Pseudomonas aeruginosa*, *Staphylococcus* spp. and *Moraxella*-like organisms occur. Other tests that are more sensitive include the standard tube agglutination test (TAT) and the 2-mercaptoethanol test (2-MET) TAT. Titers of 1/200 for TAT and 1/100 for 2-MET are considered diagnostic.⁵⁰ Titers of 1/100 or higher usually indicate specificity for *B. canis*, but the definitive test is to isolate the organism from whole blood using either a blood culture tube or EDTA or heparinized blood. Titers of 1/100 or higher usually will yield *B. canis* from blood cultures because these titers are usually the direct response of a constant bacteremia. A more sensitive test offered by a few diagnostic laboratories is the AGID test using a cell-wall antigen of either *B. canis* or *B. ovis*. Another AGID test utilizing a cytoplasmic protein antigen is offered by the Diagnostic Laboratory at the New York State College of Veterinary Medicine.²³⁴ Animals that are positive by rapid plate, both TAT and 2-MET test at 1/100 to 1/200 or higher, and are positive on both AGID tests are considered serological positive and would probably yield *B. canis* on blood culture. Cultures of *B. canis* from enlarged lymph nodes, bone marrow, vaginal discharge, semen or prostatic fluids are also excellent definitive diagnostic tests.²³⁴

Once diagnosed the prognosis for cure is poor and it is difficult, time consuming and costly to eliminate the organism from affected dogs. Gonadectomy with treatment usually will control the spread of this disease to others. Complete elimination of *B. canis* from breeding dogs is difficult and intermittent shedding is possible. Two regimes of treatment have been used most successfully: (1) Tetracycline hydrochloride is given orally (tid) for 3 weeks at 30 mg/lb of body weight. A second course is given following 3 to 4 weeks without treatment. Streptomycin (20 mg/lb, bid) with or without sulfadimethoxine (25 mg/lb, bid) is administered with the second treatment of tetracycline.^{53,139} (2) Minocycline hydrochloride can be given orally (tid) for 14 days at 25 mg/lb body weight. Intramuscular administration of streptomycin (10 mg/lb, bid) is given for the first 7 days simultaneously with minocycline. These dogs must remain isolated from others during and following this treatment until checked negative at 6–8 weeks by both serological and blood culture tests before leaving isolation. Re-checks should be done at 6-month intervals for the next few years.

No vaccine is available to control the disease. The best management is to follow a constant surveillance program

recommended by Carmichael: (1) test all females with a history of recent abortion or infertility; (2) test males with scrotal irritation, epididymitis, orchitis, prostatitis, or poor semen quality; (3) test any new dog prior to introduction into the kennel; (4) test dogs that have been boarded for prolonged periods or used in field trials; (5) test dogs as a portion of all pre-breeding or fertility examinations.^{50,194}

Canine herpesvirus (CHV) is a cause of fatal septicemia in newborn pups, usually in the first week of life, but can be the cause of fatalities up to 1 month of age.^{48,52,88} It also has been reported to cause a granular or papular vulvovaginitis and balanoposthitis in adult dogs, and abortion; stillborns, mummification and infertility in bitches.^{52,113,114,115,123} Canine herpesvirus is widely distributed throughout the world and has been reported in the United States, France, Scotland, England, Japan, Australia, New Zealand and Switzerland.^{88,194,225}

In newborn pups, the virus is transmitted mainly by contact between the susceptible pups and infective oral and/or vaginal secretions of the bitch. The virus may also be spread by kennel owners or contaminated objects from other infected dogs to susceptible pups. The incubation period is between 3 and 8 days following intranasal injection. Healthy vigorous pups are observed to become suddenly dull, cry continuously, stop suckling and die within a few hours. There is no fever, but a marked thrombocytopenia develops. Usually entire litters are involved. The disease is characterized as an acute, often lethal, generalized necrotizing and hemorrhagic infection of all organs. One characteristic lesion is the multifocal areas of kidney hemorrhage and necrosis leaving the kidney with a "speckled" appearance. There may be a fibrinonecrotic pneumonia, multifocal hepatic necrosis, enlarged spleen and hemorrhage in various other organs of the body. The differential diagnosis is made by finding histologic intranuclear Type A inclusion bodies in some of the cells in the periphery of kidney or liver necrotic foci. This disease must be differentiated from canine hepatitis, toxoplasmosis, canine distemper, and bacterial septicemia caused by such microorganisms as *Escherichia coli*, beta-hemolytic streptococci and canine mycoplasmas and ureaplasmas.¹⁴⁵ There is no treatment once puppies are showing clinical signs. Subsequent litters in that kennel should be placed in an incubator at 95° F and 50–60% relative humidity since the infective virus appears to be temperature sensitive. Despite persistent infection of dogs, bitches that had lost their pups because of herpesvirus have not been reported to have additional losses at subsequent whelpings. Pups with maternal antibody are infected by CHV but do not become clinically ill since the infection remains localized, usually in the nasal area. In older susceptible pups or

dogs, the virus usually localizes causing a mild rhinitis or external genital tract infection. These animals usually demonstrate neutralizing antibody and have persistent low antibody levels for at least 2 years.

The genital form of CHV is characterized by multiple lymphoid nodules interspersed with petechia and submucosal hemorrhage in the vagina or on the penis and prepuce. There may be a preputial and vaginal discharge. Concurrently, there may be a conjunctivitis. Virus can be isolated from the nasal cavity, conjunctival sac, pharynx, and genital openings. Clinical signs following experimental infection lasted approximately 3 to 7 days. Both the conjunctivitis and genital disease are self-limiting and regressed in 4 to 5 days.¹²³

A condition called "dog pox" by European workers was thought to be canine herpesvirus and affected mainly the penis of the dog causing vesicular and papular lesions, thus the term "dog pox." Other sites affected were the conjunctiva, lower bowel, rectal-anal region, colon, and the vestibule of the bitch. In the series of animals studied by these workers, spontaneous regression occurred, but in some, lesions persisted for long periods of time.¹⁵² Lymphofollicular hyperplasia was produced in all normal puppies following the inoculation of cellular suspensions from affected dogs. No cytopathic effect was seen in the cell cultures even after 6 passages.¹³⁵ A noncytopathic viral agent or possibly a mycoplasma agent may be involved.

Inapparent infections are common in dogs and periodic shedding of canine herpesvirus in nasal secretions, similar to herpes infection in man and other animals can occur. Viral recrudescence has been demonstrated for as long as 6 months after primary intranasal infection by using immunosuppressant agents such as a corticosteroid.⁵²

Canine herpesvirus has been reported by British workers to be associated with abortion, stillbirths and infertility. Hashimoto and co-workers reported on spontaneous intrauterine infections of pups with CHV and experimentally showed transplacental infection of pregnant dogs by the intravenous route from day 30 through late gestation, resulting in mummified fetuses, dead feti, abortion, premature pups, stillborns and neonatal deaths. Characteristic lesions of CHV were found in the placenta, liver, spleen, kidney and lung of pups with virus isolation and a positive fluorescent antibody test for viral antigen in tissues.^{113,114,115}

Dogs showing active vesicular and papular genital tract lesions should not be bred. Swabbing of these lesions for culture and use of viral transport media to submit the swabs to a reputable diagnostic laboratory can be used to make a diagnosis. The best treatment is sexual rest until lesions have healed, which usually occurs in 7 to

21 days. Once exposed, most dogs will have a persistent low neutralizing antibody titer for at least 2 years. Recrudescence is uncommon unless the animals are severely stressed. Bitches that have had pups with neonatal CHV or abortions associated with CHV should be valuable breeders since this syndrome does not usually recur.

Urogenital disease caused by mycoplasmas and ureaplasmas have been recognized for years in man and cattle. They have been the cause of infertility characterized by poor conception, abortion, post-parturient septicemias, weak and diseased newborn, female and male genital tract infections. Poor semen quality has been associated with these organisms in both human and cattle infertility cases and in both, venereal transmission is recognized.⁷⁸

A survey of the mycoplasma flora of the dog by Rosendal revealed 11 *Mycoplasma* spp: *Mycoplasma canis*, *M. spumans*, *M. maculosum*, *M. opalescens*, *M. edwardii*, *M. cynos*, *M. molare*, *M. feliminutum*, *M. gateae*, *M. arginini*, *M. bovigentialium*, and one unclassified mycoplasma strain (HRC 689); 4 serological groups of ureaplasmas as well as *Acholeplasma laidlawii*.²¹⁸ In this study, mycoplasmas were cultured from the nasopharyngeal cavity of 100% of both healthy and diseased dogs; from the colon and rectum of 13% of healthy and 70% of diseased dogs, and from the lungs of 0–7% of healthy and 90–100% of diseased dogs. Mycoplasmas were rarely isolated from parenchymatous organs of normal dogs, but the incidence increased with systemic disease. Increased numbers of isolates were made from the reproductive tract of dogs with fertility disorders. *Mycoplasma canis* was the most common isolate from the canine genital tract, followed by *M. cynos*. *Mycoplasma cynos* is also a common pathogen of the canine respiratory tract. Several of the above species of mycoplasma have been associated with canine pneumonia, vaginitis, balanoposthitis, infertility, urine tract inflammation, colitis and endocarditis.²¹⁸

In a survey of 108 healthy dogs, mycoplasmas were isolated from the prepuce of 37 males and the vagina of 21 bitches (T = 58). *Mycoplasma canis* was isolated from 8 males and 14 females, *M. cynos* from 5 and 4, *M. bovigentialium* related strains from 11 and 3; respectively. *Mycoplasma edwardii* (2), *M. molare* (1), *M. opalescens* (6), *M. gateae* (12) and an unidentified strain HRC 689 (2) were isolated only from the prepuce of the dog.⁴¹ *Mycoplasma felis* was also reported from the canine genital tract by Doig and coworkers.⁷⁷ Mycoplasmas tend to be species-specific but in the above report, both bovine and feline strains are reported. *M. bovigentialium* has been isolated from several other species, including man.

