
Chapter XVIII

INFERTILITY IN MALE ANIMALS (Andrology)

It is probable that infertility or sterility is as common in the male as in the female. Because of the greater hazards presented by parturition and pregnancy, acquired infertility or sterility is much more frequent in the female. The degree of fertility in males may vary greatly but is more easily evaluated because of the large numbers of females bred by each male, especially those males used in artificial insemination. Thirty-six to 48 percent of dairy and beef bulls used in artificial insemination are slaughtered for low breeding efficiency.^{1,2,5,6,7} Probably many of these would have provided satisfactory natural service. Only 28 percent of nearly 9,000 dairy sires used artificially were useful at 10 years of age and older. Arthritic diseases resulting in inability to copulate or reduced libido was the most frequent cause for culling of older bulls. A report of the Jockey Club showed a great range in fertility in Thoroughbred stallions with an average conception rate of 57 percent for all stallions.³ This survey considered the fertility of both the stallion and his mares. Further information on the incidence of male infertility was reported by Laing.⁴ Probably less than 0.5 percent of male animals with normal appearing testes and penis are completely sterile. However there exists a wide variation between males in their fertility.

Because the male genital organs can be readily examined and semen examination by means of the artificial vagina, or by electroejaculation in nearly all domestic animals is easily accomplished, many aspects of male infertility have been studied. With the rapid advances made in artificial insemination in recent years has come a greatly increased knowledge concerning male infertility. Whenever a serious infertility problem with a marked drop in conception rate occurs in a group of females, the male or the semen is always to be suspected until proven otherwise. The selection of males for sires should be done very carefully from the genetic standpoint since the male is responsible for 50 percent of the genes present in his daughters, after 3 generations the sires used in a herd are responsible for 88 percent of the genes in the females.

When any genital organ becomes severely impaired by

disease, it usually cannot be restored to its ideal physiological state. For this reason one must look with extreme skepticism on cures claiming a high rate of complete recovery. The prognosis in treating sterility or infertility in males should always be guarded. There is increasing evidence that the genetic make-up of a sire largely determines his fertility and potency. Only severe diseases, nutritive deficiencies, aging effects or injuries have important or lasting effects on male fertility. There is usually little that treatment or therapy can do to significantly improve the level of fertility in a congenitally infertile male.

The Anatomy of the Testes and the Male Genital Tract

The **scrotum** is present in all the domestic animals and encloses the testes. The scrotum of the domestic animals with the exception of the boar and tom is located between the thighs. In the boar and tom the scrotum is located caudal to the thighs and caudal and ventral to the ischiatic arch. It is composed externally of skin that is relatively free of hair except in toms, rams and bucks.

Beneath the skin is the **dartos** consisting of fibro-elastic tissue and unstriated muscle. The dartos is connected closely with the **tunica vaginalis** and the remnant of the gubernaculum forming the **proper ligament of the testis** and the **ligament of the tail of the epididymis**.⁷ The testis and epididymis are fixed in the scrotum by means of these ligaments and the **mesorchium**. The latter is a long serosal fold of peritoneum, like the mesentery, extending from the lumbar region to the tail of the epididymis and between the tunica vaginalis parietalis and the epididymal border of the testis adjacent to the ductus(vas)deferens.²¹ The scrotum has a medial septum formed by the dartos dividing the scrotum into two halves. The **spermatic or scrotal fascia** is fastened by loose areolar tissue to the dartos and this fascia is lined by the **tunica vaginalis parietalis (communis)**, a fibro-serous sac continuous with the parietal peritoneum. The tunica vaginalis is thin above, but thicker in the scrotum. The scrotum, **cremaster muscles**, and the **pampiniform plexus** regulate the temperature of the testes, keeping it lower than body temperature. The marked contractibility of the scrotum, causing wrinkling in cold weather, is due to the dartos and cremaster muscles.

The principal blood supply to the scrotum is the **external pudendal artery** and also the internal pudendal artery in the boar and tom. Innervation of the scrotum is by means of the genital nerve, a branch of the genitofemoral nerve arising from the second to fourth lumbar nerves and the perineal nerve. The smooth muscle of the scrotum is supplied by the spermatic plexus from the pelvic plexus of nerves.

The testis is supported in one of the two scrotal pouches where it is held by its tunics and by the **spermatic cord**, the latter is composed of the following: the **spermatic artery** tortuously coiled just dorsal to the testes; the **spermatic veins**, which form a plexus of veins, the **pampiniform plexus**, around the spermatic artery; the **internal cremaster muscle**; lymphatic vessels and the **autonomic nerves** from the renal and posterior mesenteric plexuses which form the spermatic plexus around the vessels in the cord, the **ductus deferens**, and the **tunica vaginalis (propria)**. The distal end of the testis is attached to the scrotum by the scrotal ligament, except in the bull.

The **testis proper** is closely covered by a thin serous membrane, the tunica vaginalis (propria). Beneath the structure is a dense, thick connective tissue capsule, the **tunica albuginea**, from which, except in the stallion, septa radiate to the **mediastinum testis** to form the lobules of the testis. Within these lobules are the **seminiferous tubules**, comprising 70 to 90 percent of the weight of the testis. These tubules are lined by germinal epi-

thelium that produces spermatozoa. The length of these seminiferous tubules has been estimated to be: for the boar 6,000 meters, the bull 5,000 meters, the ram, 4,000 meters, the dog 150 meters, and the tom 25 meters.⁵ Between the seminiferous tubules are islands of **interstitial or Leydig cells**. The seminiferous tubules converge at the apex of the lobule at the receptacle,¹⁷ to join the tubuli recti, or straight tubules that enter the **rete testis**, a structure of anastomosing spaces located in the mediastinum testis. The rete testis is most highly developed in the stallion of the domestic animals.¹ There is no mediastinum testis in the stallion, as is present in the other animals, and the equine collecting tubules join the efferent tubules. From the rete testis the sperm passes to the **head of the epididymis** through 13 to 20 **efferent tubules** or ducts.¹⁴ The **testicular artery** enters the testis from the spermatic cord and passes to the distal end of the testis before sending branches through the tunica albuginea and the substance of the testis. The veins, small at the distal end, tend to enlarge as they unite at the proximal or spermatic cord end of the testis. On examination of the testes the tortuous configuration of blood vessels is most readily noted in the tunica albuginea in the bull. This is a further provision assisting the **heat regulatory mechanism of the testis**. The consistency of the testis is usually turgid. The parenchyma is yellow to reddish brown in color and bulges on section.

The **epididymis** is composed of a single, tortuous, coiled tubule that is essential for the transportation, nutrition, storage, and maturation of the spermatozoa. It has a smooth muscle coat that moves the sperm in peristaltic waves toward the ductus deferens. Much absorptive and secretory activity occurs in the epididymis. The length of the epididymal tube is about 30 meters in the bull, 50 meters in the boar and 20 meters in the horse.¹¹ The proximal or spermatic cord end of the epididymis is more or less flat, broad and U-shaped; and is called the **head of the epididymis**. The intermediate narrow part is called the **body**, and the distal enlarged end, which acts as a storage site for spermatozoa, is called the **tail of the epididymis**. This is continuous with the **ductus deferens**. The epididymis is closely attached by fibrous tissue to the surface of the testis proper.

The **testis of the bull** is oval in shape, about 10 to 15 cm. long and 5 to 8.5 cm. in diameter and weighs about 200 to 500 gm. The long axis of the testis is vertical and the body of the epididymis lies caudal and medial to the testis. The head of the epididymis is dorsal and the tail ventral to the testis. The ductus deferens lies parallel to the body of the epididymis and medial and cranial to it.

The **testis of the stallion** is oval in shape but slightly compressed from side to side, about 7.5 to 12.5 cm.

Figure 159. The Genital Organs of the Bull. 1. Seminal Vesicle 2. Ampulla of the Ductus Deferens 3. Bladder 4. Urethral Muscle Surrounding the Pelvic Urethra 5. Bulbocavernosus Muscle 6. Ischiocavernosus Muscle 7. Retractor Penis Muscle 8. Glans Penis 9. Preputial Membrane and Cavity.

long, 4 to 7 cm. dorsal-ventrally and about 4 cm. thick. It weighs about 200 to 300 gm.^{1,12,19} The long axis of the testis is nearly horizontal. When the testis of the stallion is retracted it becomes nearly vertical. The tail of the epididymis is caudal and loosely attached to the testis. The body lies dorsal to the testis with the head of the epididymis cranial. The ductus deferens lies dorso-medial to the body of the epididymis and testis. The horizontal plane of the testis makes torsion of the testis possible in the stallion and dog, although it occurs only rarely. The **appendix testis** is nearly always present as a small protruding structure on the cranial pole of the equine and ovine testis. It is a remnant of the paramesonephric duct.

The **testis in the ram and the buck** is oval in shape 7.5 to 11.5 cm. long and 3.8 to 6.8 cm. in diameter and weighs 200 to 400 gm. The plane of the testis is similar to that in the bull.

The **testis in the boar** is oval in shape, 10 to 15 cm.

long and 5 to 9 cm. in diameter. The testis of mature boars weigh between 500 to 800 gm. with an average of 600 gm.^{9,18,21} The long axis of the testis is almost vertical. The free border of the testis is caudal. The tail of the epididymis is dorsal, the body cranial and the head of the epididymis ventral. The tail of the epididymis is quite large. The ductus deferens lies cranial and medial to the testis. The spermatic cord is long.

The **testis of the dog** is similar in location to the testis of the stallion, but lies slightly more obliquely. The tail of the epididymis is caudal and the head cranial. The testis of the dog is small, about 2 to 4 cm. in length and 1.2 to 2.5 cm. in diameter. The dog testis weighs about 7 to 15 gm.^{10,12,19}

The **testis of the tom** is similar in location to the testis of the boar. It is small, 1.2 to 2 cm. in length and 0.7 to 1.5 cm. in diameter.

The **inguinal canals** of domestic animals are well de-

scribed.³ There are marked species differences. The dog and bull are similar to the boar with large deep inguinal rings and short inguinal canals, while the stallion has a small deep inguinal ring and a long inguinal canal. The canal is a slit like space between the deep inguinal ring and the superficial inguinal ring formed by the tendon of the external abdominal oblique muscle.

The **ductus (vas) deferens** extends from the tail of the epididymis to the colliculus seminalis of the pelvic urethra. The wall of the ductus is thick and the lumen quite small. It passes parallel to the testis, into the spermatic cord, through the inguinal canal in a fold of the vaginal tunic and dorso-medially to the neck of the bladder in the medial edge of the genital fold. From its origin to the dorsal surface of the bladder the ductus deferens is of a uniform thickness of about 3 to 6 mm. in diameter in the bull and stallion, respectively. The fusiform enlarged terminal glandular portion of the ductus is called the **ampulla of the ductus deferens**. In the bull it is 10 to 12 cm. long and about 1 to 1.5 cm. in diameter, and in the stallion 15 to 20 cm. long and about 2 to 2.5 cm. in diameter. A distinct ampulla is not observable in the boar, dog or tom although luminal alterations are present. The ampullae in the bull lie dorsal to the neck of the bladder parallel to each other and in close apposition. Caudally the ampullae narrow and pass under the body of the prostate and open through a rounded prominence, the **colliculus seminalis**, into the cranial portion of the **pelvic urethra**. One or both ampullae may be entirely dorsal, entirely ventral, or intermediate in position to the vesicular glands in the bull.⁷ The blood supply of the ductus deferens is the testicular artery and internal pudic artery. The nerve supply is from the pelvic plexus.

The **accessory male genital glands** include the vesicular glands (seminal vesicles) the prostate and the bulbourethral glands. The **vesicular glands** (seminal vesicles) are paired accessory genital glands of the male located on the floor of the pelvis, cranial and lateral, to the ampullae and neck of the bladder. The lobes of the vesicular glands have small central dilatations in ruminants and the boar but a large central dilatation in the stallion.^{1,19} In the stallion, because the structure is more bladder-like with the glands in the walls, it is still called the **seminal vesicle**.²⁰ These glands secrete a clear fluid that adds volume, nutrients and buffers to the semen. They open into the pelvic urethra in close proximity to the openings of the vasa deferentia. They do not store spermatozoa. The vesicular glands are absent in the dog and tom. In the bull the vesicular glands are lobulated, 10 to 15 cm. long, and 2 to 4 cm. in diameter. In the stallion the seminal vesicles (vesicular glands) are smooth, 15 to 20 cm. long and about 2.5 to 5 cm. in diameter.

In the boar the vesicular glands are proportionately very large, 10 to 15 cm. long, 5 to 8 cm. wide and 5 to 8 cm. thick. They cover the caudal portion of the bladder and extend into the abdominal cavity. A portion or much of the vesicular glands are covered with peritoneum in the bull, stallion, boar and ram. The vesicular glands of the ram and buck resemble those of the bull.

The **prostate gland** has variable forms in all domestic animals but is located on the floor of the pelvis, caudal to the bladder and on or around the neck of the bladder where it is closely fused with the pelvic urethra. It adds its secretions to the semen at the time of ejaculation by means of many ducts opening into the pelvic urethra lateral to the colliculus seminalis.

In the bull the body of the prostate gland is 2.5 to 4 cm. wide and 1 to 1.5 cm. thick. It can be felt per rectum as a distinct transverse protuberance on the cranial end of the pelvic urethra. The **pars disseminata of the prostate gland** surrounds the pelvic urethra. Dorsally it is about 1 to 1.5 cm. thick and 10 to 12 cm. long and is covered by the urethral muscle. In the ram and buck the prostate gland has no body only the disseminate portion diffused over a large area of the pelvic urethra.

In the stallion the prostate gland is situated over the neck of the bladder and cranial portion of the urethra. It consists of two lateral lobes connected by an isthmus. Each lobe is about 5 to 9 cm. long and 2.5 to 6 cm. wide. There is no disseminate portion.

Figure 160. The Urogenital System of the Boar. 1. Urinary Bladder 2. Spermatic Vessels and Nerves 3. Ureter 4. Ductus Deferens 5. Vesicular Gland 6. Prostate 7. Bulbourethral Gland 8. Tail of the Epididymis 9. Testis 10. Urethra 11. Retractor Penis Muscle 12. Glans Penis 13. Preputial Diverticulum.

In the boar the body of the prostate gland is located dorsal to the bladder and is covered by the vesicular glands. As in the bull and ram the disseminate prostate gland around the pelvic urethra is quite extensive.

In the dog the prostate gland is relatively large and composed of rounded left and right lobes which lie at the cranial border of the pubis. It surrounds the neck of the bladder and urethra at their junction and is thin dorsally. The excretory ducts are two in number. The size of the gland varies greatly and may be quite enlarged in older dogs. In a 2 to 5-year-old, 25-pound dog it may vary from $1.7 \times 2.6 \times 0.8$ cm. to a near perfect sphere 2 cm. in diameter weighing about 7 gm.^{10,19} A few disseminate lobules of the prostate gland are present in the wall of the urethra. The prostate of the tom is similar to the dog except it does not cover the ventral part of the urethra.

The **bulbourethral (Cowper's) glands** are paired glands lying dorsally on either side of the pelvic urethra near the ischiatic arch. They are generally ovoid in shape. In the horse they are about 2.5 to 5 cm. in diameter. In the bull they are slightly smaller than in the stallion. In the ram and buck the bulbourethral glands are relatively large, 0.5 to 1 cm. In the boar the bulbourethral glands are large, dense, and cylindrical in shape about 12 to 18 cm. long and 2.5 to 5 cm. in diameter and lie on either side of the pelvic urethra. In the dog the glands are very small, about 5 mm. in diameter.¹⁹ In the tom the bulbourethral glands are nearly as large as the prostate gland. These glands have 3 to 4 excretory ducts each, opening into the urethra in the stallion.¹⁹ But only a single duct from each gland is present in the bull, boar, ram and tom. In ruminants these ducts open under a fold of mucous membrane in the dorsal wall of the urethra. This blind pouch or diverticulum at the ischial arch prevents the passage of a urethral catheter or probe into the bladder.^{12a,14b} In the castrated male the accessory glands and the penis are small and undeveloped.

Urethral glands, although prominent and numerous in man, are not present in the bull, stallion, dog and tom. The pelvic urethra in the bull, ram, buck and boar contains many glands similar to those in the prostate gland and this diffuse layer of glands is correctly called the disseminate part of the prostate gland and should not be called "urethral glands."^{16,20}

The blood supply to the accessory glands in the larger domestic animals is the internal pudental artery. In the dog it is the prostatic artery, a branch of the urogenital artery arising from the internal iliac artery.¹⁰ The nerve supply is by autonomic nerves from the hypogastric nerve and pelvic plexus.

The **uterus masculinus** is a rudimentary structure, a

remnant of the paramesonephric ducts, situated on the caudal dorsal surface of the bladder between the ampullae of the ductus deferens and the vesicular glands and cranial to the prostate. (See Figure 161.) Its presence, size, and development are variable. The uterus masculinus was found in 50 to 70 percent of the bulls examined.⁷

The **penis** is the copulatory organ of the male. It is more or less cylindrical in form in all species. It extends forward from the ischiatic arch to the umbilical region on the abdominal wall except in the tom. It is supported by the penile fascia and skin. Prescrotally it is situated in the **prepuce or sheath**. The terminal portion of the penis is called the **glans** and this lies free in the prepuce. The **body of the penis** is composed of a right and left **corpus cavernosum penis** (enclosed by a thick fibrous capsule, the **tunica albuginae**) and a **corpus spongiosum penis** surrounding the urethra. The corpora are spongy in character and divided into many cavernous spaces. They are continuous with the veins of the penis. Erection of the penis is caused by a distention of these spaces with blood.

Figure 161. The Uterus Masculinus in a Bull (It is usually located between the ampullae and dorsal to the bladder).

The boar and ruminants have a fibroelastic penis in which the trabeculae predominate over the cavernous spaces; while in the stallion and dog with a musculo-cavernous penis the reverse is present. Thus in the non-erect state the former animals have a firm penis while the latter have soft compressible penis.¹⁹ The root of the penis is formed by two **crura** that fasten the penis to either side of the ischiatic arch. The **ischo-cavernosus muscle** arises from the tuber ischii and is inserted on the crus and body of the penis. It causes erection by its compressing and pumping action on the bulbous portion of the corpus cavernosum penis underlying the muscle. The **retractor penis muscle** is a combination of striated and smooth muscle which arises on the first and second caudal vertebrae, receives some fibers from the anal sphincter and meets again under the anus. This paired muscle passes along the ventral caudal surface of the penis and attaches to the tunica albuginea of the penis. In the boar and ruminants the retractor penis muscle is inserted on the distal curve of the sigmoid flexure. Its action is to return the penis into the prepuce after erection.

The muscles of the **pelvic urethra** include the urethral muscle, which is a circular muscle consisting of dorsal and ventral layers of transverse fibers. By its forcible contraction it aids ejaculation and micturition. The **bulbospongiosus muscle** is a thick circular muscle and is a continuation of the urethral muscle on the extrapelvic urethra. It is thickest at the root of the penis. It empties the **extrapelvic urethra**.

In the stallion this muscle, enclosing the ventral portion of the urethra extends to the glans as does the retractor penis muscle.^{1,19} The blood supply of the penis is the **internal pudendal artery** in the boar and ruminants while in the stallion, dog and tom this artery and the external pudendal and obturator arteries also supply the penis. The nerves to the penis are the autonomic nerves of the pelvic plexus and the pudendal and hemorrhoidal nerves. These latter nerves are the motor nerves of the retractor penis muscle. The sensory fibers to the glans penis come from the **dorsal nerve of the penis**, a branch of the pudendal. The glans penis is plentifully supplied with nerves and nerve endings.

The **penis of the bull** is characterized by an S-shaped curve, or **sigmoid flexure**, caudal and dorsal to the scrotum. The penis in the adult bull is approximately 90 cm. long from the root to the tip of the glans. The erectile tissue is small in amount as compared to that of the stallion. The penis of the bull in the erect state is seldom over 4 to 5 cm. in diameter. The glans penis is about 7.5 to 12.5 cm. long, rather pointed and twisted slightly counterclockwise.¹⁹ During erection the S-curve is obliterated.

Bos indicus bulls have greater total penis length and prepuce length than **Bos taurus** breeds, 111 vs 105 cm. and 55 vs 49 cm., respectively. This may be related to the higher incidence of prolapse in the former breeds.^{6a} The well-developed retractor penis muscle attaches to the penis at the cranial or distal end of the sigmoid flexure with fibers extending dorsally on the penis to near the glans to unite with the fibrous tunic surrounding the distal 7.5 cm. of the corpus cavernosum. The thickened dorsal portion of this fibrous sheath is known as the **dorsal apical ligament** of the penis.⁴ At the time of erection and service the penis is protruded 25 to 60 cm. out of the prepuce.

The **penis of the stallion** has a large amount of erectile tissue. In the nonerect state it is about 50 cm. long and 2.5 to 6.0 cm. in diameter; 15 to 20 cm. lies free in the prepuce. At the time of erection the penis will double its length and thickness, with the glans penis enlarging three or more times its quiescent size. Dorsal to the **urethral process** of the glans penis is the **urethral sinus, or diverticulum**, which is sometimes filled with inspissated smegma which is called the "bean." The retractor penis muscle is not as strong as in the bull. No sigmoid flexure is present.

The **penis of the ram and buck** is characterized by a **urethral process** extending 4 to 5 cm. beyond the glans penis. The glans penis is 5 to 7.5 cm. long. The diameter of the penis in the ram is relatively small, 1.5 to 2 cm. The ram's and buck's penis is about 30 cm. long with a well-developed sigmoid flexure.

The **penis of the boar** is similar to the bull but the sigmoid flexure is prescrotal. The cranial portion of the penis which has a small glans is spirally twisted counterclockwise.^{19,21} The penis is 45 to 55 cm. in length and at the time of copulation about 20 to 35 cm. protrudes beyond the preputial opening.

The **penis of the dog** has in its caudal part two distinct corpora cavernosa separated by a median septum. The length of the non-erect penis in the dog is 6.5 to 24 cm. In the cranial free portion there is bone, the **os penis**, which varies from 5 to 10 cm. in length depending on the size of the dog. This bone is thick proximally and tapers distally. Ventrally this bone is grooved for the urethra. A penile bone is also present in other carnivores. The **glans penis consists of two parts**, the **pars longa glandis**, the distal or cranial two-third of the glans, averaging 5.3 cm. in length, and the **bulbus glandis**, the proximal one-third of the glans, averaging 2.4 cm. in length and about 2 cm. in diameter. The bulbus glandis expands greatly at the time of erection and prevents withdrawal of the penis from the vestibule of the bitch during ejaculation. The canine penis during coitus has

been well-described as a "paradox of flexible rigidity"^{12b} since during coitus the male usually dismounts and faces in the opposite direction.

The **penis of the cat** is short and is directed caudally and downward. The urethra is located dorsally. The os penis which is 3 to 5 mm. long is located distally. There is no glans penis, but merely a **terminal cap** about 1 cm. long that contains numerous, about 120 **papillae or spines** pointing toward the base of the penis.² These spines are a secondary sex characteristic. It is questionable that these cause the queen to cry out on intromission. In the tom the bulbus glandis is absent.

The **prepuce, or sheath**, is a double invagination of skin which contains, and is much longer than, the free portion of the penis when not erect. It covers the body of the penis behind the glans when the penis is erect. The external opening of the prepuce is called the **preputial orifice**. The penis of domestic animals lies against the ventral abdominal wall. The body skin covers the prepuce ventrally. The lining of the prepuce is a freely movable membrane or modified skin that is attached firmly only at the glans penis and the preputial orifice. The blood supply of the prepuce is branches of the external pudendal artery and the innervation is from the pudendal ilio-hypogastric, and ilio-inguinal nerves.

The **prepuce in the bull** is long and narrow, 35 to 40 cm. in length and 4 cm. in diameter. The preputial orifice is about 5 to 7 cm. behind the umbilicus and is small, 2 to 4 cm. in diameter, and surrounded by a tuft of long preputial hairs. There are usually two pairs of cranial and caudal **preputial muscles**, protractors and retractors, that draw the preputial opening either forward or backward. The **fornix** of the sheath in the bull is the point at which the prepuce reflects upon the penis just caudal to the glans.

The **prepuce in the stallion** has a preputial cavity extending caudally from the preputial orifice 15 to 20 cm. deep and 6 to 10 cm. in width and then a second reflection or annular fold of prepuce to form the second, more caudal cavity with a narrower lumen surrounding the free portion of the penis, **prepuce proper of the penis**. The opening between these two cavities is called the **preputial ring**. The engaging and disengaging of the glans penis in the preputial ring causes the sucking noise frequently heard when the gelding or stallion trots. The secretion of the preputial glands and epithelial debris causes the formation of **smegma** in the sheath of the horse and males of other species.

The **prepuce of the ram and buck** is similar to the prepuce of the bull but is relatively not as long.

The **prepuce of the boar** has a small orifice with long bristle-like hairs. The caudal part of the prepuce is narrow and the cranial part wide. In the dorsal wall of the

wide part is an opening that leads into the **preputial diverticulum**. This, when filled with urine, semen and smegma, can resemble an umbilical hernia.

The **prepuce in the dog** has a small preputial orifice and a relatively long cavity extending to the bulbus glandis. The **prepuce of the tom** consists of a short fold surrounding the caudally directed preputial orifice.¹⁹

Swine and ruminants tend to urinate inside the prepuce, whereas stallions, dogs and toms extend the penis beyond the sheath. Bucks may extend the penis beyond the prepuce and urinate during courtship of a doe. In ruminants and swine castrated before puberty, the prepuce remains firmly attached to the glans penis, as it is in the prepubertal state.

The Embryology of the Male Reproductive Tract

The urogenital system is formed mainly from mesodermal tissue that in early embryonic life forms the nephric and genital regions. In the cranial portion of the nephric region, segmental tubules initially form the **pronephros** each with a pronephric duct that runs to the primitive cloaca. Later other segmental tubules form caudal to the pronephros and unite with the pronephric ducts to form another temporary excretory organ, the **mesonephros and mesonephric ducts or Wolffian body and ducts**, and the pronephros degenerates. Later a third and more permanent excretory organ forms more caudally from an outgrowth of the mesonephric duct to become the **metanephros or true kidney** with its ureter and bladder. The mesonephros then degenerates but its duct system is utilized in the male to transport spermatozoa from the testes to the pelvic urethra. The development of the paramesonephric (Mullerian) duct has been described in the section on the embryology of the female genital tract. Remnants of the paramesonephric or mesonephric ducts may persist in the adult male as the **appendix testis** and the **uterus masculinus**. In the fetus most of the urine from the fetal kidneys passes into the bladder and through the urachus into the allantoic cavity.

The **testes** form initially as undifferentiated gonads late

in the embryonic period in the genital region or gonadal or genital ridge between the dorsal mesentery and the mesonephros. Although the sex of the embryo is determined at the time of fertilization, sexual differentiation does not occur until the early fetal period after the primordial germ cells have migrated, about day 26 of gestation in the bovine fetus,⁶ to the gonadal ridge from the wall of the yolk sac in the region of the hind gut and structural changes occur in the gonad. Testis cords, rete testis cords and the tunica albuginea form early in the fetal period. Primary medullary cords are characteristic of the early male gonad. These testis cords of primitive germ cells and supporting Sertoli cells remain solid until just before puberty when the seminiferous tubules are formed and join the rete testis by means of the tubuli recti. The rete testis in turn enters the efferent tubules, epididymis and ductus deferens that are formed from the mesonephric tubules and duct. Certain tubules of the mesonephros that do not form the duct system of the testis may remain as small remnants called the **ductuli aberrantes**, blind-ending ductules,⁷ **appendix testis** near the head and the **paradidymis** near the body or tail of the epididymis. During the middle trimester of gestation interstitial cells are numerous especially in the equine fetus.

In the very early fetal period the external genitalia in the cloacal region are also in the indifferent stage characterized by a **genital tubercle** which elongates to form the phallus or penis with two genital folds that form the urethra and the two genital swellings that form the scrotum. Development of the external genitalia in males is hormonally controlled by androgens presumably from the fetal gonad. (See Table 2.)

During fetal development, the testis covered by the visceral peritoneum moves caudally from its location near the caudal pole of the kidney guided by the **gubernaculum testis**.^{1a,4,6,12} At the same time the **vaginal process** forms as an invagination the body cavity with its parietal peritoneum into the genital swelling and gubernaculum. Only in the bitch is this female vaginal process still visible in the adult animal. As the testis approaches the internal vaginal ring of the inguinal canal, the caudal part of the gubernaculum increases enormously in size dilating the inguinal canal and scrotum. It may be mistaken in some fetuses for the descended testis. As the enlarged jelly-like mass of the gubernaculum decreases in size and shrinks, the testis sinks through the inguinal canal and into the scrotum where the gubernaculum forms the proper ligament of the testis and the ligament of the tail of the epididymis. It is possible that the scrotal fascia and the external cremaster muscle are also derivatives of the gubernaculum.³ Thus the testis always remains outside

the peritoneal cavity but the vaginal cavity formed between the tunica vaginalis parietalis, the parietal layer of peritoneum, and the tunica vaginalis visceralis, the visceral layer, is continuous with the abdominal cavity throughout life. If the internal inguinal ring is large, an inguinal or scrotal hernia may develop in this cavity.

Testicular descent and enlargement of the gubernaculum is probably hormonally controlled by androgens from the testes. Failure of normal testicular descent appears in most cases to be genetic in nature and results in cryptorchidism seen most commonly in boars, stallions and dogs and least commonly in bulls, rams, bucks and toms. An abnormal development of the gubernaculum and other factors^{1a} could account for the cryptorchid condition.¹² Testicular descent into the scrotum occurs in the domestic animals during the following periods: horse, 10 to 11 months of gestation; cattle, 3-1/2 to 4 months of gestation; sheep, 2-2/3 months of gestation; pig, 3 months of gestation, and dog, about 7 to 21 days after birth.^{2,8}

Physiology of Male Reproduction

Hormones—In the developing male embryo soon after the primordial germ cells have migrated to the gonads,

differentiation into a testis with recognizable medullar¹ cords occurs sooner than in the female in which cortical cords develop more slowly. The primitive testis apparently secretes or produces androgens that are responsible for the development of the mesonephric duct system and the formation of male external genitalia. The testis also produces a "Mullerian" inhibiting substance" that suppresses the development of the paramesonephric ducts.^{3,8} A lack of this substance or "androgen" which occurs when the testes are removed experimentally early in the fetal period results in differentiation into female genital organs. Excessive and prolonged doses of androgens given to animals in early pregnancy may cause a degree of masculinization of the external genital organs of the female fetuses.

Prior to the onset of puberty, releasing substances, GnRH, secreted by the sex centers in the hypothalamus, pass through the hypophyseal portal system to the anterior pituitary gland to cause the release of the protein, water-soluble gonadotropic hormones from the basophilic delta cells. The gonadotropic hormones are the same as in the female and consist of two closely associated fractions FSH and LH or ICSH (interstitial cell-stimulating hormone). FSH has been considered responsible for spermatogenesis from the initial division of spermatogonia through the formation of the secondary spermatocytes. Thereafter testosterone is thought responsible for sperm cell development. These hormones in the male animal are released in episodic surges or bursts or pulses lasting several minutes to several hours. This results in wide hourly variations in plasma testosterone levels.¹⁷ Following the injection of HCG the level of plasma androgens in stallions will double or triple within several hours. About 4 to 8 episodic bursts or releases of testosterone occur daily in the stallion.² Hormones may not be required for the progression from a spermatogonia to the late stages of primary spermatocytes.¹⁹ Testosterone is required for the reduction division of primary spermatocytes and possible early spermatid formation. ICSH (LH) stimulates the growth of the interstitial or Leydig cells located between the seminiferous tubules in the testes and the secretion of testosterone and other androgens from these cells. All gonadotropins are prepared from biologic sources as they are complex high-molecular weight proteins. Chorionic gonadotropin (HCG) from the urine of women in early pregnancy and sheep pituitary and purified pituitary products from other animals with a high LH (ICSH) content are commercially available. Equine gonadotropin (PMSG or ECG) either from the endometrial cups or equine or other purified animal pituitary products high in FSH activity are also available. Levels of gonadotropic hormone, especially FSH, are high in

castrated mature animals and postmenopausal women. (See Figure 162.) Gonadectomy or castration is widely used in domestic animals to eliminate undesirable aggressive male sexual behavior and undesirable carass qualities including boar and buck odor.⁸

In animals having a breeding season regulated by either increasing or decreasing daylight such as the horse, sheep, goat and possibly the cat, the levels of plasma ICSH (LH) and testosterone are highest in males during the breeding season and lowest during the nonbreeding season.¹⁶ Most males continue to be able to copulate and fertilize but at a somewhat lower efficiency during the "nonbreeding" season.^{2,12b,14}

Hypophysectomy is followed by involution of the seminiferous epithelium and a lack of libido; injections of FSH and ICSH (LH) can restore spermatogenesis, libido and ejaculation of normal motile spermatozoa.¹⁰ The amounts of FSH and ICSH produced and secreted are controlled by feedback mechanisms whereby high levels of testosterone and other gonadal steroids and "inhibin," peptides, from the seminiferous epithelium, probably the Sertoli cells,^{17,22} act on the hypothalamus and/or anterior

pituitary gland to decrease the production of gonadotropic hormones, especially FSH. High continuous levels of testosterone or other gonadal or anabolic steroids such as progesterone, progestins, or estrogen, maintained by either parenteral injection, feeding, or from steroid-producing tumors of the testes or adrenal gland will cause degeneration and atrophy of the seminiferous epithelium and the interstitial cells. This process can be reversed by withdrawal of the exogenous source of steroids, resulting in the "rebound phenomena."

In the stallion total androgen and estrogen plasma concentrations were 2.0 to 2.5 ng/ml. and 30 to 40 pg/ml., respectively.² An injection of 1500 IU of HCG more than doubled the androgen concentration within two hours but had no effect on the estrogen concentration in the stallion and dog. The average testosterone level in canine blood plasma was 1 to 4 ng/ml.^{9b} The high level of estrogens found normally in stallion urine is due to estrogen production by the sustentacular, supporting or Sertoli cells of the seminiferous tubules of the testis. Sertoli cell tumors of the canine testis are not uncommon and produce high estrogen levels with signs of feminization and tes-

Figure 162. Diagram of the Neuroendocrine Control of Reproduction in Male Animals.

Ver-ebooks.com
 ticular atrophy. Sertoli cells have a number of important functions including the secretion of fluid into the seminiferous tubules. Rete testis fluid and seminiferous tubule fluid differ in composition from blood plasma and testicular lymph indicating the presence of a blood-testis barrier.¹⁷

Testosterone, a steroid hormone, is soluble in oil or alcohol but not in water. In the interstitial cells the biosynthesis of testosterone is as follows: acetate → cholesterol → progesterone → androstenedione → testosterone. Testosterone is the major androgen elaborated by the testis in the bull, dog and human. In the bull testosterone is 16 times more active than androstenedione. The latter is the major androgen in the stallion testis.^{15b} These authors reported an average androgen titer of 3.0 micrograms per ml. in the peripheral plasma of 3 to 4-year-old bulls. In 3 of 4 bulls injected daily with large doses of HCG a marked increase in the androgen level was produced. Based on studies of prostatic fluid, 2.5 mg per kg. of body weight daily of testosterone was needed to maintain prostatic function in male canine castrates.^{15a} Androgens are excreted in the urine as androsterones.

Testosterone or androgens from the testis are necessary for: (1) the sexual differentiation of the external male genitalia, and the descent of the testis into the scrotum in fetuses or neonates;^{2,3,17} (2) the keratinization of the preputial epithelium, the separation of the glans penis from the prepuce; (3) the growth and maintenance of the accessory genital glands so they can contribute their secretions to the semen at the time of ejaculation; (4) sexual desire or libido and the ability for normal erection and copulation; (5) secondary sex characteristics of hair and horn growth, male attitudes, timbre of the voice, increased bone thickness, increased muscle tissue with a different distribution of fat from the female due to protein anabolic effects; (6) the maintenance of secretory and absorptive activities and structures of the efferent ducts, epididymis and ducti deferentes including the ampullae, and (7) spermiogenesis or development and maturation of the spermatids and spermatozoa in the testicular and mesonephric ducts are largely maintained by testosterone produced by the interstitial cells which in turn are stimulated by ICSH. High levels of testosterone are present in the lymph and fluid around the seminiferous tubules of the testis. Testosterone enables diakinesis and meiosis to occur.¹⁷ Testosterone can restore sexual desire and copulatory ability when injected into the castrated male animal. Estradiol when administered to steers was highly potent in stimulating most male sexual behavioral characteristics. Testosterone may exert part of its effect on steers and normal males by conversion to estradiol in the brain or hypothalamus.^{5b}

The sheath or prepuce is a modified skin membrane and not a true mucous membrane. It is rich in glands producing sebum and smegma. The preputial glands, which are under the influence of testosterone, are located in the dorsal lateral region of the preputial orifice of boars. They are modified sebaceous glands that are responsible, together with the preputial diverticulum, that fills with smegma, urine and semen from masturbation, for the typical boar odor. These preputial glands that secrete a muscone type of material, a combination of 16 androstenes,⁹ may be surgically removed along with the preputial diverticulum to eliminate the characteristic odor of boar tissues. An immunization attempt against the boar taint steroid, androstenone A, was unsuccessful.^{18a} The highly odoriferous musk-like odor characteristic of adult intact male goats may be due in part to 6-trans nonenal¹⁸ but further studies are necessary in this animal. In goats these glands are located in the caudo-medial skin at the base of the horn. By removing this area of skin, about 24 × 14 × 5.5 mm., at the time of dehorning prepubertal male goats, the odor characteristic of mature male goats is eliminated.^{6b,7,21} These odoriferous chemical compounds are called pheromones that elicit either or both sex attraction or mating behavior through their action on the brain and hypothalamus.¹²

Castration, if performed before puberty, prevents the development and function of those organs and activities requiring testosterone and if performed after puberty results in the atrophy of organs and of activities that are testosterone dependent. There are no interstitial cells in the epididymis so the early belief and practice of "cutting a horse proud" by leaving a portion of the epididymis at the time of castration is fallacious.^{4a,b} There is no antagonism between estrogens and androgens per se. Their apparent antagonism is due to their similar effects on the hypothalamus and the anterior pituitary gland in preventing the release of the gonadotropic hormones. Marked abnormal antler growth in deer with severe hypogonadism was reported.²¹ In the bull interstitial cells were active by 3.5 months of age and the androgen content of the testis increased through 5 years of age and from then on tended to decrease.¹ This decrease in plasma androgen concentration is reported in other animals at older ages.¹⁷ Undernutrition also reduces testosterone levels by reducing gonadotropin production or release.¹⁷

Occasionally male, or female, reproductive steroid hormones are produced by adrenal cells or tumors. Presently all commercial veterinary sources of androgens are synthesized from cholesterol-like compounds and are sold in solution in oil or alcohol ("Repositol"), in suspension in aqueous preparations, or in pellets for implantation. Testosterone may be administered orally especially to dogs

and cats because of their simple stomachs.

Oxytocin administered intramuscularly prior to ejaculation in a limited number of bulls has resulted in a larger volume and greater numbers of spermatozoa in the ejaculate. Contractile mechanisms involved in sperm transport in the male are in part regulated by oxytocin. (See erection and ejaculation.)

Although they are essential for normal body function other pituitary hormones such as ACTH, somatotrophic hormone, prolactin, thyrotrophic hormone, and oxytocin and vasopressin, as well as thyroxine from the thyroid gland, the glucocorticoids and adrenaline from the adrenal gland and others have only moderate secondary effects of limited importance on reproduction in the male domestic animal.

Puberty—The onset of puberty in male domestic animals occurs at approximately the same time after birth as puberty in females of the same species. About 4 months of age GnRH from the hypothalamus causes the episodic release of gonadotropic hormones, LH and FSH, from the anterior pituitary gland resulting in the secretion of androgenic hormones from the gonads that cause growth of the genital organs and secondary sex characteristics.^{17,13,15,17} Injections of gonadotropic hormones into prepuberal animals results in precocious sexual maturity. In the male the onset of puberty is characterized by secondary sex signs, sexual desire, ability to copulate and the presence of viable spermatozoa in the ejaculate. The onset of puberty is a gradual process and is variable in time since it may be influenced within a species by the plane of nutrition, breed of animal (**Bos indicus** bulls mature slowly than **Bos taurus** bulls), cross-breeding, methods of management, presence of chronic disease processes, and individual differences.^{2,6}

The development of puberty in bulls has been carefully studied.^{1,11,13-17} Primary spermatocytes appear in the seminiferous tubules by 4 to 6 months of age, spermatids by 6 to 7 months, and spermatozoa by 7 to 9 months of age in bulls. Seminal secretion from the accessory glands appears by 5 to 6 months. Separation of the penis from the sheath in bulls proceeds caudally beginning at 1 month and ending with complete separation by 8 months of age. The period from 6 to 10 months of age in bulls is characterized by the accelerated growth rate of the genital system, increases in GnRH and in plasma LH, external manifestations of puberty and the rapid onset of spermatogenesis. Puberty was reached at 10 months, 40 weeks, in well-fed, healthy Swedish Red and White bulls and by 12 months, 48 weeks, when fed on a lower plane of nutrition. However others⁷ have reported that fertile semen with conception has been produced by well-reared bulls at 6 months of age. Puberty probably commences

at 2 months and is qualitatively completed by 10 months of age in Holstein bulls.¹⁸

The onset of sexual behavior in a young male is significantly hastened by rearing with other males or females and is retarded by rearing in isolation.¹⁶ The size of the testis in prepubertal bulls increases rapidly between 4 and 8 months of age and then growth of the testes is at a slower rate and is correlated with the body weight. During the pubertal period it may be difficult, without repeated examinations over a number of months to differentiate between delayed testicular development due to poor nutrition and management or testicular hypoplasia caused by genetic or congenital influences.¹⁶

The penis of newborn ruminants and swine is without a sigmoid flexure and is adhered to the prepuce. Penile growth due to androgens between 3 and 8 months of age results in the development of a sigmoid flexure and its separation from the prepuce. A scrotal circumference of 28 cm. is indicative of puberty in bulls.^{13,14,15}

The attainment of puberty does not signify full reproductive capacity. Highly significant increases in ejaculate volume, output of motile spermatozoa and concentration of spermatozoa occur in bulls for 6 to 9 months after the onset of puberty.^{2,3,8} Puberty in bulls was defined as the age at which the first ejaculate containing at least 50×10^6 spermatozoa with 10% motility was obtained.¹⁵ Within 4 months after puberty the percentage of normal acrosomes had not yet reached mature levels.¹⁴ A marked reduction between 9 and 12 months in the number of proximal protoplasmic droplets on bovine spermatozoa was noted.² The same reduction in protoplasmic droplets and abnormal spermatozoa in ejaculated boar semen occurred between 150 and 200 days of age.¹² The rapid growth of the testis and epididymis from 4 to 8 months of age in the boar was described.^{20,21} Detachment of the sheath from the penis occurred at 4 to 6 months and sexual maturity in the boar was reached at 7 to 8 months of age. It was noted that 16 to 17-month-old stallions produced only 16.4 ml. of gel-free sperm per ejaculate with 22 percent progressive motility and 48 percent abnormal sperm cells.¹⁰ Because of the above indications of a lack of maturity after the onset of puberty and because of individual differences in libido, spermatozoan reserves, and the ability to produce large numbers of normal spermatozoa, immature male animals should be used sparingly for breeding purposes for one-half to one year or more after reaching puberty. Bulls that mature early with large testicles generally produce daughters that also mature early and may be more fertile.⁹ Scrotal size in young bulls was not highly correlated with sexual behavior or libido.¹³

The time of puberty in male animals is:

- Stallions—18 months (range 12 to 24 months)
 Bulls—9 to 12 months (range 6 to 18 months)
 Rams and Bucks—7 to 8 months (range 4 to 12 months)
 Boars—5 to 7 months (range 4 to 8 months)
 Dogs—7 to 10 months (range 5 to 12 months)^{11b}
 Toms—8 to 10 months (range 6 to 15 months)

The Scrotum and Heat Regulation of the Testes—

The testicles in all domestic animals are normally located in the scrotum. In certain wild species of rodents the testes are retained in the abdominal cavity except during the breeding season when they descend into the scrotum. The whale, elephant, rhinoceros and seal have no scrotum and the testes are intra-abdominal. In the domestic animals the scrotum performs a vital temperature-regulating function for the testes. If the testes are maintained at body temperature, as occurs in bilateral cryptorchidism, spermatogenesis does not occur. High, prolonged fevers, insulation of the scrotum or prolonged exposure to high atmospheric temperature and humidity can also seriously impair spermatogenesis. However, testosterone production by the interstitial cells or Leydig cells is not affected by temperature.

The dartos muscle, by contracting in cold weather to hold the testes against the body and relaxing in warm weather is the principal thermoregulator of the testis.² The external cremaster muscle, by raising the testis, may also play a role. In the dog, bull, boar and stallion the scrotal skin is thinner and less well covered with hair which together with increased numbers of sweat glands further assists in cooling the testes.¹⁷

Scrotal temperature in three dairy bulls varied from 93.2° F (34.1° C) to 100.4° F (37.9° C) while rectal temperature varied from 100.4° F (37.9° C) to 102.2° F (38.9° C) during the same 8-hour period.¹ Scrotal temperature can rise rapidly when bulls recline. Fluctuations of 18° F (10° C) in environmental temperature had little effect on scrotal temperature. The testicular temperature of the ram may vary from about 85° F (28° C) to about 104° F (40° C). In animals with well-developed scrotums the testicular temperature is usually 2 to 7° C below body temperature.¹²

In rams blood in the coiled internal spermatic artery winding through the pampiniform plexus of spermatic veins cools 9.4° F (5.2° C) when the testicular temperature is about 93.2° F (34° C).³ The arrangement of the spermatic artery and vein in the region of the pampiniform plexus provides an efficient heat exchange mechanism that, although it is not regulatory, rapidly transfers any benefit of scrotal thermoregulation to all parts of the testis. In this regard in the bull the extensive network of superficial veins in the tunica albuginea plays an im-

portant role in lowering the temperature of the venous blood before it passes through the tortuous spermatic vein.

The Testes, Spermatogenesis and Spermiogenesis—The testes perform a dual function in producing testosterone from the interstitial cells, and spermatozoa and "inhibin" from the seminiferous tubules. The mature male domestic animal is capable of fertile copulation at any time. However, in certain wild animals such as deer, camels and elephants there is a definite seasonal period of sexual excitement or "rut" and spermatogenesis occurs only during this period. In some domestic animals, such as the ram and stallion, there may be seasonal variations in libido and in spermatogenesis and semen quality due to environmental nutritional, length of daylight or other factors.

Spermatogenesis is a highly synchronized process whereby spermatozoa are formed from the precursor diploid cells, type A spermatogonia.¹⁷ **Spermatogenesis** includes both **spermatocytogenesis** (spermiocytogenesis) or formation of primary and secondary spermatocytes from type A spermatogonia and **spermiogenesis** or the formation of mature fertile spermatozoa from the immature spermatids. Spermatocytogenesis is under the regulation of FSH from the anterior pituitary gland and conditions favorable for spermiogenesis are under the control of LH and testosterone. Under normal conditions spermatogenesis is a very orderly continuous process. In any single small area of the seminiferous epithelium various stages of the well-organized extremely regularly occurring cycle of the seminiferous epithelium may be observed.

The duration of spermatogenesis is comprised of 4 cycles (4.68 cycles if spermatogenesis is started with a dormant type A spermatogonia) of the seminiferous epithelium starting with type A spermatogonia. At each cycle of the seminiferous epithelium the spermatogonia renew themselves by producing new stem cells and cells that will produce spermatocytes. Each cycle length in the bull and dog^{9b} is 13.5 days, in the boar 8.6 days and in the ram about 12.2 days. In the boar, bull and ram and other male animals a succession of 8 highly characteristic cellular associations or stages occur in each cycle which takes place in the form of a spiral along a portion of the seminiferous tubule as well as at one transverse area. In each stage there are several distinct groups of cells present on cross-section of the seminiferous tubule. At stage 8, for example, nearly mature spermatozoa line the lumen of the tubule. Spermatids at a certain stage in development, or a generation of germ cells, are always associated with the same types or other generations of spermatogonia and spermatocytes. The distance between two similar cellular associations or stages in the seminiferous tubule is called a spermatogenic wave.^{8,9,16} A

second classification of 14 cell associations forming the spermatogenic cycle has been described.^{8,17} (See Table 22.) Any agent that damages spermatogonia could lead to permanent damage of the testis; but if only differentiating cells are damaged, repair is possible.

Spermiogenesis begins as soon as the spermatid is formed. At this stage the spermatid has a spherical nucleus surrounded by cytoplasm containing many mitochondria in which a Golgi complex or zone soon forms. The acrosome and head cap of the spermatozoon arise from the Golgi complex. The cytoplasm and centrioles move to the opposite side of the nucleus. The centrioles give rise to the flagellum or axial filament and later the body and tail of the spermatozoon. The mitochondria later become arranged like a collar around the upper region of the flagellum as the mitochondrial helix forming the middle piece. At the end of spermiogenesis when the spermatozoa are in the head of the epididymis, unused cytoplasm and Golgi material, now called the protoplasmic or cytoplasmic droplet, is located in the neck region of the sperm cell in the testis, and is cast off as the spermatozoa pass through the epididymis.²

During part of its transformation to a spermatozoon the spermatid is closely associated with "nurse" or Sertoli cells in the seminiferous tubules. After it leaves the Sertoli cell and is "free-living" in the lumen of the seminiferous tubules it is moved into the rete testis and efferent tubules by a large volume of secreted fluid from the Sertoli cells and cells lining the rete and efferent tubules.¹⁷ There is little evidence of any contractile tissue and no cilia in the seminiferous tubules, straight tubules or rete testis. Spermatozoa do not develop any significant degree of motility until ejaculation. The testicular capsule apparently contains smooth muscle that contracts and relaxes and this alternate activity exerts a pumping action on the seminiferous tubules forcing the nonmotile sperm cells and "plasma" out of the testis and into the epididymis.

Normal bulls and stallions produce 12 to 17 million and rams 12 million spermatozoa per gram of testicular tissue daily.^{2,14,18,9,16} Boar produce 25 to 30 million sperm cells per gram of testis daily because of the shorter duration of spermatogenesis and the larger number of spermatozoa produced from one type A spermatogonium.¹⁰

Table 22. Outline of Spermatogenesis in the Bull, Boar and Ram

		Chromosome Complement	No. of** cells	Time in Days*		
				Bull	Boar	Ram
Type A Spermatogonia (dormant)		2N (diploid)	1			
Type A Spermatogonia		2N	2			
Intermediate Type Spermatogonia		2N	4			
Type B Spermatogonia		2N	8			
Primary (Preleptotene) Spermatocytes (active DNA synthesis)		4N (tetraploid)	16			
Leptotene stage						
Zygotene stage	Meiotic					
Pachytene stage	Prophase I (long, 16 days in ram)					
Diplotene stage						
Diakinesis						
Metaphase I					25-26	
Anaphase I	1st Meiotic (maturation)			40-42		
Telophase I	Division					36-37
Secondary Spermatocytes		2N	32			
Diakinesis	Meiotic Prophase II (very short, hours)					
Metaphase II						
Anaphase II	2nd Meiotic (maturation)					
Telophase II	Division					
Spermatids		1N (haploid)	64			
Spermatozoa	Spermiogenesis (long, 15 days, ram)	1N	64			

*It takes approximately 10 days in the bull and 13-15 days in the ram and boar for spermatozoa to traverse the epididymis. Thus from type A spermatogonium to ejaculated spermatozoa is about 60 to 70 days in the ram and bull and 50 to 60 days in the boar, stallion and dog.

**Theoretically in the bull and ram 16 primary spermatocytes and 64 spermatozoa develop from one type A spermatogonium; boars and rats have 24 primary spermatocytes and 96 spermatozoa from one spermatogonium. However a certain loss in cells, about 25%, is experienced during meiosis and is characterized by the presence of pycnotic nuclei.

Thus daily sperm cell production for a bull with testes weighing 400 gms each, a stallion with testes weighing 85 gms. each, a ram with testes weighing 250 gms. each, and a boar with testes weighing 300 gms. each would be 12 billion, 6 billion, 7 billion and 15 billion spermatozoa, respectively. About 70,000 spermatozoa are produced every second during the breeding season by the testes of an adult stallion.² Sperm numbers in the testis are highly correlated with testis weight, testis diameter, testis tone or consistency, and scrotal circumference.^{3,5} Testicular growth continues through puberty until complete sexual maturity occurs, which in the bull is about 4 years of age. Beef breeds, particularly **Bos indicus**, mature more slowly than the dairy breeds. Scrotal circumference in normal bulls is closely correlated with spermatozoa production since 70 to 90 percent of testicular weight is comprised of the seminiferous tubules. In most beef bulls average scrotal circumference increases from 14 months, to 26 months to 36 months of age from 33 cm. to 35 cm. to 36 cm., respectively. While in Brahman bulls the corresponding age-related average circumferences are 22 cm. to 32 cm. to 37 cm. and in Holstein bulls 32 cm. to 39 cm. to 42 cm., respectively.^{3,5} Measurements are made with scrotal circumference tapes.*

Other factors that influence bovine testicular size besides age and breed is body condition, body weight, season (heat stress)¹⁷ testicular pathology. Testicular size is highly heritable.⁵ Bulls of breeding age should have a scrotal circumference measurement of 32 to 34 cm. or more to be classified as a "satisfactory potential breeder."^{5,6} The testes of other animals also increase in size from puberty to maturity. In the stallion under 12 months of age the total testes weight is 53 gms., at 24 months it is 209 gms., at 36 months, 232 gms., and at 4 to 10 years, 317 gms.² Testicular size in stallions may be measured by calipers.¹⁴ As in other animals total scrotal width is closely correlated to testicular weight and production of spermatozoa. The average scrotal width of normal stallions is 105 mm., range 80 to 140 mm. Equine testicular size decreases 10 to 15 percent in the nonbreeding winter season and as stallions age the testes increase in size from 90 mm. scrotal width in 2 year old to 108 mm. in 15 year old horses. Individual testis width in Standardbred stallions averaged 4.6 to 6.3 cm. with the right testis slightly larger than the left in all ages. A 9 to 18 percent reduction in size of testes of like aged horses occurred in working, stressed, or hormonally treated stallions at racetracks compared to breeding farm stallions.¹⁹ During the nonbreeding season in sheep scrotal

circumference in rams was 15 percent less than during the breeding season.¹⁴

Scrotal circumference in rams varies with the weight and age of the ram. Scrotal circumference of normal, well grown rams was 26, 33, 34, 36 cm. for rams weighing 100, 150, 200, 250 and 300 pounds, respectively, with a range of 20 to 43 cm.^{16b} Heritability estimates for scrotal circumference were high and for testis consistency medium. These traits should be emphasized in bull evaluations.^{5b}

Four months after unilateral castration in the ram and prepubertal bull the weight of the remaining testis increased by about 76 percent and sperm cell production was nearly double that of a normal testis.^{1b,18} As in rabbits and dogs after hemicastration the diameter of the seminiferous tubules increased greatly to produce a compensatory hypertrophy of the single testis. Further study of this interesting observation is needed in these and other species.

The Morphology of Spermatozoa—In recent years electron microscopy has done much to elucidate the fine structure of spermatozoa. Although the size and shape of spermatozoa differ between the domestic species of animals the basic morphological structure is similar. The head length and width is about 8 to 10 microns by 4 to 4.5 microns in bull, ram and boar spermatozoa and smaller, 5 to 7 microns in length and 2.7 to 4.0 microns in width, in stallion, dog and cat spermatozoa. The head thickness is about 0.5 to 1.5 microns or less in all species. The spermatozoan body or middle piece is about one and one-half to two times as long as the head, 10 to 15 microns, and about 1.0 micron in diameter in all species. The tails of spermatozoa are 35 to 45 microns long and 0.4 to 0.8 microns in diameter. The total length of spermatozoa of domestic animals is thus about 50 to 70 microns or 1/300 of an inch.^{8,17,14}

The head of the spermatozoon is elongated and ovoid in shape, broad and flat in one plane and narrow in the other with the thickest portion at the base and tapering to a fairly thin apex. The head is entirely filled with a nearly homogenous nuclear material containing the genetic material, DNA or deoxyribonucleic acid, surrounded by the nuclear membranes. (See Figure 163.) DNA is the amazingly concentrated coded genetic material. Each spermatozoon contains about 2.5 billion bits of information necessary to form a fetus yet it takes 300 billion spermatozoa to make 1 gram of DNA.⁶ The anterior part of the nuclear membrane or the inner membrane of the acrosome forms the body of the acrosome. The anterior 60 percent of the nucleus and its modified membrane, is covered by the acrosome cap or head cap which is a double-walled pouch-like structure about 0.1

micron thick enclosing the acrosomal substance and the denser acrosomal corpuscle, body, or vacuole.^{17,4,10} The equatorial zone or segment is the posterior part of the acrosome or head cap around the middle portion of the sperm head corresponding to the area where the acrosomal substance is most scanty. The posterior 40 percent of the nucleus and nuclear membranes from the equatorial zone to the base of the cell are covered by the postnuclear cap or nuclear sheath. The differences between the acrosome cap and postnuclear cap explain the differences in affinity for stains observed in these two regions. The cell membrane composed of several layers completely encloses the head, body, and tail of the spermatozoon. The membrane is closely applied to the cell at the anterior portion of the acrosome cap, the postnuclear cap, and at Jensen's ring. The outer membrane of the acrosome cap, is identical with the galea capitis, described in the earlier literature, that is detached either

spontaneously in the tail of the epididymis by long, sexual abstinence, artificially in vitro, or during fertilization, probably as a step in sperm capacitation. Detachment occurs by rupture of the cell membrane and the outer membrane of the acrosome cap in the equatorial zone which exposes enzymes such as hyaluronidase in the acrosome that are necessary for penetration of the spermatozoa into the ovum.^{17,7} It was recommended that earlier term "perforatorium" be dropped as the function ascribed to it is performed by the acrosomal body.⁷ The detached outer membranes of the acrosome may break into two halves, or remain joined and appear as "bathing-cap" shaped structures in stained or India ink preparations of semen.

The neck, centriolar region or implantation zone, about 1.5 microns long, consists of the two centrioles and their surrounding radices or implantation plates.^{8,17} The mitochondrial sheath originating in the basal knobs or gran-

ules of the head form two counter-clockwise spiral structures, the mitochondrial helices, that continue down the body or midpiece to the terminal or Jensen's ring. The radices change into the fibrillar bundle at the posterior portion of the neck region. Most authors consider the neck region as part of the body or middle piece. The mitochondrial sheath is about 0.1 micron in thickness and surrounds the fibrils, 9 coarse or peripheral and 11 fine or central. These latter structures resemble cilia. The helix region, midpiece, middle piece, or body supplies energy for the sperm cell by metabolic processes occurring in the mitochondrial helix. The tail region, the longest part of the sperm cell originates at the terminal ring of the body and extends to the endpiece. In the tail region, the fibrils are surrounded by the fibrillar coil sheath or tail sheath consisting of pair of spiral coils with each of the coils making more than 400 spirals. The endpiece or terminal portion of the tail is about 3 to 4 microns in length and consists of the terminal portion of the fibrils covered by the cell membrane but the fibrillar coil sheath of the tail is absent.¹⁰ The wave-like or whip-like action of the tail originates in the neck region of the body and generates contractile force as it proceeds distally. Helical oscillations of the tail of the spermatozoon are very rapid and provide the force necessary for sperm cell motility which under optimum conditions of temperature, and medium is about 100 microns per second, range 10 to 352, in bull spermatozoa,^{3,9,11,12,13} or about 4.23 mm. per minute.² The motility rates for equine, ovine and human spermatozoa were 80 to 100, 200 to 250 and 30 to 75 microns per second, respectively.

Spermatozoan Transport, Maturation and Storage and Accessory Gland Secretion—Spermatozoa are carried in a large amount of fluid secreted by the seminiferous epithelium into the rete testis and the tortuous efferent ducts (ductuli efferentes) usually about 13 to 15 in number, located adjacent to the head of the epididymis and opening into the epididymal duct.^{8,17} These structures since they arise from the mesonephros have kidney-like functions in respect to absorptive and secretory activities. As mentioned previously contractions of the testicular capsule probably aids in forcing semen from the testes into the efferent ducts. Nearly all of the fluid, 200 ml. daily in the bull, entering the efferent ducts and head of the epididymis in the bull, as well as the boar, was reabsorbed there.^{17,10} About 30 ml. of fluid passes daily from the rete testis into the efferent tubules of the ram.³² The sperm cell concentration in this fluid was 100 million per ml. Ligation of the efferent ducts and possibly the head of the epididymis caused an accumulation of fluid or edema in the testes followed by atrophy while no accumulation occurred if the ligature was placed around

the more distal portions of the epididymis.^{17,28} Both secretory cells and cells with cilia beating toward the epididymis are found in the efferent ducts. The ciliated borders of these cells in the bull may become detached and excreted with the semen at the rate of one "medusa head" per 10,000 spermatozoa or about 500,000 in the average ejaculate.⁹ Smooth muscle activity as well as ciliary activity help transport sperm through the efferent ducts.