Experimental chronic orchitis and epididymitis in the

dog and endometritis in the bitch were induced using a strain of *M. canis* isolated from the vagina of a bitch with an abnormal estrous cycle.¹²⁸ Mycoplasmal agents have been isolated and reported from three spontaneous cases of unilateral epididymo-orchitis by the author.¹⁶³ Canadian workers have found an association between canine mycoplasmas/ureaplasmas and infertility in stud dogs and breeding bitches.⁷⁷ They found a significantly higher incidence of ureaplasma in the prepuce of infertile stud dogs than those that were fertile and a higher rate of recovery from bitches that were infertile with purulent vulvar discharge versus those that were clinically normal. In the Canadian study, ureaplasmas were always isolated in association with a concomittant mycoplasma infection in the female. Ureaplasma was isolated in pure culture from the prepuce of one infertile male, whereas all others were in association with mycoplasmas.

Clinical studies carried out by the author confirm the Canadian workers findings. Clinical histories reveal a syndrome of infertility characterized by poor conception, early embryonic death, embryo and/or fetal resorption, abortion, stillborn pups, weak newborns and neonatal death. The Diagnostic Laboratory at the New York State College of Veterinary Medicine has isolated mycoplasmas and/or ureaplasmas from all phases of this syndrome. This syndrome is most frequently recognized in breeding kennels where close intensive living conditions and environment provide an opportunity for large numbers of these organisms to develop and affect the bitch and stud dog. Frequently, the same conditions are seen with bacterial opportunistic infections such as the beta hemolytic *Streptococci* spp., *Hemophilus canis*, *Pseudomonas* spp., *Proteus* spp., *Escherichia coli* and other bacteria found on the mucosa of the genitalia of dogs. Frequently, bacteria and mycoplasma/ureaplasma infections are mixed and concomittant. Historically, mycoplasma and concomittant bacteria cause severe disease or mixed infections in such conditions as chronic respiratory disease (CRD) of chickens and kennel cough in dogs. Intensive labor saving husbandry used for large numbers of closely-housed cattle results in a build up of mycoplasma and ureaplasma in genital and nasopharyngeal populations and can cause infertility in cattle.

Dogs kept for house pets in small less intensive managed kennels are not likely to be affected. In some infected kennels, several bitches will be involved and fertility rates may drop drastically. Normal reproductively sound dogs can also harbor these agents. Affected dogs may show no overt urogenital tract infections or discharges, but embryos, fetuses, or newborn pups may become infected in-utero following breeding, during pregnancy or at the time of whelping from the mycoplasma/ureaplasma/bacterial vaginal flora. In some individual

dogs, mucopurulent vulvar or preputial discharges are associated with vaginitis, endometritis or balanoposthitis, prostatitis and epididymo-orchitis, respectively.

Mycoplasma/ureaplasma/bacterial infertility in the bitch and stud dog should be suspected when a history of infertility is reported and characterized by reduced conception, early embryonic or fetal death, abortions, stillborns, fading pups, neonatal death, and metritis. Individual dogs with mucopurulent urogenital tract discharges and upper tract infections are also suspect.

Diagnosis is made by a history of infertility and isolation of the organism. A deep vaginal swab for culture is taken from the affected bitch with a guarded culture swab or a preputial swab or a sample of semen or prostate fluid is submitted from affected stud dogs. Aborted pups, placentas, post-resorption discharge, stillborn and dead neonates should all be submitted for culture and histopathologic study. Culture swabs should be placed in Amies transport media without charcoal (Amies transport media, Difco Laboratories, Detroit, Mich.) and sent refrigerated, **not** frozen, to a laboratory capable of isolating these agents. Entire pups and placentas should be iced, **not** frozen and also submitted. Since mycoplasma and ureaplasma organisms are very fastidious and require special media and a different atmosphere to grow, laboratories should be consulted prior to submission to find out if they are equipped, trained and capable of isolating and identifying these agents.

Bitches that are in large kennels affected with this syndrome are difficult to treat since there appears to be little immunity developed in the urogenital tract and the nasopharyngeal area against the carrier state of these microorganisms. Therefore, the syndrome continues through repeated breeding periods if adequate numbers of these organisms are present. The best control measures in affected kennels is to change the husbandry and management by isolating the bitches and stud dogs with or without chemotherapy, into smaller less intensive groups. This disperses and dilutes the population and contact so that the microorganism numbers of the carrier state are reduced.

Treatment for mycoplasma and ureaplasma infections or carrier states consist of parenteral treatment of small isolated groups with chloramphenicol or tetracycline, the drugs of choice for these microorganisms. Treatment should be given for 10 to 14 days. These drugs are contraindicated in pregnant bitches. Chloramphenicol is reported to be safe in the latter half of pregnancy.⁷⁴ Erythromycin or ampicillin, although not as effective against these agents, are safe to be used during pregnancy. A mild 1% tamed iodine solution (**Betadine**) vaginal douche may be administered two or three times during the parenteral antibiotic therapy. Bacterial infections should be

treated with the antibiotic showing the best antimicrobial effects. Records of pregnancy rates, litter size, and weaned puppy numbers are then assessed post therapy. Periodic cultures of the deep vaginal cavity of bitches with aborted or stillborn pups should be carried out. Reinfection can take place following treatment. Isolation of these agents from healthy dogs with no clinical signs of infertility does not require treatment since these agents are frequently normal flora and only cause problems when the numbers increase causing infertility problems. Further research to establish pathogenicity of species and strains and the role these agents play in causing infertility is needed.

Fisher in his survey on mortality in neonatal pups and kittens showed that the highest mortality was in the first week of life. He believed that the "fading pup" syndrome is caused by both infectious and non-infectious causes, but that the two causes can occur concurrently. Hypothermia, a non-infectious cause, enhances the growth of canine herpes virus in newborn pups. Initial starvation leads to low-colostral antibody uptake and leaves the neonate unable to deal with facultative pathogens. These organisms can then invade or proliferate in the gut of the neonate elaborating toxins or endotoxins which can lead to cardiopulmonary failure or appear as a non-infectious cause of death.⁹⁶

Miscellaneous Infections of the Genital Tract

Escherichia coli was isolated from the vagina of a 5-1/2-week pregnant Airdale Terrier with genital tract hemorrhage. Two fetuses were aborted on day 41 of gestation. Antibiotic therapy consisting of parenteral ampicillin, resulted in cessation of the hemorrhage until day 61 when again, an abnormal vagina discharge was observed. Caesarian section revealed 3 dead and 2 live pups which died within 2 days. *Escherichia coli* was isolated from the uterine contents.¹⁷⁰

Group B streptococcal septicemia caused neonatal death in 2 litters of Beagle pups in a breeding colony. The B streptococcal organisms were isolated from the vaginal secretion of both bitches following parturition. One bitch also had a postpartum septicemia. All pups appeared healthy at birth, but within 1 day, pups began to die. This appeared to be an ascending vaginal infection, similar to that reported for *E. coli*.¹⁵⁸

Microorganisms can also infect the uterus and puppies as a septicemia. *Campylobacter jejuni* and an unidentified *Campylobacter* sp. were isolated from aborted pups from 2 bitches. One bitch, a 1.5-year-old Wheaton Terrier, aborted pups on the 45th day of gestation following exposure to 2 children with an undiagnosed gastrointes-

tinal illness approximately 2 weeks previously. *Campylobacter jejuni* was isolated from the placenta, stomach contents of the pups and vaginal swabs from the bitch. The bitch showed no gastrointestinal disorder. This syndrome would be similar to that seen with *Campylobacter fetus* var *intestinalis* causing abortion in ewes and cattle. The other cases consisted of a kennel with adult dogs showing repeated episodes of diarrhea and vomiting followed by weak and dead pups at birth. Aborted pups showed histologic pneumonic lesions suggestive of bacterial or viral infections. Later, premature pups from another bitch were sacrificed and a *Campylobacter* sp. was isolated from their tissues.⁴² Another septicemia probably following oral ingestion of a microorganism resulting in abortion of pups was reported from 2 Boxer bitches. *Salmonella panama* was isolated from their aborted pups. During pregnancy both bitches were regularly fed cooked offal from a slaughter house and one of the bitches was fed uncooked tripe.²¹⁰ *Dirofilaria immitis* microfilaria were reported in newborn puppies and amniotic fluid of an infected bitch demonstrating that transplacental transmission of the microfilaria does take place in some bitches.²⁴⁴

Many bacteria have been isolated from the urogenital tract of the dog as reported in a recent literature survey by Jarvinen.¹³⁶ *Escherichia coli* was most frequently isolated from the urogenital tract which included the vagina and urethra of both normal and infected dogs.^{124,136} Other frequently isolated bacteria included *Streptococcal* sp., *Staphylococcus aureus*, *Proteus* sp., *Pseudomonas* sp., *Enterobacter* sp. and *Pasturella* sp.^{136,171,202} *Micrococcus* sp., *Corynebacterium* sp., *Bacillus* sp., *Staphylococcus epidermidis* and other unclassified bacteria were reported found in the vagina, urethra and infected urine. *Neisseria* sp., *Moraxella* sp., *Flavobacter* sp., *Hemophilus* sp., and *Clostridium* sp., as well as other anaerobic bacteria were reported found only in the vagina. *Klebsiella* sp., *Bordetella* sp., *Mimia* sp., *Alcaligenes* sp., and yeasts were found only in infected urine. *Nocardia* sp. was only isolated from the infected uterus.¹³⁶ Uterine culture results suggest that bitches do not normally harbor aerobic bacteria in the uterus.¹⁹⁹ Exudates from bitches with vaginitis contain the same bacteria as the normal vagina, but in greater numbers.¹²⁴ Vaginal swabs from 297 bitches with genital disorders yielded mixed cultures with *Streptococcus* sp., *E. coli*, *Staphylococcus* sp. and *Proteus* sp. the most frequent isolates.¹⁹⁸ Coagulase-positive *Staphylococcus* sp. were isolated more frequently from prepuberal bitches than from postpuberal bitches.¹⁹⁹

Another study revealed that aerobic and anaerobic mi-

croflora were identified and quantitated in 82 vaginal and 78 uterine samples obtained from mature bitches at different stages of the estrous cycle.¹³ The common organism isolated from vaginas were **Bacteroidaceae**, **Streptococci**, **Pasteurella** spp and **mycoplasmas**, **Staphylococci** and **mycoplasmas** were frequently isolated from uterine contents even though no histopathologic lesions were present in most uteri.

Anaerobic organisms were always recovered in mixed cultures, most frequently with **Proteus** sp.²⁰² In a study of 22 breeding kennels, 9 normal, 13 affected with "fading puppy" complex, **Cl. perfringens** was more frequently isolated from affected bitches (18/22) than from normal bitches (10/53).²⁸ This study indicated that **Cl. perfringens** can appear in the feces of apparently normal puppies 24 to 28 hours after birth and that possibly factors such as incorrect milk supplementation, hypothermia and prophylactic antibiotic therapy will affect the natural balance of intestinal flora and permit the microorganisms to gain pathogenic significance as it has been demonstrated in other neonates, such as lambs, calves and piglets.²⁸

Vaginitis should be suspected when abnormal vulvar discharges are present. Vaginitis can occur as a single entity or be part of an upper tract infection involving the cervix and uterus or the urinary tract. A thorough history and physical examination, utilizing a vaginoscope, vaginal cytology and culture, abdominal palpation and a complete blood count will help differentiate the extent of the disorder. Vaginitis can be secondary to foreign bodies and vaginal tumors. Vaginitis should not be confused with normal vulvar discharges of proestrus-estrous hemorrhage, normal lochia of the postpartum period or subinvolution of placental sites. History and vaginal cytology are important in differentiating these conditions. Non-infectious problems, such as vaginal tumors, clitoral hypertrophy and vulvar or vaginal congenital or acquired anatomical abnormalities must be considered in differentiating the cause. Occasionally vaginitis in the spayed bitch may be secondary to a fistula from an infected uterine stump or a stump abscess or granuloma. Vaginoscopic examination, abdominal palpations and radiography may be needed to confirm the etiology. The author has seen one case of tetanus following a routine ovariohysterectomy performed with surgical instruments used for both large and small animal surgery that were routinely cold sterilized in disinfectants. **Clostridium tetani** organisms were present in the uterine and ovarian stumps at necropsy.

A vaginal swab must be obtained for culture from the anterior vagina using a sterile guarded swab or a sterile otoscope head and a smaller sterile unguarded swab as

described in the section under mycoplasma/ureaplasma/bacterial infertility. The anterior vagina of larger dogs can also be cultured by placing a glide (**Playtex Gentle Glide**, Playtex, Inc., Dover, Delaware) in the posterior vagina and then pass a guarded culture instrument through the glide into the cranial vagina as described by Olson.^{198,199,201} Transport media for aerobic, anaerobic, mycoplasma/ureaplasma and viral microorganisms are commercially available from several scientific companies.

The entire vagina should be evaluated for inflammation or other abnormalities such as tumors, foreign bodies, anatomical problems, by a sterile fiberoptic vaginoscope or modified infant human proctoscope or otoscope in the case of the small dog or cat. Smears for cytology should be examined for the type and extent of inflammation and presence of microorganisms. Large numbers of toxic and degenerate polymorphonuclear leukocytes containing phagocytized bacteria are usually present in dogs with vaginitis. Non-toxic polymorphonuclear leukocytes are present in normal dogs in the early metestrus/diestrus period. Bacterial culture results should be interpreted as to their significance taking into account the number of organisms isolated, ranging from none or scant to moderate and many, pure or mixed culture, vaginal cytology and history of vulvar discharge and infertility, and the vaginoscopic exam findings indicating an active inflammation or no evidence of inflammation. Antibiotic sensitivities on isolated microorganism should be obtained and followed for the most successful therapy. Parenteral antibiotic therapy is discussed under the section on mycoplasma/ureaplasma/bacterial infertility. Parenteral therapy is most desirable because of its effect on other potentially affected sites, such as the nasopharyngeal and urinary tract. Antibiotics may be infused directly into the vagina or applied as vaginal suppositories with or without systemic antibiotic therapy. Mild antiseptic douches, such as a tepid 1% tamed iodine (**Betadine**) solution are useful in chronic vaginitis and are delivered as a high volume douche by passing a disposable plastic treatment pipette into the anterior vagina and lavaging the entire vaginal canal. In smaller dogs or cats a disposable bovine teat cannula or a tom cat or dog urethral catheter can be passed and by syringe the vagina can be lavaged. The author utilizes this lavage treatment regimen along with systemic antibiotics usually 2 or 3 times during a 10 to 14 day systemic treatment. Judicious use of estrogens such as oral 0.5 to 1.0 mg diethylstilbestrol tablets for 5 days or 0.25 mg of ECP administered intramuscular may be helpful in spayed bitches or prepuberal bitches with vaginitis.

Puppies can have vaginitis prior to puberty. Juvenile

vaginitis is not normal, and is usually difficult to cure, but usually subsides without treatment following the first estrus.^{198,199} Vulvar-vaginal anatomical abnormalities should be ruled out. If therapy is necessary, cultures prior to therapy should be studied, antibiotic sensitivities performed on significant isolated microorganism and these results used for the most effective treatment required.

Vulvitis may occur with or without vaginitis. The vulva is usually hyperemic and edematous. The bitch may be quite uneasy and lick the vulva after frequent urination. Difficult and frequent urination may be present. Vulvar-fold or perivulvar pyodermatitis is a common disease of obese dogs with immature, juvenile or inverted small atrophic vulvas. Many of these dogs have been spayed. Urine scald and urinary incontinence aggravates the problem. Some dogs may become febrile and septic when this condition becomes an acute deep ulcerative pyodermatitis. Culture of the vulva or perivulvar tissue may be obtained for specific microorganisms and tests for antibiotic sensitivity test result in the most successful therapy. Systemic antibiotics and anti-inflammatory drugs are frequently used when this condition becomes systemic. Otherwise, frequent cleaning and topical antibiotic, anti-inflammatory or chemotherapeutic ointment or powders are applied daily. Judicious estrogen therapy as described for vaginitis treatment may be used. The most successful method has been episiotomy, the surgical removal of excess perivulvar skin folds and the repair of the perineum with improved caudal positioning of the vulva.^{80,157}

Clitoritis and granular or lymphoid nodular hyperplasia of the vulva and/or clitoral fossa may cause a mucopurulent vulvar discharge, licking of the vulva and attraction of males. It may be seen in prepuberal, intact cycling or spayed bitches. This condition can be caused by any irritant, microorganisms, anatomical abnormalities, clitoral hyperplasia, especially noted following the use of androgen therapy, and in pseudo- or true hermaphrodites (see section on congenital defects). Treatment with mild antibiotic and/or anti-inflammatory ointments or mild cauterizing ointments and liquids are beneficial. Anatomical problems should be corrected surgically. Clitorectomy may be necessary with clitoral hyperplasia, especially with the presence of an os penis. Persistent or recurring vulvar or clitoral lymphoid nodular hyperplasia is best treated by sedating the bitch and scraping the granular or lymphoid nodules with a scalpel blade or sterile gauze pad until they hemorrhage or are removed. Following the control of hemorrhage, post-operative therapy consisting of 2 or 3 times a day application of an antibiotic and anti-inflammatory ointment (**Panalog**—Upjohn Company, Kalamazoo, Michigan) is

helpful. This will usually result in a temporary, if not a complete cure. If this condition recurs, repeated treatment and further examination to find the cause, especially if an anatomical abnormality is present, may be necessary. This condition can be very difficult to completely cure in some bitches.

Inflammation of the ovary and oviduct in the dog is rare. Abscess of a corpus luteum or pyosalpinx may occur secondary to a pyometra.^{24,25}

Cystic Hyperplasia, Endometritis, Metritis and Pyometra

Cystic hyperplasia, endometritis, metritis and pyometra, in the dog and cat are common and may be seen in intact bitches and queens of all ages, but is most frequently seen in animals over 3 years of age. **Pyometritis** in the bitch and queen can occur spontaneously, secondary to a systemic bacterial disease process, a postpartum metritis or following iatrogenic administration of long-acting progestational compounds to delay or suppress estrus, or following the administration of estrogens to mismated bitches or to treat juvenile or senile vaginitis, as a post-copulation or post-insemination infection, and as the final sequela of cystic endometrial hyperplasia-pyometria complex.^{7,165,233} This complex most commonly occurs in bitches starting at 3 to 4 years of age. The incidence increases with age and several non-pregnant cycles. This complex also affects intact queens and increases in incidence with age following repeated non-productive matings, pseudocopulation and spontaneous ovulation.

Canine pyometra is an acute or chronic polysystemic, metestrous disease of the mature dog.¹⁰⁶ In the bitch and queen, progesterone plays the major role in producing endometrial hyperplasia as this condition can be produced most promptly by the alternate administration of estrogen and progesterone. Exogenous estrogen alone can produce marked hyperplasia and endometritis followed by pyometritis in the bitch. Cystic endometrial hyperplasia may lead to mucometra or hydrometra and atrophy of the myometrium. An unusual case of uterine enlargement in a 12-year-old female Poodle with progressive abdominal enlargement and dyspnea was reported.⁹⁸ The cause of the uterine enlargement was cystic endometrial hyperplasia and adenomyosis. Another report of a 10-year-old female miniature Poodle with a pendulous abdomen for several months was diagnosed as hydrometra following surgical removal.¹⁴¹

Dow reported 4 subdivisions or gradations of the cystic hyperplasia-pyometra complex in the dog.^{81,82,83} **Type**

I was characterized by uncomplicated cystic hyperplasia of the endometrium with a mucoid discharge during metestrus. Twenty-three of the 100 bitches in the study were in this group. **Type II** was characterized by diffuse plasma cell infiltration of the endometrium superimposed on cystic hyperplasia. There were 17 of the 100 bitches in this group and in 14 animals *E. coli* was cultured from the uterus. A mucous discharge from the vagina persisted for several weeks in the metestrus/diestrus period and a mild leucocytosis was present with 12,000 to 15,000 W.B.C. per cmm. **Type III** was characterized by an acute endometritis, metritis or pyometra superimposed on cystic endometrial hyperplasia. The distention of the uterus was dependent on the patency of the cervix. Forty-nine of the 100 bitches were of this type. *E. coli* was cultured from 40 bitches, staphylococci from 6 and streptococci from 5 bitches. Most of these cases were presented 5 to 80 days with an average of 30 days after estrus. Illness of 4 to 10 days duration had been present with 32 dogs experiencing increased thirst, and 21 had vomited. Thirty-eight of the 49 bitches had a vulvar discharge; 40 had a distended abdomen and 8 had an elevated temperature. A leucocytosis with white cell counts of 19,000 to 145,000 per cmm, mainly neutrophils, was present. Counts over 50,000 per cmm were indicative of pyometra. **Type IV** was characterized by a chronic endometritis, often with squamous metaplasia of the endometrium. The chronic endometritis was either mild or severe with corresponding degrees of leucocytosis, abdominal distention and illness. These dogs were usually 10 to 13 years of age. There were 11 cases in this group.