In the epididymis peristaltic activity of smooth muscle is largely responsible for sperm transport. Microvilli are present in epididymal cells but they are nonmotile. The contractile mechanisms involved in sperm transport in the male are partly regulated by oxytocin. The epididymal epithelium has absorptive and secretory functions producing variations in the sodium, potassium, calcium, chlorine and phosphorus ion concentrations and in the concentrations of proteins, enzymes and glycerylphosphorylcholine in the luminal contents in different portions of the epididymis.¹⁴ The composition of epididymal plasma is closely related to testicular function, the passage of sperm cells and the hormonal and physical testicular environment. Plasma volume in bulls was doubled by secretions in the caput and halved by absorption in the cauda; while in boars the epididymal content underwent continuous dilution from the caput to the cauda epididymis. The time required in the domestic animals for spermatozoan transport through the head, body and tail of the epididymis is about 7 to 15 days. Frequent ejaculations hasten the passage of spermatozoa through the tail of the epididymis.²

Although physiologic mechanisms of the epididymis are largely under the hormonal control of testosterone they are not well understood. The sperm cell undergoes maturation and other changes including the ability to become motile and fertilize an ovum,^{2,17} in its passage through the epididymis. An example of this maturational process is the passage of the cytoplasmic droplet from the neck region, down the middle piece and tail from which it is lost before ejaculation. This is most commonly described in ungulates. Proximal protoplasmic droplets were present on 44% of the spermatozoa in the caput and only 2% in the cauda epididymis of bulls.⁴ The percent of proximal protoplasmic droplets in the caput of swine is higher. Spermatozoa removed from the tail of the epididymis were 2 to 10 times more fertile than spermatozoa from the caput apparently due to abnormalities in locomotion of the sperm cells taken from the head of the epididymis.^{8,24} The percentage of motile bovine sperm cells in the caput and cauda epididymis were 0 and 41, respectively.^{16,17} Staining with an eosin or vital stain revealed equal numbers of live, unstained cells and

morphologically normal spermatozoa in both sites. Spermatozoa removed from the cauda epididymis exhibited normal fertility. Only about 1 ml. of fluid per day flows through the ovine epididymis but the epididymis does secrete compounds such as glycerylphosphorylcholine.⁸

The seminal fluid in bulls is concentrated as it passes through the epididymis, especially in the head region, so sperm cell concentration in the tail of the epididymis in bulls is 4,000,000 or more per cmm. In the epididymis sperm cells exhibit a very low rate of motility and are resistant to cold shock.⁷ In the tail of the epididymis storage conditions are optimal. Spermatozoa can remain viable and fertile for up to 60 days in the ligated epididymis of the bull.⁹ After long periods of sexual rest, however, many spermatozoa in first ejaculates may be dead or infertile. Bulls have about 70 billion spermatozoa outside the testis proper, extragonadal sperm reserves (ESR), with 19 billion (29%) in the head, 5 billion (7%) in the body, 37 billion (53%) in the tail of the epididymides, 2 billion (3%) in the ducti deferentia and 6 billion (8%) in the ampullae.¹ Thus the major storage site for spermatozoa is the tail of the epididymis. Depletion trials in the bull, consisting of 20 or more ejaculates taken within several hours, removed about 53 percent of the extragonadal sperm reserves. In the ram depletion trials reportedly removed only 31 percent of the extragonadal sperm reserves. In the bull these depleted extragonadal sperm reserves are completely replenished within about 7 days and a significant replenishment of spermatozoan numbers in the tail of the epididymis occurred within 60 to 90 minutes after the last ejaculate. During depletion trials no increase in proximal protoplasmic droplets or abnormal spermatozoa were noted.

Unejaculated, defective²⁷ spermatozoa or spermatozoa confined to the epididymis by resection or ligation of the ductus deferens or vasectomy have been reported to be removed from the epididymis, rete testis and efferent ductules by selective phagocytosis by macrophages and epithelial cells or resorbed.^{4,13,20,25,27,29} Histologic examination has only occasionally shown degeneration or phagocytosis of sperm cells in the rete testis or epididymis.¹³ Many workers have reported that spermatozoa were voided in the urine.^{2,21} The number of sperm cells voided daily in the urine of sexually-rested rams was about the same as the total daily sperm cell production. Long term vasectomy in the bull did not abolish spermatogenesis and testis size was unaffected even after 5 years.¹⁸ Thus a mechanism must exist for the removal of sperm cells from the epididymis. Further work is needed to elucidate the fate of unejaculated or defective, dead sperm cells. Masturbation in domestic animals may cause some de-

pletion of sperm cell reserves from the tail of the epididymis. Thus there are apparently several routes for eliminating excess, dead, or abnormal spermatozoa from the testis and epididymis.

The ductus (vas) deferens is a firm muscular duct, about 2 mm. in outside diameter in the bull, that transports spermatozoa by peristalsis especially at the time of precoital stimulation and ejaculation to the ampullae and the pelvic urethra. The ampulla of the ductus deferens, present in the bull, stallion and ram, is a thickening of the ductus abundantly supplied with glands that are similar to the vesicular glands. The ampullae have a limited role in the storage of spermatozoa. There is no noticeable enlargement of the terminal portion of the ductus in the dog, tom or boar.

The accessory glands including the vesicular glands; (seminal vesicles), the prostate; and bulbourethral (Cowper's) glands are under the control of testosterone from the interstitial cells of the testis and secrete the major portion of the seminal plasma into the urethra at the time of ejaculation. The seminal plasma acts primarily as a carrier for spermatozoa and secondarily stimulates spermatozoan activity by providing fructose, a readily available energy source, and buffers. While seminal plasma is capable of influencing the fertilizing ability of spermatozoa there is no evidence it is essential for it.

In 7 vesiculectomized bulls the volume of the ejaculate decreased as did the motility of the spermatozoa while the concentration of sperm cells increased. Five of these bulls were mated with heifers and had acceptable fertility. Seminal vesiculectomy in bulls nearly eliminated fructose in semen and reduced the protein level and ejaculate volume.¹⁹ There was a greater loss in sperm cells after freezing in the treated bulls but the libido was not affected. The vesicular gland secretion is not essential, as the metabolic needs of the sperm cells are provided by the secretions in the female genital tract. In the bull the vesicular glands contribute slightly to the presperm semen fraction but mainly to the sperm cell rich fraction of the ejaculate.¹² The vesicular glands secrete fructose, citric acid, potassium, proteins, enzymes and other substances. Certain prostaglandins have been reported to be present in the seminal plasma of man, guinea pigs and rams. These have a strong pharmacodynamic effect on the smooth muscle of the genital tract of females facilitating sperm migration.³¹ In certain Holstein, Hereford and Guernsey bulls, and possibly in other breeds, the semen may have a definite yellow color due to riboflavin secreted by the vesicular glands. This may be inherited as a dominant character. Upon standing in sunlight for several hours the yellow color will fade.³³ In the boar, secretions from the seminal vesicle and bulbourethral

lands when mixed form a gelatinous, waxy, tapioca-like material. Certain horses, especially grade animals and only occasionally Thoroughbreds, produce a thick, gelairy, "egg-white," sticky secretion from the vesicular glands.^{2,6,11} This is of interest in light of the production of a vaginal plug or coagulum in the rat and guinea pig when Cowper's gland and the secretions from the coagulating gland, a portion of the prostate, combine with secretions from the seminal vesicles.¹⁵ This promotes fertility in these latter species by sealing the vagina and preventing the escape of semen. No useful function of this viscous portion of the ejaculate is evident in swine or horses.

About 50 percent of the volume of semen in the bull and 20 percent in the boar come from the vesicular glands. The prostate gland in the dog and tom provides most of the volume of the ejaculate as in these species the vesicular glands are absent and bulbourethral glands in the tom are fairly small. In the boar the prostate gland is relatively small weighing about 20 gms., compared to the other large accessory glands.

A number of references appear in the literature referring to urethral glands in domestic animals. As indicated previously urethral glands are not present in domestic animals; it is likely that some authors are extrapolating from the human or mistake the disseminate or diffuse portion of the prostate glands around the pelvic urethra for urethral glands. The bulbourethral (Cowper's) glands are relatively small in all species except swine where they provide about 20 percent of the volume of the ejaculate. The clear watery secretions dribbling from the sheath or penis during sexual stimulation in bulls, stallions, and rams are considered to originate from the bulbourethral and possibly the prostate and vesicular glands,^{2,9,12,23} and may assist in clearing and flushing the urethra before ejaculation.

After castration or vasectomy, spermatozoa may be found in small numbers in the ejaculates of stallions, dogs, rams and bulls for up to 21 days, indicating the presence of residual spermatozoa in the ductus deferens and ampullae. In geldings no motile spermatozoa were obtained after 7 or 8 days after castration.³⁰ The numbers of spermatozoa were very low in the ejaculate, 20×10^6 and 40×10^3 in the stallion and dog, respectively. Thus it may be prudent not to allow males to associate with females for 1 to 2 or 3 weeks after castration or vasectomy if pregnancy is to be avoided.²⁶

Erection and Ejaculation

The penis has a twofold function—the expulsion of urine, and the deposition of semen in the genital tract of

the female. Before the latter process can occur the penis must become erect. This is provided for by the erectile structures, the 2 large corpora cavernosa penis and the small corpus cavernosum urethrae (spongiosum) that become distended by blood. In the stallion the cavernous spaces of the corpus spongiosum extend into the glans penis and cause "belling," flowering or great dilation of the glans during erection and ejaculation.^{2,8} Stimulation of the nervi erigentes composed of parasympathetic fibers from the pelvic and sacral nerves results in erection. Erection is accomplished by blood from the internal and external pudendal arteries to the penis and relaxation of the helicine arteries. The cavernous blood sinuses dilate with blood, the outflow of which is retarded or blocked by the contractions of the smooth muscles of the corpora cavernosa and the extrinsic ischiocavernosus and bulbospongiosus muscles at the base of the penis.^{2,1,3,4,5}

The dilation and filling of the bulbous areas of the bovine penile crura under the ischiocavernosus muscle together with 4 or 5 contractions of this muscle "pumps" blood into the corpus cavernosum causing rapid penile erection with the resulting blood pressure peak in the corpus cavernosum penis averaging 14,198 mm of Hg (about 275 pounds per square inch (PSI)), range 8000 to 24,000 mm. of Hg, at the time of coitus and ejaculation in the bull.⁴ Thus if forced ventral angulation or bending of the erect bovine penis at the time of copulation occurs, a dorsal rupture and hematoma may result.² In the stallion the highest peak of pressure in the corpus cavernosum penis was 7,900 mm. of Hg. and the average peak pressure in the corpus spongiosum penis during coitus was 994, range 642 to 1784, mm. of Hg.³ The contractions of the bulbospongiosus muscle at the time of ejaculation forced about 8 waves of blood distally in the corpus spongiosum moving the semen down the urethra.^{2,3} In the buck the corpus cavernosum penis peak pressure during coitus was about 10,000 mm. of Hg and the peak pressure in the corpus spongiosum penis was 750 to 1250 mm. of Hg.¹ Since the high blood pressure in the corpus cavernosum is maintained for only a short period of time, it is suggestive that full erection only persists as long as the ischiocavernosus muscle is contracted and forcing and holding the blood in the penis. The mechanism of the erection in the dog which is aided by the contraction of the vulvar sphincter muscles after intromission¹² has been well-described.^{5,7a} A similar pumping action to that in the bull and buck is noted in the dog and ram.¹² This "pumping" action of the pelvic urethral muscle and the bulbocavernosus muscle causes an intermittent increased blood pressure or wave in the corpus cavernosum spongiosum to compress the urethra to expel semen.

The anatomic structure of the male penis influences

the precoital and coital sexual behavior of the animal.^{7b} The vascular penis in the stallion and dog is slow to erect and foreplay before copulation is essential. The fibro-elastic penis of the bull, ram, and boar, containing much less vascular erectile tissue, erects rapidly and there is less foreplay in these species. The acts of erection and ejaculation are reflex, with the centers being located in the lumbar region of the spinal cord.²⁰ Normally the nervous paths responsible for erection and ejaculation also involve the cerebral cortex of the brain. Erection can take place, however, even if the spinal cord is divided in the thoracic region. Reflex stimulation from the testicles, urethra, prostate, or penis, especially the glans penis, causes erection. Sectioning of the sensory pudendal or dorsal nerve of the penis prevents ejaculation when the glans penis is stimulated. Erection is predominantly under the influence of the parasympathetic system and ejaculation is controlled by the sympathetic system.⁸

Animals such as the stallion, dog, and boar, which ejaculate large amounts of semen have a prolonged period of coitus. The bull, ram and tom ejaculate small amounts of semen and their period of coitus is short. The duration of coitus or copulation in the domestic animals, including erection, mounting, intromission, ejaculation, withdrawal and dismounting is approximately as follows:

Stallion	1 to 3 minutes	Bull	5 to 10 seconds
Boar	4 to 6 minutes	Tom	10 seconds
Dog	5 to 45 minutes	Ram	3 to 5 seconds
		Buck	3 to 5 seconds

Although copulation initiates ejaculation by sensory stimuli from the glans penis, certain stimuli are more important than others in the various species.^{7b} In the bull and ram the warmth of the vagina is most important and pressure and friction less important as stimuli for ejaculation. In the stallion, boar and dog pressure on the penis is relatively more important than temperature.

The non-erect penis of the stallion is about 50 cm. long and 2.5 to 5.0 cm. in diameter and when erect it doubles in length and thickness and the glans penis enlarges 3 to 4 times.² In the bull penile extension from the sheath was about 55 cm. or 22 inches.^{10,11} The interval of time from contact of the glans penis with the vulva to ejaculation averaged 1.0 second. Semen emission time averaged 0.29 seconds. During more than half of the ejaculations by 8 Holstein bulls a twisting of the glans penis was observed ranging from a slight bending to a 360° counterclockwise coil 6 cm. in outside diameter. In the ram the urethral or vermiform process engorges with blood, the urethral dilatation in the base of

the process fills with semen and the semen is forced through the narrow orifice at the end of the urethra under considerable pressure producing a back and forth spraying or "fire hose" effect at the time of ejaculations.⁹ In the boar the corkscrew glans engages in the thick-walled, spiral, transverse ridges of the sow's anterior vagina and cervix that are erect and edematous at estrus. The porcine penis becomes "locked" in the cervix by further erection and dilation of the corpus cavernosum before ejaculation commences.

In the dog two stages of coitus have been described.^{7a} The first stage which lasts several minutes is characterized by intromission without erection, which is made possible by the large os penis, followed by the marked enlargement of the bulbus glandis which is rigidly anchored to the os penis that prevents the withdrawal of the penis from the caudally constricting vestibular structures of the bitch. During this first stage the sperm-rich fraction of the semen is ejaculated. The second stage of coitus lasting 5 to 45 minutes is characterized by the male dismounting and facing in the opposite direction from that of the bitch. This results in an 180° bending of the penis in the middle of its body caudal to the os penis. This act delays detumescence by causing venous occlusion. The major portion of the seminal volume is ejaculated during this stage into the "closed" vagina. This may possibly assist in forcing the semen cranially into the uterus. Human restraint to impose the first stage posture during the entire act may result in reduced fertility.^{7a}

The process of ejaculation starts in the epididymis and travels along the ductus deferens. At the same time the walls of the accessory glands contract and force their contents into the urethra. Sexual stimulation in the bull and possibly males of other species may involve oxytocin release as an increased volume and total number of spermatozoa of the ejaculate followed oxytocin injection.⁶ It would seem logical that oxytocin might be involved in the transport of semen in the epididymal tail and the ductus deferens. The urethra is emptied by the rhythmic contractions of the urethral, ischiocavernosus, and bulbocavernosus muscles.²⁰ The stallion, for example, requires about 10 seconds for complete ejaculation, and about 10 pulsations of the urethra occur approximately a second apart.

Semen and the Ejaculate

Semen or sperm is the entire seminal discharge of the male during normal ejaculation. It consists of cellular elements, or spermatozoa produced in the seminiferous tubules, and seminal plasma or the liquid portion of the

Semen produced by secretions of the seminiferous tubules, epididymis, ducti deferentes, and ampullae, vesicular, prostate, and bulbourethral glands. Sperm cells constitute about 10 percent of bull semen by volume. Two to 5 percent of boar semen is made up of spermatozoa and epididymal secretions. The amount of semen and concentration of spermatozoa varies greatly between species and individuals. (See Table 23.) In species having photoperiodic breeding and nonbreeding seasons variations in semen volume, concentration of spermatozoa, testosterone and LH plasma concentrations and libido occurred between these seasons.^{14,33} Environmental influences had little or no effect on semen output in AI bulls.¹¹ By "teasing" bulls before service the amount of semen and the numbers of spermatozoa per ejaculate can be increased.^{15b} In stallions such "teasing" may increase semen volume but does not increase spermatozoan numbers.^{23b} Some bulls producing a small volume of semen with a low total number of sperm cells in either collection with the artificial vagina or electroejaculation

may produce larger ejaculates with much greater sperm cell numbers if given 50 to 100 units of oxytocin intramuscularly 5 to 10 minutes before collection.

Frequent ejaculation reduces the amount of semen and the concentration of spermatozoa and if carried to extremes, as in depletion or exhaustion trials, marked reductions may occur. These trials have been used extensively as a method of estimating sperm reserves in the live animal. In 44 depletion trials in 21 adult bulls where 20 consecutive ejaculations were collected in an artificial vagina from each bull within 1-1/2 to 7 hours, the average volume of semen declined from 4.2 ml. to 2.1 ml. between the first and twentieth ejaculate. The concentration of spermatozoa decreased from 1.35 billions per ml. to 0.3 billions per ml. and the total average number of spermatozoa per ejaculate decreased from 5.8 billion to 0.65 billion. Except for a slight reduction in semen volume, semen characteristics including concentration of sperm cells had returned to normal within 7 days.⁵ Weekly output of spermatozoa was increased 112 percent in 10

Table 23. Semen Characteristics in Domestic Animals

Semen Constituent	Bull	Stallion	Ram (Buck)	Boar	Dog	Tom
Volume (ml)	4* (1-15)**	70 (30-250)	1 (0.7-3.0)	250 (125-500)	10 (1.0-25.0)	0.04 (0.01-0.12)
Spermatozoan Concentration (millions/ml)	1200 (300-2500)	120 (30-600)	3000 (1000-6000)	150 (25-1000)	125 (20-540)	1730 (96-3740)
pH	6.8 (6.2-7.5)	7.4 (7.0-7.8)	6.8 (6.2-7.0)	7.4 (7.0-7.8)	6.7 (6.0-6.8)	7.4
Total Spermatozoa per Ejaculum (billions) (Approx.)	4.8	8.4	3.0	37.5	1.25	0.057
Fructose (mg/100 ml)	530 (150-900)	2 (0-6)	250	13 (3-50)	0	—
Glycerolphosphorylcholine (mg/100 ml)	350 (100-500)	— (40-120)	1650 (1100-2100)	— (110-240)	180 (110-240)	—
Potassium (mg/100 ml)	140 (80-210)	60	90 (50-140)	240 (80-380)	—	—
Sodium (mg/100ml)	230 (140-280)	70	190 (120-250)	650 (290-850)	90 (50-124)	—
Phosphorus (Total in mg)	80	17	375	66	13	—
Citric Acid (mg/100 ml)	700 (300-1100)	25 (8-60)	140 (110-260)	80 (60-100)	Trace	—
Inositol (mg/100 ml)	35 (25-46)	30 (20-47)	12 (7-14)	530 (380-630)	—	—
Sorbitol (mg/100 ml)	— (10-140)	40 (20-60)	92 (76-120)	12 (6-18)	0	—
Ergothionine	0	(40-110)	0	(6-23)	—	—

Other substances found in seminal plasma include calcium, magnesium, chloride, carbon dioxide, proteins (1-7 gms/100 ml), amino acids (cattle and sheep), lipids, urea, uric acid, lactic acid, ascorbic acid, phosphatase, muco-proteins, fatty acids, vitamins (riboflavin), peptides, other enzymes, hormones, and water (85-98%), * = average, ** () = Range.

bulls by collecting six ejaculates per week instead of two. Bovine semen collected daily showed no difference in ability to store or freeze, fertility, abnormalities of spermatozoa, motility, or pH from semen of bulls collected only once weekly.^{16,17} The volume of semen, concentration of spermatozoa, percent motility and total spermatozoa per ejaculate for bulls collected one time per week vs bulls collected 6 times per week were 9.5 vs 6.2 ml., 1.9 vs 0.8 billion/ml., 63 vs 69 percent and 17.8 billion vs 4.8 billion per ejaculate, respectively. Deficiencies in the quality of semen of abnormal bulls may be revealed by a high frequency of collection but are not caused by a high frequency of collection.^{3,4,5} Semen characteristics were most severely affected by a high frequency of ejaculation in young immature bulls and with sexual rest they took longer to return to normal.³⁴

A study of 350 beef bulls and 870 dairy bulls from 1958 to 1966 indicated that beef bulls comprised a different "population" than dairy bulls.¹⁰ Beef bulls had lower sperm cell production, lower post-freeze motility and higher numbers of abnormal sperm cells (50 percent of beef bulls had above 10 percent abnormal cells). Beef bulls reached puberty one to three months later, and their libido was generally lower than dairy bulls. The period of recovery after ejaculation was not evident in beef bulls as in dairy bulls. Once a beef bull was sexually stimulated 4 or 5 successive ejaculates could be collected in nearly the same time as required to obtain the first ejaculate. Sexual preparation did not significantly increase sperm cell output in the following ejaculate in beef bulls.¹¹

A stallion performed 12 normal services or covers within 72 hours. Two days previously he had ejaculated 50 ml. of semen containing 8 billion spermatozoa. On the twelfth ejaculate 90 ml. of semen containing 4 billion spermatozoa were delivered.¹⁸ In a recent depletion trial in which 5 ejaculates were collected at hourly intervals from 2 to 3 year-old, 4 to 6 year-old and 9 to 16 year-old stallions the sperm cell numbers per ejaculate declined from 4.5, 9.5 and 11.4 billion to 0.5, 1.1 and 1.2 billion respectively in the first and fifth ejaculate.^{14,33} In depletion trials with stallions an average of 20.8 billion spermatozoa were obtained in each trial. After one day of sexual rest 11.8 billion of spermatozoa were obtained in a second depletion trial. With 5 days of sexual rest after the first depletion trial 25.7 billion spermatozoa were collected. Only 2 to 4 collections could be made in each depletion trial with stallions due to a lack of libido.^{8b} Stallions ejaculated daily during the breeding seasons produce about 5 billion spermatozoa per day.

In an exhaustion test a ram ejaculated 42 times in 9 hours and still delivered a total 100 million spermatozoa in the last ejaculate.²⁴

In dogs libido remained high with one to two ejaculations per day. The total sperm cell count per ejaculate dropped from 580 and 548 million in dogs collected 2 and 3 times per week to 286 million and 147 million in dogs collected daily or twice daily, respectively. The total number of spermatozoa per ejaculate returned to normal after 2 to 3 days of sexual rest.⁹

In boars collected once every 4 days and once a day for 20 days the average ejaculate volume dropped from 286 to 193 ml., the sperm cell concentration from 275 to 143 million per ml. and total average daily sperm cell numbers from 55 to 24 billion. No changes were noted in percent motility, percent abnormalities, or pH in the same boars on the two frequencies of ejaculation.¹⁵ There may be a great variation between males in the same species in respect to their ability to copulate frequently and produce a satisfactory ejaculate. (See Table 23.)

In the pig, horse and dog the seminal plasma placed in the uterus during coitus is in contact with the spermatozoa for a period of time in the uterine lumen before some of the latter enter the tubes. While in man, cattle, cats and sheep the sperm cells are in contact with the seminal plasma in the vagina, after ejaculation a relatively shorter period of time before the cells migrate into the cervical canal. In all animals however the seminal plasma is not necessary for sperm cell metabolism or prolonged survival in the female genital tract. The possible role of seminal plasma in the various species has been reviewed.²⁵

Fructose is the normal sugar providing a source of energy for spermatozoa in the semen of the bull, ram and buck, but is low in the boar, very low in the stallion and absent in the dog. It is produced mainly by the vesicular glands. The rate of fructolysis in semen is generally correlated with the concentration of spermatozoa. It is also related to the availability of oxygen and the buffering capacity of the seminal fluid. Spermatozoa can utilize glucose for energy as well as or better than fructose. Sorbitol is a sugar alcohol that can be oxidized to fructose and provide a source of energy. Lactic acid in semen increases as fructose is broken down and may reach levels in the bull and ram where it immobilizes the spermatozoa. The metabolism of sperm cells is characterized by appreciable respiratory activity. Glycerol when added to semen protects spermatozoa during the freezing process but is not readily oxidized by the cells. Of the amino acids in seminal fluid, glycine has been shown to improve sperm cell survival. Glycerylphosphorylcholine is present in high levels in epididymal secretions. By means of a compartmental analysis model in bulls, the mean volume contributions to the ejaculate were 32 to 38 percent (1.5 to 2.0 ml.) from the vesicular glands, 31 to 36

percent (1.7 ml.) from the epididymides, and 31 to 32 percent (1.5 to 1.7 ml.) from the prostate and bulbourethral glands.²⁹

Inositol from the vesicular glands occurs in a high concentration in boar semen where it may act as an osmotic pressure regulator. Ergothionine, a sulphhydryl-containing compound from the vesicular glands, occurs in appreciable amounts in boar and stallion semen. An antiagglutinin that prevents the head to head agglutination of spermatozoa is also found in the seminal plasma. Dog semen contained 7 times as much copper and 20 times as much zinc as corresponding blood samples.⁷ Catalase has been found at low levels in bull and ram semen, 0.3 to 1.1 units per ml., and its addition to bull semen prolonged sperm cell survival by preventing the formation of hydrogen peroxide.¹³

The sticky, gelatinous, tapioca-like material secreted from the bulbourethral glands in the boar make up about 20 to 30 percent of the total porcine ejaculate,³² and may act to help seal the cervix to prevent a backflow of semen during or after ejaculation. In stallions this heavy, glairy, gelatinous substance is uncommon in light Thoroughbred horses but may be present in certain individuals or certain ejaculates in amounts of 30 to 50 percent or more of the total ejaculate.

Most male animals have a low level, below 100 ng/ml. of prostaglandins in the seminal plasma. While the ram, buck and man have higher levels. Their function, if any, has not been determined. Possibly their effect on the smooth muscle of the female reproductive tract may aid the transport of spermatozoa.^{8,8,25}

Ram and bull semen which have a high concentration of spermatozoa are opaque white in color with a creamy consistency. The boar, stallion and dog semen which have a much lower concentration of sperm cells have a pearly white to grey translucent color with a more watery consistency. The difference between species in the volume of semen is largely due to the amount of secretion from the accessory glands.

Coitus and ejaculation are long in the boar and dog, moderately long in the horse, and very short in the bull, ram and buck. In the boar and the dog most of the "sperm-rich" fraction of the semen is ejaculated the first 3 to 6 minutes of coitus. In boars there may be several episodes during the long ejaculation characterized by the passage of "sperm-rich" fluid in between the longer periods in which gelatinous and "sperm-poor" fractions are emitted. The ejaculate of all domestic animals can be divided roughly into 3 portions. The first is a sperm-free, clear, watery secretion probably from the diffuse portion of the prostate or possibly the bulbourethral glands or vesicular glands that may often be observed in some animals in

the precopulatory period of sexual arousal. This is followed by the relatively short period of the emptying of the ampullae of the ducti deferentes and the urethra by the sperm-rich fraction. The third phase or portion of ejaculation is much longer and composed mainly of sperm-poor seminal plasma from the accessory glands. This latter portion in the boar and stallion contains the gelatinous material. In the stallion the last part of this third portion of the ejaculate is spoken of as the "tail end" or "dismount" sample. It is not representative of the entire ejaculate in the horse or in other species. This last phase of ejaculation comprises about 40 to 60 percent or more of the entire volume of the ejaculate. In the bull the pre-sperm fraction is low in fructose and the sperm-rich and post-sperm fractions have a high fructose content indicating admixture with the secretions of the vesicular glands.¹²

Frequency of Service—Since spermatozoan production is a continuous process not affected by frequency of ejaculation, theoretically there should be no limit to the number of services. There are, however, limitations in all males to the number of services possible within a given time. (See Table 24.) As noted previously, frequent repeated ejaculations over a relatively short period of time tend to cause a reduction in sexual desire, semen volume, and number of spermatozoa per ejaculate. Young or immature males should be used conservatively inasmuch as the decline in semen quality is probably more easily produced and undesirable behavior associated with decreased sexual desire might develop.

Each male should be handled, observed, and bred as an individual. In young males a certain degree of size must be attained before coitus can be performed with physical safety. Establishing proper breeding habits in male animals and not permitting these habits to develop in a haphazard fashion is highly important.²⁴ The frustration of small, immature males following unsuccessful attempts to copulate with females that are too large, are improperly restrained, or in an unsuitable location, conditions which may result in slipping and falling, or in head injuries because of a low ceiling, may produce both physical and psychological injury. Both may have a prolonged effect on a sire's attitude toward service. Some males develop sexual desire slowly. Proper development of breeding habits in a male is just as important as training a heifer to milk or a horse to ride. Patience, understanding and avoiding overuse or harmful experiences are necessary for the young male.

In male animals offered frequent opportunities for copulation, libido usually declines before the quality of the ejaculate is lowered to a degree that would affect fertility. In 16 bulls and 8 rams under natural mating

Table 24. Approximate Guide to the Frequency of Service and the Number of Females Allotted to Male Domestic Animals*

Species	Immature Males Hand Breeding		Mature Males Hand Breeding	
	No. of Services/week	No. of Females per Season (year)	No. of Services/week	No. of Females per Season (year)
Stallion	2-5	15-40	3-12	30-120
Bull	2-4	20-60	4-12	80-120
Boar	2-4	10-40	4-10	30-60
Dog	1-2	(20-40)	2-6	30-80
Ram (Buck)	6-12	(30-40)	6-24	40-80

Pasture Breeding		Pasture Breeding	
(No. of Females) per season (year)		(No. of Females) per season (year)	
Bull	10-15	10-25**	
Boar	10-20	20-40	
Ram (Buck)	20-30	40-80***	

*This guide will vary greatly for individual males according to their fertility, sperm producing capacity, degree of libido, age and physical condition. It will also be influenced by systems of management, size of pasture or range and nutrition of the sire and dam. Frequent short periods of sexual rest are desirable.

**This figure is for range cattle with a limited breeding season. For dairy cattle on improved pasture with a year-long breeding season this figure could be increased 3 or 4 times.

***Vigorous yearling to adult rams may breed up to 30 to 40 ewes per month; 3 to 8 percent of goat flocks should be bucks.

conditions, the bulls bred each estrous female an average of 1.73 times with the greatest number of services in a day being 10; in rams these respective figures were 4.03 and 29.³¹ In several matings with one female, libido declined in bulls and rams but finding another female in estrus rapidly restored their sexual drive. Collecting ejaculates 6 × weekly from 1 to 7 years of age greatly increased sperm harvest in AI bulls without harming the bulls' growth, reproductive capacity or fertility.³

The average optimum weekly frequency of semen collection to maintain libido and to secure the greatest number of spermatozoa were as follows: for the bull 4 ejaculations and 30 billion spermatozoa, for the stallion 3 to 4 and 30 billion, for the ram 20 and 25 billion, for the boar 3 and 110 billion, and for the dog 3 ejaculations and 2 billion spermatozoa, respectively.¹⁴ In mature bulls properly stimulated, two ejaculates collected twice per week (4 ejaculates/week) produced over 15 to 18 billion spermatozoa and was a practical procedure in AI studs.

Coital Injuries in Male Animals

Balanitis and posthitis of a severe nature frequently leading to adhesions and inability to protrude or retract the penis are occasionally observed in bulls, especially young bulls with great sexual desire the first few weeks on pasture with cows or heifers. Trauma and infection incurred by frequent service and contamination of the

sheath or by exposure to the IBR-IPV virus in the cows' genital tract may result in severe necrotic and pyogenic infections of the penis and prepuce. Young rams may be similarly affected. This type of infection involving the penis and prepuce will be discussed later in this Chapter.

Injury or Trauma to the Penis—In rare instances in the stallion this may be due to the mare kicking at the stallion and striking the erect penis at the time of service. This may cause a hematoma, paraphimosis, laceration, or rupture of the penis. It is easily avoided by the proper supervision of breeding and by being certain that the mare is definitely in estrus. If necessary breeding hobbles or artificial insemination should be used in nervous, excitable mares. In the bull, occasionally the penis catches on the vulvar lips, in a hymenal remnant, beneath the vulva, or when the bull thrusts and the penis is bent sharply at right angles by the cow suddenly collapsing, a rupture of corpus cavernosum and tunica albuginea or vessels, usually on the dorsal surface of the penis occurs opposite the attachment of the retractor penis muscle. A hematoma is thus produced. This is often spoken of as a "fractured," "ruptured," or "broken" penis. This condition is rare in handbred dairy bulls but is not uncommon in beef bulls on pasture. The diagnosis and treatment of these penile injuries and lesions will be discussed later in this Chapter.

Hemorrhage from the Prepuce and Penis following service may be due to tumors of the penis or to lacerations of the penis or prepuce. In rare instances bleeding

from the urethra may be observed in stallions and bulls. It is usually of unknown origin. Lacerations of distal portion of the boar's penis is not uncommon. It is usually due to bite wounds inflicted by other boars or sows during breeding. Some of these injuries may require local wound therapy but most injuries recover without treatment.^{3b} Several affected boars have had a small vascular outgrowth or polyp in the urethra, that caused blood to be mixed with semen at ejaculation.¹ In several bulls observed by the author irregular-shaped calculi have lodged in the urethra and caused bleeding at the time of service but for a while only slight or moderate symptoms of difficult urination were observed. In young bulls there may occasionally be a small fistula in the glans penis extending into the corpus spongiosum cavernosum. On erection a fine stream of blood comes through the fistula. Some veterinarians have described the presence on the glans penis of blue-red raised areas or ulcers that rupture and bleed. In artificial breeding, rubber bands from the artificial vagina may slip over the penis at the time the bull thrusts. These usually cause deep lacerations or even amputation of all or part of the glans penis if they are not removed promptly. Such an occurrence may be prevented by not using rubber bands on the artificial vagina, or by tying them with cord so they cannot slip off. Occasionally persons trimming preputial hairs on bulls will snip off the tip of the penis if care is not taken to hold the penis caudal to the preputial orifice. Bleeding from the urethra in dogs is frequently a symptom of fracture of the os penis.²

Tumors should be removed. Sexual rest should be given most animals with hemorrhage from the prepuce and penis. In cases of urinary calculi the prognosis is often hopeless for future breeding. When bleeding occurs from the corpus through a fine fistula, sexual rest or surgery to close the defect are indicated. In young bulls observed by the author which bled from a fine fistula or ulcer on the glans penis the fertility of the bulls when bred naturally did not appear affected. Successful incision of the urethra of a few boars and removal of the vascular tissue causing the bleeding has been reported.¹

Miscellaneous injuries at the time of coitus in the stallion may include kick injuries resulting in a ventral hernia, fracture of the hind limbs, or severe orchitis. Breeding hobbles, tying up a front leg and a twitch applied to the mare may be indicated to prevent kicking. Application of heavily padded boots to the mares rear hooves has been used. In all breeds of animals especially the larger ones, the footing of the male should be good and the female restrained properly to prevent the male's slipping and falling, possibly causing gonitis, seen most commonly in the bull; dislocation of the hip; fractures

of the limb or pelvis; fractures of the spine; muscle or tendon strains or ruptures; as well as the harmful psychological effect on the male from falling or injuring himself during coitus. Large females should not be bred naturally to small males unless restrained with their rear limbs or all four limbs in a hole or pit. Occasionally inguinal hernia with strangulation of the intestine may follow service in stallions and cause severe colic within 1 to 3 hours. The author has observed 2 improperly-handled young bulls that fractured the humerus by dismounting from a cow sideways, with the affected front leg caught across the cow's back.

Hemospermia in male animals may be caused by penile lesions or fistulas, urethritis, urethral strictures, and vascular lesions in the mucosa, secondary to infections or injury including stallion rings, lacerations or habronemiasis of the urethral process, strongyle larvae or infectious processes in the accessory glands and urinary calculi.^{1,6a,b} After a diagnosis has been reached, following a careful, complete examination utilizing visual, endoscopic, cultural, radiographic examinations of the urogenital organs, adequate, conservative, possibly surgical treatment, along with sexual rest is indicated. Blood cells in the ejaculate is often associated with low fertility.⁶

Vices of Male Animals

Vices are much more common in male animals, especially in the larger species, than in female animals because many males are improperly handled or abused, closely housed or confined in dark, poor quarters, lack exercise, sunlight, normal surroundings, and associations provided female or other castrated animals. Intact mature males are more aggressive than castrated males or females. Behavioral disorders in male animals are often related to or affect the sex act and may reduce copulatory efficiency. Androgens acting during the early period of differentiation organize neural tissue which mediates later sexual behavior in the male. The time this period occurs in the larger animals is not known but in rats it occurs within 5 or 6 days after birth.

Masturbation or Onanism is observed in male animals of all species. There is little or no evidence that it has any significant effect on fertility or even on libido or desire to copulate. If males are being used regularly and frequently for service the frequency of masturbation declines.

In stallions being raced it is considered to have a detrimental effect on training. Some persons consider accumulations of smegma in the sheath cause irritation and masturbation in stallions and therefore advise regular cleansing of the sheath with soap and water. Regular ex-

ercise under harness or saddle, in a large outside paddock away from nonpregnant females or by providing "company" in the form of pregnant mares will help control masturbation. Owners or veterinarians may also use a stallion (Man-of-War) shield or wire brush suspended just in front of the preputial opening, a metal ("bird-cage") device over the glans or a plastic or adhesive tape ring applied just behind the glans penis to prevent erection and masturbation. These latter ring-like appliances must be removed and penis cleaned once a week and before service or irritation may occur. It is the author's observation that erection is common in the confined stallion but masturbation with ejaculation of spermatozoa is uncommon. He agrees with other authors⁷ that stallion rings are cruel and of questionable value in preventing the loss of spermatozoa. They may be the cause of urethral hemorrhoids and hemospermia. Masturbation as a cause of loss of libido is rare.

In other animals regular exercise in a large outside paddock helps greatly to avoid masturbation. In bulls, rams, bucks or dogs a suture of stainless steel wire tied loosely through and across the preputial orifice may be of value. In the pet dog not used for breeding, castration can be performed. Boars may masturbate by inserting their penis into the preputial diverticulum and ejaculating there, resulting in a condition called "balling up." Once this vice has developed it can only be corrected by the surgical removal of the diverticulum.¹ Young boars in artificial insemination studs should be kept isolated in separate pens to prevent **pederasty** or rectal "copulation" which is common in this species.⁵ It may occur occasionally in young bulls or rams running together.

Viciousness in Males is often a result of confinement and ill treatment. Dairy bulls are usually confined and are much more apt to be dangerous than are beef bulls, that have freedom to run with the herd. Proper, intelligent handling of male animals from a young age, together with regular daily handling, firm training, and exercise makes most males fairly tractable and easily controlled. Since the larger intact male animals are usually closely confined and caretakers are often afraid of them they are very apt to be teased, irritated and handled indecisively which tends to encourage viciousness. Once a male of a large animal species has become vicious and difficult to manage and this vice is well-developed it is a very difficult, dangerous, and often an impossible task to correct these habits without elaborate facilities and intelligent, trained help. Not infrequently following castration a formerly vicious stallion will retain his same disposition unless he is retrained. In this respect the vicious stallion is similar to the vicious "nymphomaniac" mare.

Slowness in Breeding is often an acquired vice in male domestic animals that is favored by improper training, rough or ill treatment or painful accidents that have occurred at the time of copulation. This is discussed much more fully later in the section on impotency under forms of infertility in the male. Many male animals develop idiosyncrasies exhibited at the time of mating that usually have their origin in various restraint practices employed by owners prior to permitting service by the male.

Other vices seen commonly in stallions as a result of close, unnatural confinement are stall-walking, weaving, cribbing and self-biting or mutilation. Stall walking may possibly be controlled by regular exercise, closing the stall tightly, hobbling, or tying the animal, by placing bales of straw around the stall or by putting the stallion in a large outside paddock or pasture. Cribbing should be controlled by a cribbing strap or by radical surgery. Weaving is difficult to correct, but proper exercise, a large and well-lighted box stall, or an outside paddock may be helpful. Using a cradle, a pole between the halter and a surcingle, or a muzzle may be indicated in self-biting stallions if proper exercise and management can't control the vice.

Nutrition and Infertility in the Male

The nutritional requirements of males are similar to those of nonpregnant females. On the basis of our present knowledge, the qualitative and quantitative requirements for reproduction in the male do not exceed those for the growth of young animals or for the maintenance of mature animals in a state of good health. In bulls, rams, and boars rations that are satisfactory for normal growth to 3 years of age are normal for reproduction.¹¹ The requirements for pregnant, and especially lactating, animals are higher than for the male. In large animals the ration should include good quality roughage. The value of good pasture cannot be over-emphasized. The ration should be properly balanced in carbohydrates, protein, and minerals and supply the vitamins known to be essential for good reproduction. Although numerous attempts have been made to formulate rations that will increase spermatozoan production and semen quality, it still appears that there are no specific nutrients concerned only with fertility.¹² In few fields are there more opinions with less supporting evidence than in the field of infertility.¹¹ A definite deficiency of any single nutrient is seldom found. Natural-occurring deficiencies are usually multiple. The breeding male should be kept in good physical condition and should not be permitted to become overweight. A severe deficiency in nutrients affects the testes in a manner similar to ischemia, hypoxia and hypoglycemia and results in a chronic degeneration of the seminiferous tubules.^{13b}

A low plane of nutrition is frequently encountered in practice. As physical deterioration progresses into inanition in the male there occurs an atrophy of the testes, a decrease in the number of spermatozoa per ejaculate,

and a progressive loss of sexual desire. Delayed puberty will occur when there is a low plane of nutrition in the young male animal.^{2,4} Underfeeding during the growth period had a limiting effect on sperm cell production at maturity in bulls.¹⁵ Thus a low plane of nutrition may adversely affect reproductive functions in the male but severe effects on reproduction are not observed unless emaciation and inanition are marked.

A high plane of nutrition is frequently cited as a cause of infertility, especially in fat, overfed, obese, show animals. There is no experimental evidence that a high level of feeding and body condition has any effect on semen production. Fertile rams fitted for show continued to be fertile even though in a very high state of nutrition.⁸ Obesity did not increase rectal or scrotal temperatures or cause any degenerative changes in the testes. Some authors have suggested that certain male animals develop excessive fatness because of an endocrine disturbance such as hypothyroidism, that predisposes the male to infertility. This is possible but it has not been proven. Phlegmatic, lazy bulls tend to put on excessive weight. Rearing intensity did not affect a bull's mating behavior.¹

High body condition may result in slowness, difficulty or inability to copulate because of paunchiness, laziness, weaknesses in legs and feet and a lack of sexual desire in some males but this is not associated with defective spermatogenesis.⁴ Excessively fat bulls may possibly have enough fat around the testes in the scrotum, especially the dorsal part, to insulate the testes and affect spermatogenesis but this has not been proven. Some very fat beef bulls are highly fertile. In some bulls excessive fat in and above the scrotum may be confused with an inguinal hernia. When the obesity in these males is corrected by limited feeding and increased exercise the inguinal fat is slow to disappear. Therefore high energy intakes are not desirable for bulls past the stage of rapid growth but moderately heavy early feeding may promote early semen production by hastening the onset of puberty.

Feed Constituents. Under the usual conditions of management the possibility of deficiency in either the quality or quantity of protein fed to males seems remote. When the protein in the ration was below 2 percent, low feed intakes, loss of weight, weakness and reduced libido and sperm cell production occurred in rams and bulls.^{9,16} Urea was satisfactory as source of protein in ruminant male animals. Although some veterinarians have recommended feeding animal protein such as skim milk, fish meal, turkey mash, or other high-quality protein pellets, there is no evidence that it is necessary, providing adequate grain and good roughage are available.

Vitamin deficiencies are seldom observed as a cause of infertility in the larger male domestic animals if the roughage in the ration is near normal in quality or quantity. Vitamin A deficiency, if severe and characterized by night blindness and stiffness, may cause cessation of spermatogenesis and atrophy of the seminiferous epithelium and a decline in semen quality as well as a decrease in sexual desire. In young bulls vitamin A deficiency may result in cystic pituitary glands.^{3,5,13b} Thirty-five to 100 micrograms of vitamin A per kilogram of body weight daily is ample for reproduction in bulls.¹¹ There is little evidence that deficiencies of vitamins B, C, D, or E are even occasional causes of infertility. Although vitamin E is essential for reproduction in the rat there is no proof or indication that it is necessary for reproduction in domestic animals.^{13b}

Mineral deficiencies affecting reproduction in male animals are rare. Deficiencies of calcium, manganese, zinc, iodine, potassium and selenium have not been proven to be causes of male infertility.^{10,13b} Deficiencies of cobalt, iron, zinc and copper may cause anemia, lack of appetite and loss of weight, and thus have an adverse influence on male reproduction. These trace minerals, especially zinc which is high in concentration in ejaculates of animals, are essential constituents of enzymes.^{13b} A lack of phosphorus, often associated with a lack of protein and low levels of vitamin A under natural conditions may cause reduced appetite, a loss in condition and reduced reproductive function. Osteopetrosis with accompanying spondylitis and arthritis in the bull may result from ultimobranial body hyperplasia or neoplasia caused by excessive dietary calcium.^{6,7} Arthritis and spondylitis may cause hesitancy or refusal to copulate. High dietary calcium levels may be caused by feeding alfalfa or clover hay and dairy grain rations fortified with minerals needed by lactating cows but not by bulls.

Most reproductive disturbances related to nutrition are caused by underfeeding. If the males is fed a normal balanced ration that will produce normal growth or maintain normal health, reproduction will not suffer because of nutritional deficiencies. In some areas owners feed special fortified rations to breeding males. These special fortified rations have added amounts of various types of protein, vitamins, especially vitamin A and beta-carotene, manganese, cobalt, phosphorus and other minerals that when fed amply supply their supposed needs for a high level of reproduction. The necessity or value of these feeds is highly questionable.

Along with proper nutrition and adequate water and salt, factors such as exercise, sunlight, pasture, and other environmental influences, including parasite control and routine vaccinations, play an important role in maintain-

ing the health and activity of the breeding male and in prolonging his usefulness.

Hormonal Causes of Infertility and Related Syndromes in Males

In male animals there is no infertility condition due to a hormonal cause that uniformly responds to endocrine therapy. Therefore hormonal treatments for lowered fertility or impotency are usually disappointing and of questionable value.

A lack of sexual desire or libido and reduced spermatogenesis with testicular atrophy may be caused by a failure of ICSH, LH and FSH to be released from the anterior pituitary gland by factors originating in the hypothalamus. There are many "stress" factors, the most important one being inanition due to a low plane of nutrition, that may cause this failure. In rare cases, especially in dogs, tumors in the pituitary area may cause atrophy of the pituitary gland and failure of gonadotropin production. More satisfactory response to treatment will follow a correct diagnosis of the cause or causes of a lack of libido or reduced spermatogenesis than the use of gonadotropic hormones in an empirical manner. Because of their protein constitution animals become refractory to repeated doses of gonadotropic hormones. Successful results following their use is usually fortuitous and can usually be explained by other therapeutic or management practices.

If the pituitary gland is functioning normally and releasing ICSH, failure of libido is seldom caused by a lack of testosterone produced in the interstitial cells of the testes. Occasionally in young males, testosterone injections may hasten sexual maturity and improve sex drive. Even abdominal cryptorchid testes produce normal amounts of testosterone. Rarely Sertoli cell tumors in dogs and other males may produce sufficient estrogen to suppress the release of ICSH and cause impotency. Testosterone has been used empirically in bulls with abnormalities of spermiogenesis or evidence of an abnormal environment in the storage of sperm cells in the epididymis. As with gonadotropins; testosterone is seldom successful in the treatment of a lack of sex drive in adult intact males. Thyroidectomy in bulls and stallions resulted in lethargy and mild signs of impotency.^{8,9} Hypothyroidism may be present in some obese, lethargic males. Hypothyroidism in male animals has not been proven but a few fat males fed iodinated casein or injected with thyroid hormone have lost weight and become more alert with an improvement in libido. Thyroxine therapy has little or no effect on spermatogenesis and is not uniformly or highly successful in males lacking sexual desire.

Some bulls with low fertility have fascicular cortical nodules in the adrenal that apparently convert progesterone into large amounts of cortisol.³ This results in a high concentration of spermatozoa and a low fructose concentration in the semen.

Cryptorchidism is considered to be an inherited defect resulting in a failure of the fetal or neonatal testes to descend into the scrotum. The male is usually castrated or slaughtered. In humans cryptorchidism has been treated before puberty by gonadotropins or testosterone with very limited success. Most attempts to use hormones to induce descent of the testis have failed.¹

As discussed previously in this Chapter, testosterone is released from the interstitial cells of the testis in a pulsatile or episodic manner about 7 or 8 times a day under the stimulation of LH (ICSH) released from the anterior pituitary gland by GnRH from the hypothalamus. For this reason the plasma concentrations of testosterone vary in stallions during the day from 65 to 1600 pg/ml.² Geldings have a level basal concentration of plasma testosterone of about 12 to 20 pg/ml. The injection of HCG, 10,000 IU, into a gelding has only very slight effect on plasma testosterone concentration. If HCG is injected into a stallion or cryptorchid ("rig") or a male that has one or both testes retained in the inguinal canal or abdominal cavity, the plasma testosterone concentration rises within one-half hour to 290 to 3750 pg/ml., average 1450 pg/ml.² This dramatic prompt rise in plasma testosterone concentration in the true "rig" or cryptorchid horse either one-half to one hour after the injection of HCG, demonstrated by pre- and post injection blood samples, is an excellent diagnostic procedure to conduct on horses that have no observable testes yet have strong male behavior. This test may also be supplemented by determining the plasma concentration of estrogen which is elevated in the stallion and equine cryptorchid due to the presence of sertoli cells that secrete estrogen. HCG injection however has little effect on the plasma estrogen concentration. Estradiol concentration in the plasma of stallions and geldings was 30 to 60 and 5 to 10 pg/ml, respectively.¹⁶

Treatment of stallions with 200 mg of testosterone propionate IM every other day for 88 days or with anabolic steroids, boldenone undecylate, 1.1 to 4.4 mg/kg or nandrolone decanoate, 1.1 mg/kg IM every three weeks for 15 weeks caused a decrease in spermatozoal concentration and motility, a decrease in total sperm per ejaculate and a reduction in scrotal width and testicular size as well as a depression in the plasma LH concentration.^{13,14,15} These treatments had no effect on sexual behavior, libido, or seminal volume or character. Even though these adverse effects were reversible and normal reproductive parameters returned by 90 days after cessation of treatment, testosterone or anabolic steroid ther-

apy is contraindicated in stallions.^{13,14,15} Libido and ability to ejaculate were gradually lost after castration of stallions. Testosterone restored both these aspects of sexual behavior. Estradiol at a high dosage restored libido however the ability to ejaculate was impaired in geldings.¹⁶

Prostatic hyperplasia in old male dogs is due to excess testosterone produced by the testes and can be alleviated to some extent by injections of estrogens. A more satisfactory method is castration, which removes the source of testosterone in the body. Prostatectomy is difficult and only seldom performed in dogs. Estrogenic therapy is often temporarily successful because it inhibits secretion of the gonadotropic hormone FSH and LH, from the pituitary gland necessary for androgen production from the interstitial cells in the testes resulting in atrophy of the prostate gland. No function has been ascribed to oxytocin in the male but it is most likely concerned with sperm transport and ejaculation. The oxytocin levels in the plasma of men and women are similar.¹²

Zearalenone, an estrogenic mycotoxin, from moldy corn, besides producing effects in the female pig previously discussed, caused reduced libido and depressed plasma testosterone and LH concentrations in young prepubertal and pubertal boars.¹ At the level of zearalenone fed to the treated boars no adverse effects on body or testis size or sperm production was noted even though sexual behavior was delayed.¹

Castration of male animals greatly reduces intermale aggression, and male sexual behavior including mounting, and in dogs and toms reduces urine marking or spraying, and objectionable roaming. In bucks and boars castration eliminates the male sex pheromone odor which is testosterone dependent. Progesterone therapy will frequently improve patterns of problem behavior in castrated or intact males and spayed females. Long-term therapy in males and females, especially the latter should be avoided because of possible side-effects such as mammary tumors or metritis.⁴ The doses recommended for dogs and cats are 2.2 to 11 mg/kg of medroxyprogesterone acetate (**Depo-Provera**) IM or SC or 0.5 to 1.0 mg/kg of megestrol acetate (**Ovaban**) orally. About 50 percent of behavioral problems improve significantly with drug therapy. Like castration results of therapy depend on species, environmental background and individual genetic differences.⁴ The author has used megestrol acetate and repositol progesterone, 500 mg., or progesterone in oil 200 to 300 mg. IM every 24 to 48 hours to reduce undesirable sexual behavior in stallions prior to transport, showing or other activities.

A recent study has demonstrated that **active immunization or ram, lambs and bull calves, against GnRH (LH-RH)** can be produced by an adjuvanted product

injected subcutaneously at 4 to 6 week intervals. This resulted in reduction in size or atrophy of the testes with low plasma gonadotropin and testosterone concentrations after 13 to 15 weeks.⁷ Further studies are necessary to develop this procedure to the point it may replace castration. Many recent studies have been undertaken to produce immunoneutralization with active or passive immunization with antibodies to steroid and gonadotropic hormones. These studies which have been reviewed^{7b} show promise of producing significant future advances in reproduction control in animals.

The **bulling syndrome** in feedlot steers is a major problem for feedlot operators. Of 55,000 steers in one study, 1907 or 2.9 percent became bullers and resulted in an annual loss of about \$325,000 due to injury and the need to isolate affected individuals.¹¹ The use of hormone implants to stimulate the growth rate was shown to be related to the incidence of bulling with a higher incidence with a combined progesterone and estradiol product.¹¹ However this syndrome is observed in feedlots not using hormonal growth stimulants. It is not related to hormonal levels or elevated estrogens in affected animals.⁶ The "buller" syndrome is apparently the result of management factors together with the inherited normal bovine male sexual behavior that usually is suppressed and not exhibited in more isolated steers. Under feedlot conditions the addition of outside, strange animals, irrespective of pen space available, causes an increase in the occurrence of bulling. Since a major stimulus to bovine male sexual activity and libido is to observe another male mount an animal, other steers become aroused and often wait their turn in line to ride the submissive or "chosen" steer.⁶ This latter animal very likely is a passive non-aggressive steer at the lower end of the "peck order."

Endocrine therapy for infertility in males is seldom indicated. It is usually used as a secondary or supportive line of therapy. It is improper and illogical to administer only hormones such as testosterone, thyroid products, or gonadotropic hormones in impotency, or gonadotropic hormones or thyroid products in cases of low fertility, and expect satisfactory results. A good history and careful clinical evaluation of the male should be made to determine, if possible; the etiology of the impotency or infertility, so that intelligent recommendations and treatments can be made. If hormones are used for therapy in male animals their limitations should be recognized.

Forms of Infertility in the Male

According to Lagerlof these forms may be divided into three general categories:

I. Reduced to Complete Lack of Sexual Desire and In-

ability to Copulate (Impotentia coeundi).

II. Inability or Reduced Ability to Fertilize due to Pathology of the Testes, Mesonephric Duct and the Accessory Glands (Impotentia generandi).

III. Miscellaneous Diseases Affecting the Reproductive Organs.

These conditions are present in males of all species. The degree of each condition present in males varies considerably between species, breeds, families, and individuals. Variations also occur due to age, season, nutrition, management and other factors. There are many degrees, from mild to severe, in each category of the various forms of infertility; a fact which demonstrates strikingly that in males there is a wide range of reproductive ability. Sometimes reduced sexual desire and ability to copulate may be associated with reduced fertility and poor quality semen but in most cases of infertility in males the two conditions are not related. In male animals semen collection is usually possible so that direct measurements of sperm quality and other tests may be applied. In examining males for infertility or sterility, accurate breeding and health records on the male and the herd should be obtained and examined. Secondly, there should be a careful, painstaking physical examination of the male including the observation of his mating behavior. Thirdly, one or more thorough semen examinations by a trained veterinarian or qualified laboratory are necessary. To evaluate the nature of a male's infertility and sterility so that proper recommendations for therapy, treatment, or rest or disposal of the animal may be made, all three of the above examinations are essential. The prognosis in nearly all forms of infertility or sterility in male animals should be guarded.

Reduced To Complete Lack of Sexual Desire and Inability to Copulate (Impotentia Coeundi)

Potency is the physical capability of the entire body to coordinate and perform the male's normal role at coitus including erection, mounting, intromission and ejaculation. A lack of potency is observed in certain males in all species and is characterized by symptoms ranging from a complete lack of sexual interest and inability to copulate to a slight slowness or delay in exhibition of libido, mounting and copulating. Mating and copulatory behavior of males has been reviewed in various species:^{12,18} in bulls,^{5,9,14,19,20,27} in stallions,^{36,37,39,45,46} in rams,^{9,23-26,40,41} in dogs,²⁹ in bucks,^{42a} in toms^{42b} and in boars^{9,28} (see Chapter 12). In the female animal repro-

ductive behavior is relatively simple requiring only a willingness to stand to be mounted, or an attitude of immobility and acceptance. This attitude is primarily under the control or influence of estrogen which may be enhanced by progesterone. In the male animal reproductive behavior is more complex requiring identification, seeking out, teasing and then the performance of the complicated act of copulation. This is under the control or influence of testosterone and other central nervous system mechanisms. There is little relationship between blood testosterone concentrations, libido and semen quality or quantity.^{7,9,11}

The components of the act of copulation consist of sexual excitement, courtship, erection, mounting, intromission, ejaculation, dismounting and refractoriness. There is great variation in the duration of these components between species and individual males within a species. Mating behavior depends to varying degrees on visual, olfactory, auditory, and tactile cues. In all species visual and tactile cues are most important in the actual act of copulation. In the dog olfactory clues are highly important in locating females in estrus. In sheep and swine and to a lesser degree dogs and horses the estrous female actively seeks the male. (See Coitus in Chapter 12.) Even blind males may copulate if experienced.

Height, width, and color of the female, attitudes of acceptance, such as her stance as the male approaches, reaction of the female to pressure of the bull's head on her rump or back, pressure of the shoulder on the mare's rump or biting of the skin of the mare's rear parts by the stallion and by the boar's snout lifting the sow's rear quarters, possibly odor of the rear parts and urine in horses and cattle and sheep utilizing the **flehmen reaction**, which is characterized by the lifted head, outstretched neck and curling of the upper lips that facilitate the introduction of odors or pheromones from the urine or genitals into the vomeronasal organ, and vocalization by the stallion, boar, ram and buck are all significant factors in the pre-copulatory and copulatory acts of domestic male animals.

Sex drive, libido, sexual desire or potency of the male is largely determined genetically but environmental influences play an important role in modifying it.^{2,9,22,23,41,44,47}

It is well known that males differ widely in their ability to copulate frequently. In male guinea pigs, rams and bulls it was demonstrated that those with strong sex drive before castration returned to a strong sex drive when treated with increasing amounts of testosterone after castration whereas animals with a weak sex drive returned to a weak sex drive.^{6,7,9,11,15} It was postulated that the differences between animals were due to the reactivity of their tissues, such as the brain, rather than to the dif-

ferences in the amount of hormone secreted or present in the body. Thus variations in endocrine function may be linked with changed reactivity in the target organs and receptors especially the central nervous system, as well as in the hormone-producing organ.