It was significant that corpora lutea were present in the ovaries of 96 of the 100 bitches in the study. Ovarian cysts were present in 19 and granulosa cell tumors in 8. Most of the bitches had shown irregular estrous cycles. A history of previous attacks of postestrous endometritis, especially in **Type IV** cases, was common. Nearly all were nulliparous or had had litters 3 to 11 years previously. A few had histories of phantom or false pregnancies.

Dow also reported rather similar groups of cases in cats affected with the cystic hyperplasia-pyometra complex.⁸⁷ **Group I** consisted of 16 of the 100 unselected intact nulliparous female cats that had cystic glandular endometrial hyperplasia without any superimposed inflammatory changes. Most of these cats were over 3 years of age. Four of these cats exhibited hemorrhage from the vulva from which one cat died, and the others had a chronic discharge of blood and were severely anemic. This bleeding was due to torsion of endometrial polyps that ranged from 1 to 6 cm in length and were attached by narrow pedicles. **Group II** consisted of 39 cats, 3 to

11 years of age. Most were nulliparous and nearly half had been in estrus within 2 months. These queens had an acute endometritis and pyometra with an illness that had been present for 3 to 14 or more days. The inflammatory reaction was superimposed on a cystic hyperplasia of the endometrium. All cats in this group were dull, depressed and anorexic. Vomiting was a fairly common sign. The vulvar discharge was green, brownish or blood-stained in two-thirds of the cats; abdominal distension also was present in about 60 percent of the affected cats in this group. Total blood leucocyte counts ranged from 23,000 to 74,000 cells per cmm. Thirty-four of these 39 cats were treated successfully by ovariohysterectomy. Many uteri contained variable amounts, up to 2 liters, of pus; the pus was yellow-green in color unless bleeding had occurred into the uterus. Thirty-two of 37 cases were positive on culture for *E. coli* and six yielded streptococci. Corpora lutea were present in 33 of the 39 queens; a few follicles or follicular cysts were present in the remainder.

Group III consisted of 10 of the 100 cases. These cats had a subacute inflammatory reaction superimposed on cystic endometrial hyperplasia. Cats in this group were 4 to 11-years-old, and 7 were nulliparous. Illness was marked but of a longer duration, of 2 months or more, than Group II. Total white cell counts ranged from 21,000 to 32,000 per cmm. A chronic vulvar discharge was present. Most of these cats were thin. The uterine horns were slightly enlarged containing about 10 to 15 ml of greenish-grey mucopurulent exudate. *E. coli* was recovered from all uteri. Luteal tissue was present in 9 of the 10 cases. **Group IV** contained 22 queens with chronic endometritis and cystic endometrial hyperplasia. Their ages ranged from 5 to 14 years, and 14 of them were nulliparous. Fourteen of these cases had shown an intermittent vulvar discharge for 3 to 10 months; all 14 recovered after ovariohysterectomy. The remaining 8 cats were ill, some near collapse, with the history of a chronic low-grade endometritis with a discharge and an acute illness occurring within the last 7 to 10 days. In all of these 8 cases the abdomen had recently become greatly enlarged and anorexia was present; 4 of these cats had severe attacks of emesis. W.B.C. counts ranged from 24,000 to 64,000 per cmm. In these cases the cervix was patent and the uterus was only moderately enlarged. *E. coli* was isolated from 18 and hemolytic streptococci from 6 of these queens. Corpora lutea were present in 18 cats; 2 cases had normal follicles and 2 cases had follicular cysts. There was a degree of cervical fibrosis in all cases. In the distended uteri; all layers of the uterine wall were atrophied. Atrophy and squamous metaplasia of the endometrium were present in most cases.

In these 4 groups of cats over 75 percent were over 6 years of age. No cats under 3 years of age had cystic endometrial hyperplasia. The similarities between this complex in the bitch and queen are striking. There is also a similarity between these older affected bitches and queens and the "infection prone" older and often nulliparous mare. Over 77 percent of affected cats were nulliparous and had corpora lutea in their ovaries. Dow speculated on this high incidence of corpora lutea present in older nulliparous cats, a species that is considered to ovulate only after the stimulus of coitus. He indicated that possibly petting and stroking of the cat by the owner might be sufficient to induce ovulation. This disease in cats seldom appeared during the anestrus season of October through January. In the cat, as in the bitch, pyometra often becomes clinically evident in the metestrus/diestrus or pseudopregnant period. In breeding queens, early signs of cystic endometrial hyperplasia and a low grade endometritis were characterized by a succession of normal pregnancies, followed in order by stillbirths, a decreased number of fetuses in a litter, abortion at 42 to 52 days, and finally endometritis and sterility.

Dow showed experimentally that cystic hyperplasia-pyometra complex in the cat and dog were basically similar.^{84,87} In the latter species the cystic endometrial hyperplasia could be produced by cyclic treatment with estrogens and progesterone. The inflammatory reaction of endometritis and pyometra is progesterone-dependent. Progesterone greatly increases the susceptibility of the uterus to infection, maintains the functional closure of the cervix and causes a relaxation of the myometrium.^{175,176,177}

Further evidence of the hormonal basis for this syndrome is the numerous reports in the mid-sixties describing cystic glandular hyperplasia, mucometra, and pyometra in bitches injected with progestational compounds, such as medroxyprogesterone acetate (**Promone**—Upjohn) given intramuscularly or subcutaneously to prevent estrus. These long-lasting injections would effectively suppress estrus and ovulation for 6 to 24 months or more. Not all bitches or queens would develop endometritis and pyometra but a sufficiently large enough number, over 10 percent, were affected that these products were withdrawn from the market and presently are contraindicated, especially for a female that is expected to be bred at a later date.³⁶

In dogs severely affected with acute pyometritis, a high white blood cell count, septicemia, and a febrile reaction are common. The total white blood cell (WBC) count ranges from 20,000 to 100,000 +/cu mm. Higher counts are associated with the acute syndrome and a closed cervix or closed pyometra versus an open draining pyome-

tra with a vulvar discharge and a lower WBC count. Chronic cases or prolonged cases with toxemia result in bone marrow depression and anemia. The WBC may be lower than normal with frequently a shift to the left or increased band cells. Laboratory findings may include varying degrees of one or more of the following: regenerative neutrophilia, degenerative neutropenia, anemia, azotemia, hyposthenuria, hyperproteinemia, hypercholesterolemia, hypoalbuminemia, hyperbilirubinemia, and elevated BUN, alkaline phosphatase, LDH and PCV (dehydration).^{31,32,33,34,105,106,107,108} Polydipsia, and polyuria are frequent signs of pyometritis. Ascheim has shown that a membranous glomerulonephritis may be present and that the lesion by electron microscopic study is a membranoproliferative glomerulonephritis caused by immune-complexes.¹² Impaired renal tubule capacity to concentrate urine in dogs with pyometra is also common. This inability to concentrate urine is caused by endotoxemia.^{31,107} *Escherichia coli* and probably other bacteria probably play an important role as the cause of the antigen for the immune-complex disease and production of endotoxin in this kidney syndrome. Both of these kidney disorders are reversible following hysterectomy or successful medical treatment of pyometra. *Escherichia coli* strains isolated from urine specimens as well as from the infected uterus were identical.²²³ This study concluded that subclinical urinary tract infection is associated with pyometra and that the uterus will be infected at early metestrus, when receptors for *E. coli* are developed in the progesterone-primed endometrium and myometrium, thus enhancing the colonization of bacteria in the uterus.²²³ Adhesion studies have confirmed that urogenital isolates of *E. coli* have a specific trophism and receptors for binding to this tissue.¹³⁶

Pyometra is also associated with liver malfunction, usually as intrahepatic cholestasis sometimes followed by hepatocyte degeneration.²⁴ Endotoxin from *E. coli* may result in adrenal cortical necrosis and medullary hemorrhage and endotoxic-type lung damage in the terminal case.³⁴ Pyometra is unique in the magnitude of endotoxin effects with the uterus, kidneys, bone marrow, liver and probably other organs being affected and suffering disturbed function until the infected uterus is removed or successfully treated.³¹

The cytology of vaginal smears may be diagnostic in cases of pyometra with either an open or closed cervix. Most dogs in early metestrus/diestrus will have non-toxic normal polymorphonuclear leukocytes (neutrophils). By the 10th to 20th day postestrus, most neutrophils have disappeared and only small, non-cornified or larger epithelial cells containing a large round nucleus with some having highly vacuolated cytoplasm are present. Vaginal

cytology from dogs with pyometra is characterized by excessively large numbers or masses of toxic, degenerate neutrophils undergoing necrocytosis. The more toxic the environment, the more rapid the death of these cells characterized by karyolysis, karyorrhexis and pyknosis.^{18,106,201}

The presence of pyometra can be detected in most dogs with little difficulty, especially an open draining pyometra. Closed pyometra may be more difficult to diagnose. A pregnant bitch without a history of recent breeding may pose a problem since the enlarged gravid uterus is radiographically indistinguishable from a pyometra until skeletal structures of the fetuses are seen after about 43 to 45 days of pregnancy. Many pregnant bitches may be anorectic similar to those with an early pyometra. Ultrasonography is a preferred procedure to detect viable fetuses from approximately day 22 to 26 of pregnancy to term. Both closed pyometra and pregnancy develop following estrus. Prior to surgical removal, the uterus should always be carefully palpated to confirm the diagnosis of pyometra or pregnancy. A total white blood cell count is helpful. Pregnant bitches will also have a pregnancy anemia, but this is a hemodilution effect and not a true anemia. A moderate leucocytosis may be seen in later pregnancy as a result usually of increased eosinophils probably elicited by fetal-placental antigens and/or parasite larval antigens. Closed pyometra will usually have a severe leucocytosis with a shift to the left or a toxic leucopenia, but still with a shift to the left.¹⁶⁵

The clinical signs associated with pyometra and renal failure may be similar. Diseases associated with polyuria and polydipsia including diabetes mellitus, hyperadrenocorticism, and generalized hepatic diseases may simulate pyometra. All of these conditions may cause a pendulous abdomen and similar clinical signs and indeed may occur concomitantly with pyometra. Diagnosis can usually be made from clinical signs, laboratory tests, radiographs or ultrasonographs and microscopic examinations of vaginal smears. Urinalysis, hemograms and serum concentration of creatinine or BUN should be evaluated in the suspicious cases. Other appropriate diagnostic tests may be needed in the clinical and laboratory evaluation of the patient.^{106,165} Unusual cases of pyometra have been reported. Pyometra has been diagnosed in a male hermaphrodite with retained testes containing a Sertoli cell tumor and a uterus with pyometra.¹⁹¹

The early syndrome of cystic endometrial hyperplasia with or without superimposed endometritis may be associated with a blood-tinged discharge. Frequently there are no clinical signs. Infertility, small litter size, early embryonic death, abortions, and irregular estrous pe-

riods may be other indications of cystic endometrial hyperplasia. The lifetime reproductive history of this individual is important. The use of soluble radiopaque fluid to perform a hysterosalpingography and outline the cystic formations or the use of ultrasonography to possibly view the fluid-filled cysts are highly desirable. Hysterosalpingography should only be done on the non-infected uterus during estrus or anestrus when the cervix is open. If the uterus is infected, retrograde infection of the oviduct, ovaries and peritoneal cavity can take place. Palpation of an endometrial cyst 1 cm or more in diameter may be possible in some dogs and cats. Laparotomy or use of a laparoscope and biopsy of the uterus are also useful. Endometritis, and certainly metritis will be characterized by a vulvar discharge plus the signs mentioned earlier for cystic endometrial hyperplasia.

Cystic hyperplasia of the endometrium may involve all or part of both uterine horns or all or part of one horn.²⁵² Adenomyosis, or the presence of endometrial glands in the uterine muscle is common in some bitches. On the serosal surface these may have a gross appearance of a leiomyoma or fibroid until cut across and the "swiss cheese" appearance of the cystic glands in the muscle are noted. Pyometra following parturition or abortion in the bitch is seldom observed unless a dystocia handled with poor hygiene or a dead fetus and/or retained placenta causes a severe metritis which usually results in a very thin-walled friable and sometimes emphysematous uterus filled with a thin fetid serosanguinous exudate. Uterine rupture and parametritis are common sequelae because of the thin wall and acute nature of this condition. If a bitch is regularly pregnant, pyometra does not occur. Canine pyometra is usually seen with corpora lutea present in the ovaries and/or occasionally cystic follicles or lutea cyst. Several early workers felt that prolonged and/or high progesterone levels from retained corpora lutea or luteal cysts were the cause of pyometra. In a study by Chaffaux and Thiber, they found no evidence of an essential high or prolonged progesterone secretion in bitches with pyometra. Luteolysis occurred normally about 60 days postovulation and was not postponed by pyometritis. In some animals early luteolysis occurred.⁵⁷

Other uterine lesions noted in cystic hyperplasia and secondary endometritis are: edema, hemorrhage, diffuse leukocytic infiltration of the endometrium, fibrosis of the uterine wall, and occasionally ulceration, abscessation, necrosis, and thrombosis. The cystic endometritis tends to be latent or quiescent at all stages of the cycle except metestrus, at which stage most cases exacerbate under the influence of progesterone with clinical signs of varying degrees of severity. In pyometra there is a cystic

hyperplasia of the endometrial glands and severe leukocytic infiltration of the endometrium. The cystic glands may or may not be filled with exudate. Certain portions or most of one horn may be more severely affected than other portions of the same horn or the opposite horn. Necrosis of the endometrium may be present in advanced cases. The myometrium may show some evidence of fibrosis and invasion by endometrial glands or adenomyosis. If pyometra and stenosis or functional closure of the cervix results in distension of the uterus, all layers of the uterine wall are markedly stretched and atrophied.

Symptoms of the cystic endometrial hyperplasia-endometritis-pyometra syndrome in the dog and cat are as follows:

In cystic endometrial hyperplasia seen in intact animals over 3 years of age no clinical signs of illness are present, as no infection is present in the uterus. The vulva may be hypertrophied and swollen the first half or throughout the metestrous period. There may be an excessive discharge of mucus from the vulva that contains no bacteria, red blood cells and few or no leucocytes. Atresia or functional closure of the cervix may produce mucometra or hydrometra with one or usually both horns distended by a clear, watery or yellowish-grey, non-odorous fluid with a secondary distension of the abdomen in a few cases.

In cystic hyperplasia associated with endometritis and metritis, clinical signs and illness usually appear in the metestrous period, 10 to 90 days after estrus. Breeding may or may not have occurred. Some veterinarians report that affected bitches often have a history of breeding failures, irregular estrous cycles, pseudopregnancy, and are nulliparous. A study of affected bitches and 248 intact control bitches of the same age, average 7.7 years, found there was no correlation between estrous cycle irregularities, abnormal estrus, pregnancies, and cystic endometritis and pyometra.⁹⁵ Pseudopregnancy characterized by lactation, and abnormal signs exhibited by the bitch about 60 days postestrus was observed less frequently in dogs that developed an infected diseased uterus than in the control dogs. The injection of progestagens causing a prolonged progesterone-like effect on the genital tract and an artificial anestrus may cause this syndrome in young, one to two-year-old bitches.³⁶

Dogs and cats with secondary endometritis and metritis may or may show signs of illness with an elevated temperature and heart rate, anorexia, dullness, debility, and a rough, dull haircoat. The blood leucocyte levels are often somewhat elevated to 20,000 to 30,000 per cmm. Most of these animals will have a fetid mucopurulent discharge from the vulva that will persist for several weeks or more and must be differentiated from a discharge caused

by a vaginitis or cystitis. After a number of weeks, the signs spontaneously regress only to reappear following the next estrous period often in a more severe form. Chronic endometritis may be associated with stillbirths, abortion, embryonic deaths, small litters and infertility in dogs and especially cats.

In pyometra there is usually a nearly complete closure of the cervix preventing the escape of the mucopurulent, odorous exudate from the uterus with a distension of the uterine horns and definite to marked signs of illness, usually occurring during the metestrous period. The general condition and hair coat may be good or poor, depending upon the acuteness of the onset of the condition. Pyometra may develop rapidly within a week or may take several months. The body temperature in acute cases may be elevated, in chronic cases normal, or in severe toxic cases it may be subnormal. Anorexia, thirst, polyuria, dehydration and occasionally vomiting may occur. Polydipsia and polyuria are common. In toxic cases, nephritis with an elevated BUN will be noted. The white blood cell count in pyometra is usually elevated to over 50,000 cells per cmm and most of the leucocytes are neutrophils. The discharge from the vagina may be absent, scanty, or occasionally profuse. The discharge varies in color from yellowish-gray to reddish-brown and usually has a characteristic fetid odor. The degree of toxicity or dullness will depend upon the severity of the condition. Usually those cases with a closed cervix are more toxic than those in which a discharge is present. The pulse is usually elevated and rapid. The mucus membranes may be pale and in some chronic cases, anemia is present. The abdomen in some cases may be distended and pear-shaped. Palpation of the abdomen may reveal the distended uterus.

The course of pyometra is variable. Some cases become acute and severe within a week or two and require immediate and early attention to save the patient's life. In other cases, especially those with an open cervix from which pus is draining, the disease may run a course of a month or more. Frost reported on a strangulated inguinal pyometrocele in a bitch.⁹⁷ Bloom has reported on 2 cases of pyometra with unicornual uterine torsion.²⁵ He reported that in the cat a purulent peritonitis may occur secondary to pyometra, while in the dog a perimetritis, a parametritis or a peritonitis may occasionally develop. Remissions in the condition may be frequent in middle or late metestrus or early anestrus. Remissions would not occur in animals in which the cervix was obstructed by a tumor. A possible genetic relationship of obesity, diabetes mellitus and pyometra in certain breeds of dogs such as the Rottweiler and St. Bernard has been reported.¹⁵⁹

Treatment for pyometra, metritis, endometritis and

cystic endometrial hyperplasia in the non-breeding bitch and queen is ovariohysterectomy with supportive therapy consisting of systemic antibiotics, fluids and blood if necessary. Prior deep vaginal cultures with antibiotic sensitivity of the isolated microorganisms is important if post-surgical septicemia and peritonitis are present. *Escherichia coli* is most frequently isolated. In one study, 68 to 74% of the clinical cases were *Escherichia coli*.^{106,107} Other isolates include staphylococci, streptococci, *Proteus* spp., *Klebsiella* spp., *Salmonella* spp., *Pseudomonas* spp., *Pasteurella* spp., *Nocardia* spp. and *Mycoplasma* spp.^{106,107,136,165}

Animals with severe toxicity may be treated more conservatively with antibiotics, fluids, blood and prostaglandin therapy to promote drainage. With tranquilization and local anesthesia, the uterus can be marsupialized by suturing the uterus to the ventral abdominal wall and creating a fistula for drainage and local topical treatment until the bitch's condition improves and an ovariohysterectomy can safely be performed. Monitoring kidney function and other postoperative complications including peritonitis are important. Parenteral antibiotic therapy for 10 to 21 days may be necessary. Post-surgical uterine and ovarian stump granulomas and adhesions with sinus formations are the most commonly encountered lesions. Uterine and ovarian stump granulomas can usually be avoided by not using multifilament non-absorbable suture material including nylon, silk and linen for ligatures. Ligatures of 2-0 chromic gut showed no ovarian or uterine stump granulomas in 377 cases.²³⁸ Suture granulomas may result in abscessation, urinary dysfunction, partial bowel occlusion due to adhesions or fistulous tracts that may discharge into the vagina, paralumbar area, inguinal region, flank or medial aspects of the thigh.