Many of the complex components of copulatory behavior are determined by hormone action during various stages of development and may persist after castration.^{7,15,22} Studies on identical twin bulls showed many similarities in copulatory behavior between brothers but large differences between pairs.² A significant relationship between the degree of libido in father and son groups of Swedish Red and White bulls was reported.²⁷ Sex drive also varies between different lines of bulls within a breed.⁹ Herefords, Shorthorns, Guernsey and North Devons are genetically slow breeders.^{9,47} It is extremely difficult to evaluate the libido and mounting ability of Brahman, Zebu or Santa Gertrudis bulls since these breeds copulate mainly at night and rapidly so the copulatory act can only rarely be observed.^{9,35} Low libido in Zebu bulls was not associated with a deficiency of LH or testosterone.⁹ It may be necessary in these breeds to place a bull with non-pregnant cycling cattle and then check them for pregnancy in 40 to 80 days or to use the chin-ball mating device (Frank Paviour Ltd. Hamilton, New Zealand) to determine if the bull in question mounted cows in estrus. This latter device marks a cow's back as the bull's chin rubs over it during copulation. But European breeds, especially the dairy breeds, will actively mount confined bulls, steers, and cows in any stage of the estrous cycle. Excessive ambient temperatures may have an adverse effect on sexual activity in boars and bulls.^{9,14,28}

Innate virility is reflected in the number and frequency of copulations that occur in a period of time and these vary widely between males. One study reported on two bulls one of which ejaculated over 40 times in 4 hours and another bull under similar conditions that ejaculated only 10 times.¹ With a new stimulus animal or mount the first bull produced over 30 more ejaculates within the next hour. Some virile rams copulated an average of 20 times a day over a 7-day period whereas rams with low libido averaged only 4 copulations per day.²³⁻²⁶

When bulls with high and medium libido, 9 to 10 services vs 2 to 3 services within a daily 7-1/2 hour pasture mating period, were pasture bred at a ratio of 3 bulls to 114 cycling heifers for 3 weeks, the conception rate on first service was 77.5 vs 59 percent respectively for the high and medium libido bulls. By six weeks the difference in conception for the two groups was only 2.3 percent. Thus bulls with high libido when exposed to large numbers of fertile heifers produced earlier conception.⁶ When only 10 to 12 ewes were single-sire mated to rams

with either high or low libido there was no difference in conception rates.³⁴

Depending on the degree of injury, the age of occurrence and the degree of socialization permitted,^{22,24} lesions of the medial preoptic area of the brain can impair male copulatory behavior in animals. Although libido is genetically influenced, mating ability has a learning component essential for its full expression. **Sexual inhibition of males** is seen in all species of animals where rearing or management systems have prevented or reduced socialization, especially in the young male, by isolation either singly, as may occur in valuable show animals, or in bachelor or all-male groups.^{9,29,33,41} In these all-male groups homosexual behavior is common. Furthermore in all-male groups the dominant males intimidate the weaker more submissive males. Thus the latter lose their male aggressiveness, become sexually "inhibited" and may in the future be an undesirable or "problem" male requiring careful reconditioning, training or culling.

In pasture-bred herds or flocks, social ranking or dominance in males occurs. This is largely controlled by age, seniority and size, not by testosterone concentrations in the plasma or degree of libido.^{5,9,40} These dominant bulls or rams if infertile or lacking in libido could markedly decrease the conception rate since they prevent the less dominant or subordinate males from breeding and spend more time in this activity than in breeding cows. If bulls of different ages are used for natural breeding on pasture or range, the owner should consider dividing the females into smaller single-sire groups to obtain the highest fertility and to avoid injuries to males.^{5,9} This is favored by the observation that most pasture-breeding bulls rarely serve the same heifer twice. Also new females coming into estrus were more attractive to males and could promptly restore libido in bulls and rams apparently satiated by formerly-bred females that might still be in estrus. A study of the effects of the male to female ratio and single- vs multiple-sire groups on efficiency of bulls in natural service revealed that although a few bulls were unable to adequately service large numbers of cows, most bulls with acceptable semen quality, libido and mating ability would achieve good pregnancy rates at a ratio of 1:44 or 1:60 females.^{8,40a} A bull to female ratio of 1:25 was inefficient in realizing a bull's breeding potential. In multiple-sire groups social ranking affected the number of females mated by each bull with subordinate bulls mating fewer females. It was difficult to identify bulls with acceptable libido and mating ability before the pasture breeding season.

In over 2000 rams the incidence of sexually-inhibited rams reared separate from ewes when they were first

placed with ewes was about 30 percent. Within a few days 80 percent of this inhibited group of rams developed normal libido and sex drive. In about 2000 stallions examined each year for 3 years a low incidence of 0.34 to 1.07 percent of stallions with a lack of sexual desire or libido was reported.^{4,37,39,45} Impotency is not uncommon in stallions and is occasionally characterized by normal intromission and failure of ejaculation or abnormalities of ejaculation.

About 16.7 percent of 625 beef sires of English breeds selected by artificial insemination studs were disposed of because of problems in the collection of semen, mainly refusal to serve an artificial vagina.³⁸ Very few Brahman or Zebu bulls will mount and ejaculate into an artificial vagina. Selection of bulls for their femininity, docility and gentleness tended to favor the selection of bulls with reduced desire.³² However in one study with Santa Gertrudis bulls there was no relationship between masculinity and libido scores.^{8,9}

Although sex drive, mating behavior or libido is largely genetic in nature it is subject to great modification by many environmental or physical factors. Males with a strong sex drive require more severe and prolonged environmental and physical insults to significantly affect their mating behavior than do males with a weak sex drive.

Environmental Factors Affecting Sex Desire and Copulatory Ability: Nutrition—Thin, emaciated, semi-starved males or those suffering from deficiencies of TDN., vitamin A, protein, and certain minerals such as phosphorus, zinc and cobalt may have a reduced sex drive. If inanition is severe enough, a complete lack of libido results. As indicated previously a low level of energy intake in growing males retards puberty and the onset of libido.

Overfed males tend to become obese and lazy and often suffer from joint and foot troubles related to their overweight condition. Excessive roughage fed to older bulls and rams may cause great enlargement of the rumen and abdomen interfering with normal, easy copulation and contributing to a lack of sexual desire.

Male animals should be fed a properly balanced nutritive ration in adequate amounts to maintain a fair to good body condition. Exercise is important in maintaining active, healthy male animals.

Systemic diseases—Any chronic or acute, severe, debilitating disease resulting in rapid or prolonged marked loss of weight, or in anorexia, depression, and weakness will cause a varying degree of loss of sexual desire. These diseases may include: pneumonia, enteritis, tuberculosis, paratuberculosis, severe mange and pediculosis, actinomycosis, lymphocytoma, progressive fat necrosis,

severe internal parasitisms, advanced metastatic tumors, alveolar periostitis, traumatic gastritis, severe chronic peritonitis, anaplasmosis and others. In anaplasmosis the loss of libido was associated with anemia and low hemoglobin and packed-cell volume. All bulls, especially in an AI stud, should be given magnets orally at about one year of age to prevent traumatic gastritis or pericarditis.¹⁰ Routine vaccinations of males vs the common infectious diseases of each species is indicated. Early and prompt diagnosis and treatment of all diseases of male animals is imperative to prevent possible loss of reproductive ability.

Age—Very young males or old males frequently exhibit a reduced-to-complete lack of sexual desire. In older animals this may be due to a possible decline in testosterone levels, to senility, to a loss of condition, to overuse or to arthritis. In experiments with identical twins it was shown that the time of onset of the lack of sexual desire in older bulls seemed to be largely determined genetically.²

There is a great deal of variation in young bulls in the onset of sexual desire and puberty. That this may be modified significantly by the nutritive level has been well-demonstrated. High feeding levels hasten the onset of puberty and sexual desire whereas low or subnormal feeding levels greatly retard the time at which the young male shows sexual desire and will mount and copulate with females.

Management practices—Libido will vary within animals depending upon their inherent sex drive and the way they are trained, handled and managed. Young males which are isolated apart from others of their species are frequently frightened by the presence and activity of females and other males and are slow to mount and copulate because of their inexperience and timidity. This is not uncommon especially in bulls, rams, stallions and dogs. Young males should be carefully patiently and quietly trained and handled, especially if they are to have their semen collected in an artificial vagina. If a male associates "sex" with pain or punishment, he may decide to give up "sex"! Males with a lack of libido or naturally "slow breeders" can be easily discouraged and made slower by the insertion of a nose ring in a bull, harsh or abusive handling of the male by attendants, improper restraint of the mount animal, improper footing, mount animals that are not in estrum or are too tall or wide, use of an artificial vagina that is too cold or hot, improper preparation of the male for mounting, breeding large males in a confined area with a low ceiling, unskilled persons using an artificial vagina, and excessive use of a male. Males lacking libido if continually used on the same female for semen collection frequently develop sexual in-

difference or satiation. Frequent changing of the stimulus or mount animals and the breeding site are indicated in bulls inclined to show a lack of libido. The presence of other males near the mount animal or in sight of the breeding male provides further stimulus.^{20,21} Proper sexual preparation of dairy bulls by prolonging the period of sexual stimulation beyond that adequate for mounting and ejaculation will produce higher quality semen with 36 to 250 percent more spermatozoa in the ejaculate.^{20,21} This is accomplished by a longer period of restraint before permitting copulation, frequent changing of the mount animals, allowing several "false" mounts where copulation is not permitted, and moving the male to several different sites for "teasing" or "stewing." Olfactory stimulation has not been demonstrated to play an important role in the sexual behavior in bulls.¹⁹ Some stallions and jacks with low desire will fail to copulate with mares that are well-scrubbed and their tails bandaged. Others will so vigorously bite the withers and neck of the mare after mounting that erection is lost. Muzzling of these males or placing a heavy pad or blanket over the neck and withers of the mare is indicated. Other stallions will perform intromission and make thrusting movements but fail to ejaculate. This is common in stallions with reduced libido that are being used too frequently for their reproductive capacity.^{36,39,45} This failure to ejaculate can be noted by careful observation of the male at copulation by the absence of the usual "flagging" of the tail, which can be misleading, the absence of "pulsations" of the penile urethra felt by manual palpation during coitus, the failure of the stallion on dismounting to be "content" and "relaxed," and also the lack of spermatozoa in the "tail-end" sample of the ejaculate collected from the penis as the stallion dismounts.

Psychic factors interfering with normal coition and resulting in impotency have been observed in males of all species, especially stallions.³⁶ Males with a genetically lower sexual desire are much more apt to develop psychic refusal to breed. Usually there is no obvious clinical reason for this failure but if a good history is available it often reveals a traumatic, painful experience or several of them at the last few attempts at copulation.^{30,36} Some bulls and stallions with apparent psychic impotency may actually be afflicted with lesions of the spinal column as described in the next section.^{13,36} These bulls would apparently have good sexual desire, mount rapidly, have lordosis in the lumbar region and the penis would be directed at the escutcheon well below the vulva. Rapid pelvic thrusts and "seeking" motions would occur but penile exposure was greatly reduced. A prolonged period of sexual rest, a change in the site of copulation and careful preparation may be necessary to encourage

the male to again start to breed. Shy or slow breeding boars may also be observed.⁹

Males should be properly handled and exercised to maintain optimum physical condition. They should be observed and managed so as to prevent their being bred excessively and losing their sexual desire. The frequency of breeding or the individual capacity of each male should be determined. If the male is bred repeatedly over a short period, this should be followed by a period of sexual rest. These above management factors should encourage the timid, slow breeding male, and control and conserve the vigorous active male.

A reduced libido or sex drive in stallions is usually an important cause of concern for the owner(s) because of the value of the animal and the mares presented to him and the loss accrued from failure to impregnate most of "booked" mares within a breeding season. Furthermore in the stallion electro-ejaculation is presently not possible and artificial insemination is limited to certain breeds. The lack of libido in the stallion not only encompasses his reluctance to tease, mount and obtain intromission but many "inhibited" stallions will fail to ejaculate even though a visually normal copulation occurs. The third associated condition in the stallion that is not reported in other male domestic animals is the occurrence of a functional disturbance of the neural mechanism controlling ejaculation. This may result in a normal ejaculation of seminal fluid from the accessory glands without the ejaculation of spermatozoa from the tail of the epididymis and ductus deferens, azoospermia, or the release of urine into the ejaculate usually after the second or third jet of normal semen. No lesions have been found to explain these functional or possibly psychic causes of reduced libido and failure of ejaculation in the stallion.^{36,37,45} It has been noted that "belling" or "flowering" of the glans penis of the stallion following erection is necessary for ejaculation. However if a normal erection does not occur, ejaculation can often be obtained by using an artificial vagina³ without "belling" or "flowering" of the glans.

Psychogenic impotence is common in stallions because they are often reared in isolation, given little freedom for socialization with other males and females during puberty, vigorously trained and disciplined firmly for exhibiting normal male sexual behavior during puberty and their early formative years and are expected to perform instinctively and repeatedly the complete sex act promptly on being retired to stud duty. The most common causes for impotency or lack of libido are overuse as a young stallion, injury during service from being kicked by the mare, and excessive discipline or chastisement during the sexual act. Overuse in older horses

may cause reduced libido but they respond to sexual rest, while too often effects of overuse of a young stallion may be permanent.³⁶ Impotency in a stallion may be manifested by indifference or excessive aggression toward the mare or the handler. The latter aggression is apparently caused by definite signs of frustration on being unable to ejaculate. The author observed this in one older stallion that was aggressive toward the mare, obtained intromission repeatedly, sweating profusely, and emitted a definite "squeal" of frustration on each withdrawal and dismount.

Tests for the Measurement of Libido

Since libido or potency is a highly significant component of the fertility of male animals but is difficult to assess easily and accurately, a number of test procedures have been developed and used.^{6,9} These include:

- 1) the percentage of times that copulation and ejaculation occurred when a male is exposed to a suitable "stimulus" on different occasions, (either by natural service or collection with an artificial vagina)
- 2) the comparative number of completed or uncompleted copulations in a given time period with a "stimulus" female
- 3) observation of the time elapsed between exposure of a male to a "stimulus" animal and the first copulation (This is called the "reaction" time)
- 4) assessment of the ability of a male (bull) (ram) to mount a restrained nonestrous female and ejaculate into an artificial vagina 3 times within a limited time (10 minutes)
- 5) assess the degree of sexual behavior or libido in beef or range-type bulls placed in a small enclosure with a stimulus or ovariectomized, estrogenized heifer (Up to 11 categories of behavior are listed)
- 6) using a "serving capacity test" by utilizing restrained nonestrous cows at a ratio of 5 beef or dairy bulls to 2 to 3 cows and noting the number of services by each bull within a forty-minute time period.

To be of diagnostic value these tests should be conducted under controlled conditions by experienced observers. Some of these tests are not adaptable for use in individual or small herds.

Hypothyroidism, hypogonadism, or a pituitary deficiency causing a diminished secretion of thyroxine, testosterone, or gonadotropin has not been described or proven by radioimmunoassays in normal intact male animals as a cause for a lack of sexual desire. It is possible that moderate deficiencies of these hormones might exist without clinical symptoms other than reduced sexual desire. It is the opinion of the author, based on results of hormone therapy, that a hormone deficiency is not a

common cause for a lack of sexual desire in male animals.

The prognosis in reduced sexual desire or impotency is guarded to poor depending upon the cause and the degree of the inherited or acquired lack of libido. The environmental factors causing or promoting the lack of sex drive can be overcome or moderated so that libido and breeding ability can reach their maximum expression for the individual male. For males affected with a lack of libido it often requires 3 to 6 months or more of proper handling for sexual desire to noticeably improve after adverse influences have been corrected.

Treatment should only be instituted after a careful study of the male's breeding history, after a thorough physical examination of the male, and after careful and repeated observations of the male during coitus. Proper balanced and restricted amounts of good quality grain and roughage should be provided to reduce obesity, if present, or to increase body condition if the male is too thin. Sufficient exercise should be provided. Chronic disease states, especially parasitisms in young males, should be corrected or alleviated if possible. The virility and service potential of the male should be assessed and the frequency of service should be reduced, if necessary, to the male's inherent capacity. Often a period of several months of sexual rest is desirable in males that have been excessively overused. If necessary, changes should be made in the location where service occurs to assure good footing and adequate room. Proper restraint of the female, and care, consideration and patience in the handling of the "slow breeding" male may improve his sexual behavior. If the male is collected with the artificial vagina then a skilled operator should be used. The artificial vagina should be neither too warm nor too cold and adequate pressure should be applied to the penis. Some bulls prefer a coarse, heavy rubber liner to a light, smooth, thin one. A bull that is a "slow breeder" at an artificial insemination stud may benefit from a long period of sexual rest or transferring to another stud with a different group of handlers and different practices. Frequent changes of mounts and a longer period of "teasing" or stimulation is often helpful. In some instances libido may be restored by allowing the male to run loose with one or more quiet non-pregnant females in a pasture or enclosure. As a last resort when the condition fails to respond, bulls, rams and boars may be collected by electroejaculation and dogs may be collected by manual manipulation.

Treatment of impotency in male animals, especially stallions, requires a careful complete history, a complete physical examination and careful repeated observations of the male before and during the sex act under a number

of environmental and management situations and most importantly patience and understanding. This often requires a long period of sexual rest as horses have a long memory. Retraining should only take place during the regular breeding season in photoperiodic animals. Keeping discipline to a minimum during the sex act and promoting all factors that will make the sex act a pleasurable experience is essential for the "inhibited" male. The "stimulus" or mount animal should be highly attractive or desirable to the male, be quiet, the right size and strongly in estrus so it will remain immobile during the sex act.^{36,37,39,45} The use of an artificial vagina by a skilled operator has proven helpful in many impotent stallions.^{30,36} In some timid, shy, arthritic, lame or overly aggressive stallions, training them to mount a phantom or mannikin and collection with an artificial vagina has been successful,³¹ especially if an estrous mare is positioned next to the phantom. In other stallions it was necessary to permit unrestrained coitus with highly receptive mares in a paddock or pasture environment. This increases the possible risk of injury. In many instances following the recovery of the impotent stallion or male, careful, supervised and understanding breeding practices together with the use of the artificial vagina resulted in the male returning to satisfactory service. Some cases of impotency may be incurable.

Pickett and co-workers³⁶ and Rasbech³⁷ have cited a number of impotent stallions where urination occurred during about 30 percent of the ejaculations. Using a special funnel device and shortened artificial vagina the ejaculates of these stallions were fractionated and the contaminated portions were discarded.³⁶ Testicular biopsies and/or aspiration sample of the contents of the tail of the epididymis may be necessary to diagnose whether azoospermia is due to a functional, organic or degenerative condition. The latter two would occasion a very poor prognosis.

Drug and hormone treatments are of questionable value in most males lacking sex desire. Testosterone in oil or in the "Repositol" form may be used in intramuscular doses of 100 to 500 mg. in bulls and stallions, 50 to 100 mg. in boars and rams and 10 to 50 mg. in dogs and repeated every 2 to 10 days for several injections. Prolonged high level androgen therapy should be avoided because of the possibility of producing testicular degeneration and atrophy caused by the suppression of the gonadotropic hormones. One or more injections of chorionic gonadotropin at 4 to 7-day intervals in doses of 5000 to 10,000 IU for large animals and 100 to 500 IU for dogs may help stimulate testosterone production by the interstitial cells. Other forms of ICSH or LH may also be used. Males that are obese or lazy, possibly due

to a hypothyroid condition, may benefit from feeding iodinated casein with a 3 percent thyroxine potency at a rate of 1 gm. per 100 lbs. of body weight daily. Thyroxine may also be used. This helps increase the metabolic rate, hastens the loss of weight and occasionally improves the libido. Benzidine and other stimulants as well as the glucocorticoids and tranquilizers have been used with very questionable success one-half to 24 hours before breeding the impotent male. Injections of vitamins and feeding of trace minerals, protein and iodine have little value in most slow breeding males. In lame, arthritic stallions or those with laminitis, butazolidin or a similar drug may reduce pain and encourage copulation. Two stallions with failure of ejaculation apparently responded to pilocarpine and ephedrine.³⁷

Other factors such as structural lesions of the limbs and diseases of the penis and sheath may cause a reduction in libido in some males but in others can actually interfere with or prevent normal copulation. Initially males that develop an inability to mount and ejaculate may exhibit good libido, but with repeated failures, or due to painful lesions, sexual desire may become greatly reduced or lost.

Joint, Muscle, Nerve, Bone and Tendon Injuries and Pathology. Lesions affecting these structures particularly if they involve the rear quarters may cause a reduction or even cessation of mating behavior and copulation especially in males with genetically reduced virility or sex drive. Coxitis is seen most commonly in dogs as hip dysplasia and in boars, and less frequently in bulls, rams, bucks, and stallions. It is characterized by a short stride and adduction of the limb. Rupture of the round ligament may be observed in bulls with degenerative coxitis. Occasionally bulls or other males may have one or both hips dislocated resulting in inability to copulate. (See Figure 174.) Gonitis is common in bulls and is characterized by a short, stiff gait and distention and enlargement of the capsule of the stifle joint. Rupture of the anterior cruciate ligament of the stifle occurs rarely in bulls but is common in the smaller breeds of dogs. This condition in the adult bull usually prohibits mounting. Excessively straight rear limbs, resembling the Elso-heel condition described in cattle⁸ predispose bulls and stallions to injury of the stifle joint and tarsus. Gonitis, tarsitis or degenerative joint lesions (osteocondrosis) in the fetlock or phalangeal joints, or ringbone, may result in pain and reluctance or refusal to mount and copulate.

Other conditions causing similar signs of reduced libido include over-grown claws or hooves, suppurative pododermatitis, quitters or interdigital granulomas, especially in beef cattle, foot rot or interdigital necrosis,

tendonitis, suppurative arthritis of the coffin joint, laminitis or founder,⁷ traumatic injury to the peroneal nerve resulting in a "dropped" hock and "cocked" fetlock joints, myositis or muscle rupture especially involving the gastrocnemius or large gluteal or croup muscles and other traumatic lesions of the lower portions of the rear limbs. A progressive lameness resembling laminitis eventually resulting in refusal to stand, was described in related Hereford bulls and was probably caused by a recessive character.⁴ Polyarthritis may occur in swine due to erysipelas, streptococci, mycoplasma or other organisms. Occasionally polyarthritis may occur in bulls secondary to a primary site of infection. Fractures of the pelvis are rare in males.

In bulls, dogs and occasionally other males symptoms of impotency may be related to spinal disease and characterized by stiffness and soreness in gait, spinal rigidity, and pain over the vertebrae. If the spinal cord is compressed then a slight to marked paresis may be present with a swaying, unsteady gait a slightly flaccid tail and dragging of the rear limbs. Vertebral osteophytes were very common in dairy and beef bulls over six years of age with the possible exception of Brown Swiss bulls and resulted in ankylosis and spondylosis of the thoracic and lumbar vertebrae with occasionally a secondary fracture of the spine.^{2,6,9} A later study indicated that vertebral body osteophytosis were similar in bulls bred once or 6 times a week for 4 to 8 years. The influence of these osteophytes on libido in bulls were minor with only a slight increase in reaction time in bulls, with the larger lesions.¹ Synostosis of the sacroiliac joint begins at 2 to 4 years of age in the bull and is complete at 6 to 10 years of age. This is physiologic and no inflammatory signs are observed. Bulls with spondylarthroses especially of the lumbosacral joint, would mount too far caudally on the cow, exhibited lordosis and the penis was extended only a short distance and directed too far ventrally but sexual desire was good.² Bulls with spondylosis, often involving most intervertebral spaces and discs, exhibited kyphosis, a stiff back, short stiff hind leg movements or "goose stepping," and loss of liveliness and mobility. In some bulls mounting was aided by the jaw and neck of the bull pressing on the back of the cow. Spondylarthrosis affected bulls at an average age of 5 years and spondylosis was most common in older bulls, about 10 years of age. Although common dysplastic lesions in bulls might be genetically conditioned² the possibility that these conditions and arthritis might be nutritional due to excessive calcium intake was demonstrated.⁶

In dogs, especially those of the brachycephalic breeds, such as the Dachshund, prolapse of the intervertebral discs

causing compression of the spinal cord results in similar symptoms associated with an inability to copulate. Rarely tumors, such as lymphocytoma may invade the spinal canal producing compression of the spinal cord and chronic progressive paresis. Depending on the severity of the spinal cord compression, stallions with the "wobler syndrome" may or may not be able to mount and copulate. Swedish Landrace boars, especially certain sire lines, had difficulty in copulating due to bone and joint lesions or arthrosis deformans.⁵

In spastic syndrome, crampiness or "stretches" in bulls, severe acute attacks may interfere with or prevent copulation due to the prolonged spasm of the skeletal muscles of the rear limbs and back. (See Figure 175.) Spastic syndrome has been observed in all breeds of cattle but most commonly in the Holstein Friesian and Guernsey breeds. It is probably inherited as a single recessive factor with incomplete penetrance.^{3,8} It is seen most often in bulls over 3 years of age and is often associated with arthritis or painful lesions of the rear limbs. Spastic signs are not observed when the bull is lying down but become evident on standing. In most bulls the signs are mild and persist for the lifetime of the bull with occasional periods of exacerbation.

The **prognosis** for future breeding in males with joint, muscle, tendon, bone, or nerve lesions depends upon the nature and severity of the condition and the species, age and value of the animal.

The **treatment** in most cases will consist of sexual rest and restriction of activity enforced by confinement in a box stall or small paddock with good footing. In fractures of the spine, dislocation of the hips and compression of the spinal cord due to arthritic lesions and tumors in large animals, the prognosis is poor to hopeless. In arthritic lesions, the prognosis is also poor but often two to eight months or more of rest may permit limited use of the male. Improved or recovered males should be handbred where the footing is good and where the rear parts or the entire female animal are placed in a pit so the male can easily copulate, or breed an artificial vagina. In bulls or rams judicious use of an electroejaculator might permit the collection of semen from males that are unable to copulate or that might further injure themselves if allowed to mount naturally. Some males can be trained to ejaculate into an artificial vagina with all four feet on the ground. In dogs with disc lesions surgery may be indicated. In suppurative arthritis of the coffin joint prolonged conservative therapy, not amputation of the claw, is indicated so ankylosis of the joint will occur. Even if the joint is left deformed it will help the remaining normal claw support the animal's weight. Quittors or interdigital granulomas should be removed

surgically followed by stall rest and possibly wiring the toes together. In bulls with acute attacks of spastic syndrome where treatment is necessary, "Tolserol" (Squibb) or "Mephinesin" (Abbott) in 8 to 10 gm doses orally three times a day (24 to 30 gms daily) for 2 to 3 days may be administered. Tranquilizers will also help these affected bulls but the bulls should then be observed closely for the duration of the treatment to prevent injury to themselves upon rising. Glucocorticoids or butazolidin or other nonsteroidal prostaglandin antagonists for several days may also be of supportive value for the alleviation of arthritic signs. Regular hoof trimming is desirable for all large male animals. Lesser infectious or traumatic lesions should receive appropriate and prompt treatment.

Diseases of the penis and prepuce are common causes for inability or difficulty in copulating and frequently result in a marked reduction in sexual desire.

Inability to normally protrude the penis (phimosis) may be due to: (1) a congenital anomaly in the development of the penis and prepuce, with or without hypospadias, or male pseudohermaphroditism. This may be observed in all species but is seen most commonly in Boston Terriers in which the penis is very short and opens through a defective prepuce just anterior to the scrotum.⁵ Copulation is not possible. The author has observed one case of a double penis, diphallus, in a bull that prevented normal copulation because of its forked configuration. The urethra was present in only one of the two glans of the penis. (See Figure 164.) A congenital urethral opening ventral to the anus associated with two separate scrotums each containing a testis has been described in a ram.¹³

(2) A congenitally short penis has been described in bulls, bucks, boars and horses. The author and others⁴ suspect this condition may be hereditary since the latter observed it in 20 sons of a Hereford bull and the former observed it in two closely-related Guernsey bulls. The retractor penis muscle in these bulls was normal. No adhesions or lesions were present in the prepuce or around the penis preventing normal extension of the penis. As young bulls these affected males may breed heifers naturally even though only 6 to 15 cm. of the erect penis protrudes from the sheath. As the bulls get older, their abdomen gets deeper and they become less agile, copulation is impossible as the penis cannot reach the vulva of the cow. In one Guernsey bull the penis was 22 cm. shorter from the tip of the glans to the ischial arch than a penis from a similar-sized bull of the same age. These males can still be collected by an artificial vagina but their use as sires should be discouraged. The author has observed one 12-year-old stallion with a short penis the

Figure 164. Diphallus in a Bull.

glans of which failed to "bell" when copulation occurred. This stallion had a normal breeding history from 5 to 10 years of age but then an inability to ejaculate on intromission developed. In bulls with a short penis the sigmoid flexure does not form a sharp S-curve in the resting state. A similar defect was described in bucks,¹⁵ and in boars.^{1,10} In the latter the pendulous, infantile,

incompletely erect penis would only extend 2 to 5 cm. beyond the preputial orifice.

(3) A congenital short retractor penis muscle was described as a probable recessive character in Friesians in Holland and symptoms were similar to those exhibited by bulls with a short penis.⁶ Myectomy of this paired muscle midway between the anus and the base of the scrotum, or removing a 4 cm. section of muscle, resulted in improvement in the ability to protrude the penis at erection in some of the affected young bulls. This operation was forbidden in the Netherlands because of the hereditary nature of this defect.¹⁶ It is possible that some of the affected young bulls failing to respond to the operation had a short penis. Ten of 38 affected bulls mated normally as young bulls and the other 28 cases were diagnosed at a young age. Of interest in regard to the above condition is the observation¹² that old bulls may have the retractor penis muscle nearly completely calcified yet copulation may be normal with a fully extended penis.¹⁰ If myectomy of the retractor muscle is performed it should be done just below the ischial arch to prevent adhesions which occurred if the operation is performed just above the sigmoid flexure of the penis.⁹ Passive stretching of the retractor penis muscle was of value in some cases.

(4) Other conditions that cause an inability to normally protrude the penis are psychic impotency,^{7,11} injury or lesions of the lumbar or sacral region,^{2,8} phimosis due to adhesions in the sigmoid flexure area of the penis or of the prepuce, stenosis of the preputial opening from congenital, traumatic or infectious causes, and tumors of the penis and sheath. Rare instances of eunuchoidism have been described^{3,17} in bulls and dogs characterized by a complete lack of sexual desire and marked hypoplasia of the genital organs and penis. This might be a congenital condition in young males or due to Sertoli cell, pituitary, or hypothalamic tumors. In three psychic infertility cases, the affected adult bulls would protrude their penis normally but then on mounting the cow the penis would be retracted before coitus.¹¹ Sexual rest and the use of an artificial vagina on one bull and resection of the retractor muscle on the other two bulls restored their ability for natural service.^{2,11} The inability of a bull and boar to obtain and maintain an erection and protrude the penis may be due to vascular shunts or anomalous venous drainage of the corpus cavernosus penis. (See Miscellaneous Causes for Inability to Copulate.)

If a bull is unable to protrude his penis normally a careful physical examination of the penis and prepuce should be made. The use of tranquilizers, pudendal nerve blocks or an electroejaculator may be helpful in arriving at an accurate diagnosis. A good history and careful observation at several attempts at natural service are very

informative. The penis should be withdrawn from the prepuce and the penis, the retractor penis muscle and the prepuce should be carefully examined. Occasionally young poorly-grown males may be slow to reach puberty and the inability to protrude the penis may be due to the normal prepuberal adhesions between the prepuce and the penis. Bulls with a short penis should be slaughtered and not used for breeding purposes because of the possible hereditary nature of the defect.

Deviation of the penis or phallocampsis is a common cause for difficulty or inability to copulate and a loss of libido. These deviations, of persistent penile frenulum, spiral or "corkscrew" glans penis, S curve or "rainbow" curve of the penis are observed most commonly in the polled, English beef breeds including the Angus, Short-horn and Hereford^{7,8,9,14,20,21} and are seldom observed in the Charolais, Brahman and dairy breeds that have a larger thicker penis. Deviations of the penis may also be due to congenital persistence of the penile frenulum in many breeds of bulls, especially Angus, and uncommonly in dogs and boars.^{1a,10,11} It was observed in six of 18 closely related, inbred, subfertile Angus bulls.⁸ The incidence of persistent penile frenulum in Angus bulls was about 1 percent with some herds having an incidence of 4 to 5 percent.⁷ The use of these bulls after treatment is questionable for genetic reasons. Two Cocker Spaniels had persistent penile frenulums.^{6,16}

A persistent frenulum is a band of tissue that extends from near the ventral tip of the glans penis to the prepuce. It is seen occasionally as a cause for a sharp ventral bending or deviation of the glans penis in bulls.^{1b} It has been reported in dogs where it caused discomfort and pain at puberty,^{12,13} and also in boars.^{1a} At birth the epithelial surfaces of bovine porcine and canine penis and sheath are fused and ventrally the penis and prepuce are united by a band of connective tissue called the frenulum. Epithelial separation and rupture of the frenulum occurs normally at puberty. When a persistence of the frenulum occurs there is usually a blood vessel present in the center of the tissue band comprising the frenulum. Cutting of the connective tissue band, without ligation, is a simple procedure and is uniformly successful for the correction of a persistent frenulum. Congenital curvature of the penile bone in the dog is rare.¹⁰

The spiral or "corkscrew" type of deviation of the penis is most commonly seen in young bulls, 2-1/2 to 5 years of age. (See Figure 165.) Many affected bulls have successfully bred cows for a year or more before the deviation is noted as a cause of infertility.^{3,7,20,21} There is evidence to indicate that this condition may be inherited as cases have been noted in sons or closely related descendants of an affected bull, especially in the polled

Figure 165. A Spiral or Corkscrew Deviation of the Penis of an Angus Bull.

beef breeds.³ In most cases of a spiral deviation, the corpus cavernosum appears longer than the supporting structures of the penis including the fibrous tunics. The anatomical basis for the spiraling of the bovine penis is well-described.²⁻⁵ When complete erection occurs the corpus cavernosum in the free end of the penis rolls inside the fibrous tunic and the penis slips and pushes laterally under the dorsal apical ligament through the less dense portion of the fibrous tunic and the glans spirals counterclockwise, ventrally and to the right around the line of the penile raphe. This may be favored by the early maturation of the supporting structures of the penis and the later maturation and growth of the penis under the continued influence of testosterone especially in the English beef breeds that have a narrow, thin penis. "Corkscrewing" of the penis occurs at the peak of erection when the integument covering the free end of the penis is stretched. If erection is only partial it does not occur. This may account for the fact that some bulls will only be observed to "cork-screw" occasionally. The author observed an affected Angus bull that was collected several times in rapid succession in an artificial vagina. On the fourth collection "corkscrewing" of the penis did not occur until after the penis entered the artificial vagina. Thus the report of Seidel and Foote^{18,19} who photographed the penis through a transparent artificial vagina at the moment of ejaculation and noted a transient twisting of the penis during more than half of the ejaculations in normal Holstein bulls is significant. Up to 30 percent of Hereford bulls have a normal straight penis on intromission but have a curled or twisted penis on dismounting.^{2,5,17} Spiralling of the penis after intromission in normal bulls may increase the tactile stimulus and promote ejaculation.⁵ In affected bulls premature full

erection occurs prior to intromission resulting in "corkscrewing" that prevents the completion of coitus. Contraction of the retractor muscles of the sheath during erection might be an additional causative factor in spiralling of the penis.² Spiralling of the glans penis is also observed in bulls being collected by the electroejaculator. Some bulls that show a spiral deviation during electroejaculation, especially if the penis is manually manipulated, may breed cows naturally without a deviation being evident.

Other less common types of deviations of the penis are the ventral or "rainbow" and the mild S-shaped curvatures which are also caused by an insufficiency of the apical ligament of the penis.^{2,6,21} The latter is of little importance and some affected bulls breed successfully. The former definitely prevents normal copulation as the more erect the penis becomes the greater the ventral curvature. A persistence of the frenulum or a short retractor penis muscle are not present. Rarely trauma and scarring of the penis and/or prepuce may cause a penile deviation.

Treatment of the spiral deviation, the ventral or "rainbow" and the S-shaped deviation usually requires a surgical operation in which either a portion of the fascia lata is implanted between the apical ligament and the tunica albuginea or the apical ligament is firmly fastened to the penile tunica albuginea.^{20,21} Various synthetic prosthetic implants have been used unsuccessfully to repair spiral or ventral deviations of the penis. Carbon fiber implants show some promise of being of value in producing a strong adhesion between the apical ligament and the tunica albuginea.¹⁵ These surgical techniques to correct a spiral or "corkscrew" curvature assist in preventing the rotation of the corpus cavernosa within the

Figure 166. Ventral or "Rainbow" Deviation of the penis of a Hereford Bull.

Figure 167. A Persistent Frenulum, a Cause of Deviation of the Bovine Penis.

fibrous tunic by producing adhesions between the two structures.

Hematomas, Adhesions of the Penis and Prepuce, Tumors, Phimosis and Paraphimosis—Decreased libido and inability to copulate may be associated with phimosis of the penis due to adhesions of the sigmoid flexure of the penis or the deeper portions of the prepuce, tumors of the penis and prepuce, stenosis of the preputial orifice, paraphimosis or paralysis of the penis or a stenosed preputial ring.

1. **Adhesions of the penis in the region of the sigmoid flexure** in bulls and rams may be due to trauma from horn injuries or in bulls from injections of local anesthetics to block the dorsal nerve of the penis as was earlier performed to produce anesthesia of the penis to aid withdrawal from the sheath. These connective tissue adhesions prevent obliteration of the S-curve and penile protrusion at the time of erection. Treatment to relieve

these adhesions often results in more severe adhesions.

Adhesions of the deeper or caudal portions of the freely-moveable prepuce to the abdominal wall or to the skin in the region of the fornix produces a more severe phimosis than adhesions of the cranial portion of the prepuce. These adhesions may be secondary to lacerations of the prepuce especially in young bulls where the prepuce has not yet completely separated from the glans, or in older vigorous bulls, especially those used in artificial breeding studs and collected with artificial vagina, in which a vigorous thrust may tear the prepuce away from its attachment to the glans for one-third to the entire circumference of the penis. Infection that follows this injury may produce abscesses and/or adhesions to the surrounding structures preventing the free movement of the prepuce and penis at erection. (See Figures 168 and 169.) Prompt antibiotic therapy both locally in an oily base and parenterally for 7 to 14 days is recommended together with sexual rest for 6 to 12 weeks. Suturing of the prepuce to the mucous membrane of the glans and the underlying connective tissue appears indicated but permitting healing by second intention without suturing has proven more satisfactory for the author.

A ruptured, "fractured," or "broken" penis with a secondary hematoma is usually observed in the bull but in rare instances may occur in the stallion due to the mare's kicking the erect penis as the stallion mounts. In the dog, fracture of the penile bone may be caused by a traumatic injury and may require amputation of the penis or resection or removal of the penile bone.¹² Similar traumatic injuries in the other species are uncommon. In the bull, the condition of a "fractured," "broken," or ruptured penis occurs most commonly in active bulls

Figure 168. Tearing of the Prepuce from its Attachment to the Glans Penis in a Bull.

Figure 169. A Chronic Abscess Causing a Severe Phimosis in a Bull. (This abscess was probably secondary to a laceration of the prepuce or a small hematoma or "fracture" of the penis.)

with a strong sex drive breeding cows on pasture. It is rarely observed in dairy bulls that are hand bred. The injury apparently occurs at coitus either when the cow or heifer suddenly goes down under the weight of the bull, or due to a sudden ventral bending of the erect penis against the escutcheon of the cow at the moment the bull thrusts, causing a dorsal rupture of the tunica albuginea usually near the distal portion of the sigmoid flexure and opposite the initial attachment of the retractor penis muscle. Penile hematomas are apparently due to a sudden angulation or bending of the erect penis at service. They are not only due to a high blood pressure in the corpus cavernosum. Pressures of more than 10,000 mm. of Hg may occur in the corpus cavernosum penis at coitus.^{2,8,25}

Rupture of the penis usually occurs in 2- to 4-year-old bulls and is seen most commonly in Herefords. The symptoms of the injury include a shortening of the stride, stiffness, pain and a slight arching of the back that are generally mild and may not immediately prevent subsequent copulations which produce a larger hematoma. A swelling rapidly develops just cranial to the scrotum that varies in size depending upon the amount of hemorrhage from the ruptured penis and the tissues involved.^{16,17} Hemorrhage is profuse and in a "hand grenade" effect because of the very high blood pressure present in the erect corpus cavernosum penis. Prolapse of the prepuce may occur secondary to the edema that often develops. There is usually no difficulty in urination. At first the swelling is soft and fluctuating; later it becomes firm as the hematoma clots and organizes. Pain may be evident but heat is slight. Systemic symptoms are usually lacking. The bull shows definite reluctance and inability to copulate. If treatment is not undertaken

the clot organizes. The hematoma may become infected producing an abscess. (See Figure 169.) Adhesions may occur between the prepuce, penis, abdominal wall and skin rendering the bull useless for future service. A differential diagnosis from other conditions such as tumors, chronic fibrous adhesions, lacerations of the penis and prepuce and rupture of the urethra should be considered.

The prognosis in these cases should be guarded even when an operation is performed. If an aseptic surgical operation cannot be performed an operation should not be attempted. In this latter situation the bull should be given large doses of parenteral antibiotics for one to two weeks to prevent abscessation. About 50 percent of bulls may recover spontaneously with 3 months of sexual rest. Due to the high rate of recurrence and other complications, surgery is usually recommended for valuable bulls.²⁵ Hematomas that become infected seldom respond to treatment and surgery. The size of the lesion rather than its location was of greatest importance in the prognosis.^{24,25} Some affected bulls damage the dorsal nerve of the penis at the time of the "rupture" so they lose sensation in the glans. Therefore upon recovery these bulls can't find the vulva and achieve intromission and ejaculation. Before surgery the penis should be withdrawn from the sheath. If the penis can be extended completely or up to 6 to 8 inches and sensation is present in the glans the prognosis is good and surgery may not be necessary.^{16,17} If the penis can only be extended 2 to 4 inches the prognosis is guarded and if the penis can't be withdrawn from the prepuce and/or the glans lacks sensory innervation, the prognosis is poor.^{16,17} Nearly 50 percent of the hematomas not operated upon and untreated become infected by the second week after the injury.^{20,25} If abscesses are present, they should be drained and allowed to heal before surgery is performed. Conditions requiring surgery to remove extensive adhesions, abscesses, and scar tissue have a poor prognosis.

The operation commonly undertaken to correct this condition of a ruptured penis and hematoma should not be performed until after the blood in the hematoma has clotted firmly and before organization of the clot occurs. This is usually between the fourth and seventh days after the rupture has occurred. Surgery may be attempted after the third week following the injury but is contraindicated between 10 and 21 days.²⁵ From the time of the occurrence of the hematoma until the time of the operation the bull should be given parenteral antibiotics. Prior to surgery the electroejaculator may be used to determine if normal engorgement of the penis occurs and if sensation is present in the glans penis.^{24,25} If normal engorgement of the penis does not occur, an intrapenile hematoma preventing normal distention of the distal por-

tions of the corpus cavernosum is probably present. If either of these two conditions is present the prognosis is poor.

To perform this operation the bull should be restrained in lateral recumbency after the administration of a pre-anesthetic tranquilizer and gas anesthesia or chloral hydrate^{17,25} or after a large dose of epidural anesthesia (40 to 60 cc of a 2-percent procaine or xylocaine solution) together with a narcotic dose of chloral hydrate, if necessary. This latter method of anesthesia is supplemented by local anesthesia under the skin at the operative site. The operation should be under favorable conditions with as close an approach to an approach to aseptic surgery as possible, since second-intention healing produces many adhesions. After shaving and disinfecting the operative site, an oblique incision 6 to 10 inches long is made through the skin over the swelling.²⁵ All bleeding must be controlled. The clotted blood in the hematoma is carefully removed and the penis brought to the incision. The fibrin is removed. The break in the tunica albuginea is thoroughly exposed, using great care not to injure the dorsal nerve of the penis, coagulated blood in the corpus cavernosum is expressed, and the rent in the tunica albuginea which is usually 2 to 4 cm. long, spiral, oblique, or longitudinal in direction, is sutured with No. 2 chromic catgut with a shoelace stitch. Most ruptures are in the dorsal or dorso-lateral portion of the penis just cranial to the terminal curve of the sigmoid flexure and opposite the attachment of the retractor penis muscle. Following complete control of hemorrhage, the cavity may be flushed with an antibiotic or saline solution. The elastic layer of fascia containing the vessels and nerves is carefully replaced and sutured. The subcutaneous tissues are approximated with catgut and the skin closed with nylon sutures. The wound should heal by primary intention. Following the operation, parenteral antibiotic therapy is continued. Suturing the tunica albuginea is necessary to prevent a possible venous shunt between the corpus cavernosum penis and the dorsal veins of the penis.²⁵

Copulation should not be permitted for at least 2 weeks and preferably longer, 4 to 8 weeks.^{5,15,16,17,25,26} Success in preventing the development of firm adhesions around the penis was reported by keeping the bull sexually stimulated. Housing it next to a heifer or cow in estrum or teasing the bull daily was recommended. Extending the penis several times a week under tranquilization was recommended.¹⁶ Using the electroejaculator was not recommended¹⁷ until healing had taken place. Daily massage of the affected area for 10 to 20 minutes to break down adhesions and prevent new ones was also recommended.¹¹ This should be continued for 2 to 3 months.

Conservative treatment resulted in recovery in 37 of 47 cases.¹¹ Complications of penile rupture include abscess formation, adhesions preventing protrusion, analgesia of the penis due to injury to the dorsal nerves, a recurrence of the hematoma or a shunt between the corpus cavernosum penis and the dorsal vessels of the penis or the corpus spongiosum on erection.²⁵

Chronic abscesses secondary to hematomas or perforating injuries to the prepuce should be drained into the prepuce if possible to prevent adhesions between the prepuce and skin that occur when abscesses are drained through skin incisions. (See Figure 169.) If the abscess heals but adhesions preventing normal function of the penis and prepuce remain, then the bull may be operated on as described above to separate the adhesions of the prepuce and the penis from the skin or abdominal wall. The prognosis is guarded to poor.

2. Tumors of the penis and prepuce in bulls, stallions, boars and dogs may cause phimosis or paraphimosis or prevent normal intromission. In bulls the only significant tumor is the **transmissible fibropapilloma**.^{9,14} (See Figure 170.) There is definite evidence that this tumor and cutaneous papillomas, or warts (*verruca vulgaris*) in cattle are similar and caused by the same agent. It is probably infectious in nature and the etiologic agent is considered to be a virus. The fibropapillomas are similar to those observed on the vulva of heifers. They are single or multiple, firm, cauliflower-like growths. Young, susceptible bulls, 9 to 18 months of age, are most commonly affected with papillomas. Young bulls housed together frequently mount each other and may injure the prepuce, affording an invasion site for the tumor virus. Injury to the penis is also predisposed by breeding the young bull before the prepuce and glans

penis are fully separated. For these reasons young beef bulls are most commonly affected. Hemorrhage from the sheath after service and hesitancy or refusal to copulate are frequently noted in bulls with penile tumors. In boars a virus-induced papilloma of the penis which is venereally transmitted has been described.^{9,14}

In stallions tumors of the penis are uncommon and when present are usually **squamous cell carcinomas** of low malignancy. (See Figure 171.) Benign squamous papillomas, angiomas and melanomas may occur in or on the sheath and penis of horses.^{6,9} Carcinomas often ulcerate and usually bleed at the time of service and produce a fetid preputial discharge. They should be differentiated from granulomas caused by *Habronema* larvae. Squamous cell carcinomas may be favored in the stallion, bull and dog by the smegma in the sheath.⁹

The **transmissible venereal tumor** is the most common one seen in the penis and prepuce of dogs. It is usually spread by coitus. In rare instances the disease may be spread by licking of the vulvar or preputial discharges of affected dogs. Intact cells must be transplanted to transmit the tumor; it is not transmissible by filtrates. The incubation period is from 5 to 6 weeks. All breeds of dogs are susceptible. It is characterized by a discharge of a bloody, fetid exudate from the vagina of the female and from the prepuce of the male. When the penis is exposed, greyish-red nodular growths are observed on the penis and the prepuce. The tumor masses are friable and bleed when handled. In advanced cases the tumor may also be observed involving the inguinal lymph glands. The tumor ulcerates easily. It may be found in other cutaneous sites but internal or metastatic involvement is uncommon.^{9,10,14} The transmissible venereal tumor has been reported widespread throughout the

Figure 170. Transmissible Fibropapilloma of the Penis in a Young Bull. (Courtesy K. McEntee.)

Figure 171. Squamous Cell Carcinoma of the Penis and Sheath in a Stallion.

world but most commonly in tropical countries. The disease may be common in an area and then in the next decade or two disappear or be rarely observed. Papillomas, squamous cell carcinomas, sarcomas, and other tumors may occur in the sheath or on the penis of dogs.³ Recent reports have indicated that removal of the canine venereal tumors by electrocautery or surgery followed by chemotherapy with vincristine¹³ or by vincristine alone, 0.025 mg/kg. IV, once weekly for about 4 weeks⁴ appear promising. However spontaneous regression of tumors is frequent and may occur within 2 months.⁹ Tumors of the sheath and penis of rams, bucks and toms are rare.

In the treatment of penile tumors in the bull it should be noted that spontaneous recovery from infectious fibropapillomas usually occurred in an average time of less than 4 months, range 1 to 15 months.^{1,14,19} The nearer the bull was to 2 years of age the better the prognosis.⁷ If the tumors are multiple on the penis, treatment may be difficult and some veterinarians have empirically recommended the use of wart vaccine. The tissue vaccine was more effective in producing an immunity than was the egg-yolk vaccine.¹ Formalin-killed vaccine given intradermally to calves at 2 weeks to 6 months of age provided good protection.¹⁹ The vaccine was of questionable value in affected bulls. They recommended that semen from affected bulls not be used or frozen because of the danger of transmitting the virus to cows. Disappearance of penile tumors in 4 out of 5 young bulls was reported after the administration of an autogenous vaccine.²¹ However, others¹⁹ found the vaccine induced no appreciable regression in experimentally induced warts. The value of wart vaccine in the treatment of cutaneous papillomatosis is questionable on the basis of their work, which indicated fairly rapid spontaneous recoveries. Fibropapillomas have been removed by the author and others²³ from the penis of bulls when they had a narrow base or were pedunculated, by grasping and pulling them off as the bull mounts a cow. Some bleeding occurred, but it was not excessive. By means of a pudendal block or tranquilizers and local anesthesia the penis can be withdrawn from the sheath and the tumors removed with scissors or by cautery and the mucous membrane of the penis or prepuce sutured with fine catgut. The prognosis is good whatever treatment is used.

In the stallion the occasional squamous cell carcinoma can be removed by a liberal incision or if necessary by amputation of the penis. Castration should be performed prior to amputation of the penis, since both operations performed simultaneously might cause excessive tissue reaction and swelling. The operation for amputation of the penis is a standard one described by Williams and

modified by other authors,^{22,25,27} to prevent a future stricture of the urethral orifice. After restraining the animal in lateral recumbency and giving general or local anesthesia, the penis is withdrawn and thoroughly washed and prepared for surgery. A catheter is introduced into the urethra. To control hemorrhage, an elastic ligature is placed tightly around the proximal end of the extended penis. In the prolapsed equine penis the operative site is just distal to the internal preputial ring. A triangular incision is made over the urethra with the base of the triangle cranial and under the amputation site. The urethra is opened and sutured to the edges of this triangular incision. The penis is cut off at the base of the triangle. By using strong nylon sutures, the urethral wall, the ventral and dorsal portions of the tunica albuginea, and the dorsal skin of the penis, or the prepuce, but not the corpus cavernosa are drawn firmly together with many interrupted sutures, to control hemorrhage.

In the dog, surgery may be indicated for the removal of the transmissible venereal tumor. The earlier surgery is undertaken, the better the likelihood of a successful operation. Liberal excision of the involved tissue is desirable. Complete removal of the penis and prepuce is questionable as even in advanced cases the tumor may regress spontaneously. Dogs which recovered were immune.³ Whole-blood transfusions from an immune dog resulted in a cure or regression of the tumor in affected dogs. In severe cases where it is difficult or impossible to remove all of the involved tissue, radiation therapy may prove of value. Claims for cures of this disease in dogs should be considered with caution because of the high incidence of spontaneous regression usually occurring in less than six months.³ Spaying of females and elimination of stray dogs is very helpful in controlling the disease.¹⁰

3. Phimosis or stenosis of the preputial orifice, chronic prolapse of the prepuce, and paraphimosis preventing normal protrusion of the penis is a cause of inability to copulate. It may occasionally be congenital in young dogs, toms and stallions. Stenosis of the preputial orifice is usually acquired due to injuries, wounds and infections. In cattle with pendulous sheaths, the preputial orifice may be stepped on causing severe contusion and swelling. In beef bulls chronic prolapse of the prepuce is a very common cause of posthitis and phimosis (See Figure 172.)

Congenital stenosis of the external preputial orifice in dogs may be successfully corrected by a dorsal incision of the orifice. Incising a stenotic internal preputial ring in a stallion to permit normal erection and protrusion of the penis was described.⁴ Removal of the preputial ring in a young cat with dysuria and paraphimosis was re-

Figure 172. Chronic Prolapse and Stenosis of the Preputial Orifice of a Santa Gertrudis Bull.

ported.⁶ In the bull, dog or ram the usual procedure to correct a simple stenosis of the preputial orifice caused by cicatricial tissue is to remove from the ventral of the sheath a triangular portion of skin. The base of the triangle is at the preputial orifice. After the skin is removed an incision is made through the midline of the prepuce to the apex of the triangle and after careful hemostasis the preputial membrane is sutured to the skin by interrupted catgut sutures.

Chronic prolapse of the prepuce is most common in **Bos indicus** cattle such as: Santa Gertrudis, Brahman or Zebu, or their crosses, in **Bos taurus** cattle it is less common but is seen in the polled beef breeds such as: Angus and Polled Hereford cattle. It is occasionally seen in other beef breeds and is rare in dairy cattle. It probably is an inherited trait. (See Figure 172.) In Polled English breeds prolapse of the prepuce may be due to a genetic absence of the retractor muscles of the prepuce.¹¹ In these breeds the circumference of the preputial orifice and the length of the prepuce was similar to the normal breeds. In the affected breeds the prepuce commonly prolapses 7 to 20 cm. and depending on the nature of the grazing area, especially the height and type of brush or herbage, and time of year, the prolapsed sheath becomes dry, traumatized, lacerated, frost-bitten, edematous, swollen and fibrotic. Screwworm infestation may also occur resulting in phimosis and rarely paraphimosis.

In mild cases diagnosed early the affected bull may be confined in a well-bedded stall. The prolapsed organ should be carefully washed, cleansed and dried. Oily antibiotic or bland antiseptic preparations are applied and the prolapse replaced and held in place by a purse-string suture around the preputial orifice. Repeated treatments

two to three times a week for three to four weeks before allowing breeding are indicated. In more severe cases where replacement is not possible, circumcision or even amputation of the affected portion of the prepuce may be necessary.

Before surgery in severe cases the sheath and penis should be cleaned with hydrogen peroxide and furacin solution, and oily antiseptics or antibiotics and lanolin be applied for about a week to the prolapsed structures under a stockinette held in place by a rubber band.^{8,18} The pendulous sheath and prolapsed membranes should be supported for this period to possibly control or reduce the swelling and edema. Hydrotherapy consisting of spraying the prolapsed sheath with warm water at frequent periods daily may be helpful. Systemic administration of antibiotics and diuretics may be indicated. Other authors suggested that immediate circumcision was more practical and economical.^{2,5} In any surgical procedure as much of the prepuce should be conserved as possible. Removal of large portions of the prepuce may result in inability to protrude the penis the necessary length for natural service. In all severe preputial lesions requiring surgery or extensive treatment, a long recovery period of 30 to 90 days is required for complete healing before service should be permitted. Depending on the type and degree of prolapse of the prepuce, the breed and value of the bull and the operator's experience one of three (3) general operative procedures may be employed.¹⁸ a) **circumcision** may be employed to correct chronic prolapse of the prepuce.^{10,13,16,17,18} In Brahman bulls the prepuce is usually long enough to permit a removal of a portion of it by circumcision without causing limitations on penile extension during erection. In the English breeds the operator must conserve as much preputial membrane as possible so the reefing or resection^{8,15,18} operation is preferred. Following tranquilization and restraint in lateral recumbency the prolapsed tissues are washed, cleansed and anesthetized.^{8,18} General anesthesia may be used. An inverted triangular incision, 5 to 7 cm., 2 to 3 inches, on a side is made on the ventral, posterior aspect of the sheath through the skin only. The base of the triangle is at the preputial orifice. After removal of the skin an incision is made through the ventral caudal midline of the prepuce to the apex of the triangle. Careful hemostasis is highly essential before placing interrupted nonabsorbable nylon sutures to secure the internal preputial membrane to the skin. This later prevents the possibility of scarring and stenosis of the preputial orifice. Then the diseased prolapsed portion of the prepuce is removed after placing interrupted nylon sutures around its circumference firmly securing the internal preputial membrane to the external at the preputial orifice. These

sutures are usually about 4 cm. apart on the outside and 1.5 cm. apart on the inside. They should be drawn tightly and overlap to completely control hemorrhage then the prolapsed portion of the prepuce is removed about 1 cm. distal to the suture line. Following the operation the sheath should be supported against the body wall for two weeks.

The sutures can be removed in about 6 to 8 days. Parenteral antibiotics should be given for 7 to 10 days. b) **"reefing" type of operation** involving resection and anastomosis is superior to other procedures, particularly when the midportion of the prepuce is involved, or when as much prepuce as possible must be conserved.^{8,15,18} An incision is made at the skin line of the preputial orifice and at the distal end of the prolapse where the "inner" preputial membrane is normal. A longitudinal incision is made between these two initial transverse incisions and the diseased "outer" preputial membrane and underlying edematous, fibrous or abscessed tissue is removed. Hemorrhage must be carefully controlled. Electrocautery, maybe a useful adjunct to ligatures. The normal preputial membrane and underlying tissue is sutured carefully by many interrupted catgut sutures to the skin and subcutaneous tissue at the preputial orifice.^{2,5,8,15,17,18} Antibiotics should be administered locally and systemically for the next 7 to 10 days. A large Penrose drain fastened into the sheath and around the penis to prevent irritation of the suture line by urine and a purse-string suture in the skin at the orifice to invert the suture line was recommended.¹⁵⁻¹⁸ This purse-string suture is removed after one week. If following this treatment constriction of the preputial orifice occurs then a second operation consisting of a triangular-shaped incision on the ventral-caudal aspect of the preputial orifice is performed as previously described. As a preventive measure in bulls affected with chronic prolapse of the prepuce, removing a large-V-shaped wedge of skin from the suspensory skin flap of the sheath to reduce its pendulous attachment has been suggested.^{1a}

Where the prepuce is more extensively involved some veterinarians¹⁸ use an c) easier amputation technique where the entire prolapsed part is removed by through and through overlapping sutures over a perforated plastic ring securely fastened by interlocking sutures into the preputial orifice. This may result in too great a loss of normal preputial membrane.

Bulls with a lack of libido and sex drive may fail to breed satisfactorily after these treatments because of pain associated with erection and coitus. Chronic prolapse of the prepuce may be prevented or controlled by the selection of bulls with smaller preputial orifices and with less tendency to prolapse their preputial membrane. It is questionable and probably undesirable to operate on af-

fected bulls since this condition is genetically predisposed. These bulls should be culled to decrease the frequency of this trait in the population. Males should be selected for lighter, less pendulous sheaths with smaller preputial orifices and stronger retractor penis muscles.^{7,14} Surgical procedures for prolapse of the penis and prepuce in boars and dogs has been described.^{1a,c}

Paraphimosis, the inability to withdraw the penis into the prepuce, results in edema, swelling, and balanoposthitis. It may occur following erection of the penis through a stenotic preputial ring or orifice caused by a congenital or acquired stricture or by tumors as noted above under phimosis. Paralysis of the penis and paraphimosis may be due to spinal disease or trauma. Paralysis of the penis is seen in bulls with rabies and in horses in the late stages of dourine. It is possible that the posterior paresis reported in a few cases of rhinopneumonitis, due to equine herpesvirus 1, might be the cause of occasional unexplained cases of penile paralysis in stallions. Resection of the retractor penis muscle in bulls with pendant sheaths may cause paraphimosis. It is not observed in the dairy breeds with a sheath that is closely attached to the abdominal wall. The author has observed and had reported to him at least 15 cases of paralysis of the penis with paraphimosis in geldings and stallions following the use of phenothiazine-derived tranquilizers. The product most commonly associated with prolonged or permanent paraphimosis has been withdrawn from the commercial market.