Several investigators have reported on the clinical treatment of pyometra, metritis and endometritis with prostaglandin F₂ alpha.^{44,140,142,165,190,236,253} Prostaglandin F₂ alpha is very effective in causing luteolysis in late metestrus/diestrus or about 30 days post estrus, cervical dilatation and myometrial contraction. (see section on prostaglandins in Physiology of canine and feline Reproduction) It is highly effective in causing uterine evacuation in open pyometra, metritis or endometritis even when no corpora lutea are present. This condition is frequently seen in mismated bitches treated with estradiol. In the authors' experience, these bitches will frequently not have functional corpora lutea and only baseline levels of blood progesterone present (1 ng/ml). Usually within 24 to 96 hours after treatment with prostaglandin a great reduction in uterine size and an increase in myometrial tone can be palpated and vaginal discharge is abundant. The uterus will become quite rigid and de-

velop an irregular almost twisted or "ropey" feeling.¹⁶⁵

The subcutaneous median lethal dosage for PGF₂ alpha in the bitch is 5.13 mg/kg.²³⁷ Clinical signs of reaction and toxicosis include excessive salivation, emesis, diarrhea, hypernea, ataxia, urination, anxiety, and pupillary dilatation followed by constriction. Severity of side effects depends on the individual and are dose dependent. At low dosages, defecation is more frequent, while at intermediate dosages, hypernea, anxiety, hypersalivation, vomiting and defecation have been observed. Higher doses have caused ataxia and slight depression. The reported dose range has been from 0.02 to 1.0 mg/kg or 20 ug to 1000 ug/kg in the dog and 0.22 to 1.0 mg/kg or 220 to 1000 ug/kg in the queen administered intramuscularly or subcutaneously. Side reactions are seen in 20 to 120 minutes post-injection. Bitches appear to adapt with side effects diminishing by the fourth or fifth treatment. Cats appear to tolerate higher doses. Prostaglandins have not been approved for use in small animal medicine and should be considered as an experimental treatment by clinicians and owners of pets should be so informed.

The bitch has been reported to be treated for pyometra, metritis and endometritis with dosages of PGF₂alpha from 25 to 1000 ug/kg of body weight. Success has been obtained with single doses of 250 to 1000 ug/kg or with multiple injections of 25 to 250 ug/kg every 12 to 24 hours to effect. Daily single injections of 250 ug/kg have also been effective. Most of these dosage regimens were administered to effect (usually 3 to 5 days). Burke recommended a final dose be given 3 to 5 days after the initial treatment regimen to insure that the uterus is not refilling with exudate.⁴⁴ The author prefers to use a series of injections every 12 hours to effect. The dosage ranges from 25 to 250 ug/kg. The lower dosage is used first to evaluate the effect of the drug on each individual dog and to open the cervix and initiate mild myometrial contractions. The queen can be treated with the same dosage and regimen. Two queens with *E. coli* pyometritis were successfully treated with 200 ug/kg/day for 2 days and 500 ug/kg/day for 5 days along with oral administration of trimethoprim-sulfadiazine, 30 mg/kg bid for 30 and 21 days, respectively. Both cats were successfully bred and queened healthy litters.¹⁴⁰

Bitches and queens with pyometritis, metritis or endometritis were treated to effect with PGF₂alpha by the author.¹⁶⁵ Within 2 to 5 days, vaginal discharge was scant or absent and the uterus was reduced to a very firm small size. Parenteral antibiotics must be administered during PGF₂alpha treatment and continued for at least 10 to 30 days depending on the severity of the condition. If possible, antibiotic therapy should be initiated 24 hours prior to PGF₂alpha administration. Deep vaginal swabs for

bacterial, mycoplasma and ureaplasma culture and sensitivity should be taken to determine the most beneficial antibiotic therapy. Chloramphenicol is the drug of choice because it has a broad spectrum effect on several microorganisms and is highly effective against most strains of *E. coli*, mycoplasma and ureaplasma. Daily vaginal douches with 200 to 500 ml of a tepid 1% tamed iodine solution (**Betadine**, Purdue Frederick Co, Norwalk, CT) are beneficial in promoting vaginal drainage, cervical dilatation and uterine evacuation while systemic treatment of PGF₂alpha and a vulvar discharge is present. Daily abdominal palpation for size and consistency of the uterus, radiographs and the quantity of vulvar discharge should be used to determine the PGF₂alpha dosage regimen. This regimen has proven to be successful in both bitches and queens.

Several other medical treatments for pyometritis, metritis and endometritis in bitches and queens have been tried. These include the use of estrogens to open the closed cervix, oxytocin or ergonovine to cause uterine contractions and evacuation, indwelling uterine catheters to treat the infected uterus with various chemotherapeutic, antibiotic or disinfectant solutions on a daily basis, but none have been as effective as the combination of prostaglandins and antibiotic therapy.

The prognosis for medical treatment of this condition should always be guarded. The success rate decreases with age, degree of cystic degeneration, the development of microabscesses, adenomyosis, sacculated blind segments of the uterus, and endometrial polyps. The necrosis caused by an acute pyometritis or metritis is beneficial as it causes sloughing of the cystic endometrium. The author has been amazed that even older dogs that prior to this type of therapy would have been considered sterile have been treated successfully and are fertile. Young bitches, such as those that develop pyometritis or metritis secondary to an injection of estradiol for mating, will nearly all have a successful outcome following this therapy.

The most difficult condition to diagnose and treat is cystic hyperplasia of the endometrium. There are few overt clinical signs and the size of the genital tract makes it almost impossible to surgically or chemically or traumatically curettage the endometrium. Further investigations with fiberoptoscopes and chemical curettage may be indicated.

Successfully treated bitches and queens should be bred on the next estrus, especially those that are older and have had cystic endometrial hyperplasia. Recurrence of hyperplasia and reinfection are directly related to age and the number of non-productive estrous cycles. Following treatment, owners should watch for any sign of abnormal

vulvar discharge and/ or uterine filling. Deep vaginal swabs for culture and cytology should be obtained late in anestrus or early in proestrus to interpret the success of treatment and guide possible management and treatment prior to breeding.

Research in the prevention and treatment of this syndrome in the bitch and queen is needed. Prevention of non-productive estrous cycles is possible with the use of drugs for estrus control (see section in physiology on estrus control). Research on early luteolysis in non-bred dogs to eliminate the progesterone effect or physiological pseudopregnant state would be important. Good hygiene during breeding, whelping and postpartum care and routine genital tract examination will also decrease the incidence of this disease condition.

Miscellaneous Disorders of the Genital Tract

Miscellaneous disorders of the genital tract in dogs and cats include **endometrial polyps** which occur rarely in dogs and more commonly in cats as a further expression of cystic endometrial hyperplasia. These polyps may be single or multiple and can be the size of a fetus or larger. Many will have a small stalk attaching them to the uterine lumen wall. They are usually cystic, containing cystic endometrial glands. They can prolapse through the cervix and may also twist on their pedunculated stalk. This will lead to a bloody and/or mucopurulent fetid vulvar discharge. Vaginoscopic examination may reveal the prolapsed polyp and cause confusion concerning a differential diagnosis with a neoplasm. Large endometrial polyps can be palpated as a mass in the abdomen and radiographs following the infusion of soluble radiopaque fluid into the uterus using a Foley catheter in the anterior vagina during estrus or anestrus will reveal the polyps. The author has observed the death of a queen with an endometrial polyp following treatment for pyometritis with PGF₂ alpha. The polyp would not allow the evacuation of exudate through the cervix and exudate entered the peritoneal cavity via the oviducts resulting in a fulminating septic peritonitis. The author was also the prosector of a necropsy on a mature German Shepherd bitch that died suddenly (torsion) as a result of a unilateral torsion of a uterine horn containing a "potato-sized" endometrial polyp. The bitch died of acute hemorrhagic shock.

Adenomyosis, or the downgrowth of hyperplastic endometrial glands into the myometrium is also a sequela of cystic endometrial hyperplasia. The affected areas of myometrium appear as a firm tumor and is frequently confused with a leiomyoma or fibroid. On cut section,

the "swiss cheese" appearance of the cystic glands differentiate the condition from smooth muscle or fibrous tissue tumors of the myometrium.¹⁷⁶ A report of a 9-year-old Siamese cat with an enlarged abdomen and intermittent emesis was attributed to a 6×10.5 cm and 2 cm thickening of the body and horns of the uterus, respectively, and was diagnosed as adenomyosis.²⁰⁴ Large cysts or macroabscesses in the endometrium are secondary to obstruction of endometrial glands possibly secondary to inflammation in both dogs and cats.

Large serosal cysts or multiple serosal cysts may be seen in old multiparous bitches and are caused by trapping of the serosal epithelium in the involuting myometrium.¹⁷⁶ They are harmless and appear as multiple thin-walled cysts similar to cysticercus lesions caused by tapeworm larva. Lateral to the uterus, cervix and vagina, in the broad ligament in some females lie the remnants of the mesonephric ducts. If present, these may be cystic and be multiple or single cystic structures or long cystic tubules that can extend from the ovaries to the caudal vagina. The secretory lining epithelium of these **mesonephric cystic remnants** is stimulated by estrogen—progesterone of the estrous cycle.

Torsion of a uterine horn usually is associated with pregnancy, pyometra, endometrial polyps, hydrometra or mucometra or any condition that causes an increased uterine horn size.¹²⁶ A bilateral torsion of the right uterine horn of 1,080 degrees and the left uterine horn of 270 degrees was reported.²³⁵

Extrauterine pregnancies with or without severe ascites are a frequent finding in the cat. These may be incidental findings at the time of surgery or necropsy. Usually the mummified fetuses are adhering to abdominal organs or omentum. Some of these have been present for years and are mineralized masses. Extrauterine pregnancies may be either primary as a result of the zygote being dislodged from the oviduct and dropping into the abdominal cavity or intraabdominal fertilization, or secondary, as a result of uterine rupture. Most are secondary, although some have been reported as primary when attachment of fetuses to a blood supply have been found or when fetuses are found well after the time of ovariohysterectomy.^{29,180} Some believe that queens spayed at estrus or soon after, may have zygotes traumatically released into the peritoneal cavity that attach forming a blood supply and growing to a limited size before death.¹⁸⁰ The uterine horn should be examined closely for scars and adhesions, although the uterine horn will heal frequently without visible scars even following a caesarian section.^{75,221} (See pages 218 and 222)

Miscellaneous diseases of the genital tract in the queen include chronic vaginitis. Prepuberal vaginitis is

uncommon in the queen.^{63,167,239} Chronic vaginitis may be secondary to an open pyometritis or metritis, but more frequently is secondary to a dystocia or abortion and is caused by trauma of the cervix and/or vagina. The vulvar discharge is variable from scant and intermittent to abundant and continuous. It is usually mucopurulent. Vaginal examination with a small sterile otoscope (4 mm in diameter) following sedation or tranquilization of the queen may reveal a stenosis and fibrosis or scarring of the cervix and/or vagina. The prognosis is poor for any future breeding use of a queen with vaginal or cervical scarring. Ovariohysterectomy is advised. Vaginal cultures and cytology should be taken via the sterile otoscope head utilizing small 4 mm diameter sterile swabs and transport media for bacteria, mycoplasma, ureaplasma and viruses as described for the bitch earlier in this section. A specimen for cytology may also be obtained by flushing the vagina with sterile saline using a sterile eye dropper and aspirating the cells from the vagina. Abdominal palpation for evidence of pyometra should be carried out. Successful breeding following antibiotic therapy can occur if the birth canal is not damaged.

Several infectious diseases can cause fetal resorption, mummification, abortion, stillborns and teratogenic effects.^{63,132,167,239} These are discussed further under the section on diseases during gestation. These include feline viral rhinotracheitis, panleukopenia, toxoplasmosis, and ureaplasmas. Feline leukemia virus (FELV) and feline infectious peritonitis (FIP) have been associated with repeated services, poor conception, early embryonic and fetal death, resorption, abortion, mummification and stillborns in some catteries. Queens affected with these syndromes should be tested for evidence of FELV and FIP. Aborted fetuses, stillborns, portions of resorbed fetal material, placentas and vaginal swabs for culture should be submitted to a laboratory for both histological examination and culture for bacteria, mycoplasma, ureaplasma and viruses or fluorescent antibody detection of specific viral antigens.

Habitual and repeated abortion in some queens occurring always at the same time of gestation may be due to premature regression of corpora lutea of pregnancy or inability to successfully convert from luteal to placental progestogenic maintenance from day 45 to 50 to over day 60 of gestation. These queens should be checked for evidence of any infectious disease process and always be confirmed pregnant. Blood progesterone studies and ultrasonography for fetal viability throughout pregnancy would be of great scientific and clinical interest in these queens. A treatment consisting of intramuscular administration of repositol progesterone, 0.5 to 1.0 mg per lb.

beginning 7 to 10 days before the time of previous abortion and repeated at weekly intervals until 5 to 7 days before the anticipated date of parturition has been reported to be successful in some queens.^{167,239} Overdosage of progesterone may lead to masculinization of female kittens and prolonged gestation. The predisposition for this premature regression of corpora lutea of pregnancy and the inability to successfully carry fetuses to term may be inherited.

Subinvolution of Placental Sites

Subinvolution of placental sites (SIPS) results in a persistent or intermittent postpartum bloody vulvar discharge that continues longer than the normal discharge of postpartum lochia in the bitch. The etiology of this condition is unknown. Presumptive diagnosis is based on persistence of a sanguinous vulvar discharge beyond the normal postpartum discharge period. This may be continuous, or appear to be intermittent, with some indication that a heavier discharge may be seen postwhelping. A differential diagnosis must be made from metritis. Spontaneous recovery has been reported and in the author's experience, this can occur anytime between the normal postpartum lochial period to the next estrous period.

The first case report of subinvolution of placental sites was in 1966.²⁰ This condition was described and distinguished from other causes of persistent hemorrhage including normal postpartum lochia, postpartum endometritis or metritis, endometrial hyperplasia, urogenital tract neoplasia, trauma, urinary tract infections such as cystitis and pyelonephritis.

One or more or all of the placental sites may be affected. The placental sites that are involved appear from the serosal surface of the uterus as large ellipsoidal swellings, the diameter of the largest being about twice the size of the normal involuting site. The lumen or mucosal side of the uterus contains a small amount of blood-tinged fluid, sometimes large blood clots are present, and the affected placental sites are irregularly thickened, rough, and gray to brown, with areas of hemorrhage of various sizes. The myometrium over these sites is very thin, and in some the serosal area appears as a red or congested band around the uterus and may be quite friable or appears to be easy to rupture. The normal involuted placental sites after 9 weeks will show no ellipsoidal swellings on the serosal surface and on the mucosal surface only a brown color from hemosiderin laden macrophages will be seen at the placental site and the lumen site will be uniform in diameter and narrow. All reported cases

to date have been made from pathologic and/or histopathologic studies of tracts following ovariohysterectomy except for one case reported as a spontaneous recovery. (See page 345)

Normal and abnormal postpartum uterine involution of the bitch was studied and reported by Al-Bassam and co-workers.^{2,3} Of 95 reproductive tracts studied, 20 had subinvolution of placental sites. In this study, normal postpartum uterine involution occurred in 12 weeks and was considered complete when both placental and interplacental areas of the endometrium were covered by a single layer of small basophilic epithelial cells.

The gross description of **uterine involution** during these 12 weeks indicated that it was difficult to tell after 9 weeks that the normal uterus was not completely covered with an endometrial epithelium. During the first week postpartum, the uterus was dilated, edematous and showed signs of contraction on the serosal surface as longitudinal folds. The endometrial surface of the interplacental sites were covered with dark brown mucus, the placental sites were 1.5 to 2 cm in width and the surface was rough, granular and also covered with dark brown mucus and a few blood clots. During the second week, the uterus was smaller, the placental sites were visible from the serosal surface as swelling in the uterine wall. The entire mucosal surface was still covered by a dark brown mucus, but less in comparison to the first week. Placental sites were thicker and their surface was granular, grayish-tan and mixed with blood clots. By 4 weeks, the uterus was much smaller and the placental sites appeared on the serosal surface as ellipsoid swelling. The interplacental sites were less folded and covered with clear mucus. The placental sites were grayish-tan and contained 8 to 12 small grayish nodules and a few pinpoint hemorrhagic foci and blood clots were seen within the nodules. By 5 weeks the uterine horns were much smaller in diameter. The placental sites were small ellipsoid swellings. During the sixth and seventh week, the mucosal surface was light brown and narrow. About 6 to 8 grayish nodules were still present. By 8 weeks, the diameter of the uterine horn reached its smallest size. The uterine horns were uniform in shape and the placental sites were visible from the serosal surface as small ellipsoid shapes. Only a few grayish nodules were at the placental sites. By 9 weeks the uterine horns were uniform in shape with a narrow lumen; the placental sites were only differentiated from the interplacental endometrium by the brown color of hemosiderin filled macrophages.

Histologically, the plane of separation of the placenta at parturition usually lies in the distal portion of the spongy layer where there were only thin-walled partitions be-

tween the greatly dilated glands. Following placental removal, a necrotic mass forms over the basal glandular zone of the endometrium. This mass of eosinophilic staining material contains remnants of fetal placenta, fragments of the separated spongy layer, fibrin, erythrocytes, necrotic thrombosed blood vessels, nuclear debris, and large eosinophilic cells scattered in the upper loose connective tissue layer of the basal glandular zone and just under the necrotic mass. These cells are considered to be decidual maternal cells and/or trophoblastic fetal cells. The possibility of both being present is likely since some appear to be mostly nuclear with a binucleated nucleus similar to trophoblastic cells while others are highly secretory, with abundant eosinophilic granular cytoplasm similar to maternal decidual cells. The combination of both is quite possible since the presence of trophoblastic cells in the endometrium induces the formation of maternal decidual cells which are protective cells as well as a nutritional, secretory and possibly hormonal type cells. During the second week, collagen proliferation from the fibroblast in the lamina propria of the endometrium replaced the necrotic tissue. The necrotic debris was sloughed into the lumen of the uterus. This continued until maximum production of collagen was present in the placental site. A mononuclear cell infiltrate was present in the lamina propria at this time consisting of macrophages, lymphocytes and a few plasma cells. The surface over the collagen masses was still necrotic at this time and contained hemorrhagic areas. By the beginning of the 5th week, a massive sloughing of the collagen masses into the uterine lumen took place. Sloughing was to the level of the attachment of the endometrial lamina propria. This area was soon regenerated and covered by a single layer of columnar epithelial cells from the mouth and neck of the involuting uterine glands. By the end of 8 weeks, all of the collagen masses had sloughed and the entire placental sites were covered with a single layer of epithelium between 9 to 12 weeks postpartum. The interplacental sites, made up of hyperplastic endometrium containing primary and secondary folds, also became necrotic with complete loss of surface epithelium and formation of a necrotic surface. A collagen proliferation did not take place as in the placental sites. A complete single layer of new endometrial lining was produced from the mouth of the involuting glands. This process was also completed between 9 and 12 weeks postpartum.