The prognosis in paraphimosis in males is guarded and depends upon the promptness of treatment and the degree of trauma or necrosis present. Support of the prolapsed penis and sheath is essential to minimize gravitational edema.^{13,18} Cases of paraphimosis in horses following castration and the use of tranquilizers should have the penis supported or held within the sheath within an hour or two of its occurrence to prevent a chronic prolapse of the organ often necessitating amputation. Cold packs and pressure may reduce the swollen penis and allow replacement. In some cases in dogs and occasionally in bulls, enlargement of the preputial opening is necessary in order to replace the penis and prevent a recurrence of the condition. For necrosis of the penis secondary to acute paraphimosis and for chronic paralysis and prolapse of the penis in dogs and cats is amputation is recommended. To correct chronic protrusion of the tip of the canine penis due to a "short" prepuce, a "long" penis or inefficient cranial preputial muscles surgically shortening these muscles or removing an elliptical portion of skin cranial to the prepuce to draw the prepuce over the penile tip is recommended.^{3,6a,b,9}

In bulls cleaning of the penis, removal of necrotic tis-

sue, and the liberal application of ointment was recommended.¹⁷ Gauze should be wrapped around the penis to protect it. The penis with its gauze dressing should be placed inside the sheath as soon as possible. Petroleum jelly should be packed into the sheath to prevent adhesions. Frequent withdrawal of the penis and applications of ointment are indicated.

Balanoposthitis due to infectious or noninfectious causes may produce a stenosis of the preputial orifice, adhesions of the penis and prepuce to each other or to the surrounding tissues or produce sufficient pain and discomfort that copulation is impossible or not attempted. Balanitis is an inflammation of the glans penis, and posthitis is an inflammation of the prepuce. They are often both involved in an inflammatory reaction because of their close apposition. Balanoposthitis is common in the bull, ram and dog and uncommon in the boar and cat. It is observed occasionally in the stallion.

The preputial cavity in the bull may normally contain a wide variety of bacteria, molds, protozoa and viruses including: *Campylobacter fetus venerealis*, *E. coli*, streptococci, staphylococci, *B. pyocyaneus*, *Pseudomonas aeruginosa*, *C. pyogenes*, *Proteus*, *Actinomyces necrophorus*, actinobacilli, molds (*Aspergillus*, *Mucor*, *Absidia*), mycoplasmas, ureaplasmas, *Klebsiella*, *Hemophilus*, *Trichomonas fetus*, **IBR-IPV virus**, and other pathogenic and saprophytic organisms.

Other male animals have a similar variety of infectious agents as inhabitants of the prepuce. It is often difficult to recover specific slow-growing pathogens from the prepuce of bulls and other males because rapid-growing contaminants overgrow the cultures. Granular venereal "disease" lesions or hypertrophy of lymphoid nodules on the penis and prepuce of bulls and dogs are common, but are not associated with any specific organism and have little significance. (See Figure 173.) Sexual rest and protective antibiotic solutions in oil infused into the sheath usually alleviate acute signs of granular venereal disease or mild balanoposthitis. No obvious balanoposthitis generally accompanies the presence of the above organisms in the preputial cavity with the possible exception of **M. tuberculosis** and the acute form of IBR-IPV virus infections.

Tuberculosis of the sheath, penis, prepuce, and penile lymph glands of bulls has been described.³⁷ This avenue of invasion in the bull is invited by tuberculosis of the female genital tract. Tuberculosis of the sheath and penis may be characterized by enlarged, granulomatous bleeding lesions of the glans penis, adhesions of the penis, prepuce, and sigmoid flexure with secondary phimosis. The penile lymph glands are enlarged and are likely to be abscessed. In suspicious cases either culture of the

Figure 173. Chronic Granular Venereal Disease Lesions of the Bovine Penis and Sheath.

lesions or a tuberculin test will probably establish the diagnosis. This type of tuberculosis has not been reported in recent years in the United States. Several rare cases of actinomycosis affecting the sheath and glans penis of bulls have been reported.³⁷ The lesions resembled those of tuberculosis.

Trauma, abrasions, lacerations of the prepuce or glans penis usually result in the introduction of the above wound-infection organisms into the deeper tissues with resulting swelling, inflammation, pain and preputial discharge. This is observed most commonly in young bulls especially those in which the glans penis is not completely separated from the sheath. In artificial insemination studs injuries from the artificial vagina may occur including the loss of a rubber band from the vagina onto the glans penis. This may cause a deep laceration or amputation of the glans. Young bulls running together in the early spring months may, by their homosexual behavior and frequent mounting, draw hair into their prepuce where it forms a stenotic ring at the base of the glans with an associated balanoposthitis. In rare cases this ring of hair may result in the sloughing or amputation of the glans penis. Mild balanitis and posthitis have been observed in virgin bulls or in young bulls after they have bred older cows. *C. pyogenes*, *E. coli*, and other organisms present in the prepuce of certain bulls may cause a temporary vulvovaginitis in females after coitus.³ Although many miscellaneous organisms may be introduced into the prepuce, recovery is usually spontaneous with no clinical lesions.

The herpesvirus of cattle, IBR-IPV, can produce an

Figure 174. Dislocated Hip in a Jersey Bull.

acute inflammation and ulceration of the penis and prepuce (infectious pustular balanoposthitis (IPBP)) accompanied by a short period of elevated body temperature when introduced into the preputial cavity of susceptible bulls.^{7,26,34} This disease was formerly called vesicular venereal disease in the U.S. or Blaschennausschlag in Germany. The initial area of involvement is the epithelium over the lymphoid follicles that becomes necrotic and sloughs. The ulcers on the glans and prepuce caused by the virus are secondarily infected by the bacterial flora of the sheath resulting in a severe pustular balanoposthitis. Abrasions of the penis and sheath that occur at copulation make the lesions in the acute stage more severe. The virus can usually be recovered from the acutely affected bull's prepuce and penis for about 10 to 14 days. Bulls may spread this disease during this period to cows by copulation producing pustular vulvo-vaginitis. Some

cases of balanoposthitis may be so mild that infection may go undetected. The recovery of this virus from the prepuce of bulls for a period of up to 361 days has been reported.²⁹ These are often refractory or immune animals. Serum antibodies are developed but the titers are low 1:10 to 1:100 on the serum neutralization test.²⁵ On histologic section of affected tissues eosinophilic nuclear inclusion bodies may be found in many cells. Epizootic outbreaks of balanoposthitis in young range bulls might be due to this agent.¹¹ Lymphoid follicular hyperplasia was noted in the prepuce and penis following outbreaks of infectious pustular balanoposthitis (IBR-IPV) in bulls.^{19b} A few outbreaks have been reported in artificial breeding studs where there is a great danger of this virus being disseminated in liquid or frozen semen since antibiotics commonly placed in semen extenders have no effect on this virus.²⁵ Coital exanthema due to the IPV virus was common in dairy herds and was occasionally seen in AI centers in Germany.³² It was demonstrated by electrophoresis that the IPV virus differed from the IBR virus even though by serological methods they were similar.³³ A highly attenuated vaccine was prepared that would protect the cows and bulls if instilled intranasally and intravaginally or into the prepuce of bulls yet would not produce signs of the disease even if semen from recently vaccinated bulls was used for artificial insemination. The field strain of IPV virus if present in the semen would reduce conception rates by about 7 percent and produce signs of the disease. This highly attenuated vaccine was administered as noted above twice at 6-week intervals and then once yearly thereafter. No abortions were produced by the vaccine given to pregnant cows and challenged cattle showed no evidence of disease. The local immunity produced by this vaccine was better than the immunity produced by an intramuscular injection of a vaccine. Bulls in one large AI stud in the U.S. are rou-

Figure 175. Spastic Syndrome or Stretches in an 8-year-old Holstein Bull.

tinely vaccinated with an IBR vaccine intranasally twice or three times a year. There is no evidence that bulls vaccinated with this vaccine have transmitted the IBR-IPV virus in the semen. This has been determined by routine cultures of over 70,000 ejaculates.^{15,26}

In severe cases acute swelling, pain and later local scarring may cause difficulty or slowness in copulation. True adhesions were not observed.^{7,34} In range bulls with great libido repeated abrasion of infected and inflamed tissues might occasionally produce adhesions. For treatment sexual rest is recommended together with local antibiotic therapy of the sheath. Most bulls recover within one to two weeks but it may take up to a month before normal copulation will occur. Because of the infectious nature of this disease bulls should not be used for service until 6 to 8 weeks after the onset of the attack. Since herpes viruses tend to persist in the body, recurrent dissemination of virus may occasionally be possible.^{25,29}

Balanoposthitis in rams, "pizzle rot" or "sheath rot," may be infectious or noninfectious. The most common infectious form of balanoposthitis is due to the virus that causes ulcerative dermatosis (lip and leg ulceration or necrotic venereal disease). This disease has been described in the U.S., England, France and Germany.^{17,20} The lesions on the preputial orifice, prepuce and glans penis are ulcerative and covered by a scab. Removal of the scab reveals a shallow, raw, bleeding crater containing a creamy odorless pus. The preputial lesions may cause phimosis or paraphimosis, and an extensive penile lesion may render the ram useless as a breeder. Lesions may also be present on the lip, nostril, feet, or vulva. The disease should be distinguished from contagious ecthyma and common non-specific lesions occasionally seen on the preputial orifice of rams. Ulcerative dermatosis is spread by venereal contact and other means. The disease in rams may persist for weeks or months. Affected rams should not be used for breeding. There is no vaccine available nor is there any specific treatment for the lesions.

Noninfectious balanoposthitis has been described in the U.S. and Australia. Two types of lesions are recognized, an ulceration of the prepuce near the preputial orifice and a stenosis of the orifice with a secondary chronic ulceration of the deeper portions of the prepuce accompanied by an accumulation of pus and necrotic material. This occurs mainly in wethers, sheep and goats, or occasionally rams 2 to 4 years of age. It is often associated with a wet spring and pasturing sheep on lush fertilized grass, rye, clover or lucerne pastures that are high in protein and the presence of a urea-hydrolyzing *C. renale* in the wether's sheath. The urine degradation products are more irritating to sheath tissue than normal

urine.^{22,28} The preputial orifice and prepuce may be ulcerated and scarred so urination is difficult. Changing of the diet to dry feed with a lower protein intake, or fasting, results in an improvement of the balanoposthitis. Young rams housed together may develop similar lesions possibly due to trauma and contamination. In severe cases the sheath may have to be surgically opened ventrally to permit urination to save the life of the animal. Extending the preputial incision too far caudally may render a ram useless for service. Superficial external lesions may be treated by proper local therapy.

A clinically similar type of posthitis was observed in many young beef bulls, but not steers, in South America and Australia. A high incidence occurred in bulls on high planes of nutrition possibly due to the presence of *C. renale* in the sheath that hydrolyzed urea to ammonia that caused the lesions. The clinical history and histologic examination indicated the condition was not due to the IBR-IPV virus. Further studies are indicated.²⁴

Balanoposthitis in the horse may occur in geldings or stallions. A thick, fibrous, fatty or edematous sheath is often diagnosed erroneously as due to a balanoposthitis when no inflammatory lesions are present. Balanoposthitis due to bacterial agents are uncommon in stallions even though various infectious agents may be carried from mare to mare on the penis and prepuce. Early symptoms of dourine, a reportable venereal disease of horses transmitted by coitus, are swelling, edema and reddening of the penis and prepuce. This disease, not seen in the U.S., is caused by *Trypanosoma equiperdum*. Later in the disease process depigmentation of the skin of the genital organs may occur.⁸

An equine venereal balanitis and vulvitis, formerly called genital horse pox or coital exanthema, caused by a herpesvirus has been described.^{9,13} (See Figure 147.) After an incubation period of 6 to 8 days circular, confluent, poxlike lesions occur on the skin of the penis. These lesions heal in 10 to 14 days if secondary infections do not occur. Depigmentation of affected areas is common. There is no effect on fertility but affected stallions may refuse or hesitate to copulate. Withholding affected stallions from service to prevent the spread of infection to susceptible mares and local conservative treatment of the lesions is indicated. One attack does not confer a permanent immunity.¹⁸ This virus is not the rhinopneumonitis virus. The disease is occasionally seen in the U.S. especially on breeding farms where it may spread rapidly by coitus or grooming.

Cutaneous habronemiasis, summer sores or genital bursatti may affect the equine penis and prepuce. The Habronema larvae may produce fungoid granulomatous growths 1 to 3 cm. in diameter that may contain firm

necrotic, irregular-shaped masses or "kunkurs." These lesions bleed readily on manipulation.^{18,31} The lesions are not seen on the genitals of mares. These lesions may produce intense pruritus. In some cases their presence near the urethral process results in difficult frequent urination with spraying similar to that produced when the urethral diverticulum is distended with smegma causing compression of the urethra. In the colder northern states these lesions subside and usually disappear during the winter months. These granulomas may be treated by topical organophosphates, amputation of the penis or the urethral process depending on its size and location.^{14,31} Local treatment with camphophenique in scarlet oil or an organophosphate preparation daily and a systemic organic phosphate insecticide ("Ronnel") at a dose of 90 mg/kg by stomach tube repeated in two weeks was recommended.³⁶ In countries where the screwworm or *Cochliomyia* fly is present, severe infestations of the sheath and glans penis of geldings or stallions may occur resulting in pain, bleeding and swelling. Good restraint, often requiring general anesthesia, is necessary to get adequate exposure for local treatment of lesions with Smear 62 or camphophenique. Further infestation should be prevented by confining the animal in a barn and treating the external preputial opening with fly repellent. Multiple, small ulcerous lesions on the penis and prepuce of a horse associated with spirochetes was reported.²³ The lesions healed in about three weeks and the spirochetes disappeared. In some horses excessive accumulations of smegma within the prepuce may be associated with a keratin-like coating of the penis and prepuce. Manual cleansing of the equine sheath with soap or oily antiseptic solutions is accomplished by restraint and the liberal use of cotton swabs. Wearing plastic or rubber gloves is advisable because of the odor of the smegma. Occasionally a heavy growth of *Pseudomonas* and/or *Proteus* organisms are present in the equine sheath causing an objectionable odor and excessive smegma. Regular cleaning of the sheath with mild soap and water and occasional application of neomycin, or a similar antibiotic, in a vegetable oil vehicle may be indicated.

Balanoposthitis seldom occurs in the boar. The preputial diverticulum in the boar often fills with foul-smelling urine and smegma and externally may resemble an umbilical hernia. (See Figure 160.) This can readily be differentiated from a hernia on clinical examination by squeezing the enlarged diverticulum and expressing its odoriferous contents. In boars concretions and preputial calculi and diversion of the penis into the preputial diverticulum occasionally were present, causing difficult urination and inability to protrude the penis.¹⁹ Extirpation of the preputial diverticulum of boars will markedly

reduce the bacteria in semen collected for artificial insemination and also greatly reduce the boar odor.^{1,19} The boar's sheath may become infested with screwworms. In pigs with hog cholera ulcers of the prepuce as a result of infarction have been reported.¹² Ulcerations of the porcine penis due to other causes may be observed. These conditions in boars are usually easily diagnosed and treated. Surgical procedures for prolapse of the penis and extirpation of the porcine preputial diverticulum have been described.^{6,19}

In the dog, balanoposthitis is occasionally observed but seldom if ever, is a cause of failure of copulation. It is characterized by a discharge of pus from the prepuce and it usually responds well to mild antiseptic douches followed by bland antibiotic ointments or solutions. Balanoposthitis in the dog should be differentiated from the prostatitis as both are characterized by pus appearing at the preputial opening. Suppurative, ulcerative and follicular balanoposthitis or preputial catarrh is common in the dog.⁵ It is interesting to note that follicular lesions occur in the prepuce of the dog and are similar in nature to the enlarged lymph follicles or to the granular venereal disease lesions seen in the prepuce of the bull. (See Figure 173.) As noted under IBR-IPV infection of the prepuce and penis in bulls isolation of a herpesvirus from the sheath of dogs has been reported.¹⁰ Balanoposthitis in the dog, as in other animals, is due to mixed infections, trauma, foreign bodies, other general diseases, and debility. The malicious or ill-considered placement of a rubber band around a dog's penis causes great discomfort, severe balanoposthitis and even necrosis of the penis. In the dog acquired phimosis is less frequent than is congenital phimosis.⁵

The prognosis in balanoposthitis depends upon the severity of the trauma or the infection. In mild cases the prognosis is good. In severe chronic cases with adhesions between the penis and prepuce or between the prepuce and adjacent tissues, the prognosis is guarded to poor. Some males may be slow to regain their libido following a painful balanoposthitis.

Treatment of mild cases of balanoposthitis may consist of douching the prepuce with aqueous or oily antiseptics or antibiotic preparations such as saline, 50 to 200 ppm. of chlorine solution, 1:2,000 acriflavine or very dilute potassium permanganate solutions, 1 percent hydrogen peroxide solutions, one ounce of bismuth formic iodide in a 500 ml. of mineral oil, 1 gm. iodine in one gallon of mineral oil, infusions of aqueous furacin and other antibiotics in oil in about 25 to 100 ml. volumes. Caustic or irritating antiseptics should be avoided. Treatments may be repeated at daily to weekly intervals. In cases of severe balanoposthitis with extensive necrosis

of the prepuce and penis adhesions may result if frequent oily antiseptics or antibiotic ointments and systemic antibiotics are not employed. Regular gentle protrusion of the penis may be desirable to prevent possible adhesions. Tranquilizers, anesthetics, pudendal nerve block, electroejaculator, and adequate restraint are helpful in applying treatment for balanoposthitis. Sexual rest is essential during and for sometime after the treatment of acute balanoposthitis to promote recovery and to prevent a loss of libido associated with the painful condition.

Miscellaneous Causes for Loss of Libido or Inability to Copulate include: 1) hernias 2) premature erection 3) short penile bone (dog) 4) loss of sensory innervation of the glans penis 5) vascular shunts causing failure of erection 6) urinary calculi and 7) other causes.

1) Umbilical and ventral hernias as well as a deep pendulous abdomen may interfere or prevent normal copulation by affecting the entry of the penis into the vagina at a natural mating. Umbilical and small ventral hernias may respond to surgery but since umbilical hernias may be hereditary the affected male should not be used as a sire. About 1 percent of Santa Gertrudis bulls and Holsteins in Australia have umbilical hernias.¹⁴ These affected animals should be culled and not operated upon. Extensive unilateral hernias or a deep "paunchy" abdomen usually observed in older bulls or rams may interfere with normal intromission and thrusting especially if arthritic lesions are also present. Marked reduction of roughage and bulky feeds is indicated in these males but the prognosis is usually guarded to poor.

2) Premature erection may occur in the dog, stallion and certain bulls and interfere with normal intromission. Premature erection in the dog as an obstacle to coitus and a cause of impotency has been described.¹¹ Complete erection normally does not take place until the canine penis is in the vagina. Artificial insemination was recommended as the quickest and easiest solution for this problem.¹¹ In stallions the glans penis occasionally becomes too large by "flowering" or "belling" to readily enter the mare's vulva. This cause of inability to copulate can usually be overcome by helping to direct the penis into the vulva before it becomes fully erect or by lubricating the vulva. As described previously certain beef bulls with a strong sex drive and with a narrow penis develop a "corkscrewing" or coiling of the free end of the penis at premature full erection that prevents intromission. (See Figure 165)

3) Occasionally a dog will have a short penile bone with a long flaccid cranial portion of the penis that is difficult to direct into the vulva at coitus.⁹

4) Loss of sensory innervation of the glans penis prevents natural intromission and the "thrust" reflex nec-

essary for ejaculation and leads to a pronounced decline in sex drive. Lack of sensation of the glans penis may be caused by injury to the dorsal nerve of the penis secondary to rupture and hemorrhage of the corpus cavernosum penis, by the improper technique of injecting local anesthesia on the dorsal nerve of the sigmoid flexure of the penis, occasionally by an operation to correct the spiralling of the bovine penis or by a rubber band from an artificial vagina or other source that is placed around the penis and not removed for several days. Lack of sensation of the glans penis may also be due to necrosis of the mucosa of the glans secondary to severe balanitis of an infectious etiology or due to trauma resulting in severe scarring. Amputation of the glans penis by a rubber band or following extensive surgery for a tumor produces the same local "anesthetic" effect. Males that have had experience breeding before the loss of sensation in the glans penis remain sexually active but suffer from a definite loss of libido. Immature males with a similar loss seldom show much sexual desire as demonstrated by mounting and actively seeking the vulva with their penis. In bulls topical anesthesia of the glans penis caused intromission to be difficult and delayed but copulation occurred. Topical anesthesia of the glans as well as the free portion of the penis blocked the ability to copulate. Infiltration of the glans penis with a local anesthetic prevented ejaculation. Bulls with unilateral dorsal penile nerve neurectomy were able to copulate but time to ejaculation was prolonged. Bulls with bilateral neurectomy were unable to copulate.⁴ Thus it is possible the bulls may recover from a hematoma or penile surgery and in a few weeks or months develop signs of decreased ability or inability to copulate due to adhesions around the penile nerves with secondary degeneration due to subsequent injury or stretching. An experimental study of the results of desensitization of the glans penis in the cat was reported.¹ Damage to the nerve supply of the ischiocavernosus muscle may cause its atrophy and result in the inability of the penis to become erect.

5) **Vascular shunts causing failure of erection.** In bulls exhibiting a flaccid penis or only a partial erection that was lost rapidly during attempts at natural service or on stimulation with an electroejaculator before intromission or full erection was accomplished often were shown to have shunts between the corpus cavernosum penis and the extrocarporeal circulation of the penis.²⁵ Some of these shunts were acquired after rupture of the tunica albuginea of the penis and hematoma formation with spontaneous healing, deep lacerations of the penis and surgical operations to correct penile deviations. In other bulls multiple shunts of a congenital nature were observed in the distal portion (glans) of the penis. Serial

contrast radiography confirmed the suspected diagnosis,^{22,25} and surgical correction was described for valuable bulls with only one or a few shunts. Using a wedge resection of the tunica albuginea, surgery was successful in 4 of 8 bulls.²⁵ English workers described 6 bulls in 3 breeds with good libido but 5 were unable to erect the flaccid penis to protrude it from the sheath. This was caused by major venous drainage of the corpus cavernosum penis by the dorsal venous system.³ A similar impotence was reported in five boars with inability to obtain or sustain penile erection and copulate. This condition was developmental in origin with abnormalities of the dorsal venous system allowing blood to drain from the corpus cavernosum penis.²

6) Urinary calculi lodging in the urethra may occasionally be a cause of acute pain, obstruction and rupture of the urethra in male domestic animals and cause reluctance to copulate and inability to ejaculate. Urinary calculi were described in a bull with inability to copulate and exhibiting impotentia coeundi.²¹ The author has observed several bulls with urethral calculi, that refused to copulate and one that copulated and bled from the urethra. In cases of urinary or urethral calculi the prognosis for the future breeding life of the male is grave. Although an operation can be performed and the calculi removed, suturing of the urethra often results in a stricture. When the urethral and skin incisions in the bull are left open to heal by second intention, in order to save the animal for future breeding an urethral fistula or strictures often form. Other calculi may lodge in the same area; or adhesions form in the region of the sigmoid flexure and the ability to protrude the penis is lost. Leaving the skin and urethra open to heal by second intention is however occasionally successful in the dog and has been reported in the bull. Depending on the location of the urethral fistula the male may be unable to properly place the semen in the vagina. A urethral calculi retriever (Haver-Lockhart Lab., Shawnee, Ks.) modified after a human retriever for urethral calculi has been described.¹⁵ This has proven successful in cases where tranquilizers and muscle relaxants when administered early failed to result in the passage of the calculi from the usual site of lodgement at the sigmoid flexure. The bull is placed in lateral recumbency under tranquilization. Pudendal nerve block may also be used. The penis is fully extended and the retriever with proper lubrication is passed beyond the calculi and then withdrawn removing the obstruction. Stricture formation was reported not to be a serious problem.

In the ram calculi may lodge in the sigmoid flexure area as in bulls but are more commonly found in the urethral process. Amputation of the urethral process just

proximal to the calculi is usually performed. If most of the urethral process is removed conception rates might be markedly reduced due to poor distribution of semen in the vagina at the time of ejaculation.¹³

Calculi are common in the male cat¹⁶ and uncommon in the dog.⁶ In order to preserve the breeding potential of these animals conservative therapy such as massage and flushing in the removal of the urethral calculi and in the aftercare is indicated, surgery should be used only as a last resort. The use of a loop of no. 26 twisted steel wire to remove urethral calculi and mucous plugs in the anesthetized cat has been described.⁵ Up to 1 percent of male cats may develop calculi and recurrence is common.^{16,17} Using a 3" nasal lacrimal duct needle rather than a tom cat catheter and small amounts of 50 percent vinegar in water to remove urethral calculi from anesthetized cats was recommended.^{16,17} There was experimental evidence that several infectious viral agents were important etiologic factors along with other environmental and nutritional factors.^{16,18} Antibiotics such as chloromycetin, reduction of minerals in the diet, lowering the pH of the urine and increasing the water intake and other conservative therapeutic measures¹⁶ may be helpful in controlling urolithiasis in these animals. In the dog calculi tend to lodge at the caudal end of the os penis since the urethra passes along the ventral groove in the penile bone.^{10,23} Urinary calculi ruptured urethras and bladders, greatly enlarged bulbourethral glands and vesicular glands in footlot lambs or wethers given 12 to 15 mg. implants of stilbestrol or 2 to 5 mg. of stilbestrol daily in the feed was reported.^{12,20} This occurred as early as 10 to 14 days after the administration of the stilbestrol.

6) Pain caused by infection of the genital organs or peritoneum may be a cause of impotency or refusal to copulate. A stallion with infection of the ampullae and seminal vesicles refused to copulate.²⁴ The author has observed several bulls with severe acute semino-vesiculitis that were slow or refused to mount. Two boars with brucellar orchitis refused to copulate and two more had a markedly reduced libido.⁸ Acute prostatitis in dogs might similarly affect copulation. Necrobacillosis of the liver and traumatic gastritis with acute peritonitis may be associated with failure or refusal to copulate in bulls. Severe congenital or acquired cardiac diseases often result in dyspnea and inability to perform coitus by male animals.

Incapacity or Reduced Capacity to Fertilize in Males, Including Hereditary Disorders: (Impotentia Generandi)

Fertility is the normal functioning of the testes, accessory glands and ducts to deliver sperm of normal quantity and quality. Fertility and potency are not correlated or related and may be divergent in the same male animal. Infertility or sterility in males is usually characterized by normal sexual desire and the ability to copulate and ejaculate, but a complete or abnormally high percentage of failure of fertilization or conception, or delayed returns to estrum indicating early embryonic death in the females.

Although most of the causes of incapacity or reduced capacity to fertilize in males is due to acquired diseases or pathological lesions, a significant number of causes are congenital or hereditary and should be recognized to avoid their perpetuation or increase in future generations. Some of these hereditary conditions causing a mild or moderate problem in young males, such as hypoplasia of the testes, can predispose the male to testicular degeneration and more severe infertility or sterility. Excellent reviews of the inherited disorders of cattle related to infertility and fertility have been published.^{12,25}

The incapacity or reduced capacity to fertilize may be characterized by either of two findings following a complete semen examination. In one the semen is essentially normal on examination, and in the other the semen is abnormal in morphology, concentration, motility or other qualities. The former condition is often difficult to explain satisfactorily with our present knowledge; however, recent findings in cytogenetics and electronmicroscopy have indicated several promising leads.

Impotentia Generandi Associated with Apparently Normal Semen Production in cattle has been reviewed

in Chapter XIII in the discussion of herd infertility, "repeat breeders," or failure of conception in females following service by bulls infected with brucellosis, vibriosis, trichomoniasis, and possibly IBR-IPV virus, mycoplasma, ureaplasma or other organisms. Active brucellosis in a herd of cattle is associated with symptoms of infertility; and the intrauterine insemination of brucella-infected semen usually results in infertility. Boars infected with *Br. suis* may carry and transmit the organisms to the female at coitus resulting in early embryonic death and signs of infertility as well as abortions. After examining 828 bulls for infertility in 1953 it was determined that 374, or 45.2 percent were affected with vibriosis or trichomoniasis.²² In this series of cases, however, only 15 of the 374 bulls had trichomoniasis. Sixty percent of 105 herds in all parts of Sweden in 1955 were or had been infected with vibriosis.⁷ The incidence of vibriosis in naturally-bred herds, especially beef herds, in the United States is possibly equally high.

A number of herds with infertility resembling vibriosis were investigated but without finding the cause.¹⁰ Another study reported on herd infertility problems arising in 47 herds in which no diagnosis could be made because no pathological conditions were found in the bulls or cows to explain the sterility.²² Errors or deficiencies in management, as discussed in Chapter XIII may also be the cause of widespread infertility in some herds. Infertile, disease-free male animals with an apparently normal semen picture in regards to motility, concentration and morphology are uncommon if their reproductive management is good.

Abnormal acrosomes, knobbed spermatozoa, related to defective spermiogenesis involving the Golgi apparatus has been described in bulls, boars and dogs as a cause of infertility in semen with normal motility and concentration of spermatozoa. Certain of the stains or techniques used for preparing spermatozoa for morphological examination do not reveal this defect; while others such as nigrosin eosin, India ink or Giemsa show a refractile unstained or lightly stained area in the anterior pole or acrosome of the head of the spermatozoa. An eosin B. and fast green stain of the acrosome of spermatozoa permits examination by a light microscope.^{23,24} Certain sterile Swedish Landrace boars had as many as 80 to 90 percent of their spermatozoa with an acrosomal, knobbed defect.³ Males with about 50 percent of their spermatozoa with acrosomal defects had low fertility. Phase contrast microscopy revealed these defective acrosomes. Sometimes the anterior border of the spermatozoa was flattened due to a protrusion and bending over of the acrosome.³ Nearly all of the spermatozoa in some bulls were affected. The defective acrosome apparently

rendered the sperm cell incapable of penetrating and fertilizing the ovum.⁸ The nature of this defect in bulls was seen under the electronmicroscope has been illustrated.^{3,6,8,19,20} This defect in spermiogenesis is apparently due to an autosomal recessive sex-linked defect in Friesian cattle.⁹ This defect has been reported in a sterile Boxer dog and in Charolais and Holstein bulls in the U.S.¹⁸ (See Figure 178.) This defect was described in two subfertile bulls, a Holstein and a Jersey.²⁰ They had nonreturn rates from AI of 40 and 59 percent, respectively. Three of four sons of the Holstein bull were similarly affected. In the latter Holstein bull 0.3 to 6.2 percent of the spermatozoa had knobbed acrosomes, 1.7 to 9.1 percent had ruffled acrosomes and 2.1 to 21.9 percent had an incomplete or missing portion of the acrosome. This was a defect in spermiogenesis and could be seen in the spermatids.^{19,20} Aging of spermatozoa also produce acrosomal changes and infertility.²¹

Two nearly sterile bulls had semen with normal motility and concentration of spermatozoa. After staining with opal blue and examining the stained cells with a phase-contrast microscope, eversion of the galea capitis and crater-shaped depressions in the nucleus were found.¹ Apparently similar invaginations of the nuclear envelope in the bull and the boar were described that were associated with a severe disturbance of spermiogenesis with many other abnormalities of the sperm cell.⁵ Feulgen stain and phase-contrast microscopy revealed these invaginations to be located near the anterior border of the post-nuclear cap in the equatorial segment of the sperm head. These crater-shaped depressions in the nucleus have been the subject of further studies in which depending on the type of staining and microscopy have been called "diadem sperm," "pouch formations," nuclear lesions and vacuolar defects.^{8b,18b} The percentage of affected spermatozoa in ejaculates is variable. When over 20 to 30 percent of sperm cells are affected, fertility is moderately to severely reduced even though the motility and numbers of spermatozoa were normal. This defect apparently is not hereditary, but the cause is not known. Special staining and examination procedures are necessary to observe these nuclear lesions.

A sterile Ayrshire bull produced sperm cells with normal motility and concentration but with up to 20 percent abaxial tails and 17 percent swollen midpieces.² Even though the concentration and motility of sperm cells in the ejaculate is normal, special staining and examination of cells from infertile males is indicated.

Studies in cytogenetics have shown that gene or chromosome defects may occur at the time of meiosis and result in infertility. An apparently normal semen picture may accompany these defects. Certain bulls with excel-

lent appearing semen in which genital infections were excluded had a low fertility due to intrachromosomal aberrations.^{15,16} The spermiogenic epithelium showed a cytologic picture indicative of structural changes in the chromosomes including translocations and inversions. Although affected spermatozoa may fertilize the ovum, the zygote will often lack a balanced gene complement and death often results at an early stage of gestation or this defective chromosome complement may be carried into the next generation where usually about 50 percent of the male individuals are affected with infertility. Some offspring from affected bulls may be completely normal. Generally the greater the number of genes involved in translocation or inversion the greater the degree of infertility. In affected bulls diagnosis at present can only be made with an electronmicroscopic study of the germinal epithelium. By this technique acquired disturbances in spermatogenesis can be distinguished from the congenital or constitutional disturbances. These forms of sterility represented only a small number of all those that actually occurred.¹⁶ Gustavsson¹³ reported on a translocation defect of the chromosomes in the Swedish Red and White breed of cattle. About 14 percent of the cattle were heterozygotes and 0.34 percent were homozygotes for the translocation. Daughters of translocation sires exhibited a greater infertility rate, apparently due to early embryonic deaths, than daughters of normal sires.

The metaphase and anaphase figures from the meiotic divisions of the spermatocytes in the seminiferous epithelium in 4 boars and 7 bulls with normal semen pictures that were relatively or completely sterile were analyzed.¹⁴ Two boars had acrosomal defects of their spermatozoa. This study concluded that even though some chromosome changes were apparent, the primary or principal cause of defective spermatozoa was to be found in the nonchromosomal structures, namely the divisional apparatus.

The relationship of spermatozoal DNA and male infertility has been reviewed.¹¹ The conclusions are presently equivocal. A group of stallions with impaired fertility with semen of normal quality were studied.¹⁷ The infertility might have been caused by an inherent enzymatic disturbance that resulted in the early death of the sperm cell in the female genital tract.

These above preliminary studies on infertile males with essentially normal semen and spermatozoa have indicated that defects in genes and chromosomes especially during meiosis, and developmental defects of the sperm cell during spermiogenesis may occur. Future studies in the fields of cytogenetics, cellular biology and electronmicroscopy will undoubtedly further elucidate the mechanisms of male infertility occasionally associated with an

apparently normal or nearly normal semen picture.

Impotentia generandi associated with abnormal semen production is much more commonly observed and is due to pathology of the testes, the epididymis, the ductus deferens, the accessory glands and the urethra whereby sufficient numbers of healthy fertile sperm cells are not deposited properly at the time of coitus to cause the fertilization of the ovum and the normal development of the embryo. Abnormal semen may be due to congenital, hereditary or acquired causes. The latter are the most common. The former is highly important in the selection of sires because of the genetic implications. Occasionally both groups of causes are involved in an infertile male.

Pathology of the Testes with Abnormal Semen Production, Hypoplasia

Prior to the work of Lagerlof in 1934¹² studies on the pathology of the testis were incomplete and generally limited to the more obvious and severe clinical lesions such as orchitis and fibrosis. Since then a great amount of work has been done on correlating semen abnormalities with testicular pathology. The two are closely related and semen examinations reflect fairly accurately the conditions present in the seminiferous tubules of the testes. However, it is necessary to consider that it requires about 60 days from the first stages of spermatogenesis to the ejaculation of spermatozoa.

Lagerlof¹² divided the pathological conditions affecting the testis proper into testicular hypoplasia, testicular degeneration, testicular fibrosis, and testicular inflammation. The author believes that since testicular fibrosis usually follows testicular degeneration and testicular inflammation, and since testicular inflammation usually produces an acute, severe testicular degeneration, testicular fibrosis and testicular inflammation should be considered under testicular degeneration. If this classification is accepted then the two most common changes occurring in the testes causing disturbed spermatogenesis are hypoplasia, which is congenital or hereditary, and degeneration of the seminiferous tubules, which is usually acquired but may be predisposed by genetic defects, weaknesses, or inherent constitution.

Testicular pathology due to congenital or hereditary causes includes hypoplasia, certain defects in the seminiferous tubules and sperm cells including cytogenetic and chromosomal defects, cryptorchidism and inguinal hernias. The latter two conditions interfere with the normal thermal regulation of the testes which results in sterility or infertility.

Hypoplasia of the testes is observed occasionally as a unilateral or bilateral condition at the time of puberty, or later, in all domestic animals. It is noted most commonly in bulls, rams, boars and stallions. Testicular hypoplasia was a cause of 23 percent of the testicular pathology in Swedish bulls; this did not include the cases of inherited testicular hypoplasia of the Swedish Highland breed.¹³ This is a slightly higher incidence than the 12 to 17 percent given by other workers.^{1,9,14b,20} The hereditary type of hypoplasia affected as many as 25 to 30 percent of the male and female animals of the Swedish Highland breed, a polled breed.¹³ Gonadal hypoplasia in this breed was largely limited to those cattle that were 90 percent or more, white.¹⁷ Cattle with black ears were not affected. In these white cattle hypoplasia of the left testis occurred in about 25 percent of all the bulls, in the right testis in 1 percent, and in both testes in 4 to 5 percent. This condition is due to a single recessive autosomal gene with incomplete penetrance.⁷ A similar widespread condition affecting the gonads of both males and females of a breed has not been described outside of Sweden.

Most workers agree that testicular hypoplasia is congenital and possibly hereditary in origin and is caused by a marked lack of, or reduction in, spermatogonia in the gonads during fetal life. Hypoplasia may be partial or total due to a failure of germinal cells to develop in the yolk sac, failure to migrate to the gonad, failure to multiply in the gonad or that undergo extensive degeneration after they have entered the gonad. Unilateral or bilateral hypoplasia in bulls of both beef and dairy breeds and in other species have been observed occasionally in the United States but the incidence is generally low and the condition is sporadic. (See Figure 176 and 177.) In a few instances a familial trend was noted. It has been reported that dwarfs or beef cattle with a dwarf tendency are likely to show evidence of testicular hypoplasia. Some valuable beef bulls with unilateral testicular hypoplasia have been used as breeders and may produce as many as 20 percent of offspring with hypoplasia and poor quality semen.³ Marked hypoplasia of the testes, 10 percent by weight of normal testes, may occur in bulls, boars, rams, dogs and tom cats with the rare XXY karyotypic syndrome or human Klinefelter's syndrome.⁶

The symptoms of testicular hypoplasia in bulls vary greatly. In most cases sexual desire is excellent and coitus is prompt. Because of this the owners may not suspect the sterility for some time. The degree of either unilateral or bilateral testicular hypoplasia varies from nearly complete hypoplasia and sterility to only slight and often unsuspected hypoplasia. Lowered conception rates are often evident in the latter bilaterally affected males.

Figure 176. Bilateral Testicular Hypoplasia in a Fat 3-Year-Old Angus Bull.

Severe testicular hypoplasia is usually observed in young bulls one to two years of age. In sterile bulls with bilateral hypoplastic testes the semen is usually clear and watery with few or no spermatozoa. If the ejaculate is centrifuged and the sediment stained, giant cells and oftentimes medusa cells or ciliated cells from the efferent tubules may be observed. Giant cells or multinuclear cells with 6 to 8 nuclei apparently result from incomplete maturation divisions of the primary spermatocytes. The nuclei divide but the cytoplasmic divisions are not completed.⁵ These cells are seen in testicular hypoplasia and severe degeneration. The sexual organs develop nor-

Figure 177. Bilateral Testicular Hypoplasia in a 2-year-old Holstein Bull.

Figure 178. Abnormal Acrosomes or Knobbed Spermatozoa in a Sterile Bull. (Courtesy K. McEntee.)

mally except for the affected testes. Histologically the seminiferous tubules are very underdeveloped, with usually only the basal layer of cells being present.

Males which are severely affected with testicular hypoplasia are nearly sterile, but an occasional conception may occur in females bred to them. The semen picture shows a low concentration of spermatozoa, and the possible presence of a few giant cells. If azoospermia is present in repeated ejaculates complete sterility is assured. The affected testes are one-third to two-thirds normal size, but are usually firmer, or occasionally softer, than normal. (See Figure 177.) Histologic section reveals that one-half to two-thirds of the seminiferous tubules are undeveloped. Varying degrees of spermatogenesis may be present from spermatogonia, spermiocytes,

Figure 179. Lack of Intact Sperm Cells and Coiled Tails in a Sterile Guernsey Bull. (Spermatozoan motility was nearly absent.)

spermatids, to abnormal and normal mature spermatozoa. Three types of testicular hypoplasia in 3 inbred lines of Hereford cattle were studied.³ The first type was characterized by seminiferous tubules lined only with Sertoli cells. These bulls were sterile and the line became extinct. In the second line of bulls about 30 to 40 percent of the tubules were normal but only a few tubules were stage 8 with sperm cells lining the lumen. Reduced spermatogenesis was present. In the third line the bulls had reduced spermatogenesis, conglutination of spermatids and many giant cells. In another line of cattle the bulls had large firm testes but reduced sperm cell output due to blockage of the tubules before they entered the rete resulting in sperm stasis and atrophy of the seminiferous epithelium.

In some bulls with a moderate to slight amount of testicular hypoplasia the conception rate is low, about 20 to 40 percent. The testicles may appear nearly normal in size and consistency. The spermatozoan concentration is from 100,000 to 500,000 per cmm, the motility is usually low, and the number of pathological or abnormal spermatozoa is high, 30 percent or greater.

Depending upon the degree of hypoplasia, affected bulls will have a small firm epididymis especially in the tail region indicating reduced spermatogenesis and low gonadal sperm reserves. This will also be revealed by rapidly decreasing concentrations of spermatozoa in successive ejaculates.⁹ Slight or mild cases of hypoplasia with reduced spermatozoan concentration and motility predispose the bull to testicular degeneration. In some bulls sterility due to mild testicular hypoplasia may not be observed or become apparent until the bulls reach 3 to 4 years of age.

The spermatic cords of hypoplastic testicles are shorter as the testes are less heavy and the scrotum smaller than in normal males. Postpubertal bulls that have a scrotal circumference of less than 32 cm. should be suspected of having testicular hypoplasia or testicular degeneration with atrophy. In obese bulls with much fat in the inguinal region the thermal insulation so provided these hypoplastic testes might contribute to the infertility. (See Figure 176.)

Testicular hypoplasia may be erroneously diagnosed in young immature males that are underdeveloped or are retarded in growth at the generally accepted time of puberty for the species. The fertility and the percentage of normal spermatozoa produced increased from puberty to two years of age in beef bulls.¹⁵ The diagnosis of testicular hypoplasia should not be made before two years of age in the bull and horse or before one year of age in the boar, ram, dog or tom, unless the hypoplasia is marked and the male is well-grown.

Testicular hypoplasia and atrophy were observed in about 3.4 percent of 9,000 rams examined in Australia.⁸ The condition was usually unilateral and of a permanent nature. The spermatic cord was usually short and the affected testis was drawn up toward the inguinal canal. The consistency of the testis was either soft and flabby, or hard, indurated and fibrotic. The testes were decreased in size. The semen was always abnormal, with an increased number of abnormal spermatozoa and small, round, non-nucleated, germinal epithelial cells. An association between this type of testicular hypoplasia and unilateral cryptorchidism was suggested. The fibrotic small testes in some of the rams described above might have been due to trauma or other causes, producing secondary, degeneration and atrophy.

Sterility in boars is relatively uncommon.¹⁰ In 30 boars with testicular pathology, 8 or 26.6 percent had hypoplasia. These were young boars that were sterile or of very low fertility. A genetic or hereditary factor was probably present in hypoplasia in boars.¹⁰ Young boars may only ejaculate 2 to 3 billion spermatozoa when they are bred 2 to 3 times a week. If they are bred more often, the number of spermatozoa ejaculated may drop below 2 billion and infertility result. At 10 to 12 months of age most boars have matured sufficiently so that large numbers of spermatozoa are produced and infertility due to oligospermia is not a problem.^{1a,18} In cases in which semen examination was possible, spermatozoa were either absent or present in low concentrations of 20,000 to 70,000 per cmm. The number of pathologic spermatozoa was not high but there was a large percentage of immature sperm cells with a protoplasmic droplet on the middle piece. The motility was usually poor. The average weight of the hypoplastic testes was 226 to 240 gm., while normal testes weighed 594 to 632 gm. Histologic examination showed hypoplasia varying from only a single layer of germinal cells to widespread changes in the seminal epithelium.

Eunuchoidism or complete lack of sexual desire, may rarely occur in dogs, men and bulls with testes in the normal position or in unilateral or bilateral cryptorchidism.^{2,17a,21} The testes are small and atrophic. The interstitial cells are hypoplastic or fail to secrete androgen. In man eunuchoidism is characterized by low plasma concentrations of FSH and LH.^{17a} Testosterone given parenterally will produce secondary sex characteristics but the male relapses to the eunuchoid state if injections are discontinued. This condition may have been due to the **XXY or Klinefelter's syndrome** in animals or to **testicular feminization** due to a defect in the androgen receptors and characterized by a feminine appearance, retained testes, a normal vulva and vestibule, rudimentary

accessory reproductive organs and an XY karyotype.^{16b,17a}

Hypoplasia associated with a decrease in interstitial cell activity and a failure of normal antler growth in white-tailed deer in southwestern U.S. was reported.¹⁹ Testicular hypoplasia in the dog and cat is seldom described. Gonadal hypoplasia in a strain of grey collies that also had abnormalities of the blood, eyes and digestive tract was described.⁴

In the diagnosis of testicular hypoplasia, especially where it may be associated with a lack of sexual drive, the stage of development of the male and whether or not puberty has occurred must be considered. Testicular hypoplasia may be diagnosed erroneously in young, poorly-fed, slow-maturing males, especially of *Bos indicus* breeding.

The prognosis in testicular hypoplasia is poor. Affected animals should not be used for breeding because the condition may be hereditary. Severely affected animals are sterile or highly infertile. Mildly or moderately affected animals may have only a lowered fertility but are more prone to early testicular degeneration. Libido is usually normal or excellent. The numbers of motile normal spermatozoa per ejaculate or insemination largely determine the fertility of the animal in question not the percentages of the dead, poorly viable, immotile and abnormal spermatozoa.

The treatment of testicular hypoplasia in animals has been unsuccessful. The germinal epithelium of these affected animals apparently cannot respond to gonadotropic therapy because spermatogonia are lacking or reduced in numbers.

Hereditary or Congenital Sperm Cell Defects, Male Intersexes and Cryptorchidism

Sperm cell defects, possibly heritable, have been described in male domestic animals in which a large percentage of spermatozoa produced by a male are similarly affected.

Returned tails and narrow heads were reported to be hereditary in certain bovine families of the Jersey breed exhibiting much sterility.² Another study¹² also reported on infertile Jersey bulls with coiled or returned tails with a lowered motility rate. With repeated frequent ejaculations the numbers of abnormal sperm cells was greatly reduced. The defect in these bulls was apparently genetic. These defects may be similar to the Dag-effect.

Dag defect—Danish workers have described 15 related bulls, tracing back to a common ancestor born in 1934, in the Danish Jersey breed that had a low initial

spermatozoan motility of 10 to 15 percent and very poor fertility. These bulls had about 40 to 50 percent of their spermatozoa with strongly coiled, folded or split tails, the Dag defect.⁹ The fibers in the axial filament were normal in the testis but abnormal when the cells reached the cauda epididymis. This defect was shown to be due to an autosomal recessive factor. The defect developed in the distal part of the head of the epididymis.⁹ An infertile Holstein bull with a normal volume and concentration of semen but only 10 to 20 percent motility was studied.^{11b} About 25 percent of the spermatozoa had tail abnormalities somewhat resembling the Dag defect with an aberrant, defective arrangement of the fibrils. There was no evident abnormality of the seminiferous epithelium. A Canadian worker reported on three unrelated Hereford bulls with this Dag defect.¹³

The "tail stump" defect of spermatozoa originally described in Holstein Friesian bulls in Canada,⁶ and then in bulls in Denmark⁵ and India and recently in rabbits, a stallion and a dog,^{1c} is caused by deranged spermiogenesis that results in a severe infertility or sterility. The head of the affected spermatozoa is normal but the middle piece and tail are markedly defective with a stub or stump appearance at the base of the head. This defect is caused by an abnormality on the centriolar apparatus that blocks normal formation of the midpiece and tail.^{5b} Spermatozoan numbers in the ejaculate are normal but motility is very poor depending on the percentage of "tail stump" spermatozoa which may vary from 20 to over 90 percent. Other sperm cell abnormalities may also be present such as loose or separate heads. There may be a cytoplasmic droplet around the "stump." This condition is possibly due to a recessive gene.^{1c,5b}

Corkscrew sperm defect—A nongenetic defect seen in the Red Danish, Jersey, Friesian and Aberdeen Angus breeds due to an irregular distribution of the mitochondrial sheath together with a high incidence of persistent proximal droplets in affected sperm cells was described.³

Pseudo-droplet defect—A "pseudo-droplet defect" seen in 5 related Friesian bulls was reported.⁴ From 7 to 26 percent of spermatozoa in affected bulls had rounded or elongated, thickened areas on the midpiece. Reduced motility and infertility increased as the bulls became older.

Lack of intact sperm cells was described in Guernsey bulls with a history of complete sterility.^{7,8} The ejaculates of these bulls contained practically no intact spermatozoa, but only free heads and tails. Motility was low. Intact spermatozoa were fewer than 5 percent of the total. All heads showed a deep indentation marking the point of separation from the tails. The middle piece was thickened and varying degrees of coiling of the middle piece and tail occurred. This disintegration or separation

of the heads and tails of spermatozoa in the sterile Guernsey bulls was associated with the migration of the protoplasmic droplet from the proximal to the distal end of the middle piece which occurred in the head of the epididymis.⁷ While there was no conclusive evidence that the defect was inherited, the evidence was very suggestive. Eight Hereford bulls with low fertility had a high percentage of tailless heads in their ejaculate.¹⁴

Acrosomal defects or knobbed spermatozoa have been described in bulls, boars and dogs. This defect has been reported as due to an autosomal recessive gene in Holstein Friesian bulls.^{11a} As described previously in this Chapter, certain stains and techniques are very helpful in diagnosing this defect in what often appears to be a normal semen sample associated with complete sterility or infertility.

Deficiency in tail development and lack of motility was reported in stallions of one Thoroughbred blood line in which the condition might have been genetic in nature.¹⁰ The author has studied two stallions with congenitally lowered fertility with 50 to 75 percent of their spermatozoa having a single abnormality; in one stallion, a Standardbred, a grossly defective midpiece and the other, a Thoroughbred, an abaxial attachment of the midpiece to the head in over 60 percent of the spermatozoa. In stallions abaxial attachment of the midpiece to the head of the spermatozoa is commonly observed and this usually is not associated with infertility in the stallion and boar as it often is in the other species of animals. (See Semen Evaluation.) A sterile Ayrshire bull with up to 20 percent abaxial tails and 17 percent swollen midpieces was described.^{1b} Sperm cell concentration and motility was normal.

Ciliary diseases in man and animals have been reviewed.^{1a} Many of these are congenital or hereditary diseases affecting all body cilia in the respiratory and genital tracts resulting in chronic upper respiratory infections and infertility or sterility. These ciliary diseases usually result in the immotile-cilia syndromes.^{1a} One of these in humans is called **Kartagener's syndrome** that is usually characterized by sterility associated with immotile sperm cells and other cilia in the body and in many cases **situs inversus**.^{1a,8a} The normal concentration of live spermatozoa is present. Two similar cases have been described in dogs.^{1a} This defect of the tail and midpiece resembles several other defects in animals characterized by living sperm cells grossly lacking in motility.

Inbreeding, Chromosomal Aberrations and Intersexes

Inbreeding generally results in reduced fertility accompanied by an increase in the number of abnormal

seminiferous tubules, lowered semen quality and hypoplasia.^{4,5,19} Inbreeding in dogs resulted in lower conception rates, lower numbers of pups whelped alive and in reduced ejaculate quality of studs by lower sperm counts compared to outbred dogs.²⁴ There were wide differences in fertility between inbred lines of cattle from a few with excellent fertility to those in which the line died out because of infertility. The response to inbreeding with respect to fertility is variable with each line or family. Inbred lines usually undergo a period of infertility or sterility and if the line does not become lost due to deleterious genes, the fertility of the remaining animals in the line is often fairly satisfactory.^{17a} Five inbred, related bulls showed a low sperm cell concentration and a large number of pathological spermatozoa with a reduced motility.¹³ The infertility in these bulls was considered to be due to an autosomal recessive gene. In identical twin bulls great similarity of the semen and spermatozoa, duration of motility, and frequency of abnormal sperm heads has been noted.^{1a} The great difference between identical twin pairs of bulls and the similarity of each bull of a twin pair indicated that the differences between the twin pairs as well as the similarities within the pairs, were genetic, since all were reared under similar conditions. Hereford, Angus, Holstein and Shorthorn bulls had the best conception rate in England.²⁵ In the United States and Canada Guernsey bulls generally have a lower conception rate than other breeds.² Nine of 19 Guernsey bulls used for artificial insemination had lower than average non-return rates, below 64% at 60–90 days. Two of these 19 bulls had 1/29 centric fusion with 59 chromosomes and 3 others had achromatic gaps and chromatid breaks.² In 743 young bulls examined cytologically in the U.S. no translocations were found.¹⁰ Other cytogenetic studies on bulls, horses and swine were reported.²⁰ Aneuploid cell lines in two related boars were associated with reduced litter size in their offspring as well as some of their daughters.²³

Cytogenetic disturbances in spermatogenesis caused two abnormalities in the primary spermatocytes including (1) "stickiness" of chromosomes in which they failed to separate at anaphase, and (2) a pyknotic nucleus and multiple spindle formation due to a dysfunction of the mechanism of cell division due to extra centrosome divisions resulting in the formation of giant cells with a number of nuclei.¹⁶ In both conditions the semen was thin and watery. In the former the semen centrifugate was made up almost entirely of pyknotic nuclei and was characteristic for this condition seen most often in the Swedish Lowland Holstein Friesian breed in which intensive inbreeding had occurred. The latter condition occurred in only a few bulls. The semen centrifugate was

composed of giant cells and pyknotic nuclei and these affected bulls belonged to the same family so a recessive gene might have been involved. As mentioned previously, the Gustavsson anomaly or a Robertsonian 1/29 chromosomal translocation occurred in Swedish cattle that resulted in a degree of infertility characterized by early embryonic deaths.¹⁴ A translocation anomaly in a boar was associated with reduced litter size.²⁰ Probably other primary cytogenetic disturbances of spermatogenesis occur and will be described in the future.

The male tortoise-shell, black and orange stripes or including white, tricolored or calico **tom cats** are uncommon because the genes for yellow or orange color are carried on the female, X, chromosome. However, rare male tortoise-shell cats have an abnormal sex chromosome constitution of XXY resembling Klinefelter's syndrome in man. This condition in cats has been well-described.^{11,18,22} These male cats have very small testes and are sterile due to failure of the seminiferous tubules to develop. One affected cat had no spermatogonia in the seminiferous epithelium. The possible incidence of male to female tricolored cats was 1:200 to 1:3000.^{11,18} Other types of chromosome combinations in tricolored male cats: XXY, XX/XY, XX/XX/XXY, XX/XXY, XY/XXY, and XX/XXY have been reported.^{11,18,22}

A recent study and review of male tortoiseshell and tricolored cats^{17b} indicated that those with the 39XXY karyotype were all sterile with very small testes, no germinal epithelium, no libido and no secondary sex characteristics. Those with a 38XY/38XX and 38XY/39XXY karyotypes had a variable fertility with libido and secondary sex characteristics. While those with 38XX/38XY karyotypes were fertile normal males. It was suggested that because of their coat color these cats were examined cytogenetically but other cats with a different color might also show chromosomal abnormalities.

A polled Hereford bull with good libido had very small, one-tenth normal-sized testes, azoospermia and a 61,XXY karyotype.⁷ This XXY or Klinefelter's syndrome seen in about 1 in 500 live-born human males has also been reported in rams, boars and dogs.⁷ Undoubtedly cytogenetic defects occur in stallions as have been described in mares but defects of the reproductive organs are much more obvious in stallions and seldom would these animals be selected for service.

Infertility in hybrids usually occurs when there are major differences in the chromosomes of the parents. Minor gene differences may be overcome so fertility is possible. The failure of gametogenesis in some hybrids is apparently due to asynapsis during the first meiotic division of the primary spermatocyte. Sterility is more common in the male hybrids. Even in some intraspecies

crosses where the chromosomes are nearly similar, hybrid fertility, particularly of males, may not result.^{1c} A common example of the above hybrid infertility in domestic animals is the horse and ass cross producing the hybrid mule, with chromosome numbers of 64, 62 and 63, respectively. Hybridization attempts in goats and sheep obtained conception but all the embryos died.¹⁵

In the bison x domestic cattle cross, as well as the yak X domestic cattle, and yak X zebu crosses, the bulls are likely to be sterile.^{6,12} This was believed due to the inheritance of the small, thick scrotum from the bison or yak causing an elevated scrotal temperature that adversely affected the large testes inherited by these hybrids from the domestic cattle or zebu that required a lower testicular temperature for the normal functioning of the seminiferous tubules. Recent cytogenetic studies indicate that chromosomal incompatibilities are more likely a cause for the infertility of these hybrid males.

In bovine twins of unlike sex the female twin or freemartin is sterile due to the vascular anastomosis with the male twin which is usually considered to be normal. (See Chapter IV.) Most bulls born cotwin with freemartins are chimeric with from 5 to 95 percent of their blood lymphocytes being XX cells. Of 12 chimeric bulls studied in an AI stud, 58 percent were culled for poor semen quality and infertility associated with testicular degeneration and hypoplasia.^{3,8} One of the infertile bulls had a skewed sex ratio of 29 males to 71 females suggestive of germ cell chimerism.⁸ Further study on bulls cotwin to freemartins is indicated.

Male intersexes are invariably sterile. Intersexuality may arise from aberrations of genetic or chromosomal origin, aberrations of gonadogenesis, and reversal of sex involving the accessory or external genital structures.^{1b} **Male pseudohermaphroditism** is found in the caprine, porcine and occasionally the bovine, equine and other species. **True hermaphroditism** is uncommon. In both horses and cattle this latter condition was characterized by ovotestes, no scrotum, an underdeveloped penis, uterine tissue and vesicular glands and chromosomal chimerism.⁹ True hermaphroditism is also seen in the other domestic animals including the goat, dog, pig and cat.^{9,22} In the Saanen and Toggenburg breeds of goats the incidence of intersexes varies from 5.8 to 14.9 percent. They have a wide range of abnormality from phenotypically nearly normal males to nearly normal females. This condition in goats is caused by a single recessive sex-linked gene linked to the dominant gene for polledness. (See Chapter III.) No case of a horned pseudohermaphrodite has been described. Most affected goats have testes, often intra-abdominal, and external genitalia of an intermediate type. They are genetic females (XX) with

positive sex chromatin. A high incidence of infertility in polled Saanen goats was described in which the recessive character caused pseudohermaphroditism in female goats and hypoplasia, sperm granulomas of the epididymis and a high percentage of sperm cell abnormalities in some male goats.²¹ The infertility problem in Saanen goats could be largely avoided by raising for breeding purposes only those goats with a horned parent.

Intersexes in pigs are common but not as common as in goats. They also are of the male pseudohermaphrodite type. The condition is probably caused by a recessive gene. The affected animals are genetic females, the testes are invariably intra-abdominal and externally a characteristic "fish hook" vulva with a prominent "clitoris" or phallus is present.^{19b} Male pseudohermaphrodites are also occasionally observed in cattle, horses, sheep and dogs.^{21a} Three affected sons of a Brown Swiss bull have been reported.¹²

Cryptorchidism in animals, if bilateral, results in sterility. In horses cryptorchids may be spoken of as "ridglings," "rigs" or "originals." Unilateral cryptorchidism is more common and usually results in near normal fertility because of normal sperm production from the testis located in the scrotum. The term "monorchidism" is incorrect and should not be used. Cryptorchidism or incomplete descent of the testis or retention of the testis occurs in all domestic species but is seen most commonly in stallions, boars, dogs, less commonly in rams and bucks, uncommonly in bulls, and rarely in tom cats. (See Chapter III.) The undescended testis may be located anywhere from just caudal to the kidney to within the inguinal canal. Many abdominal testes are located close to the internal inguinal ring. Often the loosely attached epididymis in the horse may have descended into the inguinal canal.

Occasionally testes not in the abdominal cavity, inguinal canal or scrotum may be located ectopically under the skin of the ventral caudal abdomen, especially in bulls, alongside the penis, or rarely in the femoral canal or in the perineal region. This is more commonly the case in male pseudohermaphrodites where no scrotum is present.

In some animals in which the testis is retained in the inguinal canal it will descend spontaneously into the scrotum in a few months to a year after birth. In a few cases in colts, testes may have descended into the scrotum at birth and later became cryptorchid and located in the inguinal canal. Although a noted veterinarian^{18b} has reported that the testes of newborn colts can invariably be palpated in or just above the scrotum, further study, confirmed by castration, should be undertaken since the gubernaculum is large in newborn foals. By 30 days after

birth the gubernaculum is greatly reduced in size and the testes can be readily palpated in most foals. It would seem very unlikely the descended testes at birth could, with time, assume the internal relationships found in abdominal cryptorchidism. All retained or cryptorchid testes are small, soft and flaccid weighing in the horse 25 to 131 gms.; normal descended testes usually weigh 170 to 325 gm.⁴ No spermatozoa are produced by the retained testis but well-developed or degenerate seminiferous tubules may be present. Spermatogenesis is completely inhibited by the elevation of the temperature of the affected testis. The interstitial or Leydig cells are not affected so sexual activity is normal or even exaggerated in some cryptorchids. Cryptorchid animals should not be used for breeding.

The Technical Development Committee²⁰ in England reported that cryptorchidism in the horse is inherited in a dominant manner while in the other species it is a recessive trait. Unilateral cryptorchidism more often affects the right testis especially in dogs, possibly because the right testis develops in the embryo a greater distance from the scrotum.⁵ In 4 studies,^{4,8b,11,19b} from university clinics it was reported that in over 1000 cryptorchid horses about 90 percent of the inguinal or abdominal testes were unilateral and of the abdominal testes about 70 to 75 percent were left-sided. These reports indicted that in about 60 percent of the presented cases the cryptorchid testis was intraabdominal. Based on his field experience the author strongly suspects this latter figure is biased. Many of these latter cases of cryptorchidism were probably referred to the clinics for specialized surgery. Most practicing veterinarians can detect inguinal testes by palpation assisted by heavy tranquilization and remove these retained testes by a slightly modified routine castration. Three of the cryptorchid testes contained teratomas or cysts, two of these were abdominal.⁴ Removal of cryptorchid equine testes has been well-described.^{1,2,11} The latter described a paramedian laparotomy approach for the removal of the abdominal testes.

In dogs cryptorchidism is seen most commonly in the brachycephalic breeds including: Boxers, Pomeranians, Dachshunds, Sealyhams, Cairn Terriers, and also in Whippets, Chows, Cocker Spaniels, Poodles, and others. The incidence of cryptorchid testes in dogs in England was reported to be between .05 to 0.1 percent.²⁰ In most dogs the testes are in the inguinal canal at birth and descend into the scrotum during the first week after birth. In some dogs the testes don't descend till near puberty.³ Possibly because dogs are maintained intact for many years, retained testes are predisposed to neoplasms. Sertoli cell tumors and seminomas in undescended testes tend to be more malignant.^{5,6,13,18} A highly

significant association of cryptorchidism and testicular tumors was reported with 58 or 53 percent of 108 Sertoli-cell tumors and 23 or 33.8 percent of 68 seminomas occurring in retained testes.¹⁸ These tumors affected the retained or abdominal right testes more frequently than the retained left testes. Dogs with scrotal testicular tumors were older than dogs developing cryptorchid testicular tumors.¹⁸ Signs of feminization were present in 16.7 percent, 50 percent, and 70 percent of the dogs with Sertoli cell tumors in the scrotum, inguinal canal and abdominal cavity, respectively. This may be due to the earlier detection and removal of affected testes in the external sites. Cryptorchidism and cryptorchidectomy in the dog and tom cat has been recently reviewed.²⁵ Tumors of undescended testes in man occurred 50 times more often than tumors of scrotal testes.⁸ Early removal of undescended testes is recommended.

Cryptorchidism in swine is a monogenic sex-limited recessive.¹⁵ To eliminate this condition in swine or other species, all parents of cryptorchid animals should be discarded as breeders. The incidence in swine may reach 1 to 2 percent in some herds. If affected pigs are fattened rapidly and sold at or before six months of age very little or no boar odor will develop in the carcass. In sheep cryptorchidism is seen in all breeds especially in inbred families, as it probably is due to an autosomal recessive or a dominant gene with incomplete penetrance. The incidence in sheep is 0.5 percent with 90 percent of unilateral abdominal cases involving the right testis.^{10a}

The rapid progress possible in the elimination of cryptorchidism, probably due to a recessive defect with incomplete penetrance, in flocks of Angora goats by rigid culling of parents and even close relatives of affected animals was described.^{19,23} An excellent bibliography on cryptorchidism in dogs and other animals has been compiled.¹² A few cases of left-sided cryptorchidism in Hereford cattle have been reported in which the condition appeared to be due to a dominant gene with variable expressivity.²⁴ Cryptorchidism is common in male fetal monsters and other defective individuals.

Treatment of cryptorchid animals, especially those where breeding is to be considered, should be discouraged. In humans where treatment is more frequently undertaken only those testes that would ultimately descend spontaneously would descend after gonadotropin therapy.⁸ Orchiopexy has proven to be a failure in producing satisfactory spermatogenesis.

Torsion or rotation of the descended testis is observed occasionally in the stallion^{17b} and rarely the dog.^{17c,d} It may be associated with an excessively long mesorchium, caudal ligament of the epididymis and the proper ligament of the testis. Torsion must be greater than 180°

to produce circulatory disturbances in the testis with strangulation and pain associated with a unilateral scrotal swelling and a stiff, "hiking" abduction of the rear leg in the affected side. It develops most frequently in the Standardbred but the author has observed the condition several Thoroughbreds. Apparently some horses at their racing gait are unable to draw the testis out of the scrotum. Suspensories have been tried on horses but are of limited value. Unilateral or bilateral castration is indicated.

Torsion or rotation of the retained or cryptorchid testes with strangulation of the spermatic cord is most commonly seen in the dog in association with testicular tumors, especially the Sertoli-cell tumor.^{17c} Symptoms may be acute or chronic with signs of abdominal pain and/or obstruction. Diagnosis is suspected by a retained or cryptorchid testis in an older dog and is confirmed by laparotomy. Torsion of a retained testis has been observed very rarely in the pig.

Manual torsion or "twisting" of ram lambs is an old castration technique of shepherds. The tail of the epididymis or ventral portion of the testis is manually rotated dorsally and then after several rotations of the testis around the tensed spermatic cord, the entire structure is pushed into the inguinal canal where it is retained and undergoes degeneration and atrophy due to the interruption of circulation.

Imperfect descent of the testes in cattle not associated with cryptorchidism has resulted in testes located horizontally and fairly high in the scrotum. This may be due to the attachment of the cremaster muscle to the caudal aspect of the testis, fixation of the distal end of the scrotum to the perineal region,²⁶ or lower than normal attachment of the gubernaculum. (See Figure 180.) This imperfect descent of the testes may result in impaired fertility with degeneration and atrophy due to difficulty of the thermoregulatory mechanism of the testes to operate properly. This condition might be genetic.⁷ Stallions that carry the testes high in the external inguinal ring may have low fertility for the same reason.

Multiple heterotopic nodules of testicular tissue scattered over the peritoneum have been described in a few pigs.²¹ These may be confused with a malignant neoplasm.

Scrotal or inguinal hernias, if large, may seriously depress fertility by markedly interfering with the normal thermoregulatory function of the scrotum and testes resulting in testicular degeneration. (See Testicular Degeneration.) If the inguinal ring and hernia is small there is a greater chance for strangulation of the intestine. Inguinal hernia is considered a common hereditary defect in horses and pigs; it is less common in bulls, dogs and

Figure 180. Abnormal Attachment of the Cremaster Muscle to the Left Testis Causing a Nearly Horizontal Position of the Testis High in the Scrotum (The right testis of the bull was normal).

rams, and rare in the tom cat. The incidence in swine was greatly increased from 7.5 to 43.2 percent in two generations by selective inbreeding.²² It was most common in the left side of the scrotum. Hernias usually appeared from birth to 30 days of age. It was considered to be a double recessive character. In cattle leftsided scrotal hernias were most common especially in the Hereford or Polled Hereford breeds.^{10,16,17} (See Figure 181.) In an inbred strain of Basenji about 75 percent of the pups had inguinal hernias.⁹ Animals with inguinal hernias should be castrated and not used for breeding. Reduction of the hernia and closure of the hernial ring can be performed through the inguinal canal, through an incision in the abdominal wall just cranial and medial to the ring or by a flank incision above the ring.

Acquired Testicular Pathology

Testicular Pathology Due to Acquired Causes is much more common than congenital or hereditary causes and includes testicular degeneration, orchitis, fibrosis and

calcification. (See Figures 180 through 190.) Lagerlof and others estimated that 75 to 80 percent of testicular pathology is related to testicular degeneration including fibrosis and orchitis. The epithelium of the seminiferous tubules is highly sensitive to any adverse influences with resulting marked effects on spermatogenesis. Testicular degeneration may be mild or severe and is usually bilateral as it is most commonly due to generalized disease processes. Unilateral degeneration can occur secondary to local testicular lesions such as tumors. Testicular degeneration may develop very rapidly within a few days or hours; while testicular regeneration proceeds slowly over weeks and months. If the basal layers of the germinal epithelium including the spermatogonia and Sertoli cells are destroyed regeneration of the germinal epithelium is not possible and the animals remain sterile. The pattern and signs of testicular degeneration are about the same despite the species or the etiologic factor(s) involved. In all cases degenerative changes in the mechanism of cell division or centrosomes are present in the primary spermatocytes and are responsible for reduced motility and increased numbers of pathologic spermatozoa with an abnormal morphology. Sperm cell numbers and concentration are decreased depending on the degree of degeneration of the seminiferous tubules. In severe disturbances of spermatogenesis, spermatocytes with restitution nuclei, with double the normal number of chromosomes as well as pyknotic nuclei are present in the ejaculate.¹⁷ Testes with degeneration of the seminiferous tubules are usually atrophic, softer and smaller than normal testes. In chronic cases the testicle may be firm due to fibrosis; even calcium may be deposited especially in the areas just peripheral to the rete testis. Histologically it may be difficult to distinguish between slight degrees of testicular degeneration and hypoplasia. Hypoplastic testes have a predisposition to degeneration.

Setchell²⁸ has described the natural and induced disfunctions of the testes in man and animals and has provided an extensive bibliography covering the testicular effects of radiation, heat, cold, nutrient supply, chemical and immunological damage, chromosomal, hormonal, viral, neoplastic and miscellaneous disease factors on the testes.²⁸

Causes of Testicular Degeneration include:

Thermal influences associated with elevation of the testicular temperature such as: cryptorchid and ectopic testes; inguinal hernias; (See Figure 180 and 181) scrotal dermatitis due to, irritants, choriopic mange in rams^{26a} and bulls (See Figure 182), myiasis in sheep, and lo-

Figure 182. Scrotal Dermatitis and Edema in a Bull Secondary to Chorioptic Mange. (Temporary testicular degeneration and infertility resulted that lasted for 2 to 3 months.)

calized skin infections, pox lesions or wounds; contusions and hematomas of the scrotum and testes; prolonged elevated body temperature as in certain infectious diseases and in prolonged high environmental temperatures, particularly associated with high humidity. Testicular degeneration is most common in tropical climates and involving breeds originating in the temperate zones.³ "Summer" infertility in bulls in the temperate zone is usually an individual bull problem. As many as 20 to 30 percent of bulls in a midwestern AI stud required air conditioning to maintain production of high quality semen during summer months when the ambient temperature and humidity are high. Direct heating of the scrotum may also be involved.²² Bulls were exposed to heat stress for 8 hours a day for 7 days; this resulted in a deleterious effect on semen quality reaching its peak at 2 to 3 weeks after the stress with recovery by 9 weeks.¹⁶ Rams maintained at ambient temperatures of 90° F. or above develop a marked drop in semen quality with about 10 percent motility and 70 percent abnormal sperm cells within a few weeks.^{4,8a,24} Recovery was not complete until 2 to 3 months after normal temperatures were restored. Shearing rams, especially their scrotums, monthly during the summer months greatly improved conception rate and embryo survival.¹² High ambient temperatures will also cause lowered fertility due to testicular degeneration

in boars.^{29,31} Heat primarily affects the spermatocytes but usually does not affect the spermatogonia, elongated spermatids or epididymal spermatozoa in the bull.²⁷ Heat has no effect on the Leydig cells. Even 10 to 20 hours insulation of the scrotum with a plastic bag that raised the skin temperature to 35° C had a definite depressing effect on semen quality that lasted for 3 to 9 weeks with a return to normal semen quality by 13 weeks.²⁷ Lagerlof¹⁹ carried out early classical experiments demonstrating that overheating or insulation of the scrotum of bulls caused rapid testicular degeneration and when normal scrotal temperature was restored, recovery was slow. Males that lie down for long periods of time such as bulls with bovine spastic syndrome, or males that are unable to rise, often develop testicular degeneration and atrophy due to the prolonged elevation of testicular temperature from the testes being held close to the body. When the scrotal temperature of bulls was raised to 38.4° C or 0.3° C below body temperature, the motility and percent of live spermatozoa in the semen decreased to zero by the second week.^{8b} After normal scrotal temperature was restored 11 weeks elapsed before motile cells were observed and 18 weeks were required for the recovery of normal semen quality. Application of an irritating ointment to the scrotum of boars resulted in increased heat to the area with testicular degeneration that was characterized initially with many immature sperm cells with a protoplasmic droplet followed by an increase in morphologically abnormal spermatozoa as the condition advanced.¹⁰

Colorado workers⁶ have reported on the damage to spermatogenic function induced in range beef bulls by low temperature down to -25° F. associated with winds of 60 miles per hour causing frostbite, necrosis of skin, scrotal dermatitis, heat, swelling, testicular degeneration and adhesions. Older bulls with pendulous scrotums were most seriously affected. The severity of the after effects were related to the amount of adhesions produced. Bulls provided proper wind shelter and dry bedding were not affected by such temperatures and wind. Scrotal frostbite resulting in infertility was reported in boars in Minnesota.² Scrotal dermatitis in dogs or other males due to any cause may result in testicular degeneration due to the elevation of the temperature of the testes.^{19b} This is favored by mild degrees of testicular hypoplasia. The presence of excessive fat in the inguinal region probably has little effect on the thermoregulatory mechanisms of the scrotum and testes unless short spermatic cords or other defects in the testes are present. The author has observed several bovine cases of mild scrotal hydrocele of unknown etiology where semen quality was not significantly affected. A severe chronic hydrocele resulting

in poor semen quality in a 3 year old bull was described. The bull responded to unilateral castration with a return to normal fertility 3 months after the operation.¹¹ A hydrocele secondary to a tumor of the tunica vaginalis was described in a dog.²⁵

Vascular lesions of the testes—Interference with the circulation and infarction of the testis can be produced by manual **torsion of the testis** or by the emasculator used for castration of lambs or calves. Congestion and pain of the scrotal testis due to naturally-occurring torsion or contusion has been reported in racing stallions, particularly Standard-bred trotters. With vigorous exercise these animals would start to spraddle their rear legs, become lame and then change from a trotting to a pacing gait. Affected Thoroughbred stallions would race normally for nearly one-half mile and develop an altered "hopping" gait. The testes would be swollen, congested and painful for the next 3 to 4 days. Dogs with inguinal or abdominal cryptorchid tests may occasionally develop torsion of the testis with a sudden onset of pain and associated symptoms. The author has observed one case of testicular torsion in a cryptorchid pig. Hemorrhagic infarction of the testis may follow torsion. Tumors of the abdominal testes may also predispose to torsion.

Testicular biopsies, particularly in bulls, often result in focal areas of testicular necrosis because of vessel damage when a desirable size of testicular material is obtained.²⁶ For this reason a technique of aspiration biopsy in bulls for cytologic but not for histologic studies was recommended.^{17,18} Testicular biopsies are more easily and safely done in the stallion and other animals.^{1,14} Testicular biopsies, even with a biopsy needle, may occasionally cause a degree or area of testicular degeneration due to interruption of the blood supply. In one study in dogs in which 28 biopsies were performed, one resulted in unilateral testicular degeneration and atrophy.¹⁴

Inflammation of the testicular artery in the horse may be caused by strongyle larvae, the equine arteritis virus and other unknown agents. This may produce areas of testicular degeneration.²⁰ Strongyle larvae can produce adhesions between the testis and its tunics. Age-associated vascular lesions such as hyaline degeneration in older bulls, rams and dogs may cause degenerative changes in the seminiferous tubules.²⁰ Suspensories of any type whether solid or mesh should not be used in shipping male animals. They have not proven necessary. The solid type might result in over-heating of the testes and both types might become maladjusted and cause pressure on the spermatic cord and affect testicular circulation.⁷

Varicocele is seen occasionally in the internal spermatic vein of rams and stallions but not bucks. (See Fig-

Figure 183. Varicoceles or Thrombosis of the Spermatic Vein in a Ram. (Courtesy K. McEntee.)

ure 183.) As in man the adverse effects on semen quality especially motility are probably slight to moderate.^{5,15,21,28} A severe case of infertility due to bilateral varicoceles in a 4-year-old ram with a high percentage of abnormal acrosomes along with other spermatozoal abnormalities and degeneration of the seminiferous epithelium was reported.²³ Varicocele may effect both the circulation of blood and the heat regulatory mechanism of the pampiniform plexus. Varicoceles may be palpated in rams.¹⁵ In a recent review^{15b} of varicoceles in rams it was proposed that this condition was caused by excessive venous pressure in the internal spermatic vein possibly due to arterio-venous shunts. The condition develops slowly over several years so it is usually seen in older rams. The incidence is low. In severe cases the varicocele may reach a size of 7 to 15 cm. and cause immobility, reduced libido as well as testicular degeneration, and infertility secondary to hypoxia of the seminiferous tubules. In large varicoceles a laminated thrombosis may be present. Affected rams should be culled as no cure is available and the condition might be hereditary.^{15b}

Irradiation, as other causes of degeneration of the testes, produces interference with spermatogenesis by injuring spermatogonia, spermatocytes and spermatids. The spermatocytes are most sensitive to irradiation while Leydig and Sertoli cells are quite resistant. The amount

of irradiation and length of treatment are highly important in the degree of effects produced and the rate of recovery. The first change in the semen noted was abnormal sperm cells about the sixth week after exposure of bulls to 100 to 400 roentgens.¹² A decrease in sperm cell numbers occurred by the eighth week and these numbers did not begin to return to a normal level until 15 weeks. All bulls had reached nearly normal levels by 24 weeks after exposure. Bulls given doses totalling 600 to 1100 roentgens, developed aspermia by 16 weeks, remained aspermic for 10 weeks and fairly good recovery had occurred by 12 to 24 months.^{13,14}

Hormonal causes—Testicular degeneration and atrophy of the testes occurs in the dog and rarely in other animals due to tumors of the anterior pituitary gland or hypothalamus interfering with the production of gonadotropic hormones. This is called **dystrophia adiposogenitalis syndrome** in dogs.^{8b} Besides testicular atrophy, obesity and other signs commonly develop. Excessive estrogenic hormone produced by Sertoli cell tumors and testosterone, and rarely estrogens, produced by Leydig cell tumors may suppress FSH and LH production and cause testicular degeneration. In the past (1950's) infertile men with oligospermia were treated with large doses of testosterone for a prolonged period to completely suppress spermatogenesis. Following this treatment a "rebound phenomena" was reported in which higher than normal concentrations and numbers of spermatozoa were produced. In summarizing this data only 7.5 percent of 840 men treated showed any significant improvement.³ Prolonged doses of testosterone, estrogens or anabolic steroids should not be given to male animals.¹¹ (See Hormonal Causes of Infertility in Males.)

Age Effects—McEntee¹⁰ stated "Permanent and progressive testicular degeneration occurs fairly frequently in all species without any indication of its pathogenesis." Senile atrophy of the testes is common in dogs over 10 years of age and in cats over 12 years of age.¹ A decline in fertility in bulls as they became older has been reported.^{4,5} Vibriosis might have been present as a factor in the latter report. A decline in fertility of 0.31 to 0.51 percent per year in over 150 bulls used in artificial insemination as measured by nonreturn rates was reported.⁷ Aged bulls, 7 to 13 years old had a lower sperm cell output per ejaculate than young bulls, 2 to 6 years old, 7 billion and 10 billion, respectively.⁷ Aged bulls had 10 percent fewer morphologically normal spermatozoa and the motility rate was lower. Degeneration of the testes based on semen examinations in aging stallions was similarly described.⁹ The author has observed that older bulls after they reach 8 to 10 years of age may develop testicular degeneration fairly rapidly at any time.

It is an uncommon bull that produces good quality fertile semen up to 15 or more years of age. Many disease, genetic and management factors influence this age effect.

Subacute or acute trauma, stress, or disease may cause rapid or progressive testicular degeneration in males. Those that have been associated with reduced fertility and a decline in semen quality are: shipping under adverse conditions of heat and cold, severe fatigue, excessive physical work, traumatic gastritis in bulls,⁶ liver or abdominal abscesses, multiple severe contusions with fractured ribs as would occur in a fight between bulls, severe arthritis, severe myiasis or "fly strikes" in rams, severe screw-worm infestations, moderate to severe foot rot in rams, suppurative arthritis and severe quitters in bulls, acute laminitis in rams, horses and possibly other species, buckshot wounds especially of the scrotum and testes, kick wounds and resulting hematomas of the testes and scrotum in stallions, and extensive infected wounds. Good care and management will do much toward avoiding testicular degeneration due to these causes. Although Polish workers⁸ reported a temporary reduction in fertility for about three months after shipping 29 bulls from Holland to Poland, 60 bulls, used for artificial insemination, moved 300 to 2000 miles in the U.S. without a suspensory and no reduction in semen quality was noted in the months following shipment.¹⁵

Acute or chronic, localized or systemic infectious diseases are common causes of testicular degeneration with moderately to severely reduced fertility in males. Infections producing orchitis or epididymitis have a direct effect on the testes due to the inflammatory reaction causing heat, edema, congestion, circulatory interference, ischemia and even infarction due to the thick firm tunica albuginea that restricts normal swelling of the testicular parenchyma. In bacterial diseases localizing in the testes, abscessation may occur. (See Figures 184 and 185.) Infectious agents resulting in orchitis are: **Brucella abortus**, both field strains and Strain 19 in bulls;¹⁷ **Brucella suis** in boars; miliary or chronic tubercular infectious with **Mycobacterium tuberculosis** of the testes in bulls and boars; **Corynebacterium pyogenes**, usually carried to the testes by the blood from primary infectious sites in bulls and rams; **Actinomyces bovis** in bulls,¹⁴ **Malleomyces mallei** (glanders organism) in horses; **Salmonella abortus equi** and "epizootic cellulitis" due to the arteritis and the **influenza viruses** in horses; **Corynebacterium ovis** and **Pasteurella pseudotuberculosis** in rams; lumpy skin disease in cattle; sheep pox virus in rams;¹⁹ an enteric virus, possibly IBR-IPV virus, that markedly affected the spermatocytes and caused arrested spermatogenesis in bulls has been described in

Figure 184. Acute Orchitis of the Right Testis in a Holstein Bull.

Belgium.^{1,2} These workers^{1,2,10} reported on a G-UP virus isolated from the genital organs of bulls that caused infertility and an abnormal sperm picture, degeneration of the seminiferous epithelium, ulcers in the mouth, stiff gait, anorexia and other lesions highly suggestive of foot and mouth disease. A more chronic virus orchitis of bulls has been reported in Czechoslovakia.²¹ Other possible related viruses may cause orchitis in bulls.¹² The IBR-IPR virus when injected into susceptible bulls may cause a severe and rapid degeneration of the seminiferous epithelium and sterility.^{26,29} Most bulls recovered and were fertile in about 3 months. During the height of the degeneration only Sertoli cells and spermatogonia lined the seminiferous tubules. A few bulls developed an edema of the scrotum and fibrous adhesions occurred around the testes and spermatic cord.

Canine distemper affecting sexually mature dogs may cause a mild orchitis and testicular degeneration as well as an epididymitis.^{5,19} *Brucella canis* in dogs caused

scrotal swelling and dermatitis, orchitis, fibrosis, atrophy and sterility.^{5,6,7a,11,22} After oral inoculation of dogs with *Br. canis* 20 to 80 percent of the sperm cells were abnormal, including swollen midpieces and distal protoplasmic droplets within 3 to 4 weeks after the inoculation. By 8 weeks nearly all spermatozoa exhibited marked defects generally attributed to the epididymitis and seminiferous tubule degeneration.¹¹ (See Abortion and Epididymitis due to *Brucella canis*.) Any acute or subacute epididymitis would reduce fertility both because of the inflammatory reaction and heat produced as well as by obstructive lesions in the epididymal tube. (See Epididymitis due to *Brucella ovis*.) The probable viral disease of specific bovine venereal epididymitis and vaginitis, "epivag," also causes an orchitis with testicular degeneration and atrophy.³ A mycoplasma was isolated from three ovine cases of orchitis,²⁰ and *Mycoplasma hyorhinis* infection in swine often results in swelling of the scrotum and adhesions between the testes and the tunics.²⁸ *Chlamydia psittaci* may cause orchitis as well as polyarthritis in rams.²³ This organism was recovered from two other cases of orchitis in rams.⁸ A seminal vesiculitis syndrome in bulls characterized by seminal vesiculitis, epididymitis and orchitis was described by Colorado workers²⁷ from which they re-

Figure 185. Acute Orchitis and Periorchitis Secondary to a *C. pyogenes* Infection. (After unilateral castration and a 6 to 8 month rest period this bull (Figs. 184 and 185) recovered and was fertile for over 3 years.)

Figure 188. Advanced Testicular Degeneration, Fibrosis and Atrophy, Especially of the Left Testis.

covered a chlamydial agent. *Nocardia farcinica* in bulls,³ and *Besnoitia besnoiti* have been occasionally reported as a cause for orchitis in bulls.^{7b,16,24} Severe obstructive lesions such as sperm granulomas affecting the efferent ducts may cause a back pressure from the spermatozoa and the testicular secretions resulting in testicular degeneration. (See Figure 189.) The affected testes may be somewhat enlarged.¹⁹ Sporadic infections of the testis with

Figure 187. Testis with Advanced Testicular Degeneration, Fibrosis and Calcification (Courtesy K. McEntee).

Figure 189. Fibrosis and Sperm Granuloma of the Tail of the Epididymis of the Left Testis in a Ram due to *Br. ovis*. (Note the moderate atrophy of the left testis compared to the normal right testis.) (Courtesy P. C. Kennedy.)

staphylococci, streptococci, *E. coli*, *Proteus* and *Pseudomonas* organisms have been reported as a cause of orchitis in dogs and other male domestic animals.²⁵ Erythematous lesions of horses resulted in edema of the legs, sheath and scrotum and orchitis with secondary testicular atrophy.¹³ During the acute disease inclusion bodies were commonly observed in the leucocytes. This disease should be differentiated from equine infectious anemia, piroplasmiasis and dourine.

Infectious diseases of a systemic nature that cause testicular degeneration and lower fertility temporarily due to the accompanying high fever include: pneumonia and shipping fever, possibly IBR-IPV, equine infectious anemia, actinobacillosis, strangles, blue-tongue virus vaccination,⁹ and tick-borne fever infection in rams.³⁰ (See Figure 190.) Pseudorabies in swine had no effect on semen quality or fertility unless severe clinical signs developed.¹⁸ Those infectious diseases causing gradual debilitation, loss of weight and testicular degeneration with atrophy include: foot and mouth disease, actinomycosis, John's disease, pyelonephritis, chronic peritonitis, and lymphomatosis.

Nutritional factors related to testicular degeneration are usually those caused by severe underfeeding or starvation. (See Nutrition and Infertility in Males.) Diets for males sufficient for growth and maintenance are adequate for fertility. **Chronic disease states** associated with

inanition and debility and testicular atrophy may include: severe parasitisms, either external or internal such as: lice, mange, ticks, roundworms, flukes, and etc., senile changes due to worn or diseased teeth, chronic arthritis, tumors, fat necrosis around the large intestine in bulls, severe spastic syndrome and other possible diseases interfering with the intake and passage of food through the gut. Malnutrition may complicate these other chronic diseases. Improper care and management of bulls accustomed to special care and feeding may cause a marked loss in weight resulting in impotency and testicular degeneration and atrophy. This has been observed in several instances when a young fertile, but timid, bull was introduced into a new herd and permitted to run with the cows in a small, confined area. The cows would drive the bull away from the feeding racks causing the bull to become emaciated and sterile. Severe vitamin A deficiency characterized by night blindness, lacrimation and ophthalmia usually precedes testicular degeneration and poor semen quality. Under range conditions during drouths vitamin A deficiency usually is accompanied by protein and carbohydrate deficiencies. Malnutrition, debility and cachexia produce degeneration and atrophy of the seminiferous epithelium by causing a suppression of the release of gonadotropic hormones from the pituitary. Zinc deficiency may be associated with certain cases of infertility in animals.¹⁴

A high level of feeding and the accompanying obesity has no effect on semen quality in a normal male, but does effect their libido and willingness to breed. The author has observed a number of highly-conditioned beef show bulls producing semen of excellent quality. However, if obesity accompanies testicular hypoplasia, a short spermatic cord and much fat in the inguinal ring it does not follow that the obesity is the primary cause of the resulting infertility.

Poisons or toxins may adversely affect the germinal epithelium. Testicular degeneration in bulls and hyperkeratosis in rams was caused by ingestion of chlorinated naphthalenes.¹² Dipping of rams in arsenic solutions causes degeneration of the seminiferous tubules in sheep.⁷ Antimony compounds injected for the treatment of heartworms in dogs have been reported to cause temporary sterility.¹ There is no evidence that copper sulphate or phenothiazine used in worming sheep have harmful effects on the testes. There is no evidence that systemic organic phosphate insecticides affect semen quality in bulls.⁶ Severe prolonged toxemia and reduced semen quality lasting for 6 to 12 months resulted from using chlorpyrifos (Dursban 44) pour-on for the control of lice in AI bulls.⁴ This compound, which did not affect steers or cows, probably interacted in some manner with tes-

Figure 190. Edema of the Scrotum of A Standardbred Stallion, Associated with Equine Infectious Anemia.

tosterone to produce these effects.

Potassium nitrate also had no effect on semen production. The author has seen no ill effects from the use of sodium iodide for actinomycosis or actinobacillosis in bulls in artificial insemination studs. A number of chemical, metals and rare earth salts can produce degeneration of the seminiferous epithelium in a variety of species.¹¹ Setchell¹⁴ has cited many references on chemical compounds that affect testicular function including cadmium salts, other heavy metals, diesters of methane sulfonic acid, nitrofurans, halogenated compounds, alcohol and actinomycin D in animals and man.^{12,14}

Auto-immunization might play a role in a few cases of testicular degeneration. Degeneration has been produced experimentally in rams, bulls and laboratory animals by the subcutaneous injection of autologous testicular material together with Freund's adjuvant. Degeneration may occur with or without inflammation. No natural cases of testicular degeneration due to autoimmunization have been reported.^{2,9,10,12,13} Two reports have indicated that anti-LH serum or an anti-LH adjuvant product injected every 3 weeks in bull calves and ram lambs will induce testicular degeneration and sterility. This product immobilizes the male's own gonadotropic hormones and testosterone necessary for spermatogenesis. Lymphocytic thyroiditis, a possible genetic autoimmune disease of dogs, especially Cocker Spaniels, Corgis and Beagles, may also be associated with lymphocytic orchitis and infertility.^{8b}

Testicular Neoplasms. Testicular tumors are uncommon in most domestic animals except the dog and possibly old bulls. Primary testicular tumors are usually of three main types and originate from the interstitial cells,

Figure 191. Bilateral Interstitial Cell Tumors of a Testis in an Old Infertile Guernsey Bull. (Courtesy K. McEntee.)

Figure 192. Sertoli Cell Tumor of the Testis of a Bull. (Courtesy K. McEntee.)

the Sertoli cells and the germinal epithelium. The increased incidence in dogs may be due to a genetic predisposition in dogs and to the maintenance of intact male dogs until they become senile. The incidence of tumors in cryptorchid or retained testes is high, especially in dogs, for the same reason. In the larger animals relatively few uncastrated males are kept until they reach an advanced age. Sperm cell production and fertility of bulls with testicular tumors over 1.0 cm. in diameter were significantly lower than in unaffected bulls or bulls with small tumors.⁶ Bulls with large interstitial tumors had 30 percent of their ejaculates discarded as unfit for use for artificial insemination while normal control bulls had only 2 percent of their ejaculates discarded. (See Figure 191.) Thus large tumors result in testicular degeneration probably due to the compressing effect of the tumor on the adjacent seminiferous tubules. The degeneration may also be due to the excess steroids produced by the interstitial, or Sertoli cell tumors.¹² (See Figure 192.) Lymphosarcoma of the testis of animals is rare.

In bulls testicular tumors are seldom observed except in old animals. Interstitial cell tumors of a benign type are occasionally observed in bulls over 7 to 10 years of age. These may be multiple and in some cases they are large enough to be palpable as small, round, masses, liver-like in consistency, and causing the testes to feel lumpy on palpation. Interstitial cell tumors were found

in 19 percent of 52 Guernsey bulls.⁶ This was significantly higher than the 6 percent incidence in 164 bulls of the other breeds. An interstitial cell tumor in a testis of a 3-month-old calf was described.⁹ This type of tumor usually has a deep ochre or orange-brown color with a homogeneous, glassy consistency resembling a corpus luteum.¹² (See Figure 191.) An adenocarcinoma, seminomas and several Sertoli cell tumors have been described in bulls. (See Figure 192.) The benign interstitial cell tumors in old men, dogs and probably bulls may be related to a hormone imbalance.⁹ Small fibropapillomas or melanomas and varicose dilatations of scrotal veins occur in older bulls and are occasionally seen on the scrotal skin. These small varicose lesions on bulls' testes may be associated with improper temperature regulation of testes and infertility during the hot summer months.

In stallions testicular tumors have been described only occasionally. Uncommon dermoid cysts or teratomas of the testicle of the horse are most often found in cryptorchid testes.^{4a,b,13,24,28} They often contain large cystic structures and hair or bone. Forty-nine testicular tumors

of a total of 142 neoplasms were found in 77,000 slaughtered horses.⁹ Rare seminomas in stallions were described.^{9,10,13,26} The latter report described two equine seminomas that metastasized.

Only one testicular teratoma was found in 700 horses castrated at the New York State Veterinary College.¹² An adenocarcinoma in a retained testicle in a horse with metastasis to the lungs and mediastinum was described.⁹ Occasional interstitial cell tumors of the equine testis have been reported.^{12,23} In some of the cases the affected animals were extremely aggressive and vicious but after castration became gentle and quiet. Sertoli cell or sustentacular cell tumors in horses were rare.¹³ A melanoma of the scrotum has been observed in a stallion.⁷ Lipomas on the surface of the equine testis are not uncommon.¹²

In rams testicular tumors are rare. No large series of testes in old boars, rams, or cats has been examined.⁹

In boars testicular tumors are very unusual. A malignant tumor of an undescended testis in a boar was described.²⁸ A teratoma was observed in a cryptorchid porcine testis.⁴ A seven-year-old boar with a seminoma of a testis that was four times as large as the opposite testis was reported.⁸ When the boar was bred, about 250 ml. of semen was collected but no spermatozoa were present and on histologic section areas of necrosis were found in the tumor.

In cats testicular tumors apparently are rare. Several Sertoli cell tumors in this species have been reported.^{13,27}

In dogs testicular tumors are observed at any age but most commonly in dogs over five years old. There was a higher incidence of testicular tumors in dogs than in humans.⁹ An incidence of 16 percent of tumors in 580 unselected adult dogs was reported.⁵ The three principal testicular tumors in dogs are, seminomas, Sertoli cell tumors (tubular adenomas), and interstitial cell tumors.¹³ Their comparative incidence is noted in Table 25. Teratomas have not been recorded in canine testes.⁴ Most canine tumors are usually benign but up to 10 percent of the Sertoli cell tumors and a few seminomas may be malignant in character.^{5,17} Of 177 tumors in 85 dogs, 55 percent were multiple, 45 percent were bilateral and 35 percent of the dogs had two or more types of tumors.¹⁹ Five percent of all tumors developed in cryptorchid testes. There is a significant correlation of Sertoli cell tumors and seminomas with cryptorchidism in dogs, (See Cryptorchidism). The age of the affected dogs averaged 10 to 11 years but the range was 3 to 20 years. Dogs with affected cryptorchid testes were younger than dogs with affected scrotal testes.

In another survey of 198 dogs with testicular tumors, the numbers of seminomas, Sertoli-cell tumors, interstitial cell tumors and combinations of several types of tu-

Figure 193. Testicular Abscesses in a 3-Month-Old Calf.

Table 25. Summary of Reports on the Comparative Incidence of Testicular Tumors in Dogs

Tumors	Innes ⁹	Dow ⁵	Scully & Coffin ¹⁹	Mulligan ¹⁵	Totals	
					No.	Percent
Seminoma	32	45	55	14	146	35.3
Sertoli cell	15	36	33	13	95	23.5
Interstitial cell	14	56	88	12	170	41.1

mors were 47, 46, 67 and 38, respectively. Concomitant clinical changes with each type of tumor was reviewed.¹¹ In a large cohort study the incidence of testicular neoplasms in cryptorchid dogs over 6 years of age was 68.1/1000 dog-years at risk. The incidence of Sertoli cell tumors and seminoma was twice as high in dogs with unilaterally retained inguinal testicles as in abdominal cryptorchids.¹⁸

Seminomas are noted in old dogs over 7 years of age and arise from the germinal epithelium of the seminiferous tubules.¹³ These tumors originate in atrophic seminiferous epithelium and the tumor is intratubular before becoming diffuse.¹⁹ These tumors grow slowly for months but may develop rapidly at any time. They are rather soft in consistency and hemorrhage or necrosis may be present. On section they appear dull-white or gray in color. Affected dogs may exhibit lameness and pain by crouching and hunching. Seminomas were frequently bilateral and occasionally metastasized to the regional lymph nodes.^{11,12,19,22} A seminoma in an abdominally located testis was removed. Nine months later a large metastatic tumor of the abdominal cavity was diagnosed.²² In some cases seminomas and interstitial cell tumors are present together in the testis.

Sertoli cell tumors, or tubular adenomas are possibly the least common of the principal tumors of the canine testis. This tumor arises from the Sertoli or nurse cell of the seminiferous tubules and is usually seen in older dogs. The tumor is often characterized by marked feminization of the male by the estrogens secreted by the tumor cells.³ Recent studies indicated that the estrogenic substances produced by the tumor and causing feminization of the male were not the usual estrogens found in animals.²¹ The dog may attract other males. The penile sheath is swollen. There is a definite loss of hair, especially on the abdomen and lower parts of the body, and a loss of sexual desire. Mammary hypertrophy or gynecomastia, and enlargement of the nipples and in some cases development of mammary tumors may occur. Atrophy of the testicular tissues and penis develops. Pigmentation of the abdominal skin and scrotum and female distri-

bution of body fat are exhibited. The prostate may undergo marked enlargement due to squamous metaplasia and cysts; or it may become markedly involuted due to atrophy of the epithelial elements and collapse of the acini.¹⁹ Bone marrow hypoplasia due to endogenous estrogen myelotoxicosis from Sertoli cell tumors were reported in eight dogs, five of which died due to hemorrhage with thrombocytopenia, anemia and infection and fever associated with granulocytopenia.²⁰ These tumors are rather large in size, firm, nodular, and fibrous on palpation. Rarely a large hydrocele may be associated with Sertoli cell tumors, especially those that metastasize. On cross section Sertoli-cell tumors are pale-yellow or grey in color and may contain necrotic, cystic, or hemorrhagic foci. If no metastases have occurred recovery from the above dramatic symptoms takes place promptly after the affected testis is removed.

Interstitial-cell tumor, adenoma, or Leydig-cell tumor is the most common tumor in old dogs. Although this tumor is present in many old dogs, it is of little clinical significance. Most of them are found only at autopsy. They are often overlooked because of their small size; 1 mm. to 2 cm. is their usual size.¹² Although 41.1 percent of testicular tumors cited in Table 25 were of the interstitial cell type, this percentage might well have been higher if all the small interstitial cell tumors had been found and recorded. Careful work in one study showed that 50 percent of testicular tumors were of the interstitial cell type.¹⁹ Nodular hyperplasia of the interstitial cells is seen commonly in older dogs with senile testicular atrophy. Nodular hyperplasia is probably a preneoplastic change but the division between nodular hyperplasia and interstitial cell tumor is arbitrary.¹² These tumors probably produce androgens because the prostate in affected dogs is normal or hypertrophied. In uncommon instances these interstitial cell tumors may produce estrogenic compounds resulting in male feminizing syndrome with alopecia, atrophy of the prepuce and gynecomastia.¹⁴ The tumors consist of single or multiple well-circumscribed nodules, brownish-orange in color and soft in consistency. Large tumors may occasionally be palpated in the testes of old dogs. They are similar in appearance to a corpus luteum and are likely to be bilateral and often contain hemorrhagic and necrotic foci. This condition probably is nodular hyperplasia of the interstitial cells and possibly these nodules should not be called true tumors.⁹ Although two cases in which this tumor metastasized have been described, metastasis is rare.⁹

Melanomas and mast cell tumors are not uncommon in the scrotal skin of the dog. The latter are usually malignant.² A scrotal hemangioma in a dog resulted in fatal hemorrhage.²⁵ Canine tumors should be carefully differ-

entiated from orchitis or epididymitis, traumatic swellings or hydrocele. The latter condition may be either congenital or secondary to orchitis. Canine perianal gland tumors are probably androgen-dependent tumors that can be arrested by castration.¹⁶ About 85 percent occur in older male dogs with a definite breed incidence in Cocker Spaniels.

Genetic hereditary influence on acquired testicular degeneration have been reported in identical twin bulls.¹ Genetic constitution appeared to influence the onset of generalized arthritis, fat necrosis, traumatic gastritis, and associated testicular degeneration in identical twin bulls. The increased predisposition and earlier occurrence of testicular degeneration in bulls with some testicular hypoplasia was noted.¹² Certain bulls may be more resistant to testicular degeneration than other bulls when affected by similar etiologic agents. Thus the genetic constitution of each male and his seminiferous epithelium and their resistance or ability to withstand adverse influences must be considered in the etiology and signs of testicular degeneration.

The signs of testicular degeneration are similar in all species of animals despite the etiologic factor(s) involved. The signs vary in degree from mild to severe depending upon the cause and duration of the degeneration.

The fertility of the male may range from only slightly reduced conception rates, to moderate to severe infertility, to complete sterility.

The age of the male with testicular degeneration may vary from young to old with most cases in the older animals.

The size of the testes is usually reduced from normal to about one-half to two-thirds normal size depending on the duration and degree of degeneration and atrophy of the seminiferous tubular epithelium. Since 77.1, 72.2 and 49.9 percent of the testicular volume is comprised of seminiferous tubules in 2.5-year-old, adult, and one and one-half-year-old bulls¹ the close association of the degree of testicular degeneration and testicular size is apparent. In acute orchitis, other inflammatory conditions, obstruction of the efferent ducts, or testicular tumors, an increase in testicular size is often noted.

The consistency of the testes is soft and flabby in acute, moderate to severe testicular degeneration. This is understandable since about 70 percent of the volume of the testis is composed of seminiferous tubules and their contents. In mild testicular degeneration consistency differs only slightly from an elastic, tonic, slightly tense, fluctuating normal consistency. In these cases comparing the testicular consistency of the bull in question with several normal bulls of the same age may be helpful.

The use of a tonometer has proven of value in the objective measurement of testicular consistency.^{4,5} In 150 bulls in an AI stud, soft, medium and firm consistencies of the testes were found in 14, 30 and 56 percent, respectively. Bulls with soft testes tended to produce fewer sperm cells. The tonometer test correlated closely with other tests of semen quality.

Acute orchitis is characterized by a tense swelling and enlargement of the testis accompanied by pain and heat. This should be differentiated from hydrocele or hematocele. Chronic degeneration and atrophy of the testes especially in older males whether following severe acute or chronic diseases is characterized by fibrosis of the testes often with calcification. The latter is impossible to palpate but about 25 percent of 158 bovine testes from abattoir material revealed calcification on radiographic examination.² Fibrotic testes are hard, firm and often lack tonicity or elasticity. Ultrasonics can be of value in the detection of connective tissue in fibrosis of the testes.⁴ Testes containing tumors may be enlarged and have an irregular shape and consistency on palpation.

The libido or sex drive is usually not related or associated with testicular degeneration except in acute orchitis or other painful testicular diseases or in testicular atrophy associated with severe debility or inanition due to a variety of causes. As indicated previously the Leydig-cells are much more resistant to stress factors than the cells of the germinal epithelium.

The semen examination is very helpful in diagnosing testicular degeneration. Semen may be collected by the artificial vagina, by electroejaculation or other methods as will be described later. The former method is preferred. Since it requires about 50 to 60 days or more for sperm cells to develop from spermatogonia until they are ejaculated, it may be desirable in diagnosing testicular degeneration to take several samples at weekly or greater intervals. The semen production and quality in young immature bulls continues to improve in motility, concentration and morphology for months after puberty is reached. So if an initial semen sample is poor, subsequent samples are indicated. The first semen samples taken after a long period of sexual rest may also be misleading as these are often of poor quality with many dead or aging spermatozoa with acrosomal degeneration. In males in which testicular degeneration is severe, semen quality is usually poor.

Sperm cell concentration may be reduced to one-third to one-half of normal values or show severe oligospermia or azoospermia. Watery, translucent semen is common in severely affected bulls and rams.

Sperm cell motility is reduced one-third to one-half or more due to an increase in abnormal cells, dead cells,

(necropermia), or poorly viable defective cells. The duration of motility after ejaculation is shortened.

Sperm cell morphology after staining reveals an increase in dead spermatozoa and abnormal heads, tails, and middle pieces. The degree of change in the morphology of cells may vary from normal semen which usually contains from 5 to 15 percent abnormal cells, to a 15 to 20 percent increase in abnormal cells in mild cases of testicular degeneration, to a 20 to 30 percent increase in moderate testicular degeneration, and to a 35 to 60 percent or greater increase in severe testicular degeneration. The occurrence of large numbers of spermatozoa with primary abnormalities that arise during spermatocytogenesis or spermatogenesis and early spermiogenesis are more indicative of a severe testicular degeneration than the presence of secondary abnormalities that occur later in spermiogenesis or during passage and storage of spermatozoa in the epididymis.^{3,7,8} (See Semen Examination.) The appearance of primitive cells such as giant cells and spermatocytes with restitution or pyknotic nuclei together with a marked reduction in sperm cell concentration and motility are signs of severe degeneration of the testes.

Other tests for viability and longevity may be employed but are more difficult to perform and do not add greatly to the information obtained by the previous tests. The volume of the ejaculate is not related to the degree of testicular degeneration since most the ejaculate comes from the secretions of the accessory glands. Testicular biopsies may be of value in certain species such as the dog and stallion, but are impractical for technical reasons in the bull.⁸ Furthermore the above signs and additional tests of sequential semen samples will accurately reveal the relative degree of progression and regression of testicular degeneration.

Prognosis—The prognosis in testicular degeneration is variable depending upon the causative factors, the duration and degree of the degeneration, and the age and value of the male. Although testicular degeneration can occur rapidly within a few hours, days or a week or more, recovery is very slow usually requiring 3 to 6 months or more in moderate to severe cases. The prognosis in slight or mild cases of testicular degeneration in young or middle-aged bulls due to transient and correctable causes is fair to good. Controlled breeding during the recovery period may result in fair to good fertility in some males.

The prognosis is guarded to fair in young males with only moderate evidence of testicular degeneration; and in older males suddenly developing infertility due to a transient disease where advanced testicular changes do not occur, such as in; mild cases of trauma to the testes, scrotal inflammations, toxemia or poisonings, mild ex-

posure to irradiation, chronic but curable systemic diseases causing debility, and inanition due to semistarvation.

The prognosis is poor in progressive senile testicular degeneration, in acute severe orchitis especially if it is bilateral and associated with abscessation, in advanced fibrosis and atrophy of the testes, in degeneration associated with hypoplasia in young to middle-aged males, and in older males with bilateral tumors of the testes.

Once the testes have been severely damaged regeneration can never be complete. If severe secondary infections or lesions occur in the epididymides, accessory glands, or vasa deferentia the prognosis is also guarded to poor.

The **treatment** of testicular degeneration requires the correction or the alleviation of the causative factor(s). Sexual rest is usually advised, since in most cases fertility is reduced to a point where the use of the male is questionable. Males with mild degrees of degeneration not severely influencing fertility should be used sparingly so as to maintain as large a number as possible of normal, motile spermatozoa in each ejaculate. A balanced ration high in vitamin A and a good quality and variety of protein are indicated. Good-quality roughage or pasture is highly desirable. Some exercise especially on pasture is usually recommended for the larger farm animals, although it has been shown that forced exercise has no effect on the fertility of the bull.⁹ If excessive heat and humidity is the cause of the temporary infertility in bulls, air conditioning or cooling is indicated.

Hormones are of no proven value. Testosterone, various FSH products, and thyroxine have been tried but none have any demonstrated effect in the therapy of testicular degeneration or hypoplasia. Plasma concentrations of these hormones are usually normal or elevated in affected males. Furthermore the gonadotropic hormones to be of any value must be given over a period of a month or more and should be prepared from biologic sources from the same species to prevent antihormones from developing. Many studies have reported on the uniformly poor results from the hormonal or dietetic therapy of testicular degeneration in men.^{6,10,12}

In acute orchitis, sexual rest is imperative. Physical rest is usually advisable and can be provided by close confinement of the male. In the early acute stages heavy parenteral broad-range antibiotic therapy is indicated. Glucocorticoid or non-steroidal anti-inflammatory agents along with the antibiotics might be helpful in reducing the inflammatory reaction. Ice packs should be applied to the testes by a suitable sling or bag fixed between the legs and tied over the back. This therapy should be continued until the acute, severe symptoms have subsided.

When the orchitis is unilateral and severe or incurable, removal of the affected testis may hasten recovery or save the breeding life of a valuable male. The testis should be examined carefully and cultured after removal to detect the responsible agent so that suitable precautions can then be taken for the future use of the sire if his fertility returns. The Brucella-infected bull or boar should not be used either artificially or naturally in a Brucella-free herd. Heat or a mild counter-irritant ointment to the inflamed testis and swollen scrotum should never be used. The preferred treatment for testicular tumors is prompt castration or removal of the affected testis. If metastases have occurred, symptoms caused by the secondary tumors will usually develop within a few months. Cryptorchid testes should be removed while the affected males are still young to prevent the occurrence of tumors or abdominal complications common in these structures in later life.

Pathological or Functional Disturbances of the Epididymis, Ductus Deferens and Accessory Reproductive Glands in the Male Causing Failure of Fertilization or Conception.

Pathology of the Epididymis—Disease of the epididymis includes: infection of the epididymal duct and epididymitis, anomalies causing sperm granulomas, tumors, and functional or hormonal disturbances.

Epididymitis, or inflammation of the epididymis, is occasionally observed as an acquired lesion in all species of animals and is caused by or may be secondary to the same factors causing orchitis. Infectious causes of epididymitis most commonly involve the tail of the epididymis but may involve the body and head of the epididymis. These include: ***Brucella abortus*** in bulls, ***Brucella suis*** in boars, ***Brucella ovis*** and ***Actinobacillus seminis***^{23,30} in rams, ***Brucella canis*** in dogs,¹² ***Streptococcus zooepidemicus*** in the stallion,⁵¹ ***C. pyogenes*** and other miscellaneous organisms such as streptococci, staphylococci, *Proteus*, *E. coli*, ***C. pseudotuberculosis***, ***Pseudomonas aeruginosa*** and ***Mycoplasma bovis-genitalium***.⁴³ Infections may be caused by organisms, such as mycoplasma or possibly ureaplasma invading the epididymis through the ductus deferens or by way of the blood or lymph vessels. (See seminovesiculitis.) Traumatic injuries may also produce an epididymitis.⁴⁵ Canine distemper virus in sexually mature dogs causes an epididymitis.³⁷

A specific bovine venereal epididymitis and vaginitis or "epivag" has been described in Chapter XIII. This venereal and probably viral disease, found only in East, South, and Central Africa, is usually characterized in the bull by a marked bilateral hardening and swelling of the tail of the epididymis and sterility. Pathological fibrotic changes also occur in the ductus deferens, testes, and vesicular glands.^{9,32} There is no cure for affected males

but artificial insemination has been an effective control measure to prevent the spread of this venereal disease. Other diseases of the testis and epididymis of bulls in South Africa have been described.⁵³ ***Besnoitia besnoiti*** produces elephantiasis of the scrotal skin and cysts in the scrotum, inguinal canal, testes, and epididymis. These cysts may persist and calcify, causing sterility.

Chlamydia psittaci has been isolated from the epididymis of young bulls with epididymitis, orchitis and seminal vesiculitis, that is a possible agent producing the clinical seminal vesiculitis syndrome.⁴⁸

***Brucella ovis* (brucellar epididymitis)** is a common venereal disease of sheep causing ram epididymitis and infertility worldwide.^{23,25,27} In California in 1956 examination of 1882 rams revealed a 27 percent incidence of infection. Of 175 ewe lambs bred to clinically normal rams, 75 percent lambed within a 30-day period while only 47 percent of 171 ewe lambs bred to clinically-infected rams lambed during the same period.⁴² In Idaho in 1970, 1890 rams were examined in 37 large commercial flocks. Twenty four percent of the rams were clinically affected and over 97 percent of the flocks were infected. The disease was more common in the black-face breeds and crosses.⁴⁷ Ewes bred to infected rams had a greatly increased number of services per conception and fewer lambs per ewe than ewes bred to non-infected control rams.⁴⁰

The infective organism is spread mainly by venereal contact to susceptible rams breeding a ewe recently bred by an infected ram, or by rams penned together mounting each other and having rectal copulation, penile contact with a contaminated perineal region, or oral infection from infective feed or water.^{1,23,28} Ewes play a minor role in the spread of the infection and are relatively resistant to the infection; but occasional abortions due to ***Brucella ovis*** are reported. Young rams raised from infected ewes are not infected. Rams are readily infected by the conjunctival, oral, rectal or preputial instillation of the organism. Rams may spread the organism for 3 to 4 years while ewes spread infection for a much shorter period of several days after an occasional abortion. Following infection the antibody levels rise by the third to sixth week and persist for up to a year after the end of the bacteremic stage of the disease, which ends in about 60 days. The organisms localize in the epididymis, vesicular glands, ampullae, liver, and kidneys. The organisms cause perivascular lesions with edema and fibrosis in the epididymis resulting in obstruction of the lumen and stasis of the epididymal contents and finally extravasation of semen that, because of its high lipid and mycolic acid content, results in the formation of a spermatic

granuloma resembling tubercular granulomas.^{2,3,34} (See Figure 189.) Over 90 percent of these lesions affect the tail of the epididymis but occasionally the body and head of the epididymis may be involved. If the lesions are unilateral, fertility is normal or only slightly impaired; if they are bilateral, sterility is usually present.^{1,23,50} In 29 naturally-infected rams the semen quality, including motility and concentration was inferior in 50 percent of the rams and normal in only 25 percent.⁴⁰ It takes 1 to 4 months from the onset of infection to the development of the lesions in the tail of the epididymis. The tail, or occasionally other portions, of the epididymis enlarges 3 to 5 times normal size and becomes fibrotic or with an occasional abscess. Some infected rams fail to develop gross palpable lesions.

Diagnosis is based on clinical palpation of the epididymis to detect induration, spermatic granulomas, abscesses and enlargements, especially involving the tail of the epididymis. In advanced cases testicular degeneration, atrophy and later mineralization of the testis may occur. Some affected rams would be difficult to differentiate on clinical examination from those with epididymitis due to other causes such as *C. pseudotuberculosis* or *Actinobacillus seminis*. These latter infections are more sporadic, variable in location and resemble abscesses rather than granulomas. Enlargement of the head of the epididymis is more likely due to granulomas secondary to anomalies of the efferent ducts. The combination of clinical palpation of the testes, culturing the semen and the complement-fixation test on serum was most effective in locating shedders of *Brucella ovis*. Screening tests were run at 1:10 dilutions.² Other serologic tests have included the agar gel diffusion test and the ELISA test.

Controlling ram epididymitis in a flock is highly important to maintaining good fertility in the flock. Before the breeding season all rams that show clinical or serologic evidence of epididymitis should be eliminated. In valuable purebred rams semen examination and culture may be used.⁴⁰ Various vaccination procedures have been used successfully to protect rams against *Brucella ovis*. In New Zealand they have used a combination of *Br. ovis* bacterin and strain 19 *Brucella abortus* vaccine.^{10,46} In the U.S. an alum-precipitated commercial *Br. ovis* bacterin has been developed and approved^{39,41} that is given subcutaneously in two doses 3 to 6 weeks apart and followed by a single injection repeated each year. (Cutter Laboratories and Colorado Serum Co.) This vaccine may occasionally cause a granuloma and some soreness and irritation at the site of the subcutaneous injection behind the elbow, but abscessation is rare. Vaccination causes a serum titer to develop that lasts several years after the combined vaccines were given.⁴⁶ The combination of the

vaccine with other control practices was highly effective in infected flocks of sheep. One study in which clinically affected rams were culled, together with a vaccination program starting with ram lambs 4 to 5 months of age, the incidence of culling dropped from 44 percent at the onset to 2 percent after three years of the trial and remained low for the next 7 years.^{39,41} To rapidly reduce or eliminate the *Br. ovis* infection in a flock, identify and isolate or cull all rams with clinical disease, serologically test and cull positive rams every 30 to 60 days until the incidence is below 1 percent. By testing and isolation practices a *Br. ovis* clean ram flock may be established. A more practical and less expensive procedure is to follow a vaccination program.^{1,23}

Actinobacillus seminis, actinobacillary epididymitis or epididymo-orchitis has recently been described as a venereal disease of rams that is similar in many respects to the foregoing epididymitis due to *Br. ovis*. It also is world-wide in distribution; is transmitted in a similar manner with a similar incubation period and the complement fixation test on serum, clinical palpation of lesions, and culture of semen are used in the diagnosis of the disease. It differs somewhat from the brucellar epididymitis by the frequent development of clinical, unilateral or bilateral orchitis and periorchitis with moderate to severe systemic signs including elevation of body temperature to 40 to 42° C and even death in the early stages of the disease. Subclinical infections are not uncommon. After the acute stage of the disease chronic adhesions around the testes may develop, degeneration, atrophy and even mineralization of the testis may occur. The epididymis becomes enlarged and indurated due to sperm granulomas or abscesses that may involve the head, body or tail or the entire epididymis. Rarely abscesses may rupture through the scrotum and produce a discharging fistula. The diagnosis, prevention and treatment of actinobacillary epididymitis is similar to brucellar epididymitis except no vaccine is presently available for the former disease.^{23,49,50}

Canine brucellosis due to *Brucella canis* is apparently widespread in the U.S. among dogs, especially Beagles,¹² causing abortion in bitches and swelling of the scrotum, firm enlargement of the epididymis, especially in the tail, and degeneration and atrophy of the testis with sterility in males. The disease is spread by direct contact with aborted fetuses, placental tissues and the infective vaginal discharges of bitches for several weeks after abortion. Venereal transmission to females by the semen from chronically-infected males is a common mode of spread. Following exposure a bacteremia develops within one to three weeks with a generalized lymphadenitis. Antibodies develop that can be detected by the agglutin-

ation test; 1:100 is considered positive. These antibodies may last indefinitely or as long as a bacteremia persists. The organisms can often be recovered from the lymph glands, spleen, liver, prostate, testes and epididymides. Clinical lesions need not be present. The prognosis is poor in clinically-affected male dogs. Any possible effective antibiotic therapeutic regimen must be heroic and sustained. If the genital organs are seriously damaged or if the lesions are bilateral, recovery is unlikely. Efforts to develop a bacterin have been unsuccessful. Prevention and control of canine brucellosis presently is based on monthly serologic tests of all dogs in the kennel, and those entering, together with segregation and destruction of positive animals. **Brucella canis** has caused human infections. (See **Brucella canis** abortion.)