From the above studies of Al-Bassam and co-workers, it appears that a bloody lochia in the normal bitch should persist for up to 3 to 4 weeks and then continue as necrotic debris, mucous and possibly old brown blood pigment until 7 or 9 weeks postpartum.

In their study of involutional abnormalities in the bitch, it appeared that trophoblastic-like cells invaded the endometrium and myometrium about 4 days postpartum in the bitch.³ These cells migrated along the spiral uterine arteries. This invasion or migration was similar to that seen in the human during the middle of pregnancy and in the golden hamster during gestation and up to 3 weeks postpartum. In the normal involutional process of the bitch, these retained fragments degenerated. In subinvolution of placental sites, these retained trophoblastic-like cells did not regress or degenerate, but continued to invade the deeper glandular layers of endometrium and even the myometrium. The presence of these cells caused necrosis of tissue around them, hemorrhage, and inability of blood vessels in this area to become thrombotic, occlude and degenerate. Early reports of this condition considered this condition as a chorioepithelioma or hydatid mole of the fetal placenta in the bitch (see previous section on neoplasia).^{2,15} Occasionally or rarely, the myometrium becomes so thin that rupture will occur, leading to hemorrhagic shock and peritonitis. The author has also studied 3 such cases in small breeds of dogs, 2 of these were Pugs and one a terrier, at or following delivery of their 2nd or 3rd litter. Rupture of the uterus took place either during parturition or the next day postpartum from old previous areas of subinvolved placental sites that had never healed yet one or more pregnancies had taken place. The uteri from these 3 dogs had multiple irregular raised areas on the serosal surface, most containing a green to brown pigmentation from old blood breakdown, that appeared to be proliferative lesions, but on examinations were very thin areas of the myometrium not covered by normal endometrium but covered only by a necrotic surface. No previous clinical history was given but it appears that these bitches could have had persistent or intermittent bloody postpartum discharge until the next breeding. New placental sites were located next to the unhealed placental sites. One report indicated that 8 of 26 dogs with histologically confirmed subinvolution of placental sites (SIPS) did not have a history of persistent sanguinous vulvar discharge suggesting that SIPS may be present in clinically normal dogs. The author has even diagnosed this condition in one bitch following elective abortion in late pregnancy with PGF₂ alpha.

The etiology of this condition is unknown. At one time, persistent corpora lutea of pregnancy or new postpartum corpora lutea producing luteal progesterone were implicated. This has been disproven since studies have shown that serum progesterone both in bitches with SIPS and in normal postpartum bitches is low and baseline even though in both, corpora lutea remain grossly visible for up to 12 weeks postpartum.^{2,3}

No histologic changes associated with bacterial infection or inflammation have been observed with subinvolution of placental sites. At one time, this was thought to be a condition affecting only first litter bitches, but further studies have shown that multiparous bitches can also be affected. Since many first litter bitches show signs of subinvolution of placental sites, it appears that prior uterine disease is not a major predisposing factor. There appears to be no breed predisposition or influence of eutocia or dystocia prior to clinical signs of subinvolution of placental sites. This condition usually occurs in bitches less than 3 years of age, but reports of histological confirmation ranged from 1 to 11 years.²

Clinically, subinvolution of placental sites is a complaint of bloody or serosanguinous vulvar discharge which persists longer or sometimes more abundantly than what is expected in the postpartum period. In most bitches, normal lochia or bloody mucus discharge has disappeared by 3 to 4 weeks postpartum. In bitches with clinical signs of subinvolution of placental sites discharge can continue for weeks and even into the next estrous period. The quantity of the discharge is variable and the character may range from serosanguinous to hemorrhage with blood clots and occasional visible necrotic debris. The discharge may be persistent or intermittent with some indication of a worsening condition at weaning or postweaning.⁶⁵ Affected bitches are usually normal clinically, bright, active, with normal temperature, pulse and respiration rates, a normal appetite and will whelp and raise their litters successfully. Occasionally a bitch may become weak and anemic especially those that have clotting disorders or poor health due to nutritional disorders, parasitic or other infectious diseases occurring with this condition. Occasionally a bitch will suffer uterine rupture from one of the affected sites resulting in hemorrhagic shock and peritonitis. Uterine size may be abnormal with spherical or elongated bands of enlargement up to 3 times larger in the affected site or sites to no detectable variation in uterine size on abdominal palpation. On laparotomy examination, the affected sites or zones are easily seen on the serosal surface as being enlarged, thinned and congested or red to brown in color. Vaginal cytology will reveal abundant red blood cells, necrotic debris, variable amounts of mucus, a few non-cornified round epithelial cells and scant polymorphonuclear leukocytes. If an endometritis or metritis is present, the vaginal smear would also contain abundant numbers of toxic polymorphonuclear leukocytes and bacteria. The bitch would also show clinical and systemic signs of an inflammatory condition. Vaginoscopic examination would reveal a hemorrhagic discharge from the cervix. Vaginoscopic examination with air insufflation in the

first 2 or 3 weeks and possibly later postpartum will reveal the cervix relaxed and open and the ability to view the placental sites. Caution not to cause trauma with the scope is important. With the use of a Foley catheter, soluble sterile radiopaque solution can be placed in the uterus and then evacuated. After 1/2 hour the placental sites can be viewed radiographically. This procedure should not be done until vaginal cytology and vaginoscopic examination indicates that endometritis or metritis are not present. The most definitive diagnosis is to biopsy the affected area via laparotomy. The most practical approach is to rely on clinical history and vaginal cytology, deep vaginal culture and vaginoscopic examination in making a clinical diagnosis.

Ovariohysterectomy is the best treatment in bitches with SIPS not intended for future breeding use. Spontaneous recovery has been reported in one bitch and the author has seen other cases spontaneously recover, some within a few days following the examination of the genital tract with vaginoscopy and insufflation procedures. Possibly this manipulation had some effect. Use of oxytocin, ergonovine or prostaglandins by the author in treating bitches with subinvolution have not altered this condition. A study was reported of the successful treatment of 10 cases of persistent postpartum uterine hemorrhage in the bitch with a single subcutaneous dose of 25 to 50 mg, 2 mg/kg of bodyweight, of medroxyprogesterone, MPA (**Depo-Provera**, Upjohn Co., Kalamazoo, Mich.). Vulvar discharge was reported to disappear by day 3 posttreatment, and 4 of the 10 bitches were bred at the next estrus, conceived and whelped normal litters of pups.⁸ This appears to be the only successful medical treatment report to date. The product, medroxyprogesterone acetate, is the same product that caused many pyometras following its use as an injectible contraceptive in the U. S. during the 1950's, but has continued to be used very successfully in Europe and appears to be safe at this time period in the bitch as long as there is no indication of inflammatory conditions such as endometritis or metritis.

There are clinical impressions by some breeders and veterinarians that post-whelping oxytocin injections prevent the development of subinvolution of placental sites. Certainly this practice should be encouraged not only because of this clinical impression, but it does help with uterine evacuation of retained dead pups and/or placentas, controls uterine hemorrhage and initiates milk let-down. Either one or two injections 12 to 24 hours apart, with the first given after the bitch appears to have finished whelping, are administered either intramuscularly or subcutaneously. Hysterolaparotomy and gentle curettage of affected endometrial sites has been considered in selected valuable breeding bitches. The success of this

treatment has not been studied. Blood transfusions and selected antibiotic therapy may be needed for the anemic patient or the patient that develops endometritis or metritis.

Further research is needed to determine the incidence of subinvolution of placental sites, its effect on future fertility, the possibility of a genetic predisposition, and successful methods to prevent or treat this condition.

Breeding Soundness Examination

Several excellent reports on **breeding soundness examinations** and diagnosis and therapeutic approaches to infertility in the bitch^{143,149,164,166,200,213,233,246} and the queen^{43,60,63,112,121,151,167,239} are available and the author encourages the reader to review these articles further. The veterinary student, practicing veterinarian and owner of breeding dogs and cats must fully understand the normal reproduction cycle and physiology of these animals before they can understand infertility problems. A detailed history, thorough urogenital tract examination and general physical examination of the bitch and queen are indicated for a fertility examination. The history should include fertility and breeding history of the bitch or queen, littermates and maternal and paternal records if available. The breeding record of males used should also be evaluated. Genetical problems are better appreciated if pedigrees are available. General health records, diets, feed and management practices in kennels or catteries should be obtained. Psychological and environmental stresses are important in some breeding problems. The use of the animal is important, especially if showing, racing or field performance and competition are a part of the animal's activities. All breeding dogs should be routinely blood tested for **Brucella canis** and infertile bitches and stud dogs should be tested for thyroid and adrenocortical function. All breeding queens should be blood tested for evidence of feline leukemia and feline peritonitis virus. A complete physical examination for general health, a hemogram, and a complete urogenital tract examination, including vaginoscopy, vaginal cytology and palpation of the urogenital tract per vaginum, rectum and abdomen should be carried out. Vaginal cultures need only be done on infertile females. Bitches and queens with estrous cycle problems should be followed through these cycles as characterized by sexual behavior, vaginal cytology and possibly hormone profile testing for progesterone levels. Bitches and queens with poor conception or possible early embryonic or fetal death and abortion problems should be followed throughout breed-

ing and pregnancy with vaginal cytology, cultures, progesterone blood levels, pregnancy diagnosis and if possible fetal viability utilizing ultrasonography. Diagnostic methods utilizing radiography for late fetal death and hysterosalpingography utilizing soluble radiopaque fluid for detecting genital tract abnormalities and pathology are available.^{61,62,169} Laparoscopic studies of the urogenital tract and biopsy of the uterus may be indicated for further diagnosis. Excellent records, a systematic approach to examinations, clinical tests and follow-up visits, and an educated and informed pet owner knowledgeable concerning normal reproductive physiology and common problems of their bitch or queen are all necessary to a successful breeding program.