The prognosis in severe or moderate epididymitis is poor, as obstructions usually occur preventing the discharge of spermatozoa from that testis. There is no practical cure in animals once the epididymis is obstructed. In the occasional case of bilateral epididymitis the prognosis is hopeless. In recent years operations have been devised to bypass the obstructed portion of the epididymis in humans but the percentage of cures is low.

If in a valuable animal the epididymitis is unilateral and the accessory glands and the vas deferens have no lesions or infection caused by the same organisms, unilateral castration may be indicated followed by a long recovery period for the normal testis during which repeated tests and cultures of the semen may be performed to be certain the genital infection has been eliminated.

Anomalies of the Epididymis may be either congenital or hereditary and consist of: (1) a spermioistasis due to distention of aberrant efferent or epididymal tubules with the secondary formation of spermatic granulomas in the region of the head of the epididymis, (2) segmental aplasia of the mesonephric (Wolffian) duct or ductus deferens and (3) mesonephric or paramesonephric duct cysts or remnants near the epididymis or ductus deferens.^{22,34-36}

Spermioistasis, resulting in spermatoceles and in time, by the same process as described under infections involving the escape of sperm cells into adjacent tissues, spermatic granulomas, resembling tubercular granulomas, may be caused initially by blind-ending rudimentary mesonephric tubules or ductuli aberrantes.^{22,34-36} These tubules most often are defective efferent tubules. They may be attached to the rete or epididymis and therefore produce lesions involving the head region, or caput of the epididymis and only rarely other portions of the epididymis. Spermioistasis was noted in 208 (25 percent) of 836 bulls in one or more of the efferent ducts.³⁶ Sperm granuloma is common in bucks less

common in rams, uncommon in bulls and rare in the other domestic animals. The frequency of occurrence of granulomas is not related to the incidence of blind-ending or aberrant efferent tubules as found in normal animals.^{22,35} In rams it has been confused with ram epididymitis which usually causes spermatic granulomas in the tail of the epididymis. In bucks the condition is usually bilateral resulting in complete sterility. The incidence in bucks in Germany was reported to be 20 to 25 percent and therefore the condition was of great economic importance. In bulls of two Danish breeds the incidence was about 3 percent, and more than 90 percent of the cases were unilateral so most bulls remained fertile.⁴⁻⁷ There was considerable evidence that bovine spermioistasis in the mesonephric ducts is genetically determined by a recessive hereditary factor. The author has observed two related Brown Swiss bulls with spermioistasis and granulomas of the left caput epididymidis. Spermioistasis with spermatocele and spermatic granulomas develop slowly thus young, even bilaterally affected, males may be fertile for a year or more until the fibrous tissue of the granuloma completely obstructs the mesonephric duct. Spermatozoa and fluid are continued to be produced in the seminiferous tubules and absorbed in the efferent ducts and head of the epididymis if the obstruction is located at the distal portion of the head. If the obstruction is located at the proximal portion of the head or in the efferent tubules the pressure may produce testicular degeneration but the size and consistency of the testicle may remain nearly normal due to the accumulation of testicular secretions.³⁴⁻³⁶

Segmental aplasia of the mesonephric or Wolffian duct, epididymis or ductus deferens may occur congenitally in all species but has been well-described in bulls.^{4-7,34-36} The majority of cases are unilateral and the body, tail, entire epididymis, and even a part or all of the vas deferens may be missing. In unilateral cases the bull is fertile. In the latter instance the vesicular gland on the same side may also be hypoplastic or missing. (See Figures 194 and 195.) The incidence of bovine segmental aplasia of the mesonephric duct in Denmark was 0.59 to 1.18 percent.^{4,5} A 5 percent incidence in 828 infertile bulls was recorded in the Netherlands,⁵² while the incidence in 584 "normal" bulls was 1.7 percent. In 12 of 18 Simmental bulls in Switzerland the epididymal aplasia was bilateral.²⁶ This condition has been described in dogs.^{14,29} The author has observed a few cases in Holstein, Guernsey and Angus bulls in New York State. There was a strong indication that segmental aplasia of the mesonephric duct was hereditary as in 19 male offspring of a unilaterally affected bull there were 4 sons similarly affected.⁴⁻⁷ The missing segment was most often lacking

Figure 194. Segmental Aplasia of the Terminal Portion of the Right Ductus Deferens with a Marked Dilation of the Ampulla with Semen in a Bull.

on the right side. In older bulls spermatoceles and/or granulomas may develop just proximal to the missing segment.

In unilaterally affected bulls the sperm cell concentration and the total number of spermatozoa per ejaculate may be about one-half normal. Careful clinical palpation of the testes and epididymides, and a rectal examination of the ampullae and vesicular glands in the larger species will usually detect and delineate the extent of the segmental aplasia. A small epididymis accompanies severe hypoplasia of the testis. The testis associated with segmental aplasia of the epididymis is usually normal in size or may occasionally be atrophied. Palpation of a very small or missing tail of the epididymis is highly indicative of segmental aplasia. The head of the epididymis, if present, is often enlarged due to distention with sperm. If the segmental aplasia is located in the ductus deferens, the tail of the epididymis may be enlarged. In rare cases the missing mesonephric segment may be located in the

ductus deferens near the urethra causing distention of the ampulla. (See Figures 194 and 195.)

There is no treatment for this condition, other than possible surgery to reunite the unaffected portions of the mesonephric duct. Because of the possible hereditary nature of this anomaly affected males should be discarded.

Figure 195. Aplasia of the Right Ampulla and Ductus Deferens and Arrested Development of the Right Vesicular Gland in a Bull.

Mesonephric or Wolffian, or paramesonephric or Mullerian duct cysts or remnants and miscellaneous anomalies may be found in males and are of little consequence except in cases where they may be large and are confused with defects or diseases of the epididymis on palpation. Ectopic rests of adrenal cortical tissue may be found in the testis, epididymis or spermatic cord, especially in the horse.^{34,35} A rare case of a Holstein bull, twin to a freemartin, had an area of testicular rete tissue outside of the testis in the region of the head of the epididymis.¹³ This is commonly observed in the rat. Paradidymides, detached segments of mesonephric tubules, were seen on the spermatic cord and epididymis in 25 to 46 percent of calves and are of no significance.⁵ Occasional mesonephric duct cysts may be found in bulls near the head and tail of the epididymis and some may be lined by ciliated cells, "medusa cysts." Paramesonephric cysts or uterus masculinus are seen commonly in 24 to 44 percent of bulls on the dorsal surface of the urogenital fold between the ampullae and ductus deferens or rarely in or near the epididymis.^{5,6,24}

Primary tumors of the epididymis are rare in all animals. Testicular tumors in dogs or other animals may invade the epididymis or spread through the epididymis to the ductus deferens and cord. Occasionally metastatic tumors such as lymphosarcomas and Sertoli cell tumors in the bull,³⁴⁻³⁶ may develop in the epididymis. Primary tumors of the epididymis are nonexistent in the tom cat and rare in the dog.⁸ Only 2 cases of fibromas of the epididymis in dogs were described.

Miscellaneous Diseases of the Epididymis—Obstruction and enlargement of the epididymis in bulls resulted from a metaplastic process in **hyperkeratosis**.³⁸ Feeding highly chlorinated naphthalenes caused external symptoms of hyperkeratosis and complete sterility. Fertility was gradually regained in about 10 months after withdrawal of the toxic agent. **Sperm granulomas of the ductus deferens and tail of the epididymis secondary to adenomyosis** of the duct wall has been described.³⁴⁻³⁶ This condition may be related to chronic estrogen stimulation. It was observed in 6.2 percent of 695 bulls from an AI center. It has also been observed in dogs with Sertoli cell tumors and in two stallions with secondary sperm granulomas.³⁶ Sperm granulomas may also occur secondary to congenital anomalies, infectious agents, vascular and traumatic lesions and autoimmune reactions. Fifty-three (6.3 percent) of 83 bulls had sperm granulomas of the epididymis.³⁵

There is definite evidence that a **change in the environment of spermatozoa, especially in the tail of the epididymis**, due to probable changes in the epididymal epithelium may result in a reduction or absence of mo-

tility or akinesia or necrospermia associated with bent or looped cells. Testosterone maintains the function of the epididymis. Estrogens injected into adult bulls caused an increase in abnormal bent or looped sperm tails.¹⁶ Frequent collection of these treated bulls resulted in a decline of abnormal sperm cells. Three infertile Jersey bulls with many vacuolated basal epithelial cells of the cauda epididymis and with many secretory granules in the lumen of the duct were reported.¹¹ Inbred Jersey bulls with impaired fertility characterized by poor quality semen with bent, looped and coiled tails, tailless heads, abnormal heads and thickened midpieces were reported later.¹⁷ This genetic condition was caused by a reduced sex steroid production due to the subnormal formation of its precursor, alpha-hydroxyprogesterone.¹⁷

Testicular injury and reduced production of sperm cells, hormonal upsets, as excess estrogen, and insulation of the scrotum produces changes in the epididymal plasma resulting in sperm defects especially reduced motility and tail or midpiece defects. These defects develop in the corpus and tail of the epididymis.¹⁸⁻²¹ Poor sperm cell motility, seen occasionally in stallions, may not be due to an intrinsic defect of the spermatozoa but due to a failure of the epididymis to properly support the cells for their relatively long storage period in that organ.³¹ One of the first and most striking effects following hypophysectomy of young human males was the complete loss of motility in sperm cells already present in the epididymis. Exogenous testosterone therapy was suggested. Three bulls with spermatikinesia associated with a high percentage of bent and coiled tails was described.^{19,21} Exhaustion trials showed that as the storage time in the epididymis decreased the semen quality improved indicating a disturbed function of the epithelium of the cauda epididymis. The sodium and potassium levels in the seminal plasma of the cauda epididymis were very low possibly related to an endocrine imbalance.

Since about 95 percent of pet male dogs are not castrated and therefore contribute to the problem of overpopulation of dogs, it has been reported that a simple operation of injecting 1 ml. of an aqueous solution of 4.5 percent chlorhexidine digluconate into the tail of the canine epididymis, after a sedative dose of "Rompun," produces azoospermia within 4 weeks by causing a sclerosing obstruction of the epididymis or ductus deferens, chemical vasectomy.⁴⁴ Further, such studies should be pursued.

Pathology of the Ductus Deferens and Ampullitis

Infection and inflammation of the ductus deferens is usually associated with an orchitis, epididymitis, or sem-

inal vesiculitis. Infection of the ductus deferens apparently occurs less commonly in animals in which the ampullae or dilated proximal portions of the ductus deferens are absent. In the stallion and bull, infections with organisms such as *Br. abortus*, streptococci, *C. pyogenes*, tubercle bacillus, *Ps. aeruginosa*, mycoplasma, ureaplasma and others including viruses, have been observed. (See infectious causes for orchitis and epididymitis.) The infection is usually unilateral but may be bilateral.

As discussed previously segmental aplasia may occasionally be present in the ductus deferens, usually unilaterally and paramesonephric cysts or a uterus masculinus, are common in the urogenital fold between the two ampullae, especially in bulls.

Careful rectal examination will usually reveal a thickened, firm and possibly painful enlargement when ampullae are diseased. Semen examination may reveal leukocytes and the infective organisms. In some cases the semen contains clots of pus and the motility of the spermatozoa is poor. If the motility is good immediately after ejaculation, the spermatozoa often lose their motility rapidly on storage. In cases of segmental aplasia where the missing segment is near the urethra, the ampullae may become greatly enlarged and distended with spermatozoa but no inflammatory reaction is present. Often the vesicular gland on the same side as the missing segment is also hypoplastic or absent. Treatment of infected or diseased ampullae is similar to treatment for seminal vesiculitis.

Diseases of the Accessory Glands

Diseases of the Vesicular Gland, (Seminal Vesicle)—Although congenital defects, usually unilateral, of the vesicular glands including hypoplasia, cysts and either absence or doubling of the gland has been reported^{35a,b} often in association with segmental aplasia of the mesonephric duct, seminal vesiculitis is the most common condition found affecting the gland of bulls, stallions and boars. It is rare in bucks and rams. Gross inflammatory lesions are found most commonly in the vesicular gland of the accessory reproductive glands and the ampullae. The incidence of seminal vesiculitis in bulls was reported as 0.8 percent of 2000 bulls examined in Denmark,^{5,6} 4.2 percent of 828 infertile bulls examined in Holland,⁴⁷ 2.5 percent of 7359 bulls examined in Colorado,^{11,12} and 4.6 percent in 343 bulls studied in New York State.^{35a} A bovine seminal vesiculitis syndrome seen in midwestern United States was described⁴ that differed from the usual sporadic cases observed elsewhere. Up to 10 percent, or an average of 5 percent, of groups of young beef bulls running together and fed heavily and grown rapidly for sale were affected. While breeding bulls grown more slowly on limited rations had an incidence of only 1.3 percent. In housing arrangements where 10 to 20 young bulls, 10 to 15 months of age, run together, the incidence of seminal vesiculitis may reach 20 to 30 percent of the bulls.³² These young affected bulls usually recover without treatment. Seminal vesiculitis in stallions and boars is observed less commonly.

Seminal vesiculitis may be caused by a variety of pathogenic organisms. The most common cause in the United States is *C. pyogenes*. (See Figures 196 and 197.) This organism may localize in the seminal vesicle from other primary, pyogenic, infective foci such as rumenitis, liver abscess, traumatic gastritis, lung abscess or from a navel infection in a young calf.^{23,35a,b} It may possibly enter as an ascending or descending infection from the prepuce and urethra or from an ampullitis, epididymitis or orchitis.²⁵ Infection may be spread in groups of young bulls by homosexual activities and contact of the penis and prepuce to the rear parts of a bull that another had recently mounted. It is possible that certain organisms as *C. pyogenes* may invade the seminal vesicle secondary to a temporary infection with a virus or other agent, possibly a mycoplasma.

In countries where brucellosis is still prevalent, *Brucella abortus* is the most common cause for seminal

Figure 196. Seminovesiculitis in a Bull.

vesiculitis. In 30 bulls with positive brucella titers of serum and semen plasma, **Br. abortus** was recovered on culture of guinea pig inoculation of the semen in 15 or 50 percent.⁵ Twenty six of these bulls were examined and had clinical gross lesions in the genital organs and nineteen had lesions found on autopsy. Seminal vesiculitis was found in 17 bulls, ampullitis in 5 bulls, orchitis in 5 bulls, and epididymitis in 2 bulls. In some a combination of lesions were found.

Brucella suis commonly localizes in the seminal vesicles in boars.¹⁷ Examination of 9 boars serologically positive for brucellosis revealed **Brucella suis** in the seminal vesicles of 8 boars, in the epididymides of 6, in the prostate of 4 and in the semen of 7. No macroscopic lesions were present.¹⁶ In 37 boars infected with **Br. suis** orchitis was uncommon, occasional macroscopic lesions were observed in the vesicular glands, while nearly all infected boars had microscopic lesions in the epididymides and vesicular glands so that 75 percent of the boars periodically secreted organisms in their semen.⁴⁵ Pus and leucocytes were seldom found in infected semen. Infertility in boars is frequently associated with the shedding of **Brucella suis** organisms in apparently normal appearing semen. The excretion of **Br. abortus** was reported in the semen of a stallion.⁴⁶ Organisms found in infected vesicular glands included: streptococci and staphylococci in bulls and boars,²² **Pseudomonas aeruginosa** and **Actinobacillus actinoides**,²⁷ *Proteus*,³⁵ *My-*

coplasma bovigentialium^{1,9,20,21,33,37,38,41} and *bovis*,^{30,33} and **Mycobacterium tuberculosis**. **Mycobacterium paratuberculosis** was recovered from the feces and semen from an affected bull used in an AI center.³¹ On necropsy, **M. paratuberculosis** was isolated from the vesicular glands and prostate.

Ureaplasmas have recently been recovered from bovine seminal vesiculitis lesions and reproduced experimentally.^{19,33} **Hemophilus somnus** has been isolated from the accessory sex glands of bulls but not from the testis or epididymis.^{26,33} Although a higher incidence of infection was present in young bulls, the pathological significance of **H. somnus** in the bull awaits further study.

Virus infections described under orchitis and epididymitis have also been reported to cause seminal vesiculitis including the enteric virus, possibly IBR-IPV,¹⁰ and the "epivag" virus.³⁴ **Chlamydia psittaci** was recovered from the semen or organs of 6 to 10 bulls from two beef herds where the seminal vesiculitis syndrome was commonly observed in young beef bulls.^{4,33,43,44} The **Chlamydia** recovered from one of these bulls was indistinguishable from **Chlamydia psittaci** in California responsible for epizootic bovine abortion and enzootic abortion of ewes. The seminal vesiculitis syndrome reported in Colorado^{4,12,44} appeared clinically similar to those described in Wisconsin and Czechoslovakia.^{32,36}

Naturally occurring cases of seminovesiculitis in bulls due to **Mycoplasma bovigentialium** have been described along with experimental studies.^{18,33,38,41} In natural cases the semen was stringy and mixed with pus. The vesicular glands especially the cranial portions were firm, swollen and nodular. Postmortem examination and culture of all portions of the male genital tract showed

Figure 197. Ejaculates Containing Clots of Pus from a Bull with Seminovesiculitis.

the organism had become widely distributed throughout the tract. The organism persisted in the experimental bulls for at least 17 weeks and could be recovered from the semen for 11 weeks. The usual antibiotics used in extended semen had no effect on **Mycoplasma bovigenitalium**. This organism caused a necrotizing vasculitis in many bulls and was present in the carpal joint of one bull.⁴¹ Earlier studies cited by Parsonson^{40,41} reported the pathologic lesions produced in the genital tract of cows. This could not be confirmed with **M. bovigenitalium**.²¹ However these authors showed the organism was pathogenic for the vesicular glands, udder and joints. Prior to the inoculation of the vesicular glands in the experimental bulls, mycoplasma could be recovered from their preputial and nasal cavities.^{40,41} This could be done also in control bulls but on autopsy no mycoplasma could be recovered from the urethra or internal reproductive organs of the control bulls but could be from the experimental inoculated bulls. After inoculation the viability of the spermatozoa decreased markedly in bulls with seminovesiculitis, ampullitis and epididymitis caused by mycoplasma. Inoculated vesicular glands became enlarged, swollen and nodular. Many polymorphonuclear leucocytes and eosinophiles were present in the inflamed tissues and exudate.

Recent studies have shown that the presence of mycoplasma and possibly ureaplasma, in semen, especially processed frozen semen from normal bulls had an adverse effect on motility often requiring the discarding of that ejaculate of semen. Nine of 14 bulls with a post-thawing motility below 30 percent were positive for **M. bovigenitalium** on culture.²⁴ In a Czechoslovakian study²⁸ 12 of 44 semen samples from which mycoplasma were isolated had low motility, while only 2 of 31 samples free of infection had a low, unsatisfactory motility. This lowered motility might be due to the affinity of the sperm cell for mycoplasma or due to epididymal infection resulting in epididymal plasma alterations that affect the sperm cells.^{38,39} All strains of ureaplasmas (T mycoplasmas) when inoculated into bovine oviductal tissue cultures caused a cilia stopping effect (CSE) progressing to collapse and eventual sloughing of the cilia due to the cytotoxin produced by the organism.^{44a} This effect on cilia may possibly explain the decline in motility of spermatozoa in contact with ureaplasma or mycoplasma since the body and tail of the sperm cell is a modified cilia. It may also explain the infertility in cows when these organisms are introduced into the cervix, uterus and oviducts where cilia perform a necessary function in sperm transport.^{44a} Further studies are needed.

Experimental infection of the vesicular glands with **Mycoplasma bovis** resulted in a persistent infection for

at least 8 months during which time the organism was shed continually not intermittently like **M. bovigenitalium**. Furthermore there was no tendency for the infection to spread to other genital organs as there was with the latter mycoplasma.³⁰ A local semen agglutination response developed that produced higher titers to **M. bovis** in the seminal plasma than in blood serum.¹⁴

Seminal vesiculitis affects males of all ages. In bulls it has been reported as early as 10 months to one and one-half years of age. Usually there are no external signs of the disease. Occasionally however some males will show signs of mild peritonitis with an arched back, reduced appetite, pain on defecation or on rectal examination and hesitation in mounting and thrusting. These occasional signs are observed usually in bulls having abscesses of the vesicular glands caused by **C. pyogenes** infection adjacent to the peritoneum. On rectal examination seminal vesiculitis, especially bovine cases due to the latter infection, are characterized by two general findings, firstly, irregular enlargement of the gland, fibrosis, peritoneal adhesions, loss of lobulations, fluctuation, and abscessation. (See Figures 196 and 197.) In rare cases fistulas occur due to rupture of an abscess into the rectum. In the other more common cases a portion or all of the vesicular gland may become thickened and fibrotic with only slight enlargement and loss of lobulations of the gland and with no adhesions.

The first type of bovine seminovesiculitis was usually unilateral and due to chronic purulent inflammatory lesions with chronic interstitial changes and was commonly caused by **C. pyogenes**.²³ The second type of seminal vesiculitis was usually bilateral and characterized by degenerative changes in the epithelium and inflammatory changes were variable.²³ Cultures of these latter vesicular glands were frequently negative for bacteria. Large amounts of Feulgen positive chromatin masses were found in the lumen of affected glands and in the semen of the latter degenerative type of seminal vesiculitis, but not in the former. In both types varying numbers of polymorphonuclear leucocytes were usually found in the semen. In the former purulent type of seminal vesiculitis large clots or flocculi were commonly observed while in the latter the semen may be viscid or "ropy." Leucocytes in the semen may also come from other portions of the urogenital tract including the prepuce so their presence is not diagnostic of seminal vesiculitis. In some chronic cases few or no leucocytes will be present in the semen of affected bulls. Semen quality will vary between affected bulls, with a lowered motility of the sperm cells, an elevated pH, a high catalase activity, and a lowered fructose content being commonly found. Although lowered fertility has been associated with seminal vesic-

ulitis many affected bulls breeding cows naturally have a good conception rate. One affected bull with good fertility had been used for at least three years in an artificial insemination stud although periodically a number of ejaculates had to be discarded as being unsatisfactory.^{35a} In thirty cows bred to an affected bull, 7 or 23 percent aborted from three months to term.^{35a} In bulls with seminal vesiculitis 40.5 percent had satisfactory quality semen and 50 percent had semen of questionable quality, while normal bulls had 83.7 satisfactory and 11.7 percent questionable quality of semen.

The use of a bull for artificial insemination with *Brucella abortus* infection of the accessory glands or ampullae may spread the disease and cause infertility. One infected bull used artificially infected 71 percent of the cows in 41 *Brucella*-free herds.⁴² In young beef bulls with the seminal vesiculitis syndrome, 8 of 10 affected bulls had substandard quality of semen and leucocytes were consistently found in the ejaculate.^{11,12}

Blom^{5b} reported on 25 bulls with seminal vesiculitis and/or ampullitis of which 10 had malformations of the excretory ducts including: segmental aplasia or hypoplasia of the Wolffian duct, accessory vesicular glands, persistent uterus masculinus and asymmetrical implantation of the ampullae. These anomalies possibly interfered with closing of the duct orifices in the colliculus seminalis predisposing to bacterial infection. The possible genetic transmission of these defects together with the poor prognosis of a cure favors slaughter of the animals.

Not infrequently bulls with a seminal vesiculitis will have another focus of infection in the testis, epididymis or ampulla. In the seminal vesiculitis syndrome, especially in groups of young beef bulls, focal or diffuse nonsuppurative interstitial inflammatory lesions were commonly present in the epididymides, testes, ampullae, prostate and less commonly in the bulbourethral glands.⁴ This widespread infection of the male reproductive tract was also found in mycoplasmosis due to *M. bovis genitalium*.^{1,2,18,33,38,41} The viruses and Chlamydia recovered from diseased vesicular glands by African³⁴ Czechoslovakian³⁶ Belgian¹⁰ and Colorado⁴⁴ workers also affected a number of the reproductive organs besides the vesicular glands. In the seminal vesiculitis syndrome, however, the principal signs are related to the vesicular glands.⁴

Diagnosis is based on the clinical signs noted above. Ampullitis and prostatitis may be difficult to diagnose by rectal palpation in the bull and stallion. Culture of the semen is usually an unsatisfactory method for diagnosing the causative bacterial agent because of the contamination from the sheath. A technique was developed to collect non-contaminated urethral samples from

bulls.⁴² A tranquilizer was administered to quiet the bull and allow withdrawal of the penis. Rectal massage aided the protrusion of the penis from the sheath. The penis was washed with an antiseptic solution and the urethra was irrigated with sterile saline. A 10 inch or 25 cm. sterile silastic tube was inserted up the urethra leaving 1 or 2 inches, about 4 cm. protruding. Rectal massage of the vesicular glands, prostate and ampullae resulted in the collection of their secretion into sterile vials for cultural purposes.⁴² Only 4 of 158 urethral samples were contaminated.

The prognosis in seminal vesiculitis is fair to poor depending upon the causative agent, the presence of other foci of infection in the reproductive tract, the duration and severity of the infection and the value of the male. Males with *Brucella* infections, tuberculosis or possibly mycoplasmosis of the seminal vesicles, or those with secondary lesions of the testes, epididymides, ampullae or prostate should be slaughtered. Many young bulls with the seminal vesiculitis syndrome with catarrhal or degenerative seminal vesiculitis overcome the infection spontaneously in a few months.^{12,32} During this period their use for breeding purposes is questionable. Bulls with active acute lesions of seminal vesiculitis with a discharge of pus in the semen should not be used for artificial insemination as only rarely will the antibiotics used in extended semen destroy the organisms present. Many bulls with seminal vesiculitis caused by organisms other than *Brucella* or *Mycobacterium* may be used naturally or even artificially with quite satisfactory conception rates especially if a large amount of mucopurulent material is not present in the ejaculate. Further studies on the possible viral causes of this disease and the duration of the carrier state is definitely needed.

Treatment with high levels of broad range antibiotics, or antibiotics to which the causative agent is sensitive, for two weeks or longer together with mild massage of the vesicular gland to remove its contents may result in recovery or elimination of the infection in some males after 2 to 6 months. In *C. pyogenes* infection the gland is usually left severely indurated and largely destroyed. Acute cases of seminal vesiculitis tend to become chronic. Chronic cases, if abscessation does not occur, tend to become fibrotic and indurated similar to the mammary gland following a severe infection. In long-standing chronic cases pus or high leucocyte numbers are seldom observed in the semen.

In recent years surgical removal of the affected vesicular glands has been recommended for selected bulls in artificial insemination studs or where conservative treatment has failed or is not deemed advisable, and where the only detectable lesion of the genital tract is in the

seminal vesicle and extensive adhesions are not present. In an aseptic manner and under epidural and local anesthesia together with tranquilization, an elliptical incision was made in the ischiorectal fossa after suturing the anus tightly closed.^{15,29,35a} By a combination of blunt and sharp dissection the affected gland was isolated and removed close to the urethra after ligation at that point. Some difficulty was experienced if adhesions were present especially in separating the peritoneum from the cranial portion of the gland. Following surgery heavy prolonged antibiotic therapy was recommended. The results were satisfactory in all cases except in one bull that developed a degree of paralysis in the sphincter of the bladder with cystitis and urinary complications.

Regular and frequent examination of the genital tract and semen for a year or more should be followed after treatment to be certain the condition doesn't recur at another site due to a resistant or secondary focus of infection.

Disease of the prostate gland is rare in all animals except the dog in which acute or chronic prostatitis and benign prostatic hyperplasia (BPH) are common. Other less common canine prostatic diseases include neoplasms, retention or congenital cysts and rare calculi.^{7b,8} The disease conditions affect all breeds of dogs equally. These diseases in the dog resemble those in man.¹⁶ About 60 percent of all intact male dogs over 5 years of age have enlarged prostates usually due to BPH. Infection in the prostate gland may be a source of bacteria for recurrent cystitis.^{7b,8,11,12} A combination of the above prostatic lesions is not uncommon in old dogs. On rectal palpation of the prostate, abscesses, retention cysts, and tumors are characterized by asymmetrical enlargement of the gland. The other pathological conditions are usually symmetrical.^{11,12} Almost all prostatic diseases are usually clinically characterized by either or all lower urinary tract signs, systemic signs, especially in acute prostatitis, and abnormalities or difficulties in defecation.^{8,11,12}

Prostatitis in the dog is often associated with hyperplasia of the gland. It is probably due to an ascending infection through the urethra but may occur secondary to hematogenous infection or even descending infections. A wide variety of organisms have been isolated from infected glands including *Brucella canis*, *E. coli*, streptococci, staphylococci, *Proteus* and rarely blastomycetes.²² Acute prostatitis in the dog is a diffuse or local suppurative inflammatory reaction with a tendency for abscess formation.¹⁹ Bacteria, leukocytes, and blood are frequently found in the urine, the latter portion of the ejaculate, or observed at the preputial orifice. This should be differentiated from a balanoposthitis. Acute prostatitis

may be painful and characterized by constipation, in arched back, tenesmus, dysuria, elevated temperature and pulse rate, occasionally anorexia and vomiting, and a leucocytosis. Palpation of the infected gland per rectum causes pain and "splinting" of the abdomen. Chronic prostatitis is occasionally observed and may be associated with benign prostatic hyperplasia.^{6,7b,8,11,13a,b,14,19}

The treatment of prostatitis is frequently successful. Administration of broad range antibiotics are indicated over a prolonged period. If the ordinary antibiotics do not control the infection, cultures of the prostatic secretions may be made and the antibiotic sensitivity of the causative organism determined. Laxatives and supportive therapy may be indicated. If prostatitis is due to *Brucella canis* the prognosis is poor. (See *Brucella canis* abortion.)

Clinical prostatitis in the bull and boar is rare and may be caused by *Brucella abortus* or *suis*. Subclinical infections may be more common and due to a variety of bacteria and viruses as described under seminal vesiculitis.

Benign prostatic hyperplasia (BPH) is present in about 50 percent of dogs over 5 years of age that have not been castrated.^{7b,8} The condition is probably due to an endocrine imbalance with an excess of testosterone being secreted which causes an enlargement and hyperplasia of the gland. Some speak of this condition as prostatic hypertrophy but this terminology is not correct. The moderate to greatly enlarged gland may be smooth or nodular and may contain small cysts. When cysts are not present the preputial discharge from an infected hyperplastic prostate is usually purulent; when cysts are present the discharge is watery-grey or bloody. This cystic fluid may be voided with the urine producing albuminuria. Usually dogs with marked prostatic hyperplasia are constipated. Rectal impaction and tenesmus and stranguria predispose to rectal dilation and the development of a perineal hernia. Occasionally cystitis and hydronephrosis may develop. Usually little discomfort is shown by the dog with a hyperplastic prostate unless constipation, stranguria, or perineal hernia occurs.^{1,7b,8,11,12} Severe obstruction of the urethra does not occur in dogs as in man because of the bilobed-nature of the gland in the dog in contrast to the trilobed structure of the gland in man. Rarely the bladder may become strangulated in a perineal hernia.

Digital examination of the prostate bimanually per rectum and by abdominal palpation may reveal a nodular or smooth, enlarged prostate. It is often helpful to exert pressure through the abdominal wall at the pelvic brim to push the prostate caudally so that it can be palpated rectally. The consistency will vary with the nature of the hyperplasia from firm and fibrous, to soft, or even fluc-

tuating if cysts are present. Normal prostate glands are 2.5 to 3 cm. in diameter while hyperplastic glands may be twice as large or even larger if cysts are present. Prostatic cysts often occur with benign prostatic hypertrophy or from blocked prostatic ducts or vestiges of the Mullerian duct. No signs are observed until these cysts become large and press on the bladder or rectum with resulting dysuria or tenesmus with constipation.^{7b,8} Large cysts and abscesses frequently extend into the abdominal cavity. The latter are fatal if they rupture or leak intraperitoneally. A prostatic cyst in a Great Dane dog contained 15 quarts of a sanguineous fluid.¹⁴

A number of diagnostic procedures have been used to determine the nature, severity and type of prostatic disease including palpation, per rectum, ejaculation,^{7b} prostatic massage, aspiration and punch biopsy, radiography and contrast radiography, culture of urine or prostatic secretions, and in acute prostatitis white blood cell counts. These tests must be carefully performed, interpreted and evaluated with skill and experience together with a complete history and physical examination,^{2,4,7b,8,11,12,17} before treatment is recommended, particularly in older dogs and in recurrent prostatic problems.

Rectal massage of the gland may give temporary relief by reducing the size of the cysts. Estrogenic therapy with oral or injectable estrogens in low doses have been used in prostatic hyperplasia. Antibiotics should be administered along with estrogenic therapy. During estrogenic therapy it is desirable to monitor the blood picture to diagnose incipient myelotoxicosis. Gradually reducing the dose during the next few weeks may give relief but continued dosing is required. Estrogens act by suppressing the pituitary gonadotropins and this causes an atrophy of the Leydig cells and suppression of testosterone production. The estrogens do not directly antagonize the androgens. The most satisfactory method of reducing the size of the prostate is castration, as this removes the source of the androgen causing the hyperplasia. Within 2 to 3 weeks after castration the prostate gland begins to noticeably involute and by 6 to 8 weeks it is relatively small in size and atrophied. However castration does not reduce the large cysts or abscesses in infected glands or affect calculi that may rarely be present.^{8,18} In complicated cases, prostatectomy or marsupialization of the large cyst or abscess through the abdominal wall may be indicated.^{1,3,8,11,12} The urethra is transected and anastomosed into the neck of the bladder and the ducti deferentia are ligated and the proximal portions are removed. When perineal hernias have developed, perineal herniorrhaphy may be indicated.^{15,23}

Squamous metaplasia—The effect of prolonged estrogen stimulation of the prostate gland has been de-

scribed.^{8,10,11,12,19} In dogs with Sertoli cell tumors of the testes, estrogens produced by the tumor cause squamous metaplasia with enlarged cystic prostate glands or atrophy of the glands. These lesions can be produced experimentally by administering estrogens and this is another reason why castration is a more effective therapy than estrogen administration. Furthermore high prolonged dosing with estrogens may cause anemia, leucopenia and aplasia of the bone marrow.⁶ Estrogen-induced changes in the prostate are apparently irreversible in the dog. A squamous metaplasia of the uterus masculinus may also occur.

Similar, but reversible, prostatic lesions to those in the dog, occurred in wethers grazing on certain clovers such as red clover or subterranean clover that contained high levels of estrogens.⁵ The bulbourethral glands also became cystic, dilated with urine and debris and greatly enlarged in castrated sheep. In some cases urinary obstruction, prolapse of the rectum and even death occurred. A similar condition occurred in wethers in feed lots if their ration was supplemented with excessive estrogens or estrogen implants were given to provide growth stimulation.⁹

Adenocarcinoma of the prostate in the dog is rare. It is usually seen in dogs over 10 years of age.^{6,8,10,11,12,16,19} Only 3 cases of carcinoma in over 500 diseased prostate glands were reported.²¹ Persistent straining at the time of defecation was characteristic of all 3 advanced cases. Pain was a commonly observed symptom. Adenocarcinoma of the prostate results in a nodular asymmetrical enlargement of the gland. The tumor may vary in consistency from very hard to soft and is slow to metastasize and therefore signs of disease are seldom observed until the condition is terminal with emaciation and locomotor difficulties.^{8,11,12} A biopsy may reveal the nature of the tumor and differentiate it from benign prostatic hypertrophy (BPH) in the early stages.^{4,17} Castration, estrogen therapy and radiation therapy are of definite value in man in delaying the growth of the tumor even though metastasis has occurred.¹³ Prostatectomy would be indicated if the carcinoma had not metastasized. However the prognosis is poor. Other tumors of the prostate are very rare; these include: leiomyomas, fibromas, sarcomas and hemangiomas.^{10,11} Two cases of adenocarcinoma of the prostate in the tom cat were reported.¹¹

Miscellaneous conditions in the male animal including infection of the external genitalia. Tumors of the penis and prepuce have been described previously in this Chapter.

Perianal (circumanal) gland neoplasms are seen only in dogs and usually around the anal ring and tailhead but also may be found elsewhere on the body. The neoplasms involved are adenomas which are androgen dependent and carcinomas which are not androgen dependent and which must be differentiated from squamous cell carcinomas and adenocarcinomas arising from the anal sac or skin.^{4,29} Of 472 dogs with perianal gland neoplasms about 82 percent were adenomas and 18 percent were carcinomas. About 80 percent occurred in male dogs, 10 to 15 percent in spayed females and about 5 percent in intact females.^{4,29} Dogs of the Cocker Spaniel, English bulldogs, Samoyed and Beagle breeds were most often affected.

The preferred treatment of perianal gland adenomas is castration rather than excision. In ulcerated or recurrent cases excision should be considered. In 123 dogs with adenomas only 7 had a recurrence of the adenoma after castration.²⁹ About 10 to 20 percent of the perianal gland neoplasms (PGN) and nearly all of the carcinomas were malignant. Many metastasized to the iliac lymph nodes as determined by rectal palpation with resulting constipation and tenesmus. Most of these cases are inoperable and do not respond to castration. Radiation or chemo-

therapy has been tried in these cases with limited success.²⁹

Infections of the prepuce, penis, terminal urethra and semen with bacteria, molds, protozoa, viruses and fungi occur in all male animals from the external environment and from infectious diseases of the upper urogenital tracts. In normal healthy animals the upper urogenital system is free of infectious organisms. However because of the location and structure of the prepuce and free portion of the penis, similar to the vestibule and caudal vagina in the female animal, these organs harbor a wide variety of saprophytic and occasionally pathogenic organisms usually without any clinical signs of infection (See diseases of the prepuce and penis). Certain organisms present in the prepuce of "carrier" animals are considered to be venereal in nature and transmitted from the male to the female and cause an infectious disease of the reproductive tract. The organisms that are transmitted from the male prepuce to the female vagina at coitus are usually considered to be contaminants if no infectious inflammatory process is produced. A local infectious inflammatory process is most apt to occur if an older male is bred to a virgin female. A vulvitis, vestibulitis or vaginitis may develop with a secondary reaction of lymphoid tissues resulting in granular venereal vulvitis or vaginitis in the cow, ewe or bitch. This is followed in time by a local immunity with a regression of the inflammatory reaction. If organisms from the prepuce and penis are carried into the uterus at coitus as in the mare, bitch and sow, temporary or prolonged endometritis may result depending on the degree of resistance or susceptibility of the female animal and the time required for immunity to develop.

In artificial insemination in animals even if the collection and storage of semen is performed in a manner approaching asepsis many organisms from the penis and prepuce are in the ejaculate. In one study in stallions the mean bacterial population in undiluted semen collected in the above careful manner was 573,000 organisms per ml. Twenty one different species of bacteria were isolated many of which were potentially pathogenic.²⁵ Culturing the penis and preputial cavity is of questionable value in the diagnosis of infertility because of the large number and variety of organisms recovered. However, it is of value in specific venereal infections to detect a carrier animal and after treatment to determine if he is free of the infection.⁵ (See culturing of the stallion in CEM and the bull for vibriosis and trichomoniasis.) Schultz and co-workers have described a practical method to test bovine semen samples for specific pathogen-free bovine semen.^{21,22}

A compilation of the infectious organisms recovered from the prepuce, penis and semen of animals follows:

Organisms resulting in venereal infections and diseases:

in cows— *Brucella abortus*, *Campylobacter fetus venerealis* (vibriosis), *Trichomonas fetus*, *Mycoplasma bovis genitalium*⁶ **IBR-IPV virus**, **epi-vag virus** in Africa, ureaplasmas,⁶ rarely *Mycobacterium tuberculosis*, **Paratuberculosis**^{16,26,27,28} and possibly papilloma virus²¹ and Chlamydia.²⁴

in mares— *Hemophilus equigenitalis*, *Trypanosoma equiperdum* (Dourine), and equine herpes virus 3 (equine coital exanthema) [Possible "venereal" diseases, depending on the virulence and numbers of organisms introduced and the susceptibility of the mare might also include: *Pseudomonas aeruginosa*^{10,12} *Klebsiella pneumoniae* var *genitalium*, *Streptococcus genitalium* and *Actinibacillus equuli* (Shigella)]

in ewes— *Brucella ovis* and *melitensis*, *Actinobacillus seminis*, and *Spherophorus* (*Bacillus*) *necrophorus* (lip and leg ulceration) and *Toxoplasma gondii*⁷

in sows— *Brucella suis* and possibly *Staphylococcus aureus*

in dogs— *Brucella canis*⁹ and the transmissible venereal tumor

Other organisms, often called "opportunists" found in the prepuce that may either contaminate or infect females at coitus or by artificial insemination are numerous and varied and include: the ubiquitous Gram negative and Gram positive organisms and fungi and yeasts^{15,21} the most common of which are:

Streptococci spp, *Staphylococci* spp., *E. coli*, *Corynebacterium pyogenes*, *C. renale*, *Alkaligenes*, *Enterobacter* spp., *Serratia*, *Bordetella*, *Citrobacter* spp., *Proteus* spp., *Bacillus* spp., *Micrococcus* spp., *Spirochetes*, *Leptospira* spp., *Actinobacilli*, *Actinomyces* spp., *Aspergillus*, *Absidia*, *Rhizopus*, *Madura*, *Candida* (*Monilia*)^{15,20} and others.

Viruses other than those causing venereal diseases may be transmitted by bovine semen including foot and mouth disease,^{3,13,21} bovine virus diarrhea-mucosal virus (BVD-MD),^{13,23} blue tongue^{8,13,21,22} ephemeral fever, bovine enteroviruses, parapoxvirus, lumpy skin disease virus, and others.¹³ Schultz stated that it is reasonable to assume

that bovine adenoviruses, corona viruses, enteroviruses, parvoviruses and rotaviruses which are ubiquitous contaminants are occasionally present in semen but there is no evidence they play a role in genital disease or infertility.²¹ Swine semen can contain foot and mouth disease virus, swine vesicular disease virus, parvovirus, picornaviruses, adenoviruses and Japanese encephalitis virus.^{13,18} Semen should be obtained from bulls in studs free of the virus as determined by repeated serologic tests or semen cultures.^{13,21,22} Maintaining a high level of immunity by repeated vaccination with an efficacious inactivated BVD virus vaccine or with an attenuated nasal vaccine for IBR-IPV will probably prevent the elimination of these common viruses in the semen of bulls.^{22,23}

In one study a positive relationship was made between bulls latently infected with blue tongue virus that could be recovered from their semen and the presence of vesiculations between the acrosome and nucleus and virus-like particles in the affected spermatozoa.⁸ These vesiculations were different from the vacuoles, "craters" or "pouches" in the nuclear envelope of spermatozoa described previously in which the defects were hypothesized to be caused by a virus. (See spermatozoan abnormalities.)

Currently there is no definite evidence that viruses such as parainfluenza 3 virus¹³ bovine leukemia virus^{1,13,14,22,28a} or porcine pseudorabies virus¹⁷ are spread in the semen. Bovine herpes mammillitis virus has not been reported to have been found in semen.²² *Hemophilus somnus* apparently is part of the resident bovine preputial flora.¹¹ It should be noted that a number of these organisms are also common contaminants or residents of the upper respiratory tract.

It is impossible to eliminate all organisms from the prepuce and free portion of the penis or the caudal portions of the female genital tract. However it is definitely desirable to control the venereal diseases and to prevent heavy contamination of the anterior or deeper portions of the female genital tract with virulent organisms especially in susceptible females with low resistance. The control and prevention of the venereal diseases have been discussed under the chapters on infertility in the various female domestic animals.

To control the severe contamination of the female genital tract with organisms from the males' prepuce at coitus various breeding hygiene practices have been followed with bulls¹⁵ and horses. The mares' external genitalia and perineal region are carefully washed with soap and water and rinsed thoroughly. The tail is banded and the mare is restrained. The stallion's genitalia are also washed with a bland soap and water and thoroughly rinsed before copulation. Excessive dust, sawdust, sand or mud in the breeding shed or area is to be

avoided. As mentioned under infertility in mares excess washing and the use of antiseptics on the stallion may irritate the prepuce and penis, may severely alter the "normal" bacterial flora and/or favor the development of strains of bacteria resistant to the antiseptic (chlorhexidine) and possibly other antibiotics.^{2,12,19a} In the boar surgical removal of the preputial diverticulum may reduce preputial bacteria. The author has attempted to "douche" bulls' sheaths prior to collection of semen in a sterile artificial vagina with very limited success in reducing bacterial contamination of semen.

If artificial insemination is practiced the extension of the semen with extenders containing antibiotics has been a common and successful practice in reducing the numbers of bacteria introduced into the genital tract of the female and has resulted in an improvement in conception rates (See vibriosis or campylobacteriosis in cattle). The use of lincomycin and spectinomycin semen extenders to control mycoplasmas and the further addition of minocycline HCL to also control ureaplasma has been reported.⁶ The use of an extender containing penicillin and gentamycin greatly reduced the bacteria in the semen and prolonged the viability of the equine spermatozoa.^{25a} In a study comparing polymyxin B sulfate and gentamycin it was recommended that the preferred antibiotic treatment for equine semen to control *Klebsiella* and *Pseudomonas* organisms was 1000 units of the former antibiotic per ml. of extended semen.^{25b} The semen should be added to the fresh skimmed milk (heated to 95° C for 4 minutes in a double boiler before its use) extender with antibiotics and incubated at 38° C for at least 15 minutes to permit the bacteriocidal effects to occur. Similar results have been obtained with bull and boar semen (See artificial insemination). To help prevent carrying the ubiquitous ureaplasmas, mycoplasmas and other organisms from the vulva and caudal vagina into the cervix and uterus on the insemination pipette, a sterile plastic cannula, through which the pipette may be inserted, can be used.⁶ Further studies on this practice should be conducted as a recent report indicated that routine use of a "protected" or "double" sheath was of questionable value.^{19b}

DIAGNOSIS OF STERILITY AND INFERTILITY IN THE MALE AND EVALUATION OF BREEDING SOUNDNESS

The examination of a male animal to assess his fertility or breeding soundness includes both objective and subjective tests or observations usually during a single examination or over a short time period. This results in a value judgment or opinion on the part of the veterinarian. Its scientific validity is limited by the number and frequency of tests performed, their objectivity and their repeatability. In referred laboratory tests the expertise of the laboratory personnel in the fields of serology, microbiology, and pathology are also involved. Most males can be categorized as either a satisfactory potential breeder, a questionable potential breeder or an unsatisfactory potential breeder.⁹ However, a single breeding soundness examination does not indicate the males' past soundness nor his ability to cause conception in the future since too many unknown variables of management, nutrition, and disease in the male and the females to which he was, or will be, bred make retrospective or prognosticative specific judgments uncertain. For this reason the veterinarians' knowledge and experience in the fields of male anatomy, physiology, behavior and pathology are

of paramount importance in arriving at a considered judgement or opinion. The client should be informed that this is an opinion and not an absolute factual determination unless the findings conclusively indicate the male is permanently sterile. As the late noted Nils Lagerlof stated to the author, "Never indicate that a certain male is fertile based on your examination; only indicate that you see no reason why this male should not be fertile."

Since much more basic and applied research over the past 30 years has been conducted on bulls than other male animals, the discussion in this chapter on male infertility will emphasize the bovine species. However, the similarities between males of all domestic species are so marked all species are included.

The breeding soundness or fertility examination of male animals is usually requested in three situations; a pre-purchase or sale examination for either the buyer or the seller or both; the prebreeding season examination in beef bulls, stallions or rams to assure fertile males are used during the breeding season; and when an infertility problem arises in the females bred to the male to determine if the male was the cause of the problem and if so whether the condition in the male is temporary or permanent. Thus the primary objective of evaluation of breeding soundness is to determine which males are infertile so they may be temporarily or permanently eliminated from breeding. ^{1,2,6a,11} (Bulls)10, 19 (Stallions)6, 12 (Rams&Bucks)7, 8 (Boars)8b (Dogs&Toms)6a,8

Historically breeding soundness evaluations (BSE) in bulls was developed in Colorado by Drs. H. J. Hill, L. C. Faulkner, J. S. Scott, J. A. Scott, E. J. Carroll and L. Ball, following severe winters in the late 40s' and 50s' when frostbite of the scrotum of range beef bulls resulted in severe herd infertility in subsequent breeding seasons. These evaluations were made possible by the development of the bovine electroejaculator to obtain semen samples. The results of a study from 1954 to 1962 of 10,940 beef bulls in Colorado revealed that 79.2 percent of the bulls were satisfactory potential breeders, 11.2 percent were questionable potential breeders and 9.5 percent were unsatisfactory bulls to be culled or withheld from breeding.¹ A similar study of 1,005 bulls in Missouri produced similar results of 83.5, 9.8 and 6.9 percent, respectively.² Less than 0.5 percent of bulls in both studies were unable to be classified. A similar report on 1,846 bulls examined over a period of 19 years for use in artificial insemination has also been published.⁶ Both mature and immature bulls were examined and 17 to 19 percent of the bulls were rejected as unsatisfactory.

The examination for infertility of any sire should be careful and thorough, following a definite procedure so that no symptom or lesion will be missed. A complete

record of this examination should be made as the examination progresses. A careful, complete examination of a male is essential to the assessment of his breeding potential. This examination of the male should consist of three major components (1) history and/or breeding records, (2) physical examination including the assessment of libido or sex drive and the various serological, cultural and other diagnostic tests and (3) the examination of the semen.

History and Records—Breeding records are very helpful in the diagnosis of fertility. If the male was bred to a sufficient number of normal females, these records accurately indicate the relative fertility of the sire. If possible these records should be reviewed for two time intervals of 1 to 2 years and the past 6 months. This review will indicate the number of services per conception over a period of several years as well as the past few months, which is of value in diagnosing whether a venereal disease or a pathologic condition affecting the sire is acute or chronic. If records are not available, pregnancy examinations on females recently bred by the male may be necessary. The records of the females bred to this male should be reviewed to see if there is an increased incidence of abnormal genital discharges, delayed estrus or abortions occurring after breeding, indicating possible vibriosis, trichomoniasis, canine brucellosis or the presence of some other disease causing the early or late death of the embryo or fetus. If two or more males are used for natural breeding in the same herd the breeding records may be necessary to determine if one or more bulls are infertile. The conception rate in a pasture-bred herd may be a good index to the fertility of the bulls in that herd.

If possible a number of the daughters of the bull examined should be observed for conformation and the presence of any inherited defects; also, their conception rates should be noted. In multipara the litter size, and viability of the offspring of the sire and his daughters should be noted. The breeding records of the male's sire and dam should be reviewed if they are available. These animals and/or their relatives should be examined or a record obtained for any evidence of hereditary disease. If the male's sire and dam are dead the reasons for their death should be checked. Bulls that have been operated upon for umbilical hernia, deviated penis, or other defects are not desirable, as they may transmit these defects.

The health history of the male should be reviewed. Any illnesses, especially those requiring veterinary treatment, should be investigated. This review should include diseases suffered as a young animal as well as any recent sickness. The records of any and all preventive

vaccinations of the male should be secured. Information should be obtained on the ration fed the male, the amount and frequency of feeding and whether any signs of nutritional deficiency are present.

The physical examination of the male consists of noting the following: his age, according to his registration papers and his teeth; his conformation and the condition of his hoofs, limbs, and joints; any defects either congenital, hereditary, or acquired, and their severity; his general condition, attitude, temperament and hair coat. Obesity and emaciation are serious concerns in breeding males. The body temperature should be taken and a careful clinical examination made of the eyes, circulatory, respiratory, digestive, urinary and lymphatic systems, for evidence of disease that might affect his present or future health. Any unusual symptoms such as coughing, nasal discharge, bloody urine, persistent or intermittent diarrhea, and icterus should be carefully investigated. The teeth, oral cavity, eyes, and face should be examined for actinomycosis, carcinoma, blindness, or other lesions. A rectal examination of the kidney(s) and bladder, accessory sex glands and ductus deferens (ampullae) iliac lymph glands, and internal inguinal rings should be performed in large animals.

If the conformation of the male is poor or defective, the gait and manner and ease of mounting should be observed carefully. Too straight or "postleg" rear limbs, arthritis and spastic syndrome in bulls are frequently associated. Slightly "sickle-hocked" bulls and bulls with a good heel are preferred over the former. It is also desirable to discriminate against males with other conformational defects including: sickle-hocks, bow-legged or camped behind rear limbs.⁹ Any signs of posterior weakness or paresis as indicated by a limp flaccid tail and ataxia is very undesirable in breeding males. If rear limb lameness is present the joints should be examined for arthritis and the hooves examined for pododermatitis, deformities, laminitis or quittors. Twenty five percent of 600 boars purchased over a two-year period by 71 producers in Illinois were never used due to lameness or lack of libido.¹²

The examination of the male in the presence of the female is desirable and necessary in order to observe the degree of sexual desire or libido, which may vary from no interest in the female to extremely eager mounting. Any abnormalities, hesitancy, or evidence of pain on erection, mounting, copulating, and ejaculating should be noted. Tests for libido or sexual desire are often difficult, time consuming and hard to adequately carry out on a large number of males. (See prior discussion in this Chapter.) However in a cited study⁹ 20.6 percent of 548 bulls were culled as poor potential breeders with 55 per-

cent of those culled for physical abnormalities, 43 percent for poor libido or serving capacity and only 2 percent for poor semen quality. At this time the penis and prepuce should be examined for evidence of inflammation, granular venereal disease in bulls, tumors, adhesions, congenital short penis, phimosis, and deviation of the penis. Any history or evidence of vices or bad habits should be watched for before and during the physical examination. In some males it may be desirable to examine the penis further, if necessary under tranquilization, a pudendal nerve block, or general anesthesia. Some owners who sell purebred males take a motion picture of the male copulating with a female before a sale, to prevent having the male returned with the report that it would not copulate normally. At this time the male's gait and manner of moving, his positioning of himself on the mount, his seeking actions with his penis, his intromission and thrusting action and his dismounting are also noted. Any lameness or abnormal gait should be closely investigated. Spastic syndrome, or "stretches," in bulls may not be noted in the early or mild cases unless the bull is seen as it rises or is backed. Promptness and vigor of intromission and ejaculation, however, are not a guarantee of fertility.

The rest of the reproductive system should be carefully examined, clinically.^{9,11} (See Stallion,⁶ ram and buck,^{7,8} dog^{6a} and boar.⁸) The testes, epididymides, spermatic cord and scrotum may be examined by palpation. This should be done bimanually with the large male properly restrained or tranquilized to prevent injury to the examiner. The size and shape of the scrotum and the position of the testes in the scrotum should be observed. Any wryness or difference in the appearance of the two sides of the scrotum should be a cause for further careful examination. A "tilted" or "horizontal" testis in a bull is often located dorsally in the scrotum due to a misplaced attachment of the cremaster muscle resulting in testicular degeneration and atrophy. The testes should be palpated for size, shape, consistency, and the presence of adhesions to the scrotum. The scrotum of bulls, rams and possibly stallions should be measured by tape, calipers or ones' fingers. Any unusual findings should be compared with the other testis or with the testes of a normal male if one is available. The head, body and tail of each epididymis should be carefully palpated for enlargements, missing segments, granulomas and abscesses. Any unusual softness, firmness, swelling, atrophy, heat or pain in the testes, scrotum, or epididymis should be carefully checked. This examination will reveal the possible presence of scrotal hernias, cryptorchidism, testicular hypoplasia, segmental aplasia of the mesonephric duct, varicocele, hydrocele, adhesions, tes-

testicular degeneration, fibrosis and mineralization (calcium deposition), testicular atrophy, orchitis, possible tumors, and other testicular, epididymal, or scrotal pathology.

Semen production is closely related to testicular size and consistency. Many workers^{11,17,18,29} have reported a close relationship between scrotal circumference, and the number of spermatozoa produced in exhaustion trials in bulls. There was no relationship between the scrotal size and body size on the numbers of sperm cells in a single ejaculate. The average scrotal circumference in bulls is as follows:

A Compilation of Measurements of Scrotal Circumference in Centimeters of over 3,000 Bulls indicated the following Classification of Bulls of all Breeds, except Brahmas.^{11,5,6}

Classification	Age In Months				Score*
	12-14	15-20	21-30	30+	
Very good—	> 34**	>36	>38	>39	40
Good—	30-34	31-36	32-38	33-39	24
Poor—	<30	<31	<32	<34	10
[Brahmas (average)—(Pre-pubertal)]	27-29	31-33	35-37]		

*Score designated for analysis of potential breeding ability in bull evaluation procedure for Society for Theriogenology.

**Centimeters (Scrotal tapes may be obtained from Lane Manuf. Inc., Denver Colo.)

As described previously in this Chapter the scrotal circumference of rams and the testis width and length in stallions is also closely correlated with their output of spermatozoa. The number of spermatozoa produced per gram of normal seminiferous tubules or testes is fairly constant for adult normal bulls since about 75 percent of the testis is composed of seminiferous tubules. For bulls over 6 years of age the scrotal circumference as an indicator of sperm cell production may be of limited value because of chronic testicular changes in older bulls.

A tonometer was developed that could objectively measure the consistency of the testes.¹⁷ This was highly correlated with semen quality tests. Normal testes have a firm "springy" tone. A soft or very firm consistency often was related to poor semen quality, testicular degeneration, fibrosis or atrophy.

An examination of the retractor penis muscle, the sigmoid flexure of the penis, and the external palpation of the sheath and penis should follow the examination of the testes and scrotum. Often a short or limited protrusion of the penis in bulls is associated with paunchiness or excessive obesity, a "dropped loin" on mounting and inability to copulate successfully. Any swelling, fibrous

tissue, abscesses, hematomas, growths or adhesions should be noted and their significance evaluated. The **Bos indicus** bulls or their crosses often have a very pendulous and long prepuce. These breeds and the polled breeds usually have a mild to moderate eversion of the prepuce with a predisposition to trauma, infection and frostbite.

Rectal examination of the accessory reproductive glands as well as other pelvic and abdominal organs is necessary in the physical examination of the male. This can readily be done with the hand and arm in the bull and stallion, and with the finger in the dog. In the boar and ram examination is difficult or impossible. In the large animals the pelvic urethra is noted as a firm round structure on the floor of the caudal portion of the pelvis. The Cowper's or bulbo-urethral glands are covered with muscle so they cannot be palpated but they are seldom diseased. In the bull and stallion the prostate gland is palpated as a thick transverse fibrous band of tissue around the urethra at the cranial end of the pelvic urethra and just caudal to the neck of the bladder and the ampullae and vesicular glands. These accessory reproductive glands are carefully palpated for their size, and consistency. Any abnormality is carefully recorded especially if a pathological process, inflammation, induration or abscess is noted by a thickening of the part, atrophy, or swelling of the organ, and if pain is produced on palpation. In severe inflammations extensive adhesions may be present. If one or a portion of one of the accessory glands, ampulla, or ductus deferens is missing or dilated a congenital anomaly is usually present. In the dog the size of the prostate can be noted. If the gland is asymmetrical an abscess, cyst or carcinoma should be suspected and confirmed. On palpation through the abdominal wall large prostatic cysts or a distended colon may be palpated if the prostate is hyperplastic. In rare cases in the dog a perineal hernia may be present associated with a hyperplastic prostate, and should be differentiated from a dilation or diverticulum of the rectum. In the bull and stallion the kidneys and other pelvic structures may also be examined for evidence of cystitis, nephritis, or possible tumors. Fat necrosis is rarely found in bulls.

Other diagnostic tests and examinations should be performed on valuable sires especially where herd records indicate that a venereal disease might be present. These tests have been described previously in this chapter, in Chapter 3 on abortion diseases or in chapters on infectious, reproductive and systemic diseases transmitted by coitus or by artificial insemination with infective semen. These tests would include the many serologic tests, fluorescent antibody tests, cultures of preputial mucus or semen or other special tests including tuberculin tests or tests for blood parasites, or autoimmune factors. Isola-

tion of all new acquired males for 4 to 8 weeks while tests for infectious, contagious or venereal diseases and the administration of effective vaccines are being conducted is a sound practice to prevent the introduction of diseases into a herd or band of females by newly acquired males.

SEMEN COLLECTION AND EXAMINATION

The third part of a careful examination of a male is the semen examination. This is of great diagnostic value in determining the cause, severity and degree of testicular or accessory gland pathology present, as well as being of value in estimating the male's fertility. There is usually a definite correlation between testicular pathology, disease of the reproductive tract and accessory glands and the semen characteristics and fertility. The techniques and procedures used in the semen examination of bulls, rams and humans are more accurate than in the other animals because more work, research and detailed observations have been made on these species. More work on the other species of animals is highly desirable and is being undertaken. From the many reports in humans, bulls, and rams and the less numerous reports in boars, stallions, dogs and tom cats, the same general principles are applicable in semen examinations of all species. Semen characteristics or quality usually remain rather constant and within narrow limits for nearly all ejaculates from each male over a period of months and even years. Due to acute, severe, adverse influences, semen quality may decline rather rapidly but improvement is slow and usually requires months for recovery to occur. Since it takes approximately 50 to 70 days for the development of mature sperm cells from spermatogonia until ejaculation, it is possible for acute testicular degeneration to be present in the testes yet the semen quality as it appears in the ejaculate to be fairly satisfactory. The diseased state or infertility may become evident in 2 to 6 weeks. Testicular biopsies are seldom indicated in domestic animals except in aforementioned situations since one or more semen samples usually accurately reflect the condition of the seminiferous tubules of the testes. Males with the highest quality or the lowest quality of semen and fertility on the initial examination usually have the same quality when they are re-examined, of no severe systemic disease or stress occurs before times of collection (See Semen Quality, Examination and Fertility^{5,7,80,81,123}). Be slow to condemn a male or give a poor prognosis based on a single semen examination revealing poor quality semen; especially if the male is young and immature, if the male has recently been se-

verely stressed or had an acute debilitating disease, if the male is very valuable, if the male has not ejaculated recently, or if his semen has been collected and examined under adverse conditions by untrained persons. The entire ejaculate should be examined and not just a portion of it such as the "tail end" sample taken from a stallion or other male as it dismounts. Usually bulls, rams and men with good to fair semen samples have good to excellent fertility; while males with poor to very poor semen samples are invariably infertile or sterile. (See Semen Quality Examination and Fertility.^{54b,60-63,80,81}) In stallions, boars and dogs where most of the ejaculate enters the uterus poor to very poor semen samples result in reduced fertility and small litter size in the latter, to occasional sterility. Completely sterile stallions are rare. If some motile, normal sperm cells are present in the ejaculate conception is possible in all species. Occasionally males with apparently normal-appearing, good quality semen samples may be incapable of producing conception. Therefore the examination of semen samples and the physical examination of the males as a means of evaluating fertility should be performed carefully and the result should be interpreted conservatively. If one criterion used to evaluate semen is poor, the sample should be graded poor or questionable because usually for satisfactory or good fertility all of the criteria must be satisfactory or good. Occasionally one poor criterion of semen quality maybe compensated for by a good criterion, for example, good motility and low concentration often result in fair conception rates.

The Collection of Semen for examination is practical and fairly easy in all species of male domestic animals except possibly the boar and cat, in which certain individuals may require general anesthesia and electroejaculation.

The Bull may have semen collected in several ways, but only two are of practical value for semen evaluation. The simplest and earliest method of semen collection was from the vagina, by means of a spoon or syringe with a long nozzle following a natural service. A speculum may be helpful in this method. This technique is unsatisfactory because the relatively small volume of semen is mixed with a large volume of vaginal mucus so this method was not suitable for the evaluation of semen quality.

The massage technique in the bull, first described in 1925⁷ as a means of obtaining semen for examination and artificial insemination, has been further described.^{3,11,23} This method is employed rather seldom because some skill and experience are necessary to massage the ampullae per rectum; some bulls respond poorly to the procedure, and semen collections are usually not as clean and contain many more bacteria than those pro-

duced by other methods because the semen passes through the prepuce and drips from the preputial hairs. For this latter reason it is necessary to carefully wash, rinse, and dry with a brush and cotton pledgets or a clean towel the prepuce and the preputial hairs and the region around the preputial opening with warm physiological saline solution or clean warm water. This washing, if combined with stroking of the sheath, may induce urination, which is desirable inasmuch as urine is toxic to spermatozoa and massage of the ampullae is likely to stimulate urination. The prepuce should be carefully doused with 250 to 500 ml. of a physiological saline solution to remove epithelial cells, smegma, and dirt. Sexual stimulation of the bull with a cow or another bull is helpful in obtaining a satisfactory semen sample. The bull should be handled quietly and kept relaxed. The operator, wearing a glove and sleeve, gently inserts his lubricated hand and forearm into the bull's rectum, emptying it of feces. The seminal vesicles are then gently massaged a few times with the fingers by backward and downward strokes toward the urethra and a cloudy fluid containing few if any spermatozoa is expelled. An assistant with a funnel and several test tubes collects the seminal fluid and semen as it drips from the preputial opening or penis. The ampullae are then massaged similarly in a slow, rhythmic manner. With the second finger between the ampullae and the third and fourth fingers on the outside of the ampullae, the ampullae are "stripped" of semen by pressure against the floor of the pelvis and then the pelvic urethra may be massaged. Sometimes the ejaculate is retained in the sigmoid flexure of the penis or in the proximal portion of the prepuce; therefore after massaging the ampullae, the S-curve of the penis should be straightened out. About 80 percent successful collections were reported in 100 attempts on 15 bulls.²³ Twenty one bulls were massaged 102 times and semen satisfactory for use in artificial insemination was collected with an average volume of 5.9 ml. with a slightly reduced concentration.¹¹ No injury or bleeding was produced. Fertility was equal to samples collected in the artificial vagina. If massaged regularly by the same operator most bulls usually become accustomed and conditioned to this procedure within 3 to 4 weeks and produce a good semen sample promptly at the time of each collection. The indications for using the massage technique are the same as in the electroejaculation technique, namely, in bulls that are impotent, unwilling, or are unable to copulate. Another author²² has described a method of gentle manual massage of the glans through the sheath wall to produce erection and ejaculation without restraint in gentle, calm bulls in a quiet isolated environment. In practice the massage technique on bulls is seldom used because

it required more skill and patience than the other collection procedures.

Electroejaculation in bulls has proven to be a practical, easy, rapid and routine technique, especially for range beef bulls.^{2,11,3,4,5,12,14,17,21,25} This technique was first described and extensively used in rams in 1936.¹⁶ Modifications to adapt this technique to bulls has been successful. The probe is inserted into the rectum after the feces have been removed. The probe is usually available in three sizes about 60, 75 and 95 mm. in diameter with longitudinal electrodes, 3 in number on its ventral surface, and these must be kept clean and lightly sanded for good contact.¹¹ The probe is about 30 to 35 cm. long. For best results the largest probe that can be inserted into the rectum should be used. No portion of the electrodes should contact the anus when the machine is in use.² The older instruments such as the Dzuik, Marden and Nicholson electroejaculators, the former with ring instead of longitudinal electrodes, have been improved to avoid excessive stimulation of the motor nerves to the rear limbs that often resulted in damage to muscles.^{4,5} The use of a modified sine wave instead of the pulse wave for electroejaculation of bulls has also improved the ease of electroejaculation of bulls.^{2,11,4,5,14} A man should stand behind the bull being ejaculated to prevent the expulsion of the probe. These various types and models of ejaculators for bulls, rams and possibly boars may be purchased commercially.* (See footnote.)

A technique of electroejaculation using a ring or hand electrodes either slipped over the first and third fingers of a rubber glove, or held by the hand over the region of the base of the penis and prostate gland or the posterior portion of the ampullae has been described.^{11,13,25} This technique was favored over the rectal probe by some veterinarians because the bull reacted more favorably and with less vigorous contractions of the muscles of the rear limbs and back and other undesirable side reactions than with the older 4 electrode probes. The newer 3 electrode probes largely avoid these reactions. Furthermore using the ring electrodes required two men to ejaculate and collect the semen and the man behind the bull applying the electrodes cannot observe the protrusion of the penis and whether ejaculation is occurring.^{3,4} The use of the finger electrodes has declined in recent years as results were not as uniformly successful as the results with the improved electroejaculators.

*3 Electrode probe, Lane Manufacturing Inc., Denver, Colo., and Nicholson Manufacturing Comp., Chicago, Ill., Marden Electronics Co., Bryan, Texas, Standard Precision Electronics Co., Denver Colo. (Battery operated) and Production Products Inc., Lyndale, Ave., Minneapolis, Minn.

It is highly desirable to place the bull in a solid stanchion or chute with a pipe or bar behind their stifles inasmuch as they tend to push forward. The front of the stanchion should be constructed so that the bull's shoulders push against supports and choking cannot occur. The footing should be good to prevent slipping. Injured bulls may require a squeeze chute or a sling to support the bull during semen collection. All bulls stiffen slightly and arch their back or "hunch," the anal sphincter contracts and clear seminal fluid dribbles from the sheath when the current is applied. Some bulls ejaculated with the rectal probe lean to one side or raise and extend one hind leg or rarely even both hind legs. This may be caused by the probe not being located on the midline and stimulating the sciatic or pelvic nerves. It may also be due to using too much power. With the newer improved models of electroejaculators these reactions are minimal. Care should be used to not apply the current until the electrodes are through the anus and in the rectum as this is painful to the bull. Occasionally a broken or exposed wire at the base of the probe will cause abnormal reactions especially noticeable on inserting the probe and applying the current. Although the actions of the bull may make this technique appear painful, it apparently is not; repeated electroejaculation do not create fear or resistance to entering the same stall. The different variations in bulls in response to electroejaculation have been described.^{11,17,26}

The preputial hairs may be clipped and adjacent area washed, rinsed and dried or the ventral abdomen may be brushed. Teasing or sexually-exciting bulls or a rectal examination of the accessory glands prior to electroejaculation greatly aids the collection of a good sample. To prevent cold shock to the sperm cells, a rubber cone from an artificial vagina with an attached glass or plastic vial is placed in a plastic bag containing warm water at 90 to 100° F. attached to a metal ring about 7.5 cm. in diameter with a long handle.¹⁴ The amount and consistency of the ejaculate can thus be observed as it is emitted. An artificial vagina may also be used to collect semen during electroejaculation. Although modifications in technique and procedures may be required in using electroejaculation on certain bulls, stimulation should begin at the lowest power settings especially in young bulls. Power or voltage within a power step is controlled by a variable-stimulator knob. This knob should be manipulated smoothly and fairly rapidly and full power within that power step should be approached gradually by turning the knob only part way initially until maximum power in that step is reached after 3 to 4 stimuli. Stimuli should be applied for 2 to 3 seconds with a short rest interval, when the knob is returned to zero, of only about one-

half to not over 1 second. Usually 5 to 10 stimuli are applied at each power step. Usually 9 to 14 stimuli are necessary to cause erection and protrusion of the penis and 9 to 20 to begin and 18 to 35 stimuli to complete ejaculation.^{11,5} A definite regular rhythm should be maintained during this procedure. Each bull must be treated as an individual and should be observed as the current is applied to assess his particular response. Only the amount of voltage or power needed to elicit the necessary responses and gently build up stimulation should be used in bulls and rams. About 90 percent of the bulls will erect, protrude their penis and ejaculate a representative semen sample with the rectal probe. As the penis becomes erect and the glans protrudes through the preputial orifice, more power or voltage is applied and nearly full erection occurs. With more power the clear seminal secretion becomes milky and opaque indicating ejaculation is occurring and the semen should be collected. Electroejaculation usually requires about 3 to 5 minutes to accomplish. If a bull fails to protrude his penis with stimulation, change the position of the rectal probe or exert forward pressure on the sigmoid flexure above the scrotum. Occasionally the tip of the glans will catch in the prepuce near the orifice. There may be a variation in effects of electroejaculation between bulls and from time to time in the same bull. In general young bulls respond better to electroejaculation and produce more normal ejaculates than do old bulls.

Too many early stimulations at a subejaculatory level will yield much accessory gland fluid but may make it difficult to obtain an ejaculation. Too rapid an increase may lead to resistance on the part of the bull or a pre-erection ejaculation and to contamination or loss of semen in the prepuce. Neither general nor local anesthesia nor tranquilization prevented normal electroejaculation.²⁸ Tranquilization may aid in protrusion of the penis. In some bulls excessive seminal fluid may be secreted during electroejaculation resulting in semen with a low concentration of sperm cells. Experienced operators of an electroejaculator can routinely produce ejaculates nearly similar in volume and concentration to ejaculates collected in the artificial vagina. However the concentration of spermatozoa was consistently higher in semen collected with the artificial vagina and volume was consistently greater in semen collected by electroejaculation.^{1,11,2,17} The conception rates of bulls from which ejaculates were collected electrically were the same as when the ejaculates were collected in an artificial vagina.^{5,27}

Electroejaculation has become a useful adjunct to the artificial vagina in artificial insemination stations by allowing routine collections from crippled bulls without

mounting. This is useful in utilizing injured bulls; and it can be used in cases of slow-breeding, impotent bulls. However, as pointed out previously impotency may be hereditary and perpetuating this condition may be detrimental to the breed. This technique has proven of great value to veterinarians for obtaining semen from beef bulls, unaccustomed to handling and to the use of the artificial vagina, for evaluating semen of bulls before the breeding season when they go on range with cows.^{1,17} It is doubtful if artificial insemination of cows with Brahman, Zebu or Santa Gertrudis semen would be possible without electroejaculation. The art of electroejaculating bulls can be mastered with practice. However certain bulls may not respond adequately and poor "semen" samples with oligospermia are obtained. In these bulls other collection techniques should be tried including the ring electrodes, the artificial vagina or massage of the internal genitalia. If an adequate sample cannot be obtained, the bull should not be classified as questionable or unsatisfactory.^{11,4} Since semen could be collected by electroejaculation in nearly 100 percent of the attempts, this technique is superior to others for obtaining semen from untrained or intractable bulls refusing to ejaculate into an artificial vagina.¹⁵

The artificial vagina is the method generally preferred and widely used for the collection of semen from dairy bulls and bulls in artificial insemination studs, and bulls on farms accustomed to being handled. Great care must be used in handling bulls as even fairly quiet ones can become dangerous in an instant. It is best to control them with two ropes, one fastened to a heavy nose ring, the other passing through the ring and tied around the horns. A metal bull staff is not safe for restraining a bull.¹⁹ By changing the mount, changing the environment, allowing sexual rest, teasing or "stewing," and other means, it will be found that there are relatively few bulls that cannot be kept in artificial service for many years. By the use of the artificial vagina a clean, complete ejaculate can usually be promptly obtained from properly trained bulls. The early models of the artificial vagina perfected by the Russians consisted of an artificial vagina which fitted inside the vagina of a cow or a dummy. The present widely-used artificial vagina is modeled after the Cambridge type that was developed in England.^{7,10} The vagina consists of a heavy rubber cylinder about 7 cm. in diameter and 35.5 cm. long for young bulls, and 42 cm. long for older bulls; this is fitted with an inner rubber liner. The longer winter-type artificial vagina is rather awkward and heavy and is seldom used except under farm conditions during the colder winter months.^{25b} A rough-surfaced thick inner rubber liner apparently is preferred by bulls to a smooth, thin liner. The liner is longer than the heavy rubber cylinder and

is turned back over the ends. There is usually a hole or valve in the heavy rubber cylinder for introducing and removing the hot water that is used to warm the vagina. The rubber liner is usually held in place by broad, flat, rubber bands. These should be tied to the vagina so that there is no danger of their slipping off and becoming fastened around the penis of the bull at the thrust of ejaculation and resulting in amputation of the penis if undetected. A short rubber cone containing a glass or plastic collecting tube for semen is fastened to one end of the artificial vagina and is covered with a warmed insulating jacket.

The proper pressure and warmth in the artificial vagina is obtained by filling the water jacket, or the space between the inner liner and the heavy rubber cylinder, about one-half to two-thirds full of water depending on the size of the bull's penis. The temperature of the water should be 125° to 180° F., 50 to 70° C. The colder the vagina and the outside temperature, the hotter should be the water that is added. At the time of collection the temperature inside the artificial vagina should be between 105° to 125° F. or 40° to 52° C.²⁰ Only a small amount of lubricant should be applied by means of a sterile glass rod to prevent an excess of lubricant mixing with semen. The lubricant can be a water-soluble lubricating jelly such as "K.Y." jelly, which is readily obtained commercially. If the temperature of the artificial vagina is too low, the bull usually fails to thrust and ejaculate; if it is too hot, some spermatozoa may be killed, or it may cause the bull pain and he may develop a temporary fear of this method of collection. The glass tube on the rubber cone may be protected from breakage in the summer by having a piece of flannel or a paper hand towel fastened over it and in the winter a warm flannel of several thicknesses, an old coat-sleeve, or a special, quilted jacket with an impervious covering closed at one end can be slipped over that end of the vagina to keep the rubber cone and the collecting tube warm and protect the latter from accidentally breaking when the sample is collected. If collection is delayed during cold weather, this jacket and tube should be held under the arm or in the coat of the operator to keep the collecting tube warm.

Either a cow, a bull or a steer that is trained and quiet may be used for a mount since metal or wooden dummies or phantoms even though they are heavily padded and covered by a hide, usually are not as satisfactory. If a bull is a slow-breeder, a cow in estrus is desirable, or a mount, either male or female, that is highly attractive to bulls should be used. Bulls or steers are most desirable especially in an A.I. stud in order to prevent the possible spread of disease if the bull were to accidentally breed the cow used as a mount.

A few quiet and well-mannered beef and dairy bulls have even been trained to breed an artificial vagina without mounting or even having another animal close. The bull is brushed and stroked along the back and sides, and then along the abdomen, sheath, and testicles. When the penis is extended from the prepuce by this stroking, an artificial vagina is applied and ejaculation occurs.

In artificial breeding studs all dairy bulls are teased before service to increase the total number of spermatozoa ejaculated. In slow breeding bulls this teasing prior to collection also makes mounting and ejaculation more prompt and rapid when the artificial vagina is heated and ready. The animal to be mounted is placed in a breeding rack or confined in a solid fence corner where the footing should be good to prevent slipping. The mount animal if not in estrus, should be restrained with a noselead to assist in its immobilization. The bull should be properly restrained by ropes to his nose ring so when he dismounts he does not attack the collector.¹⁹ The underline and preputial hairs of the bull are brushed clean and if necessary washed and dried. Cleanliness and hygienic practices in the collection of semen from bulls is important. The location for semen collection should be clean, dry, and free from dust, dirt, and mud. Douching the preputial cavity with a warm physiological saline solution prior to service is of questionable value in reducing the bacteria present in the semen.⁸

If the semen collector is right-handed, it is easier for him to work on the right side of the bull. As the bull mounts, the prepuce enclosing the erect penis is drawn sidewise toward the collector by the cupped fingers of the left hand, thus deflecting the penis from the vulvar region or escutcheon of the mount animal. The sheath and penis should not be grasped tightly with the thumb and fingers. If the protruded penis is grasped, the bull usually retracts the penis and dismounts. The tip of the glans penis is introduced into the end of the artificial vagina that is held alongside the buttocks of the cow and tilted downward and backward so that the water collects in the lower or "caudal" end and provides the needed pressure and warmth to stimulate ejaculation on intromission. Swedish workers prefer to hold the vagina against the buttocks or ischial tuberosities of the cow, aiding the direction of the glans penis by the fingers on the prepuce but letting the bull seek, find and thrust into the artificial vagina.¹⁵ The bull should be allowed to thrust its penis into the vagina, since this thrust is necessary for ejaculation. If the operator prematurely pushes the vagina over the erect and extended penis, most bulls will not ejaculate. After ejaculation the vagina should immediately be tipped in the opposite direction so that the semen will run into the collecting tube. If an excess of water has

been used, it may be necessary to draw off a portion of that water before all the semen can drain from the artificial vagina into the tube. A possible mishap from using an excess of water is to have the rubber liner burst or the rubber bands forced off at the time the penis is thrust into the vagina. If the latter happens, the rubber bands should be counted and penis should be examined. Some operators make a small nick or hole in the rubber collection cone to release air at the time of the thrust. For some bulls a heavy rubber band about 1-1/2 inches in diameter is placed around the liner, between it and the heavy rubber casing, at the open end of the vagina to provide more resistance to the entry of the penis and thus promote ejaculation.

Since sperm cells are killed or injured by toxic substances, it is necessary that all new rubber equipment which comes in contact with the semen be carefully cleaned and sterilized before using. New rubber equipment is often coated with a powder to prevent the rubber from sticking together. This powder or coating is often highly toxic to spermatozoa. After each collection the cone and rubber liner should be rinsed immediately in warm water. All glass, metal, and rubber equipment should be washed and brushed with a lukewarm solution of 0.2 to 0.3 percent sodium hexametaphosphate such as "Calgon," or .3 to .5 percent tetrasodium pyrophosphate, or a good glass cleaner and rinsed thoroughly with warm water. The synthetic organic detergents should not be used in washing and sterilizing artificial insemination equipment.¹⁰ If they are used, very careful rinsing is necessary. After draining, all parts of the equipment are then rinsed in 70 percent ethyl alcohol and permitted to dry in a dust-free, ventilated storage cabinet. Other types of alcohol such as methyl or denatured should not be used. Some workers use a final rinse of scalding distilled water, followed by a rinse in 70-percent ethyl alcohol. The drying may be aided by replacing the liners on the vagina but a better procedure is to distend the rubber liner with ordinary clothes pins or a special metal rack. If equipment must be used before it has dried, the alcohol should be thoroughly washed away with physiological saline or a sterile citrate- or phosphate-buffer solution. The artificial vagina may be sterilized by boiling or by being placed in an autoclave but this hastens deterioration of the rubber parts.

The artificial vagina method for the collection of bovine semen produces a clean concentrated semen sample with cheap, simple equipment and provides information on sex drive. It has the disadvantages of requiring a relatively trained cooperative bull and a suitable mount. The danger of injury of the operator is greater. While the electroejaculation method of collection gives good re-

sults with few specialized facilities and even with untrained bulls, it has the disadvantages of requiring more costly equipment, a greater chance of a contaminated sample with a low concentration of spermatozoa being collected, and no indication or determination of the sex drive, libido or ability to mount and ejaculate, or freedom from lameness, of the bull is obtainable.

The stallion may have his semen collected relatively easily by using a condom,⁹ or by the use of the artificial vagina.^{2,3,8,14} The former method is seldom used at present because of the excessive contamination of the ejaculate by the penile skin.

The collection of semen from the vagina or uterus of the mare after natural service is possible and has been described.⁴ However samples collected in this manner are not representative, are diluted and possibly contaminated. This technique requires that the mare be healthy and free of any genital infection and not be in her foal heat. Strict hygienic and sanitary procedures should be followed in the collection of the semen by this method. After service by the stallion the hand encased in a sterile glove and sleeve is introduced into the vagina with a stiff rubber tube 3/16 inch in diameter and about 2 to 2-1/2 feet long. This tube is attached by a bent glass tube in a 2-holer rubber stopper to a 6-ounce sterile bottle and a 12- to 18-inch tube is similarly attached by a glass tube in the other hole of the stopper. By suction applied on the short tube with the mouth, semen is drawn into the bottle from the vagina and if necessary from the uterus. Another but less satisfactory method is to use a vaginal speculum and draw up the semen with a long nozzle attached to a syringe. These techniques are presently seldom used.

Collection of the "dismount" or "tail-end" sample of stallion semen that drips from the glans and urethra after copulation can be easily accomplished by holding a warm enamel or plastic cup or large plastic funnel attached to a warmed tube or bottle under the vulva and glans penis as the stallion dismounts. This last portion of the ejaculate has a much lower concentration of spermatozoa, has a different composition than the complete ejaculate, and is usually unsuited for predicting fertility and for inseminating purposes.⁹ The amount of semen collected in this manner is small, 10 to 30 ml., and it is commonly contaminated with smegma and dirt. Collection and examination of this "tail-end" sample is usually performed to be certain that ejaculation occurred during intromission. Semen collected in this manner, is usually filtered through sterile gauze or a coarse-paper or milk filter into a vial before it is used for insemination or "impregnation" following a natural service.

Massage of the ampullae and electroejaculation as described in bulls has been attempted in stallions without success by the author and others.⁵ With the horse completely anesthetized electroejaculation is possible, as reported in swine, but it is not practical and urine often contaminated the sample.¹ These above techniques, for obvious reasons, are not as satisfactory as collecting the entire ejaculate in an artificial vagina.

The condom or breeder's bag was used successfully on most Thoroughbred stallions.^{9*} A mare in estrus, a mare that has been given 10 to 20 mg. of stilbestrol 24 to 48 hours previously to produce signs of estrus, or a very docile, trained older mare can be used with the usual restraints as a mount.

A satisfactory condom for the stallion similar to that used by man was designed. Before use the breeder's bag or condom should be thoroughly cleaned of all rubber preserving powder by thorough washing, rinsing with plain or distilled water and then rinsing with a physiological salt solution. If the condom is to be reused it should be sterilized after washing and rinsing by immersing in ethyl alcohol and dried. Before applying the condom the penis should be carefully washed and rinsed thoroughly several times with plain water and dried to remove dirt and smegma. The condom is fitted to the erect penis, but the left loose over the glans with the air squeezed out, just prior to service. It is held in place by rubber bands and removed immediately after service. If an excess of fluid collects in the condom before ejaculation empty it out. The ejaculate is poured into a sterile bottle or graduate warmed to about 100 to 102° F. Lubricating the outside of the breeder's bag and vulva was not necessary if the stronger condoms were used. As previously indicated this technique is seldom employed at the present time because nearly all stallions can be readily trained to ejaculate into an artificial vagina.

The artificial vagina has been widely used in England, Russia, Japan, and the United States for the collection of semen from stallions. When this is performed regularly the stallion may be trained in its use. The artificial vagina is preferred to the condom because of more satisfactory results and less contaminated samples.^{11,2,3,4,6,8,12} The equipment, however, is more expensive. Some stallions that are collected regularly have been trained to mount dummies, manikins or phantoms.^{7,10,11} A mare in estrus or one in which estrus has been induced, is usually required. Strict hygienic pro-

*Condoms for stallions may be purchased from the Pioneer Rubber Co., Willard, Ohio, Youngs Rubber Co., Trenton, N.J. and Dean Rubber Co., East Kansas City, Mo. (Texas Model.)

cedures should be followed, such as: bandaging the mare's tail with a sterile bandage; careful and thorough washing, disinfection and rinsing of her rear parts; and careful washing and rinsing of penis and sheath of the stallion. The usual precautions are taken to restrain the mare and to prevent injury to the stallion, the operator, or the mare.^{11,6}

The method of constructing the Missouri-USDA type of vagina has been described.^{*4} The Mississippi model has been described by Berliner.³ Lighter more modern artificial vaginas for stallions are also available.^{**} The diameter of the vagina is about 12.7 to 17.7 cm., 5 to 7 inches, and because of its increased size and weight a handle is provided. A dam is present at the closed end of the Nishikawa (Japanese)¹² vagina that provides a place for contact for the glans penis. An equine artificial vagina has been designed and used successfully for many years in Colorado.^{***11} The outer casing is made from a nalgene pipette jar using rubber tubing similar to a bovine artificial vagina and the vagina is well-insulated. A built-in filter is provided that removes the gel from the ejaculate. A new vagina must be thoroughly washed, rinsed, disinfected with grain alcohol, and dried before it is first used, and following each use thereafter. The water-soluble lubricating jellies can be used sparingly to lubricate the opening of the vagina. The temperature of the vagina should be between 105 to 120° F. or 43 to 50° C. Temperature within a degree or two of 46° C. is desirable. This is provided by introducing hot water at 120° to 130° F. or 50 to 65° C., depending on the climatic conditions, between the jacket and the liner of the artificial vagina. Pressure in the artificial vagina simulating that of a mare's vulva may be produced by a 2 inch wide rubber band, 3 inches in diameter, placed between the jacket and the rubber liner near the open end of the vagina. Berliner advised manual pressure through the wall of the vagina. Some of the artificial vaginas such as the Japanese and Colorado types have rigid outside walls. Air and water can be introduced into the artificial vagina to produce adequate pressure on the penis. Although the operator may collect semen from either side of the stallion, most prefer the left or near side. The site

for collection should be level and provide good footing. The artificial vagina should not be shoved over the stallion's penis as he mounts but rather the stallion should be permitted with help to insert his penis into the vagina. On cold days the bottle receiving the semen should be warmed and protected. The vagina should be held firmly against the flank and buttock of the mare with the open end of the vagina held above the level of the plastic collecting bottle and pressure exerted against the penis equal to that exerted by the stallion. It usually requires about 20 to 30 seconds for ejaculation. The operator can place his fingers on the ventral surface of the caudal portion of the erect penis, to detect the pulsations of the urethra during ejaculation.^{11,6} If the stallion or jack is not properly trained or lacks desire, a quiet mare or jenny and quiet surroundings are necessary for collection with an artificial vagina. The author has successfully used a bovine artificial vagina for the collection of semen from small ponies. Stallions that require repeated intromissions before ejaculation or are slow to mount and copulate at natural coitus act similarly when semen is collected by the artificial vagina.

Patience and gentle training may be required, particularly if a stallion is to be collected on a phantom.^{7,10,11} The use of a phantom eliminates most of the possibilities for injury to the mare, stallion and collector. Because of the lower height of the phantom and its immobility it is less stressful to the rear quarters of the stallion. The use of urine from an estrous mare on the phantom is of questionable value as a sexual stimulant to the stallion.¹⁰

The ram and buck may have satisfactory semen samples collected by removing the semen from the vagina of a ewe after coitus, by an artificial vagina or by electroejaculation.

Rams may be mated to restrained diestral ewes. The ewes' vaginas are cleaned prior to use by repeatedly inserting and withdrawing saline with a collecting pipette of glass or plastic 30 cm. long and 1.0 cm. in diameter attached to a syringe until no more mucus can be removed. If the ram refuses to breed a diestral ewe, one in estrum may be used. After coitus semen is removed in a similar fashion. This is a simple method but the semen is usually contaminated. It is faster for collecting from shy, untrained rams than the artificial vagina method and it also detects rams that physically are unable to copulate. Semen evaluation can be performed satisfactorily on such samples.^{4,11}

The artificial vagina for rams and bucks is constructed like the artificial vagina for bulls but it is smaller, about 20 cm. long and 5 cm. in diameter. The temperature of the vagina at the time of collection is critical for

the ram and should be 41° to 44° C. or 106° to 112° F., with a pressure of 40 to 60 mm. of mercury.^{7,8,9,10} Rams and bucks may be readily trained in a suitable environment, with a restrained ewe or doe preferably in estrum. Later any ewe or doe, an ovariectomized ewe or doe treated with estrogen, or even a dummy may be used as a mount. As the operator holds the vagina in his hand he should be crouched next to the rear parts of the ewe and doe and be alert as mounting and copulation is very rapid. False mounts without ejaculation are common. The penis should not be touched by the hand but the sheath may be grasped to direct the penis into the artificial vagina. A refractory period of 20 to 30 minutes follows ejaculation in the ram and buck before he will mount again. A ram or buck may be collected 2 to 3 times a day for a number of days.

Electroejaculation of rams was first described by Gunn in 1936.³ In recent years improved electroejaculators are available with bipolar rectal probes about 30 cm. long and 2 cm., in diameter.* (See footnote.) The ram responds rapidly to electrical stimulation and often 3 to 5 stimulations of 3 to 5 seconds duration with 1 to 2 seconds rest, at 2, 5 and 8 volt peaks result in ejaculation.^{1,2,5,12}

Thus fewer stimulations by the electroejaculator are needed in rams and bucks than in bulls. The insertion of the rectal probe to a depth of 15 cm. instead of 20 to 25 cm., improved the rapidity of response and produced a greater volume of semen. Rams and bucks may be electroejaculated in the standing position or restrained on their side with their legs extended. The latter position is more often recommended. The penis should be removed from the sheath and held with gauze so the urethral process is directed into the collection vial or tube to avoid ejaculation into the sheath. Often the penis will protrude from the sheath with electrical stimulation as in the bull. This method results in a great variation in semen volume and lower concentration than an ejaculate collected with the artificial vagina. Occasionally urine may contaminate the sample. If the first collection is unsatisfactory it is difficult to get another satisfactory ejaculate until several hours have elapsed. Electroejaculation has the advantages that it may be used on untrained rams and bucks and is particularly valuable as a screening test of the semen quality of large numbers of rams.^{2,5} Indiscriminate use of electroejaculation without re-examinations could

lead to the culling of many potential high fertility rams as occasional samples of semen obtained by electroejaculation from fertile rams and bucks were inferior in quality. The induction of erection and ejaculation in rams and bucks by the local massage of the sheath and penis has been described.⁶

The boar may have semen collected by a modified artificial vagina, the gloved-hand technique or by electroejaculation. Before collection by any of these procedures the contents of the preputial diverticulum should be expelled and the area of the preputial orifice should be cleansed and dried.

The artificial vagina may be of various designs to provide the necessary pressure to the spiraled glans penis so that it "locks" at complete erection as it does in the anterior vaginal and cervical folds of the sow. This may be accomplished most simply by a heavy rubber casing 4.5 cm. in diameter and about 12.5 cm. long with a rubber liner and small piece of sponge rubber between it and the casing where warm water at 45° to 50° C. or 113 to 122° F., is placed to heat the vagina. The sponge rubber causes increased pressure on the penis. A continuous, smooth, thin rubber liner or tubing 40 cm. long and 3 to 3.5 cm. in diameter with a small hole in the upper portion to allow air to escape is passed through the above vagina and fastened to the outer end of the vagina and lubricated. The other end is fastened to a plastic bottle or bag of 500 ml. capacity that is in a cup or thermos of warm water at 102° F. or 39° C. As the penis passes through the vagina pressure is applied to the glans by the hand of the operator through the thin rubber tubing.^{4,6,9,10} After several back and forth motions the penis "locks" in the fingers, continuous moderate pressure is applied, and ejaculation commences and continues for about 15 minutes with much of the sperm-rich fraction being emitted around the third or fourth minute. This is a somewhat similar procedure to the gloved-hand technique but more cumbersome. Frequently there may be a series of sperm-rich fractions interspersed between periods of thin sperm-poor fractions and gelatinous tapioca-like secretions. A slightly more complex model of artificial vagina the diameter of the artificial vagina for the bull, but only 18 cm. long designed to prevent contamination of semen with preputial secretions has been described.^{10,11} A very simple model consisting of only a 35 to 40 cm. rubber tubing as described above with a key ring for an orifice that is warmed before use has also been described.^{5b} Other earlier types were similar to the artificial vagina for the bull but with attachments to it so air could be pulsed into the vagina.^{2,11}

Currently most workers collect semen from boars with only a gloved hand and a wide-mouthed thermos jug

*Nicholson Manufacturing Inc., Chicago, Ill. Production Products, Inc., (Dzuik Model) 4607 Lyndale Ave. N., Minneapolis, Minn., Lane Manufacturing Co., Hudson St., Denver, Colo. Marden Electronics Co., Bryan, Texas. Standard Precision Electronics Co., Denver, Colo., (Battery operated).

containing warm water and lined with a plastic bag to prevent chilling of the semen. This technique is easy, inexpensive, and repeatable.^{7,8} After the boar mounts the estrous or restrained sow and protrudes the penis, the hand, encased in a surgical glove, is shaped like a cone to permit the entry of the glans penis and placed several inches cranial to the preputial orifice. After the penis enters the hand the fingers are gently closed locking the spiral penis in the hand. It is critical that the distal 2 to 3 centimeters of the penis be held quite firmly with the small, fourth, and third fingers with no pressure applied to the shaft of the penis. Full erection then occurs and ejaculation follows.⁸ The mouth of thermos jug may be covered with several layers of gauze or cheesecloth to separate the gel fractions from the rest of the semen. Usually ejaculation takes about 5 to 15 minutes and occasionally some boars will have a second ejaculatory cycle, shorter than the first, before dismounting.

Boars are usually readily trained to mount a dummy composed of a metal or wooden frame covered with burlap or they may be allowed to mount a confined or restrained sow or barrow. The former is preferable. The environment should be quiet and the footing non-slippery.^{7,10,6}

Electroejaculation in boars has been described.^{3,5a,b} It is not as desirable as the gloved-hand or artificial vagina for the collection of semen because mating behavior and ability to mate cannot be assessed and the procedure and equipment is costly and the ejaculate secured is not typical. The older Dzuik model or newer small bull or large ram probe is satisfactory if the rectum is evacuated of feces before the probe is inserted. Stimuli must be applied at gradually increasing voltage peaks in a rhythmical manner similar to the technique used in bulls to first induce erection and then by inserting the probe an additional 6 to 8 cm. into the rectum to produce ejaculation. The volume of semen obtained is low but the concentration is usually high because of a lack of accessory gland secretions. Since boars must be forcibly restrained, the collection is a noisy drawn-out affair, often resulting in a heavily contaminated ejaculate. The electroejaculation of boars is not as satisfactory as in bulls and rams. For this reason the electroejaculator should be used on anesthetized boars. One to one and one-half grams of "Surital," sodium thiamylal (Parke-Davis) given intravenously in the ear vein through a 20 gauge needle produced good anesthesia for 15 to 30 minutes in 300 to 400 pound boars.^{3,5a} The genital organs were easily and thoroughly cleansed and the penis was removed from the prepuce by the fingers or by gentle traction with forceps while the initial electroejaculating stimuli are applied resulting in erection. The penis was held by the hand and

directed so the semen would flow into a warmed thermos jug lined with a plastic bag when ejaculation occurred. Under anesthesia the penis and testes are easily examined. The above method was rapid and quiet and was preferred³ for the evaluation of the semen of boars to the use of the artificial vagina which required obtaining sows in estrus or training the boar to mount and use the artificial vagina. Shy, slow, inexperienced, mean, lame or injured boars are difficult to train. Training procedures can't be standardized and are very time consuming. If a live mount is used there may be disease control problems to consider.

In the dog semen may be obtained for examination or artificial insemination by digital manipulation of the penis or by an artificial vagina. A method of electroejaculation of the anesthetized dog modeled after the procedure in rams has been described.¹ This proved useful in a very few males that could not be collected by the former two methods. Most untrained dogs respond best to digital manipulation.^{6a,11,3,7,8,11}

The collection area should be a small quiet room with minimal distractions. The dogs and teaser bitch should be handled quietly after they have become acquainted with the operators and the collection room. The footing should be nonslippery. The teaser bitch is usually fastened securely to a table leg or wall and held by an assistant with a hand under her chest and the other hand around her muzzle to prevent her from sitting down or possibly biting the male or the operator.

Manipulation of the base of the penis is the simplest, cheapest, and commonest way to collect semen in the dog. A bitch, preferably in heat, should be presented to the male. When the dog shows sexual interest the preputial skin is pushed caudally, exposing one to two inches of the glans penis. The base of the penis behind the bulbus glandis is grasped through the prepuce and moderate pressure is applied by the fingers. In an impotent male back and forth movement, masturbation, may aid in producing an erection. As erection occurs the prepuce is retracted behind the bulbus glandis and digital pressure is maintained caudal to the bulbus to simulate its engagement in the vulva. The dog during ejaculation will often step over the arm of the operator causing the penis to be extended caudally between the dog's rear legs as he faces the opposite direction. Even though no teaser bitch is present some dogs can be trained to ejaculate by manipulation of the base of the penis until erection is induced, but sperm cell concentration is usually low.

The semen is collected by means of a warm glass or plastic funnel into a 25 to 30 ml. warm tube or vial or the warmed barrel of a 20 to 50 ml. plastic or glass syringe on which a rubber adapter has been placed and

doubled over to prevent leakage of semen. Since glass collection equipment is difficult to handle with an active, thrusting dog and may break or traumatize the penis, a collection apparatus consisting of a rubber conical sheath, similar to the conical sheath used on a bovine artificial vagina but cut down or folded at the large end to reduce its size with a 15 ml. conical plastic centrifuge tube placed in the narrow end of the rubber sheath and warmed to 38 to 40° C. also prevents loss of semen during ejaculation.¹¹ A very small amount of K.Y. jelly may be applied to the inside of the rubber sheath. The first portion of the ejaculate may be lost due to a brief period of thrusting motions by the male. This is of little importance, as few spermatozoa are present in this portion. When the ejaculation of sperm cells commences thrusting motions cease. The penis does not need to enter the tube or syringe barrel and in shy or impotent males the funnel, tube or syringe barrel should not be allowed to touch the penis. It is important to maintain constant pressure behind the bulbous glandis until sufficient semen has been collected.^{6a,7,10,11,2,7,8,11} The portion of the ejaculate containing the spermatozoa is a whitish-grey milky fluid. Ejaculatory action can be noted by feeling the pulsations of the urethra in the base of the penis. Ejaculation may last 5 to 15 minutes.

An artificial vagina for the dog similar in size, 5 cm. in diameter and 19 cm. long, and similar in pattern to the artificial vagina for a ram has been described.^{4,5,6,9} A firm rubber diaphragm around the open end of the vagina to simulate a bitch's vulva was recommended.⁴ The temperature of the vagina should be about 40° to 42° C. or 104° to 107° F., and no lubricant need be used. The penis is grasped behind the bulbous glandis as described above to produce erection before the vagina is applied. Semen motility may be adversely affected by this technique.² Possibly this was due to the contact of the sperm cells with the heated walls of the artificial vagina as this finding was not reported by others that used and preferred an artificial vagina for semen collection in the dog.

In the tom cat semen collection has been described by the use of the artificial vagina¹² or by electroejaculation under anesthesia.¹⁰ Male cats were selected for their calm temperament and for their strong libido. Teaser queens were either females in estrus or ovariectomized females given 12.5 mg diethylstilbestrol, **Repositol**, every 10 days. It usually required about 2 weeks to train a tom cat for routine semen collection. The artificial vagina was a 2 ml. rubber bulb from the end of a bulb pipette or "eye dropper" with the bulb end cut off and fitted over a 3 × 44 mm. test tube. This was placed in a 60 ml. plastic polyethylene bottle. The bottle

was filled with water at 52° C so at the time of collection the temperature would be 44 to 46° C. The open end of the rubber bulb was rolled over the mouth of the bottle and smeared lightly with K.Y. jelly. The artificial vagina was slipped over the penis of the tom as he mounted the teaser queen and developed an erection. The operators other hand was used to steady the tom and teaser queen. Collection took from 1 to 4 minutes. Their study indicated that toms could be collected 3 times a week and daily use for a short period was possible without a great decline in semen quality. Daily collection did not affect the male cats' libido. The electroejaculation procedure required special equipment and rectal probe and after anesthesia was induced with Ketamine HCL the technique was similar to that used in the other domestic animals with a similar response.¹⁰

SEMEN QUALITY EXAMINATION AND FERTILITY ASSESSMENT

Examinations for semen quality can only be satisfactorily performed on approximately normal ejaculates within a short period after collection. The ejaculates must be properly protected and handled until examined. Some factors to consider in the proper handling of semen are: (1) The artificial vagina or the container used for semen in electroejaculation should be clean and free from con-

taminants that might injure spermatozoa, such as: alcohol, excessive petrolatum, powder present on new rubber liners, and antiseptics or chemicals of any kind; (2) at the time of collection excessive dirt or debris including preputial smegma and secretions should be kept out of the vagina; water and urine injure spermatozoa by creating a different osmotic pressure; (3) excessive amounts of blood and serum may adversely affect spermatozoa; (4) overheating and too-rapid chilling injure spermatozoa, (5) too much agitation and shaking of the semen damages spermatozoa; and (6) excessive exposure to sunlight should be avoided. It is important that the semen sample be examined as soon as possible after collection.⁷⁰

A good laboratory with the necessary very clean glassware and equipment and a well-trained technician, if it is within a few hours drive is the logical place to have the semen examination performed. However, all too often a semen sample is sent to a laboratory at some distance; and the motility and other qualities may be so affected during shipment that the value of such an examination is questionable or limited. In many of these instances only a morphological examination and density estimation of spermatozoa can be performed. Usually a warm "laboratory" at 60 to 80° F. can be set up in an automobile with a good heater. Portable electric incubators that can be connected to a 110 volt circuit are now available for the warming of equipment. For this reason the author firmly believes that by the use of a microscope most trained veterinarians can perform by means of a few simple laboratory procedures on the farm or ranch 3 or 4 semen tests on a male and more accurately determine his probable fertility than can a trained laboratory technician receiving a single ejaculate by mail. The veterinarian also has access to the complete breeding history, information on the male's sexual desire and frequency of service, and other pertinent information, such as his performance during copulation, from a careful physical examination not known to a laboratory. In this testing procedure as in other laboratory techniques the results must be carefully evaluated on the basis of the information obtained and what is known concerning the case; too much reliance should not be placed on the results of tests on a single ejaculate of semen. The best fertility evaluation test is the conception rate of the females bred to the male. Semen examinations, if carefully done, may provide a ready and reasonably accurate measure of whether the male is probably fertile or definitely infertile and be of value in determining the severity and the possible cause of infertility affecting a male. If special staining techniques, electron microscopy or other complicated procedures are necessary for morphological

studies on certain semen samples these must be done in specialized laboratories under the supervision of skilled and knowledgeable technicians and scientists.

Semen quality of the first ejaculate after a long period of sexual rest may have a lowered motility and an increased number of dead spermatozoa. Semen quality in many rams and a few bulls may be decreased during the hot summer months. Season of the year had a significant effect on semen quality in stallions with the best quality of semen produced late in the spring or early summer and the poorest quality semen in the winter months.^{94,95,96} Similar conditions prevail in the breeding and nonbreeding season of sheep and goats. The various common tests on semen are as follows:

Volume—The usual volume of the ejaculate in the various domestic animals has been noted previously. Repeated frequent ejaculations may temporarily lower the volume of the ejaculate. However, under the usual breeding conditions the amount of the ejaculate produced remains fairly constant for each species of animal. (See Table 21.) Under conditions of artificial insemination, teasing or "stewing" of bulls, dogs, boars and other species is often practiced to increase the numbers of spermatozoa and possibly the volume of the ejaculate. Restraining bulls for 2 to 5 minutes or more to induce sexual excitement before allowing ejaculation, was accompanied by increases of about 40 percent in the number of motile spermatozoa per ejaculate over unrestrained bulls.³¹ Small volumes of semen may be ejaculated in young males, in males used excessively, in incomplete ejaculation or failure of ejaculation, and in cases of bilateral seminal vesiculitis in bulls and stallions. An increase or decrease in volume of semen ejaculated is usually not correlated with fertility in a male unless ejaculation fails to occur.

Color—As described previously ram and bull semen is concentrated and the color is milky or creamy white and opaque. (See Tables 23 and 26.) It is normally like cream in consistency. In the stallion, boar, and dog the spermatozoa are much less concentrated and the color is pearly-white to grey and translucent. A creamy consistency of semen is present in bulls with spermatozoan concentrations of 1,000,000 to 1,200,000 per cmm. or higher; a thin milky consistency with spermatozoan concentrations of 500,000 to 600,000 per cmm., and watery, translucent or clear semen occurs with fewer than 300,000 spermatozoa per cmm.⁵³ Brownish-colored semen in bulls, probably due to blood pigment, may be observed in cases of orchitis.³⁶ The light yellow color seen occasionally in the semen of some bulls at the time of collection is due to riboflavin secreted by the accessory glands and it has no significance.

The presence of *Ps. aeruginosa* in bull semen may cause a change from a normal to a yellowish-green color when semen is left standing at room temperature.⁵³ Clumps, clots or large flakes in semen are due to the presence of pus usually from the accessory glands or ampullae. A dark red to pink color of the semen is due to the presence of varying amounts of blood from the genital tract, urethra or penis. A light brown color may be due to the presence of feces in the semen. When the semen is not a normal color and consistency, further examination should be made of the actual density or concentration of the spermatozoa, since reduced fertility may accompany a reduced or low concentration of spermatozoa or severe contamination with substances or agents harmful to spermatozoa.

Hydrogen ion concentration or pH value of the semen of domestic animals has been reported previously. Measurements of the pH of semen at the time of collection is of little practical value in the normal male for predicting fertility.^{7,114} In bulls, rams and dogs the pH of semen is neutral, about 6.7. A pH of 7.0 or higher in semen was observed in bulls used excessively, in incomplete ejaculates and in pathological or inflammatory conditions affecting the testes, epididymides, ampullae or vesicular glands.²⁰ The semen of stallions, boars and cats is normally slightly alkaline in reaction, pH 7.4. First ejaculates from stallions had an average pH of 7.47 and second ejaculates collected soon after the first were more alkaline, pH from 7.5 to 8.0.^{94,95} The pH of semen may be measured with pH paper, with bromthymol blue or a pH meter. When an inflammatory condition affecting an accessory genital organ is suspected or present and characterized by an elevation of the pH of the ejaculate, a catalase test is indicated. High catalase activity of semen, a reaction greater than 300 on the tube used for the test, is demonstrable in cases of acute seminal vesiculitis of bulls.

Concentration or density of spermatozoa in semen has been cited previously for the various domestic animals. (See Table 23.) The concentration of spermatozoa in ejaculates of fertile bulls varies from 300,000 to 2,000,000 per cmm. with an average of 800,000.⁷⁴ Ejaculates collected with the electroejaculator frequently have a lower concentration and a greater volume than those collected with the artificial vagina due to an excess of accessory gland secretion. Spermatozoan density is within normal limits in many bulls with testicular degeneration and therefore other tests are usually necessary for an accurate evaluation of semen quality.⁵³ It was indicated that concentrations of spermatozoa below 600,000 should be looked upon with suspicion. In 24 bulls with serious affections of the testes, 13 had oligospermia, fewer than

200,000 spermatozoa per cmm. and 7 of these had fewer than 10,000 spermatozoa per ml.^{16,20}

Some watery translucent ejaculates in bulls were due to incomplete ejaculation.^{16,20,108} In humans low concentrations usually were correlated with infertility but exceptions were common.⁸⁰ In fertile men with low sperm cell counts the motility and morphology of the spermatozoa were good. In general, however, there was a definite correlation between spermatozoan density, motility, and morphology. In rams⁵⁰ and boars⁵⁸ testicular degeneration is characterized by a marked decrease in the spermatozoan concentration correlating with the severity of the degeneration. As reported previously, spermatozoan concentration is usually very low, less than 75,000 per cmm., in testicular hypoplasia of bulls with complete or nearly complete sterility.^{53,74} Another characteristic of sperm cell concentration noted in many infertile or sterile bulls was the rapid decrease in spermatozoan concentration between the first, second, and third successive ejaculates, indicating poor spermatozoan reserves and reduced sperm cell production.^{53,99} Fertility declined in stallions when there were fewer than 2 billion spermatozoa in the ejaculate.³⁵ The incidence of azoospermia or oligospermia in several thousand stallions examined was low, 0.04 to 0.14 percent.^{12,13} Fertility usually depends upon the total number of actively motile normal spermatozoa in the ejaculate.

The techniques used for determining concentration of spermatozoa are as follows:

1. The color or macroscopic examination of semen in bulls and rams with concentrated semen is quite satisfactory for an approximation of the density of spermatozoa. (See Table 26.) In boars, stallions, and dogs gross examination of semen is not accurate even with the ge-

Table 26. Sperm Cell Concentration and Semen Color in Bulls and Rams

Bulls (per cmm)	Rams (per cmm)*	Color of Semen
	2,500,000	Thick, creamy
2,000,000	2,000,000	Creamy
1,000,000	1,000,000	Light creamy
500,000	500,000	Milky
100,000	100,000	Cloudy, watery, translucent
less than 50,000	less than 50,000	Almost clear, transparent, watery

*Gunn and coworkers.⁵⁰

latinous portion of the ejaculate of stallions and boars removed. Although as the examiner gains experience this method will give a fair indication of the spermatozoan concentrations in the more concentrated samples in bulls and rams; but in medium to lower ranges the visual estimation of sperm cell concentration is subject to serious errors.

2. The enumeration of spermatozoa may be made with a hemocytometer in a manner similar to that used in making a red blood cell count.³⁰

One procedure was to fill a red blood-cell pipette to the 0.5 mark with undiluted semen. A 3 percent chlorazene solution was drawn up to the 1.01-mark in the pipette; this diluted the semen and killed the spermatozoa. This mixture was shaken carefully but vigorously for 2 to 3 minutes. A few drops were released and the shaking was repeated. A few more drops were released and then a drop was placed under the cover slip in a Neubauer blood-cell counting chamber. Sperm cells in 5 large squares were counted in a diagonal direction and the total number of spermatozoa counted were multiplied by 10,000.¹⁰⁵ This procedure rapidly gives an accurate indication of the sperm cell concentration per cmm if the mixing is thorough.

3. The concentration of spermatozoa may be obtained rapidly in a well-equipped laboratory by a photoelectric colorimeter that has previously been properly calibrated by known spermatozoan concentrations.¹²¹ After adding 1 part bovine semen to 40 parts of sodium citrate buffer, the diluted semen is placed in a special tube in the photometer. By reading the dial on the photometer and comparing this reading with a chart containing previous readings with known spermatozoan concentrations, the sperm cell concentration of the ejaculate in question can be determined very rapidly. This may be adapted to dogs or other species. In the dog a dilution rate of 1 to 4 to 1 to 16 was recommended.⁴³

This technique is used in most bovine artificial breeding laboratories for determining the concentration of spermatozoa. This information is necessary for computing the dilution or extension factor.

4. The comparing chamber described by Blom¹⁶ may be used for a fairly accurate estimation of the concentration of spermatozoa by comparing the concentration of spermatozoa in a layer of semen 50 microns thick with pictures of known concentrations of 1, 0.5 and 0.2 million spermatozoa per cmm.

5. Other methods not so practical as the above for determining the concentration of spermatozoa include the measuring the packed cell volume, spermatocrit,⁴¹ and the use of the Coulter electronic counter.⁴⁸

Motility of spermatozoa at the time of collection is

commonly used and excellent measure of the fertilizing ability of spermatozoa. Care should be taken at the time of collection that the ejaculate is protected from "cold shock" or sudden reduction in temperature that has a marked depressing effect on motility. Excessive heat and chemicals or foreign agents, as well as urine or water, also affect sperm cells and reduce motility. The first ejaculate after a long period of sexual inactivity often has poor motility and increased numbers of dead spermatozoa.

For accurate results this test is best made with an electrically heated microscope stage at body temperature. Motility ratings can be made in the field by gently warming the semen slide by placing it on a flat bottle containing warm water at body temperature. Cooling semen from body temperature down to refrigerator temperature causes a gradual loss of motility of spermatozoa until near immobility is reached. Therefore, semen should always be examined at body temperature so that accurate and comparative readings can be made. It may be desirable to dilute the semen in warm Ringer's saline or 2.9 percent sodium citrate solution to more easily observe the individual spermatozoa so an estimate of the degree and percentage of motile spermatozoa can be made. A fast, accurate, photographic method of measuring the proportion of moving spermatozoa and their rate of progression has been described.⁷⁹ Motility of bovine spermatozoa is more significant as a test for fertility after thawing following freezing. A motility rate less than 20 percent after thawing will contribute to a low non-return rate.^{77a} A time-exposure photographic system with dark-field microscopy has proven a valuable procedure to determine spermatozoan motility and semen quality following thawing of frozen bull semen.^{77b} By this technique the number of progressively motile cells, which varies widely between ejaculates and bulls, can be assessed with great accuracy.

Motility is based on the estimated percentage of motile spermatozoa and their degree of motility. Most investigators described the various degrees of motility of spermatozoa in undiluted semen as follows:^{53,55}

- 0—spermatozoa are immotile
- 1—stationary bunting or weak rotary movements are exhibited by spermatozoa
- 2—oscillatory or rotary movements and fewer than 50 percent of the spermatozoa are in progressive motion, with no waves or eddies
- 3—progressive rapid movement of spermatozoa, with slowly moving waves and eddies, usually 50 to 80 percent of the spermatozoa must be progressively motile to produce waves and eddies
- 4—vigorous, progressive movement with rapid and

abruptly forming waves and eddies, indicating about 90 percent motile spermatozoa

5—very vigorous forward motion, extremely rapid waves and eddies, indicating about 100 percent actively motile spermatozoa

In the 350 micron thickness of undiluted semen in a comparing chamber at body temperature, 50 to 70 percent living spermatozoa produced rapid whirls and eddies and good to excellent motility; 30 to 50 percent produced sluggish waves and fair motility; and 10 to 30 percent motile spermatozoa produced single propulsions with no waves or whirls and with poor motility.¹⁶ In normal bovine semen initial motility of 40 to 45 percent or more was essential since lower rates of motility were associated with infertility. Most fertile bulls have 50 to 80 percent of their spermatozoa exhibiting active, progressive motility.^{16,20}

Good initial motility alone is not always an accurate indication of fertility in the bull.¹¹⁴ Examples of infertile bull semen with excellent initial spermatozoan motility that rapidly lost its motility when stored or highly motile spermatozoa that were infertile were cited. No difference was reported in conception rates of semen with 50 percent actively motile spermatozoa and higher percentages of motile sperm cells. Motility below 50 percent was often associated with lower conception rates or poor fertility.

The motility of bovine spermatozoa in testicular hypoplasia was much poorer than in testicular degeneration.⁵³ Only 10 percent of the bulls with testicular degeneration showed motility above 70 percent and a rate or degree of motility of 3 or higher, which is the average requirement. The number of motile spermatozoa was less than 70 percent in 90 percent of the bulls with testicular degeneration but the degree of motility was below 3 in only 42 percent. Ninety-two percent of 100 normal fertile bulls had satisfactory motility whereas only 32 percent of the "problem" bulls had satisfactory motility.^{16,20} Congenitally sterile bulls with a very high percentage of abnormal sperm cells, especially those with defects of the midpiece and tail, had the lowest motility.^{53,99} It is generally assumed that the duration of motility of abnormal spermatozoa is reduced.

Normal stallion spermatozoa had a degree of motility of 3 to 4, and 48 to 75 percent of the spermatozoa in the semen were actively motile about 20 minutes after ejaculation.⁸³ After the unextended semen had stood 8 hours at room temperature no reasonable degree of activity was observed.⁸³ The percentage of motile spermatozoa in 54 fertile stallions ranged from 55 to 60 percent.^{12,13} In several thousand stallions examined low motility or as-

thenospermia occurred in 0.8 to 3.4 percent and necrospermia occurred in 0.09 to 0.3 percent. Even with the minimum of handling, the motility of equine spermatozoa decreased rapidly in vitro.⁸³ This is a possible reflection of the inability of equine spermatozoa to survive in equine seminal plasma that has very low levels of reducible sugar for energy purposes in contrast to the relatively long viability of spermatozoa in seminal plasma of other animals. The addition of isotonic, 5 percent, glucose to equine semen with poor motility of the spermatozoa, may result in marked improvement of the motility.⁹⁶ This is interesting, since in the genital tract of the mare equine spermatozoa survived 72 hours or more.³⁵ (See equine reproductive physiology) In horses it is possible that seminal plasma may have an adverse effect on spermatozoa while the environment of the mare's genital tract is highly favorable for sperm cell survival. Thus some stallions with relatively poor motility in freshly ejaculated sperm may be quite fertile. Even so, in the stallion the spermatozoan motility and the quality of that motility are the most reliable estimates of fertility.¹¹⁸

In rams,⁵⁰ boars⁵⁸ and bulls a decreased motility of spermatozoa has been reported in experimentally-produced testicular degeneration. Fertile boars have semen that usually contain 80 to 95 percent actively motile spermatozoa, while rams have about 60 to 70 percent motile cells. In man 50 to 60 percent active spermatozoan motility was average and 75 percent was good.^{81,82} In men with less than 40 percent actively motile spermatozoa the incidence of sterility rose sharply.

Sperm cell defects involving the midpiece and tail are often characterized by poor motility. There is an intimate relationship between the epididymis and its secretions on sperm cell motility and tail defects as described under diseases of the epididymis.

Pus and drops of vaseline in the semen reduced spermatozoan motility.^{10,16,20} Care should be used in lubricating an artificial vagina not to apply an excess of lubricant that might melt and run into the semen-collecting tube or vial.

The importance of the number of actively motile sperm cells in the ejaculate on the fertility of the male has been stressed in different species by many workers. This fact was well-illustrated by a valuable, 12-year-old Guernsey bull used in an artificial insemination stud that developed senile testicular degeneration associated with interstitial cell tumors. A progressive gradual decline occurred in motile spermatozoa in the ejaculate from 50 to 10 percent along with a gradual increase from 30 to 60 percent in the number of abnormal spermatozoa. Extending his semen on the basis of the numbers of actively motile

spermatozoa present in each ejaculate resulted in satisfactory conception rates even though the extension rates were as low as 1 to 10 in order to provide 6 to 10 million actively motile spermatozoa per ml. for each insemination.

Longevity, viability, or liveability of spermatozoa in semen or extended semen at refrigerator, room or incubator temperatures is another measure that can be used for testing or estimating the fertility of semen. A number of studies from 1940 to 1955 were summarized in the first edition of this text and others of work performed on this type of test for assessing semen quality and fertility.^{7,98} Since that time relatively few experimental studies on these tests have been conducted because they are difficult to run as they extend over a period of hours or days, and thus are not adaptable to semen collected for artificial insemination purposes. Good quality equine semen maintained reasonably good motility for up to 8 hours after collection at room temperature.⁸⁵ Results and correlations with fertility of the male do not provide any greater predictive value than the current simpler tests of semen quality including concentration, motility, and morphology.

Differential staining to determine live/dead spermatozoa in an ejaculate was described using a vital stain such as eosin nigrosin stain.^{18,20,115} This stain, as the India ink, is a good background stain. To make the staining solution, weigh out 3 gms. of sodium citrate dihydrate and add to 100 ml. of sterile double distilled water. To this add 1 gm. eosin B and 5 gm. nigrosin and mix into solution. The eosin will stain the dead spermatozoa a pink or red color, live spermatozoa remain colorless, and nigrosin provides a blue-black background stain.¹⁸ This stain will remain stable for one year or more without refrigeration. Place a small drop of stain on a clean warm slide and add a small drop of semen to the stain and mix gently with a round glass rod or a platinum loop. After a few seconds to a minute or more smear out with the glass rod or another glass slide and dry rapidly near a flame. At least 100 to 200 cells, or preferably 500, should be counted by scanning the entire length of the semen smear. Morphologically abnormal cells may be counted at the same time. In a review on the assessment of semen quality, most workers found an average of about 20 percent dead cells in most normal bovine semen samples and there was little correlation with fertility.² After a prolonged period of sexual rest the percentage of dead spermatozoa may be increased. The live/dead sperm cell count should be evaluated critically. Poor stain or staining technique may greatly affect the findings. A high incidence of necropermia is usually associated with poor

motility and low fertility. However, poor motility may be associated with normal levels of live spermatozoa, which depending on the cause of the poor motility, may be characterized by either normal or low fertility. Presently the live-dead spermatozoan ratio in ejaculates is seldom used to assess fertility.

Examination of stained spermatozoa for morphology is of definite value in studying the severity of testicular degeneration or testicular hypoplasia and the congenital or hereditary defects of spermatozoa.

Techniques for preparing and staining sperm cells for morphology examination—The importance of making smears, and fixing them by air-drying before the semen is cooled to prevent the development of secondary spermatozoan abnormalities has been emphasized.⁹⁷ Storing semen a reasonable time had no effect on the primary spermatozoan abnormalities. Extended semen is not satisfactory for morphological examination because of the egg yolk or milk that is present. Semen samples could be diluted with a physiological saline solution to a concentration of about 200,000 per cmm. before a slide is prepared, so that the stained spermatozoa will not be too concentrated to permit observation of individual cells.¹⁸⁻²⁰ All glass slides used in making semen smears should be thoroughly cleaned, soaked in alcohol, and dried. The plasma and gel fraction of semen may interfere or make difficult the staining of equine or porcine spermatozoa. The addition of one-half to one part of five percent of isotonic glucose solution to one part of horse semen was recommended.⁹⁶ This mixture was centrifuged at 1500 rpm in a clinical centrifuge for 5 minutes. After pouring off the plasma the sperm cells in the glucose solution are stained in the usual manner.

India ink preparations, are probably the simplest and easiest for the veterinary practitioner to prepare.^{19,20} Five parts or drops of a high-grade India ink, such as Pelican Yellow Label, are gently mixed with 1 part or drop of semen. One should be careful not to contaminate the bottle of India ink with sperm cells or bacteria. A drop of this mixture is placed on the slide and spread by one of the following methods: blowing gently; drawing, not pushing, it out with a spreader as with a blood smear; or gently smearing it out with a 1/8 inch, rounded, glass rod. The smear is then air-dried or dried slowly over the warm air of a flame. The dried slide is examined under oil immersion or the high dry magnification. All abnormalities of the spermatozoa and semen may be noted. Large round cells, if present, should be recognized as leukocytes or primordial germinal cells.

Eosin-nigrosin stain is a widely-used simple and effective vital stain.^{18,115} The technique for its use was de-

scribed previously. It may be used for counting the numbers of live/dead cells as well as the morphologically normal and abnormal cells.

Wright's stain, commonly used for staining blood smears, may also be used for semen examinations. This stain is not as satisfactory as **Casarett's stain** because it tends to precipitate on the slide, producing artifacts, and it does not stain the spermatozoa as effectively. The semen should be smeared gently and thinly over a clean slide and fixed by air-drying. The slide should then be immersed in 0.5 or 1 percent chloramine T solution to remove the excess mucus, even though this procedure may cause some breakage of spermatozoa. After being immersed in this chlorine solution for 5 to 7 minutes, the film of semen on the slide is washed gently first with distilled water and then with 95 percent alcohol, and then dried. The semen film on the slide is covered with Wright's stain for 60 seconds. Distilled water is then added until a metallic luster is produced. The stain is left on the slide for 2 to 5 minutes before being rinsed off with distilled water. After the stained slide is air-dried it can be examined under the oil immersion or the high dry power of the microscope. **Hematoxylin and eosin and Giemsa's stains** are also satisfactory for the examination of semen smears for the presence of cells other than spermatozoa.

Casarett's stain is an excellent stain for semen slides.¹⁰ Thin films of fresh semen are fixed on glass slides by immersing them for 3 minutes in a mixture of equal parts of ethyl alcohol and ether; the slides are then air-dried. They are stained by immersion for 5 to 7 minutes in a dye solution heated to 40 to 60° C. The dye solution consists of 30 ml., or 2 volumes, of 5 percent watery eosin B. solution and 15 ml., or 1 volume, of 1 percent watery phenol solution. The stained smears are washed with distilled water, air-dried, and mounted in balsam. The spermatozoan structures are very clearly outlined. Other good staining techniques have been described including **carbofuchsin and eosin stain** and **methylene blue**.⁴

For long term preservation of spermatozoa, especially for acrosomal examination, adding a few drops of semen to a small amount of buffered formo-saline made up and used as follows is recommended:^{47,51,52}

Stock buffer soln*	100 ml.
Stock NaCl soln.**	150 ml.
Commercial formalin (37-40% formaldehyde)	62.5 ml.
Aq. dist. ad.	500 ml.
*Stock buffer soln.	
soln. A) $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$	21.682 gm.
Aq. dist. ad	500 ml.
soln. B) KH_2PO_4	22.254 gm.

Aq. dist. ad. 500 ml.
Take 200 ml. of soln. A and mix with 80 ml. of soln. B. Then from the resultant 280 ml., take 100 ml. as stock buffer soln.

**Stock NaCl soln.

NaCl 9.01 gm.
Aq. dist. ad. 500 ml.

Directions for use:

Add 1 to 2 drops semen to about 5 to 10 ml. of buffered formo-saline, gently shake; add 1 to 2 drops of dihydrostreptomycin, incubate for 10 to 20 min. at 37° C and then refrigerate (about +4° C); this will preserve sperm cells for up to 18 months. Another method for fixing bull or boar spermatozoa for shipping or storing was to use glutaraldehyde in phosphate buffered saline with sodium cacodylate.^{65,68}

Wet mounts for phase contrast microscopy are made in a suitably equipped laboratory from preserved samples and are far superior to smeared and stained preparations for estimating the percentage of spermatozoa with proximal protoplasmic droplets and acrosomal abnormalities. A phase contrast effect can be partially achieved in a regular light microscope by reducing the amount of light permitted to come through the substage condenser. Following one or more of the several staining procedures 100 to 200 or more up to 500 to 1000 spermatozoa should be examined under oil immersion at 1,200 magnification and classified.

An experienced technician could achieve as reliable results counting 100 cells as by counting 500 sperm cells.¹⁰⁷ Spermatozoan abnormalities may be classified as head, body, and tail defects. These three anatomical groups of sperm cell abnormalities have been classified by Lagerlof and Blom^{19,20,47} in two further groups as primary forms that occur due to disorders of the seminiferous or germinal epithelium and as secondary forms that occur after they have left the germinal epithelium, during their passage through the mesonephric ducts, during ejaculation, or in manipulations of the ejaculate including excessive agitation, over-heating, too rapid cooling, due to the presence of water, urine or antiseptics in the semen, and etc. The primary anomalies occur during spermatogenesis either during spermatocytogenesis from spermatogonia to spermatids or during spermiogenesis from spermatids to spermatozoa.

The author and others^{46,47} have serious reservations over using these latter two classifications of spermatozoan abnormalities. If a sperm cell is defective and for that reason can't fertilize an ovum it doesn't matter whether it becomes defective in the seminiferous tubules or mesonephric duct or at ejaculation. If sperm cell artifacts are due to accidents from improper handling of the ejac-

ulate or smearing or staining, a subsequent ejaculate, if handled properly, will usually lack such damaged cells. Furthermore, defects occurring in the germinal epithelium may not manifest themselves until later in the maturation of the cell such as separation of the head and neck described in Guernsey bulls^{51,52} in which the separation took place in the head of the epididymis at the time of the loosening of the cytoplasmic or protoplasmic droplet which up to this point had apparently prevented the separation.

Chromosomal defects in apparently normal sperm cells have been discussed previously and are probably genetic in nature. (See prior discussion in this Chapter on abnormal acrosomes, nuclear defects, intrachromosomal aberrations in spermatozoan development and hereditary or congenital sperm cell defects.)

Spermatozoan head abnormalities include: (See Figures 198, 199, 200)

- Microcephalic heads
- Macrocephalic heads
- Double, or multiple heads
- Elongated or narrow heads
- Pyriform or pear-shaped heads with a narrow or tapering base
- Twisted, irregular-shaped heads and abortive forms
- Round short heads

Abnormal acrosomes (Knobbed spermatozoa) "ruffled," incomplete, flattened, or "bent-over" acrosomes

Nuclear envelope invaginations "craters," "pouches," "erosions" (near equator)

Detached or free heads (Guernseys and others)

Detached galea capitis and acrosome

The latter two are possible "secondary" abnormalities. Macrocephalic heads with a broader than normal base have been shown by various tests to probably be cells with a diploid chromosome content. These were found with an incidence of 0.104% in a group of inbred or closely line-bred Hereford bulls¹⁰⁴ and as a rare occurrence in six bulls with lowered fertility.⁴⁶ Abnormal acrosomes and nuclear abnormalities may be difficult to observe or detect without phase contract microscopy, electron microscopy, or special staining procedures. A review has been compiled on recent studies on acrosomal changes associated with aging of spermatozoa and in freeze-thawed spermatozoa as another indicator of sperm quality since penetration of the ovum depends on acrosomal enzymes.^{26,101} Detached or free heads may be due to excessive agitation of the semen sample or due to improper smearing of the spermatozoa on the slides. The detached galea capitis or head cap from dead spermatozoa is seen mainly in India Ink preparations in the

Figure 200. "Secondary" Spermatozoan Abnormalities.

first ejaculate after a long period of sexual rest or in spermatozoa after prolonged storage. They resemble a bathing cap in shape. Using a special stain, less than 5 percent of acrosomal abnormalities in sperm cells from bulls being collected regularly but an average of 21 percent abnormalities of the acrosome in the first ejaculates of 22 sexually-rested bulls was found.¹¹⁹ This may be an aging phenomena.^{101,106}

An increased number of tailless heads occurred in the early stages of testicular degeneration in fertile bulls.^{19,20,53,99} Normal fertile bovine semen contained only 0.5 to 8.6 percent loose heads. The stallion and possibly the boar spermatozoan differs from other mammals by having an asymmetric head, an abaxial position of the tail and a small acrosome.^{14,15,64b,65,66}

Spermatozoan body or middle piece abnormalities include: (See Figures 199 and 200)

- Swollen neck
- Kinked neck with coiling of the middle piece and tail about head
- Stubby midpiece ("tail stump" defect)
- Naked or filiform neck
- Abaxial attachment of the neck and middle piece to the head, (normal in stallion and boar^{15,64b})
- Swelling of the middle piece, either diffuse, localized, cranial or caudal
- Double middle piece
- Coiled middle piece
- Kinked middle piece with a tightly coiled tail

"Corkscrew" middle piece

Loose or free middle-pieces and tails; these may be weakly motile

Kinked necks

Middle pieces with proximal or distal protoplasmic or cytoplasmic droplets

Bent middle pieces, with or without a protoplasmic droplet at the point of the greatest bending

In counting abnormal sperm cells, loose or free middle pieces and tails should not be recorded if free heads are counted. The presence of a protoplasmic or cytoplasmic droplet on the middle piece has been described^{19,20,74,97} and is considered to be normally present on spermatozoa from the head of the epididymis. As the spermatozoa mature in their passage through the epididymis this protoplasmic drop recedes from the neck down the middle piece and is usually lost before the spermatozoa are ejaculated. The migration of the propoplasmic droplet from the proximal to the distal portion of the middle piece occurred in the head of the epididymis. These were considered to be immature sperm cells when seen in ejaculated semen.⁷⁴ No more than 2 to 3 percent of normal spermatozoa should have this protoplasmic drop on the proximal part of the middle piece.^{16,20,74} Other authors indicated that the presence of a high percentage of middle pieces with protoplasmic droplets may possibly be due to overuse of the male and to too rapid passage of spermatozoa through the epididymis. In boars this condition was associated with testicular degeneration and

hypoplasia.⁵⁸ A localized swelling of the middle piece should be differentiated from an attached protoplasmic or cytoplasmic droplet. The true developmental abnormality of a swelling of the middle piece is an irregular enlargement which stains darkly, in which no differentiation can be seen between the swelling and the central fibril; and the ends of the swelling are tapered.⁹⁹ The protoplasmic droplet, by contrast, stains less intensely and is quite spherical. The corkscrew and "stubby" middle piece are unusual abnormalities.^{21,22b,32b} Abnormalities of the middle piece and tail interfere with fertility by reducing motility; the swollen and thickened types of midpiece abnormalities were most serious.^{53,99} A constant content of 30 to 50 percent of bent middle pieces was usually associated with impaired fertility.⁴ An abnormal environment in the epididymis may result in midpiece or tail defects. An abaxial location of the midpiece on the head of the spermatozoa is common in stallions and possibly boars and is not associated with infertility in those species.^{14,15,65,66} An incidence of 35 to 47 percent abaxial midpieces in stallions was reported.¹³

Spermatozoan tail abnormalities include: (See Figures 199 and 200)

Tightly coiled tails (Dag defect)

Double tails

Distal cytoplasmic or protoplasmic droplets (common in boar semen)

Absent or shortened tails, seen most often in stallions

Coiled tails

Bent, "hairpin" tails, with or without a protoplasmic drop at the bend

Broken tails

The latter two conditions^{66,72} are possible "secondary"

abnormalities in boars associated with infrequent use rather than overuse. Proximal protoplasmic or cytoplasmic droplets on the body or midpiece if present on a high percentage of cells is usually associated with infertility, especially in boars. Distal protoplasmic droplets are common, about 10 to 12 percent, in boar semen and are not associated with infertility.^{64b} In general abnormalities of the tail are infrequent and of little importance. Tails bent at the junction of the tail and middlepiece; either with or without a protoplasmic droplet, are fairly common. They are usually caused by cold shock or osmotic shock due to the presence of water or urine in the ejaculate.

The presence of 10 percent or more of any single type of the above head, body or tail abnormalities, normally absent from semen of males, is often associated with reduced fertility.⁵²

Cells other than spermatozoa in semen smears include:

Leucocytes are found in cases of inflammation or infection of the reproductive tract; there are very few in normal semen

Erythrocytes

Squamous epithelial cells—both nucleated and non-nucleated. These usually come from the epithelium of the prepuce or the urogenital ducts.

Boat-shaped spermatogenic cells—These are more common in abnormal than in normal semen and are more likely to be associated with deformed heads than with deformed middle pieces.^{53,99}

Spermatids—nucleated, non-nucleated, and multi-nucleated.

Spermatocytes—primary and secondary, often called

Figure 201. Miscellaneous Cells Found in Semen 1. Leukocytes 2. Erythrocytes 3. Medusa Formations 4. Protoplasmic Droplets 5. Degenerating Sperm Cell Cluster 6. Primordial Spermiogenic Cells 7. Giant or Multinucleated Cells 8. Squamous Epithelial Cells.

Figure 205. Coiled Tails and Middle Pieces in an Infertile 11-year-old Bull. (The motility rate was between 5 and 10 percent, yet the conception rate was 50 percent with liquid semen extended 1:10 to 20.)

"spheroids" or primordial spermatogenic cells.

Medusa cells or bodies—Medusa formations are portions of ciliated epithelial cells from the efferent ducts of the testis.¹⁷ They are deeply-staining cells about the size of the head of the spermatozoa, with 10 to 30 filiform, or long brush-like, projections or cilia. These cells are seen only in rare instances in the usual sperm cell preparations but may be seen in much greater number in semen preparations from males with severe testicular hypoplasia when the semen is centrifuged and the sediment is placed on a slide and stained. This finding may aid in differentiating between an incomplete ejaculation of a normal bull and a complete ejaculation of a bull with nearly completely suppressed spermatogenesis. These medusa formations are seen at a rate of about 1 to 10,000 spermatozoa in normal bulls. In stallions the incidence is higher.

Protoplasmic or cytoplasmic droplets; floating free in semen, are often observed in fertile semen and are of no significance.

Bacteria, molds, and protozoa are usually contaminants from the prepuce.

Degenerating spermatozoan clusters—were observed in 19 percent of fertile bulls and 79 percent of bulls with testicular degeneration.⁵³ Occasionally they were seen in bulls with testicular hypoplasia. These clusters of spermatozoa are apparently produced by a disturbance in spermatogenesis.

Multinucleated giant cells with 6 to 8 nuclei are seen occasionally in males with testicular hypoplasia or degeneration and are due to abnormalities in the divisional mechanism of the primary spermatocytes.³³ The cause of these latter two conditions might be similar.

The determination of the number and type of abnormal sperm cells in an ejaculate should be used along with other examinations conducted immediately after collection such as those for motility and concentration. There is a divergence in opinion as to the importance of the presence of varying numbers of abnormal spermatozoa seen on stained semen preparations. If the percentage of abnormal spermatozoa is not above 30 to 35 percent it is not correlated with fertility in the relatively fertile bulls.^{25,114} An average of 31.4 percent abnormal spermatozoa was reported with a range of 15 to 48 percent in 19 bulls with testicular degeneration⁵³ and an average of 39.1 percent abnormal spermatozoa with a range of 22 to 58 percent in 4 bulls with testicular hypoplasia. Normal fertile bulls had an average of 15.1 percent abnormal spermatozoa with a range of 6 to 26 percent. The semen of normal fertile bulls should not have more than 3 to 4 percent abnormal heads, 4 to 10 percent abnormal middle pieces, 0.5 to 2 percent abnormal tails, and 0.5

to 6 percent, tailless heads.^{53,99} Similar values of 1.2 to 10.4 percent, with an average of 4.6 percent, primary spermatozoan abnormalities and an average of 2.1 percent, with a maximum of 8.6 percent, loose heads and other secondary abnormalities were reported in normal fertile bulls.^{19,20}

Rams and bucks have very similar semen characteristics including, volume, concentration and motility parameters.^{87,91} Rams having more than 14 percent abnormal spermatozoa in their semen are probably of reduced fertility providing the ejaculate was not taken after a long period of sexual rest.⁸⁷ Normal fertile ram semen should not contain more than 5 to 15 percent abnormal spermatozoa.¹¹⁷ Rams having 0.1 percent abnormal spermatozoa in their semen had an approximate fertility of 80 to 100 percent; those with 1 percent abnormal spermatozoa had fertility rates of 60 percent; rams with 10 percent abnormal spermatozoa had fertility rates of 45 percent; those with 30 percent abnormal spermatozoa had a fertility rate of 20 percent; and rams with more than 50 percent abnormal spermatozoa were sterile.⁵⁰

Less than 14 to 17 percent with a range of 6 to 10 percent abnormal spermatozoa was observed in the semen of fertile boars.^{58,92} In 13 boars with testicular degeneration the abnormal spermatozoa varied from 3 to 36 percent and immature spermatozoa with proximal protoplasmic droplets from 1 to 95 percent. The number of abnormal sperm cell heads was over 20 percent in 5 of the 13 boars and in 5 others the percentage varied from 3 to 8. The numbers of immature spermatozoa with proximal droplets were high in most cases of porcine testicular degeneration.⁵³ Conception rates were 67.7 percent, 57.3 percent and 45.5 percent with boars with 80 to 100 percent, 60 to 79 percent and 40 to 59 percent normal spermatozoa, respectively, including sperm cells with distal protoplasmic droplets.¹⁴ The number of cells with distal and even proximal protoplasmic droplets were extremely variable between boars and between ejaculates. Tightly coiled tails appeared to be a defect in spermatogenesis and doubling of a portion of the cells occurred at a level of 0.3 percent. A majority of midpiece attachments were slightly abaxial in the boar and this defect should not be considered as a primary sperm cell defect in the boar as it is in the bull.¹⁴

Many workers have reported that it was more difficult to evaluate the spermatozoa of stallions than of bulls, rams, boars and dogs.^{12-14,71,74,83,100} In the Thoroughbred stallion infertility can exist in the presence of apparently normal semen quality and it was concluded that the actual fertility of a stallion cannot always be predicted on the basis of a semen examination.^{83,100} Other authors^{35,12-14} reported on sterile stallions with semen

containing only dead spermatozoa (necrospermia) at the time of ejaculation. In stallions of low fertility the concentrations of spermatozoa and the volume of semen were low, 10,000 to 15,000 per cmm. and about 10 to 25 ml., respectively. A fertile stallion was described with good sperm motility but with 35 to 45 percent of the spermatozoa having a proximal protoplasmic droplet and 4 to 6 percent having double heads.³⁵ Bielanski^{12,13} reported on 54 stallions with conception rates from less than 25 percent to nearly 100 percent and the primary spermatozoan abnormalities varied from 2.5 to 10 percent and the secondary abnormalities from 22 to 39 percent. The most fertile stallions had less than 3 percent primary abnormalities. The author observed a young Standardbred stallion with 60 to 70 percent grossly abnormal middle pieces and associated poor motility. Under regular handling infertility was evident but by good management, controlled breeding and breeding at the proper time of estrus he achieved a 70 percent conception rate the next four years. In general the presence of more than 20 percent abnormal spermatozoa in equine semen may be interpreted as indicating low fertility but there were many exceptions.³⁷ Some stallions may have apparently normal spermatozoa and low fertility; others are highly fertile even though a rather high percentage of spermatozoa are abnormal. Five to 13 percent abnormal spermatozoa in semen of fertile stallions was reported.⁸⁶ Up to 30 percent abnormal spermatozoa may be present in fertile equine semen.¹¹

Less than 20 percent abnormal spermatozoa were present in dogs producing good quality, fertile sperm.^{54a,69,90a} Only 0 to 10 percent abnormal spermatozoa with an average of 4.8 percent in fertile canine semen was reported in another study.^{52b} Ten to 15 percent abnormal sperm cells were reported by other authors in 11 normal dogs.^{5,24} Four to 10 percent abnormal spermatozoa were reported in ejaculates of 6 fertile male cats.^{111,a,b} The most common abnormalities were cytoplasmic droplets, double, bent, dubbed or shortened tails and enlarged middle pieces.

It is obvious from the above discussion that great care must be used in the interpretation of the morphology of spermatozoa in semen samples. Technicians differ in their classification of sperm cells, some classifying certain cells as abnormal that others would classify as normal. Differences arise due to variations in the technique of handling and preparing slides. There is probably no distinct line of demarcation between animals of good and poor fertility. The morphological examination of semen as an aid in evaluating fertility is apparently of greatest value in the detection of males whose fertility is unsatisfactory in natural matings. It is of limited or questionable value

in determining fertility in individual ejaculates from males of fair to good fertility used in artificial insemination.

The revised criteria (1976) of the American Society of Theriogenology¹¹⁰ for the evaluation of the breeding soundness (BSE) in bulls is scored or based on three reliable characteristics that have been correlated to fertility. These are:

- | | |
|---|------------------|
| 1. scrotal circumference (based on the age of the bull) | 10 to 40 |
| 2. percent abnormal spermatozoa (primary and total) | 3 to 40 |
| 3. motility (gross and individual) | 3 to 20 |
| Total score | 16 to 100 |

Bulls receiving scores from 60 to 100 are graded as satisfactory, 30 to 60 as questionable and below 30 as poor potential breeders. This presumes that the bull is normal physically, has satisfactory libido and is managed properly. In a Nebraska breeding trial with 57 satisfactory bulls, 22 questionable and 22 poor potential breeders, the conception rates were 60, 48 and 30 percent, respectively.¹¹⁰

The current, revised (1976) values for these three criteria are as follows:

Scrotal circumference (given previously in this Chapter, page 860)

Classification	Percent Abnormal Spermatozoa		
	Primary (%)	Total (%)	Score
Very good	10	25	40
Good	10-19	26-39	25
Fair	20-29	40-59	10
Poor	29	59	3

Classification	Motility (Vigor of Movement) of Spermatozoa		
	Gross	Individual*	Score
Very good	rapid swirls	rapid, linear	20
Good	slower swirls	moderately fast, linear	12
Fair	shaky	slow, linear	10
Poor	flickers	very slow, erratic	3

*Must evaluate in a compatible diluent

Although these current criteria and tests used for the evaluation of the breeding soundness of bulls have been simplified and made more repeatable, it is probably advisable to continue the "battery" of semen tests, particularly on certain bulls to identify those with unusual semen characteristics.

Bacteriological or virological examination of semen

may be indicated under certain circumstances, especially when evidence of genital inflammation or infection is present in females following breeding to a male, a rapid decline in motility of the spermatozoa occurs on storage, or an increase in pH or the presence of leukocytes or frank pus are present in the ejaculate or in the semen smear. Organisms or viral agents in the semen may come from the testes or epididymides, the accessory glands, the vas deferens, the urethra, or the prepuce or penis. Semen examination of bulls by cultural methods or by the injection of semen into test animals may reveal infection with brucellosis, trichomoniasis, vibriosis, mycoplasmosis and others. In cattle the fluorescent antibody test has proven useful in the examination of preputial smegma samples for vibriosis. In brucellosis, semen plasma agglutination tests may be indicated if the blood test reveals a positive or suspicious titer. Besides the possible danger to the female by introducing infection at the time of coitus, bacteria and their products may injure the spermatozoa and result in a rapid decline in the motility of stored sperm cells, especially in liquid or frozen extended semen. (See prior discussion in this Chapter on genital infections of the male.)

A brief summarization of the infectious organisms, either venereal, systemic, or "opportunistic" found in the semen of bulls include: diptheroids, **C. renale**, streptococci, **B. pyocyaneus**, *Leptospira* spp., staphylococci, **E. coli**, **C. pyogenes**, **Br. abortus**, *Mycobacterium tuberculosis* (bovine and avian types) *Mycobacterium paratuberculosis*,⁷⁵ **Ps. aeruginosa**, actinomycetes, *Proteus*, micrococci, yeasts, bacilli and molds. *Mycoplasma* were found in 94 percent of the semen samples from bulls.² This organism was a saprophyte in the prepuce of nearly all bulls. *Mycoplasma* were readily recovered from the sheaths of 80 percent of 160 bulls, and less commonly from the semen.^{1a,67a,90b} Which of these mycoplasma are pathogenic remains to be determined. The pathogenic *Mycoplasma bovine genitalium* has been reported from semen from bulls with seminovesiculitis.^{1b,23,57} Viruses including enteroviruses, genital fibropapilloma virus, foot and mouth disease virus,^{32a,45} *Chlamydia*, epivag, parainfluenza III virus, and IBR-IPV virus have been recovered from the semen or testes of bulls. Freezing semen for the preservation of sperm cells will also preserve most infectious agents including viruses.^{6a,b,47,84,112} Liquid nitrogen used for the storage of frozen semen may also become contaminated with a variety of organisms and viruses and thus be a source of infection for the cow. Bulls clinically infected with Johnes' disease usually have the organism in the semen.⁷⁵

Similar types of organisms as well as those responsible for venereal diseases in each species may also be found in other male animals, for example **Br. suis** in

swine, **Br. canis** in dogs, **Br. ovis** in sheep, *Trypanosoma equiperdum* (dourine) and possibly influenza and infectious equine anemia viruses and the herpesvirus of coital exanthema in horses. A vaginitis and vulvitis are commonly observed in heifers or cows after natural service, especially to older bulls caused by ureaplasma and possibly **H. somnus**. Mares may become infected with streptococci, *Klebsiella* and *Pseudomonas* organisms by being bred to stallions that have large numbers of these organisms in the sheath or semen.

Except for vibriosis, brucellosis, IBR-IPV and trichomoniasis, infections in most cows transmitted to them by natural breeding are not serious and seldom prevent conception or cause subsequent abortion. Many bulls with a seminovesiculitis may have nearly normal conception rates. However, in artificial insemination the author and others have observed several bulls with **Ps. aeruginosa**, **C. pyogenes** or *M. bovine genitalium* infection of the vesicular glands that caused a rapid loss of motility of the spermatozoa probably due to the inflammatory products in the ejaculate. The presence of pus in stallion semen caused a much more rapid decline in motility of the spermatozoa than occurred in normal semen.³⁷ *Pseudomonas* was recovered from semen of 25 of 70 stallions.⁵⁹ No lesions were observed in the stallions, no leukocytes were present in the semen and conception rates were comparable to stallions not harboring the organism. However infected stallions could produce genital disease in mares having a lowered resistance to infection.

In the collection of semen samples for bacteriological or viral studies it is essential that strict sanitary and hygienic practices be observed. Even if the semen is collected in a sterile vagina, contamination usually occurs. Taking a bacteriologically sterile semen sample in the artificial vagina or by electroejaculation is impossible because of contamination from the urethra, prepuce, penis and air. The method of taking a satisfactory sample of secretion from the accessory glands for culture as described in the discussion on seminal vesiculitis is most satisfactory. Briefly this consists of exteriorizing the penis and after careful washing and disinfection of the exposed penis, sheath and lower portion of the urethra, a sterile cannula is passed up the urethra and a sample is collected in a sterile vial by massage of the accessory glands. At present this test is seldom used except to determine the causative agent of inflammatory processes of the upper reproductive tract or accessory glands.

Disease Control in Bulls and Semen—Many studies over the past 40 years on micro-organisms that may contaminate semen and, like spermatozoa, survive processing, freezing and storage and result in transmission of disease have been reported in this and prior Chapters on infertility in female animals and have been recently re-

viewed in respect to cattle.^{6b,c,108b,c} The world wide use of bovine artificial insemination requires herd owners, veterinarians and regulatory officials be cognizant of the current status of these infectious organisms for cattle.

The semen-borne pathogens may be classified into four control-related categories of:

1. **Specific pathogen-free category** requiring the elimination of these organisms from the AI stud followed by routine testing: viruses of foot and mouth disease and rinderpest and *Mycoplasma mycoides* (contagious pleuropneumonia), *Mycobacterium bovis*, *Mycobacterium paratuberculosis*, *Brucella abortus*, *Leptospira* spp., *Campylobacter fetus venerealis* and *Trichomonas fetus* (The last three organisms are treatable. Further studies on improved diagnostic tests for *M. paratuberculosis* are indicated.)
2. **Control by surveillance category** requiring frequent serologic tests of bulls, cultures of semen and close clinical observation to recognize these organisms in a bull or stud: viruses of BVD-MD, IBR/IPV/IPB (infectious bovine rhinotracheitis, infectious pustular vulvovaginitis, infectious pustular balanoposthitis), parainfluenza, fibropapillomatosis, blue tongue, bovine leukemia, Chlamydia, Bedsonia, and *Coxiella burnetii*. [Although as stated previously in this Chapter and in a recent review,^{117b} there is no evidence that the bovine leukemia virus (BLV) present in lymphocytes of serologic-positive, infected animals can be transmitted venereally by natural or artificial service or embryo transfer. Because of the potential for such transmittal many countries importing semen or cattle from the United States require that such donor animals and imported cattle be free of the infection based on the agar-gel immunodiffusion test.]
3. **Control by Sanitation/hygiene** of ubiquitous, opportunistic pathogenic or nonpathogenic organisms including: *Pseudomonas aeruginosa*, *Corynebacterium pyogenes*, *Staphylococcus* spp., *Streptococcus* spp., *Escherichia coli*, *Proteus*, *Mycoplasma bovis*, *Mycoplasma genitalium* and *bovis*, ureaplasma, molds, yeasts and others.
4. Further control of organisms in the above 3 categories may be enhanced or made more certain by the addition of antibiotics to semen for the following organisms: *Leptospira*, *Campylobacter*, *M. bovis*, *Mycoplasma genitalium* and *bovis* and other susceptible organisms in category 3. (This is accomplished by adding penicillin, dehydrostreptomycin, polymyxin B, sulphate and possibly lincomycin, spectinomycin and minomycin in various combinations and concentrations to the extended semen.)

To realize the strict control or elimination of these infectious organisms from bovine semen a number of rig-

idly enforced procedures of quarantine, isolation, routine serologic testing of bulls and culturing of semen and even certain vaccination practices may be required.^{6b,c,108b,c} If artificial insemination becomes wide spread in other species as it has in cattle, similar in depth studies of the infectious organisms and diseases transmitted in semen would be necessary.

Total solids in the bull semen may be rapidly determined and those samples with less than 4 to 5 percent solids, often indicative of incomplete ejaculation or seminal vesiculitis, should be closely examined.^{20,42} Normal ejaculates from fertile dairy bulls averaged 8.8 to 10.0 g. of solids per 100 g. of plasma. Semen obtained by electroejaculation averaged 2.0 to 6.7 percent solids and semen in older bulls averaged 8.9 percent solids compared to 10.2 percent solids in young bulls.

Enzyme determination of semen plasma has proven of limited value in measuring degrees of damage to sperm cells before ejaculation and during the freezing process. Enzymes such as GOT, LDH, cholinesterase and alkaline or acid phosphatase and others are intimately related to the sperm cell. When the sperm cell dies these enzymes pass into the plasma. The levels of enzymes are highest in the bull, intermediate in the stallion and lowest in the boar.⁴⁹

Other tests for semen quality and fertility—in particular rapid tests that would be of value in determining the fertility of semen used in artificial insemination—have been developed and tried. These laboratory tests include those that measure the resistance of spermatozoa to temperature shock, hypertonic salt solutions, or to other inimical influences, and tests for measuring the fructolysis or oxidation rate of semen. The methylene-blue reduction test based on the dehydrogenase activity of semen was found to be closely correlated with motility and concentration.⁹ Other biochemical tests for semen quality were developed and reported by many workers and reviewed.² But as stated by Mann, "On the whole, the metabolic processes in semen are more often related to sperm density and motility than they are to the fertilizing power of spermatozoa." Semen evaluation is indicative for, but not a test of, fertility in a male animal.

Conclusions on the Assessment of Semen Quality as it is Related to Fertility. Excellent reviews and summaries of much published data have been presented^{7,15,25,27} on the relationship of semen quality to fertility in the relatively fertile males present in artificial insemination bull studs. Many semen quality tests and evaluations have been reported by many workers on known sterile or infertile males from which certain general conclusions can be drawn. Extensive surveys of semen quality in populations of males of known and unknown fertility have been performed in bulls,^{29,74} in stallions,^{12-14,35,83} in

rams,^{39,50,60,61} and in men.^{44,80-82} But fewer controlled studies have been conducted such as those in rams where semen examinations of males were followed by fertility trials in an evaluation of the factors of semen quality that were related to fertility or infertility in males.^{61,109}

Differences have long been observed between males in their apparent fertility. Bovine and porcine artificial insemination of numerous females have emphasized these differences. In a recent report 18 bulls from 7 AI organizations were used artificially in a 2500 cow dairy. Five low-fertility bulls, 7 medium-fertility bulls and 6 high-fertility bulls had conception rates of 38, 56 and 66 percent, respectively. The minimum number of 36 services was needed to determine correctly the level of a bull's fertility.³⁴

Another method for assessing the fertility of male animals, that has been shown not to be highly correlated to various semen examinations but is more accurate, is the **competitive matings** between two males in which equal numbers of spermatozoa from each male are mixed and inseminated into the same females (heterospermic matings). Thus differences in fertility of males can be determined using fewer females.^{8,38,102} This method is particularly useful in boars because the large number of offspring requires fewer females in the trial.⁸⁵

The **non-return rate of bulls** used in AI studs is a valid method for assessing fertility between the bulls and a basis for eliminating the bulls with low fertility. However a more rapid and reliable method of fertility prediction is desirable. In one report²⁸ 160 beef heifers were synchronized and superovulated and bred artificially to 8 sires, 5 of which were consistently above and 3 consistently below the average 68 percent nonreturn rates. The heifers were slaughtered 3 to 4 days after insemination and the ova were recovered and examined. The fertilization rates of the ova from the heifers bred to the above and below average fertile bulls was 89 (355 ova) and 70 percent, (155 ova), respectively.

In another similar study⁸⁹ with superovulated heifers bred to 7 bulls with specific morphological sperm cell defects compared to heifers bred to 4 normal bulls the percent of fertilized ova were 33 vs. 72, respectively.

From the above references several generalizations can be made concerning the relationship of semen quality tests and fertility in relatively fertile males used in bovine artificial insemination. The physical activity of semen was more closely related to fertility than was metabolic activity but both were closely related to each other. Presently it is doubtful if more than 20 percent of the differences in fertility can be accounted for by these semen quality tests especially in artificial insemination bulls where the fertility of bulls usually is in a narrow range

of 15 percent difference in conception rates from the most fertile to the least fertile bull. In most cases very poor quality semen resulting in a nonreturn rate of less than 45 percent would be evident and be discarded by the laboratory tests routinely used for semen evaluation.⁷⁷ For this reason in artificial insemination centers good fertility results are based on providing each cow a certain number, about 6 to 10 million, of actively motile spermatozoa. Dead, or immotile spermatozoa have no effect on the normal viable spermatozoa. For an ejaculate to be satisfactory for use in bovine artificial insemination it must have a volume of at least 2 ml. and be of normal consistency and color, a sperm cell concentration of over 500 million per ml., motility of at least 40 percent with distinct progressive movement of cells, less than 15 percent primary abnormalities and a pH of 7.0 or below.

The close correlation in swine between conception rate and litter size is well documented¹¹⁶ and further confirms observations made with uniparous species that there is a wide and definite range in fertility between males. Young, 8 to 12 month old boars should produce 80 to 150 ml. of gel-free semen, opalescent to milky in color, 60 percent motility, less than 10 percent primary defective sperm cells, less than 10% secondary sperm abnormalities and more than 10×10^9 (10 billion) spermatozoa per ejaculate. Older boars will produce to to 400 ml. of semen and have about 10 percent more abnormal sperm cells.⁶⁶ Breeding on 2 consecutive days of estrus will increase conception rates 10 to 25 percent and an additional 4 to 8 percent if different boars are used.⁶⁴

Only a certain minimum quality for each semen trait is needed for maximum fertility. Once this threshold has been reached the association between fertility and semen quality is nearly random, but below this threshold the correlation between fertility and semen quality is important. The semen quality tests most correlated with fertility in males are the concentration or numbers of spermatozoa, the percent of motile spermatozoa and particularly the rate, degree or vigor of motility.

In rams the combined physical examination including the palpation and serologic test for epididymitis due to **Br. ovis**, the assessment of libido and semen evaluation has been closely correlated to the fertility of the ram. When the fertility of rams was categorized on the basis of semen scores as very good, good, satisfactory, poor and very poor and rams in each category were bred to adequate numbers of fertile ewes, the percentage of rams in each category achieving an 80 to 100 percent conception rate was 94, 97, 97, 35 and 25, respectively.^{60,61,88} In 31 rams the scrotal circumference, which ranged from 31 to 42 cm., and semen tests were not related to fertility. However the rams with the highest

conception rate on first service sired significantly more lambs 1.04 vs. 0.89.⁸⁸ Thus, as in swine, the higher the fertility of the male the larger the "litter" size. Rams with satisfactory to very good fertility had 60 to 90 percent motile sperm cells with a moderate to high degree of vigor and progressive movement, 70 to 90 percent live normal spermatozoa and sperm cell concentrations of 1.0 to 1.8 billion/ml.⁶⁰⁻⁶² Rams with poor fertility on the basis of actual fertility trials had 15 percent or less motility with no progressive movement and little or no activity of the spermatozoa, 40 percent or less normal live spermatozoa with sperm cell concentrations of 0.1 billion per ml. or less. No male should be permitted to score higher than his poorest semen character.

About 6 percent of range bulls had poor fertility and 7 percent had questionable fertility based on essentially the same above BSE criteria for semen quality but also including a careful physical examination.²⁹ One report on 29 bulls with normal or satisfactory semen averaged 60 percent conception, range 14 to 100 percent, to the first service, bulls with questionable semen quality had a 48 percent conception rate, range 31 to 57 percent, on first service; and 11 bulls with poor or unsatisfactory semen had a 30 percent conception rate, range 0 to 69 percent, on first service.⁴⁰

In another report, forty 2-year-old Santa Gertrudis bulls were evaluated for breeding soundness. Each of the bulls was exposed to 100 cyclic Santa Gertrudis heifers for a 4 day breeding period with about 12 to 27 estrous females available to each bull. The percent of pregnant estrous females and percent of mated females was recorded. Libido was positively correlated with the percentage of pregnant females in estrus but the scrotal circumference, the spermatozoan abnormalities or motility was not significantly correlated with the conception rates of estrous or mated heifers.¹⁰⁹ In a third report beef heifers bred to 12 Angus bulls with apparently similar semen quality by single or multiple services each estrous period had a conception rate of 62.1 and 62.9 percent, respectively with a range of 0 to 95 percent in single sire matings.⁷⁸ In multiple (3) sire matings the conception rate in the heifers was 74 percent, with a range of 68 to 84 percent, or significantly higher than single sire matings. Except for the one bull, the breeding soundness evaluation tests had low correlations with the conception rates and fertility in the other 11 bulls which ranged from 12 to 95 percent. If the least fertile bull and most fertile bull were removed, the remaining 9 bulls had conception rates ranging from 61 to 80 percent.⁷⁸

If the first semen test reveals poor semen quality, subsequent tests seldom show any improvement except possibly in very young immature males or males recently

affected with a severe stress or disease. However in valuable males with poor quality semen a number of tests including breeding trials over a period of 6 months to one year may be indicated before the male is pronounced infertile or sterile. If semen collected by means of electroejaculation is of poor quality at least 3 more samples at weekly or greater intervals should be collected and evaluated especially if no physical defect is detected. Even then the ejaculator and the collection technique should be checked carefully. Evaluation of semen of range bulls, rams and possibly range stallions, is desirable before the breeding season because these males may collect and guard a "harem" of females and if they are sterile or infertile the pregnancy rate is greatly reduced even if an adequate ratio of males to females is present.

Several recent reviews on the fertility evaluation of stallions recognized that no single test is adequate, that infertility can occur in the presence of normal numbers, motility and morphology of spermatozoa in the ejaculate and that conversely stallions having poor semen quality are able to produce satisfactory conception rates if properly managed.^{71,100,122} As a practical guide to what would constitute a normal fertile stallion it was concluded that the stallion would have to demonstrate normal libido, mating behavior and ejaculation. His reproductive organs should be visibly and palpably normal and free of inflammation or signs of infection or disease. He should be able to ejaculate 400×10^6 (4×10^9) sperm cells in a first ejaculate during the breeding season with 50 percent motility and 60 percent normal morphology.¹⁴ The motility should not drop below 10 percent in fresh semen after 6 hours at 22° C. If a stallion meets these criteria he may be considered a satisfactory potential breeder. If he is borderline in 2 or more criteria or definitely unsatisfactory in 2 or more criteria or has serious permanent disabilities or imperfections he should be considered either a questionable or unsatisfactory potential breeder.^{71,100} However in a stallion the ultimate definition and prediction of fertility, as in other males, is the conception rate after breeding to normal healthy mares in a properly managed breeding program. Sterility or complete failure to settle any of a number of fertile mares is rare in stallions, probably about 3 to 5 in over 5000 Thoroughbred stallions.¹⁰³ Probably very few stallions physically acceptable as breeders would have a failure of libido or complete sterility due to chromosomal abnormalities.

Only males with azoospermia or necropermia should be pronounced sterile. Even if the semen quality is poor, if normal motile spermatozoa are present in sufficient numbers conception can occur. This is especially true in boars, stallions and dogs where the ejaculate is delivered

into the uterus at coitus and the few motile cells more readily gain access to the uterine tubes. In the other species, cattle, sheep, and humans, larger numbers of motile spermatozoa appear to be required as many are lost in the vagina and never traverse the cervix to the uterine cavity.

There is probably no single criterion aside from actual breeding tests that can be used as an accurate overall measure of sperm quality. All facets of the examination of a male should be considered in the evaluation of his fertility including the physical examination, his sex drive and ability to mount and copulate readily, and the examination of his semen. Other considerations might well include the male's genetic merit and his freedom from disease.

As a result of the widespread use and benefits of artificial insemination in the dairy and beef and swine industries, progeny testing of young males is providing needed genetic information to guide farmers and veterinarians in their selection of sires. The "genetic profile" of bulls maintained by progressive AI organizations includes information on production of milk or meat, type and conformation, especially of the feet, legs and udder, disposition, ease of calving and anomalies or defects of their offspring. Additional information is available on the fertility (conception or nonreturn rate) of the males. The above "genetic profile" could be significantly improved by the addition of several other items, with a genetic component, namely: liveability of a male's offspring including stillbirths and postnatal deaths (within one month) and the incidence of twinning and cystic ovaries in a bull's daughters which are of the causes of concern in certain dairy herds.

Such above significant genetic information obtained by extensive progeny testing, which is necessary for the improvement of a breed or species, is regrettably not generally available for the selection of sires in the other species of domestic animals.

Chapter XIX

ARTIFICIAL INSEMINATION

By Robert H. Foote, B.S., Ph.D.*

Artificial insemination, using the semen of highly selected males, has been the most powerful tool for livestock improvement ever available to the breeder. In the early days of development many books were written on the subject. However, other than in dairy cattle,¹³ there have been no recent treatises on the subject. Consequently, some historical perspective will be included here. Added information can be found in older texts and several recent reviews.¹⁻¹⁵

History

Isolated cases of artificial insemination of domestic animals have been reported for centuries. In the fourteenth century an Arab was alleged to have taken semen by means of a pledget of cotton from the vagina of a mare recently bred to a famous stallion; then by inserting this cotton into the vagina of his own mare conception was produced. Leeuwenhoek and Hamm observed spermatozoa as early as 1677.¹² The first scientific research in artificial insemination of animals was performed on dogs in 1780 by the Italian scientist, Spallanzani. This was confirmed in 1782 by Rossi. Although Spallanzani demonstrated that the fertilizing power of semen resided in the spermatozoa, few further studies or attempts at artificial insemination were conducted until the latter part of the nineteenth century. Heape reported that a dog breeder, Millais, between 1884 and 1896, artificially inseminated 19 bitches, of which 15 produced young. Isolated cases of artificial insemination in the horse about this time also were reported. In the early 1900's workers were beginning to realize the possible value of artificial insemination. In 1907 Ivanov reported the successful results of a series of artificial inseminations in mares, cows, and ewes as a means for the widespread improvement

of farm animals. As a result a laboratory was established in Russia and several hundred men were trained in the techniques of artificial insemination prior to 1914. Japanese researchers also were particularly active during this period. After the first World War, activities in this field in Russia increased greatly and by 1938 the number of animals inseminated in that country was reported as 120,000 mares, 1,200,000 cattle, and 15 million sheep. In 1936 Sorenson and Gylling-Holm organized the first cooperative artificial breeding association in Denmark and by 1958 nearly 100 percent of the cows in Denmark were bred artificially.

Artificial insemination was first performed on cattle in the United States in 1937 and 1938 at the Agricultural Experiment Station in Minnesota. The first cooperative cattle artificial breeding association was organized by E. J. Perry in New Jersey in 1938, with Dr. J. A. Henderson as the first veterinary technician.

Artificial insemination in dairy cattle grew rapidly. In 1956, 21 percent of the dairy cows in the U.S. were bred artificially; in 1969 about 52 percent or 8,000,000 cattle, including 750,000 beef cattle, were bred artificially. Most smaller AI organizations in the U.S. merged into a few large ones. By 1982 artificial insemination had plateaued for several years at about two-thirds of the nearly 11,000,000 dairy cows. Only about 4% of the beef cows are inseminated artificially. Several countries, including Denmark, Japan and Israel breed nearly 100 percent of their dairy cattle artificially. In species such as cattle, where frozen semen is readily available, semen is currently being shipped by air throughout the world.

Artificial insemination in swine has been developed and used extensively in Europe, the middle east and Asia.⁷ Only about 20,000 sows are inseminated in the U.S. Artificial insemination in horses has received widespread attention, but has limited commercial use. The development of frozen semen in horses and the newer therapeutic methods for the control of estrus and ovulation could increase the use of artificial insemination in the future.

*Jacob Gould Schurman Professor of Animal Physiology, Dept. of Animal Sciences, N.Y.S. College of Agriculture and Life Sciences, Cornell University, Ithaca, N.Y.

Advantages and Disadvantages

The advantages of artificial insemination are well known, and greatly outweigh the disadvantages; if this were not so, the rapid growth of the artificial insemination would not have continued.

1. Artificial insemination greatly increases the utilization of proven sires. The services of outstanding, superior sires are made available to many more owners. Milk production has doubled since artificial insemination was introduced through better genetics, feeding and management.^{3,15} This has been of economic benefit to the owner and the country. Many proven bulls have artificially sired between 100,000 and 200,000 calves in their lifetime. This use of outstanding sires is further increased by the ability to ship frozen semen of some species worldwide. Stallions potentially may sire over 100 foals in a short breeding season. Boars may sire over 1,000 litters of pigs per year.

2. Bulls used in artificial insemination are more carefully and scientifically selected from outstanding cows and proven sires than is possible in individual dairy herds. Computers scan the records of all the top tested cows and matings are made with the best sires available. About 90 percent of the possible genetic improvement in a commercial herd depends on the genetic improvement through artificial insemination. Artificial insemination permits earlier and more rapid proving of young bulls on a greater number of cows under varied conditions. This gives a more accurate proof of a male's transmitting ability than can the testing of a bull on only one small group of females in a herd under similar conditions of management and feeding. This mode of testing also distributes the risk so that inferior bulls cause little loss to individual owners. In bull studs it costs about \$10,000 to prove the genetic worth of a young bull even when his initial purchase price may be small. Because only about one out of seven to ten bulls tested is usually kept as a proven sire, each of these represents an average investment of about \$75,000.

3. The danger, work, and expense of keeping and handling, what in many cases proved to be, an inferior male is eliminated for the average dairyman. This added saving by the use of artificial insemination can be spent on maintaining an additional cow, which, may defray part or all of the yearly cost of breeding a herd artificially.

4. If the males are handled carefully, examined closely from a health standpoint to make certain that they are free from disease, if regular semen examinations are made and accurate breeding records maintained, artificial insemination lessens or eliminates the occurrence of ve-

neral diseases such as vibriosis, trichomoniasis, and brucellosis. Large A.I. organizations are members of the National Association of Animal Breeders and they routinely test their bulls for a battery of diseases (see Chapter XVIII). When semen is obtained from a member of the National Association of Animal Breeders, one can be assured that bulls have been carefully screened for disease. Because only high quality semen is shipped to breeders, conception rates can be improved if the semen is handled properly and the cows are bred at the proper time. Artificial insemination frequently results in improved record keeping, and in heightened interest on the part of the farmer in having cows conceive promptly. This has been helpful in the early diagnosis and treatment of genital abnormalities and has often resulted in an improved breeding efficiency in the herd. In herds affected with vibriosis and trichomoniasis, artificial insemination, may be a valuable means or aid in overcoming the disease. In fact, in herds using artificial insemination for many years, vibriosis and trichomoniasis are not found. In an emergency, such as an outbreak of foot and mouth disease, previously stored frozen semen can be used safely by an A.I. Stud.

5. With the advent of the widespread use of frozen semen and the classification of the physical characteristics of a proven sire's daughters, careful selection of bulls for type and line breeding is possible for the breeder who so desires.

6. The intensive selection and record keeping has reduced the incidence of lethals and other genetic defects.

7. Miscellaneous advantages of artificial insemination include the following:

a) It makes possible the mating of animals with a great difference in size without injury to either animal.

b) It may extend the usefulness of sires which for some physical reason are unable to copulate normally.

c) It may be used to increase the usefulness of males of monogamous species such as the fox. It is of value in experiments on hybridization where natural mating cannot take place.

d) Artificial insemination usually stimulates greater interest in livestock breeding and in better management practices.

e) Artificial insemination has proved to be of value for male dogs that are timid or have premature erection, as complete erection of the canine penis does not ordinarily occur until after entry into the female's vagina. In toy breeds of dogs it may be used to prevent exhaustion due to repeated attempts to copulate during hot weather. It may also be of value in relatively impotent male dogs.

f) It may be helpful when used in females which are in true estrus and ovulate but refuse to stand or ac-

cept the male. An example of this is in zoo animals where pairs refuse to mate. Semen can be collected by electroejaculation, frozen and used when the female is in estrus.

The disadvantages of artificial insemination should be recognized and carefully considered.

1. Well-trained operators are required to supervise the collection, examination, extension, freezing, shipping, and the insemination of the females in order to ensure that infectious diseases such as brucellosis, vibriosis, trichomoniasis and others are not spread. All major A.I. organizations in the U.S. maintain studs free of these diseases. If semen is not collected, extended and handled properly, poor breeding efficiency results. Careful observations for estrum and insemination at the proper time is important. Careful, complete records must be kept. Inseminators, if they are not careful, could be a means of spreading infectious diseases from one farm to another.

2. There is a possibility of spreading genetic abnormalities in cattle, such as: cystic ovaries, spastic syndrome, poor conformation, especially of feet and limbs, and lack of libido. However, large artificial insemination organizations have systems for routinely evaluating udder, legs, feet and other type traits. Only those sires passing this evaluation are used to produce sons for further testing. The increase in cystic ovaries in dairy cattle may be due partly to the wide use of certain bulls by means of artificial insemination. Improved feeding practices and successful treatment of cows with cystic ovaries also may have increased the incidence of cystic ovaries.

3. Miscellaneous disadvantages:

a) Intrauterine insemination of a pregnant female may result in abortion.

b) Uncontrolled or unscrupulous operators or owners could substitute sperm of less valuable animals unless blood typing is routinely employed. However, few errors have been found, so this seems to be a minor problem.

c) Service is not always available. Many dairymen take training to do their own insemination.

d) Artificial insemination cannot be used conveniently on all species or breeds of animals. In some species much more work must be done before artificial insemination becomes practical.

AI in Cattle: General and Liquid Semen

Few advances in livestock production have been so rapidly accepted and have had such a profound influence on dairy cattle improvement as has the use of artificial insemination. The ability of bull semen to be stored for long periods and the confined management conditions under which dairy cattle are kept, have made artificial insemination very adaptable to this segment of the livestock industry in the United States and other countries. Artificial insemination has been commonly used on valuable purebred beef cattle, especially on small farms or in foundation herds. It provides a convenient means of crossbreeding. Because of the large number of beef cattle scattered over a large area when on range, the principal problem and cost is that of finding cows during estrum and driving them to a central point for insemination. Most ranchers prefer to let the bull manage re-

production, despite its many disadvantages. Methods of synchronization of estrus may increase numbers of beef cattle inseminated. At present many owners of larger farms are breeding artificially to their own bulls using frozen semen or they are purchasing semen from other sources.

The collection of semen from the bull for use in artificial insemination is usually accomplished with the artificial vagina and occasionally where necessary with electroejaculation as described in Chapter XVIII. Semen collected by personnel experienced with electroejaculation equipment is comparable in quality to that collected by the artificial vagina. The concentration of spermatozoa per ml by electroejaculation often is about one-half that of semen collected by the artificial vagina, but the volume of semen is twice as large. The pH usually is higher. Thus, the motility of the spermatozoa and the total numbers of sperm cells per ejaculate were the same for the two methods of collection, and this is most important. Semen collection from Brahman and Santa Gracudas is difficult as they are shy. With proper management most mature bulls in artificial insemination studs may be collected up to four times weekly over an extended period of time.

It is important to have a properly designed place for semen collection, providing safety for the handlers as well as for the bull. Good footing is important. Proper restraint of teasers and a place to sexually prepare a bull with more than one teaser can facilitate obtaining the best semen possible. Only bulls, steers or dummies should be used for mounts and these should be cleaned or covered between each semen collection to prevent any possible transmission of disease among bulls. All collection equipment should be sterilized and aseptic techniques of semen collection used. Obviously, only bulls with excellent reproductive characteristics producing high quality semen should be selected for A.I.^{10 and 1-15}.

Semen Evaluation

This is covered in Chapter XVIII. However, it should be mentioned here that all major suppliers of semen collect and examine semen carefully.¹⁹ Each ejaculate must pass a test for semen volume, sperm motility, sperm concentration and general appearance. Frozen semen must meet rigid motility standards after freezing and thawing. Various more detailed tests are included with problem bulls. Semen that is contaminated should be discarded. Most semen collected from mature bulls trained to serve the artificial vagina should have at least 50% of the spermatozoa motile and a concentration that usually exceeds 500 million/ml.

Liquid Semen

Handling the semen after collection is very important. It should not be allowed to cool below 20° C without adding medium such as buffered egg yolk or heated milk to avoid coldshock.^{11,13,15} The dilution of semen with proper extenders protects against coldshock and prolongs the viability and fertility of the spermatozoa. Cooling the semen from body temperature of about 38° C to 5° C over a period of two hours should be done in protected containers placed in a coldroom at about 5° C.¹³ The extender should include penicillin, streptomycin and polymyxin B.^{2,6,7,11a,20}

Extenders for Liquid Semen. Most bull semen for commercial use is frozen. However the extenders used for frozen semen were modified from liquid semen extenders, primarily by adding the cryoprotectant, glycerol. Consequently, brief coverage of these extenders will provide a background for the discussion of frozen semen.^{1,3,5,9,14,15,18,21,25,26}

A semen extender should have the following characteristics:

1. Provide nutrients.
2. Protect against the harmful effects of cooling (coldshock).
3. Be buffered at the proper pH for bull semen of about 6.7-7.0.
4. Have the proper osmotic pressure and balance of ingredients.
5. Inhibit bacterial growth.
6. Increase the volume (dilute the sperm cells) without reducing sperm cell viability.
7. Protect sperm cells during freezing. A common cryoprotectant is glycerol.

The most common extenders contain either **egg yolk** or **milk**. Buffered egg yolk extender was first described by Phillips and Lardy in 1940 who used a phosphate buffer with egg yolk. In 1941 Salisbury et al. described the egg yolk citrate buffer extender which presently is widely used with glycerol as an extender for frozen semen. This extender made possible the rapid advance of artificial insemination. The egg yolk citrate diluter is prepared by adding 2.9 gms of sodium citrate dihydrate ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$) to 100 ml of double distilled water and mixing it at a rate of one part egg yolk to one to five parts of buffer solution. To prepare the egg yolk for the buffered egg yolk extender, fresh eggs should be washed in water and wiped with 70 percent grain alcohol. After allowing the egg to dry, the shell is broken with a sterile knife in a dustfree room. Egg yolks are separated from the egg white aseptically. The protective value of the egg yolk is largely due to the lecithin and

lipoproteins.^{8,13} Most extenders are prepared fresh each day in artificial insemination centers.

Egg yolk-tris also has been used widely for liquid and frozen semen.^{11c} The buffer is made with 24.2 grams of Tris, 15 grams of citric acid monohydrate and 12.5 grams of glucose per liter of double distilled water. To this 20% egg yolk (1 part egg yolk:4 parts of Tris buffer) is added, along with penicillin, streptomycin and polymyxin B. This extender has been used for frozen semen by adding about 7% glycerol by volume. With this extender, semen extension and filling of straws can be done at room temperature before cooling, thus being more comfortable for the laboratory personnel.

Boiled, pasteurized, homogenized milk, and boiled, pasteurized skim milk^{1,3,18} have been reported to be as satisfactory as the buffered egg yolk extenders as an extender for bull semen. These extenders are prepared by placing fresh homogenized or skim milk in the top portion of a covered Pyrex glass double boiler and heating it to 95° C or 203° F. The thermometer is removed, the lid replaced to avoid water loss and gentle boiling is continued for ten minutes. The boiling period should not be excessively prolonged. The boiled milk is cooled to the same temperature as the semen to be diluted. The milk can be filtered or poured slowly from the boiler leaving the surface scum of albumin on the sides of the boiler. No unboiled or improperly heated milk should be added to the boiled milk, as relatively small amounts of unboiled milk exert a harmful effect on spermatozoa. Copper-lined utensils should not be used. Ordinary fresh pasteurized milk or fortified skim milk has not proven as satisfactory as pasteurized homogenized or skim milk as a semen extender and their use is not recommended. The milk can be boiled the day before use and stored in a refrigerator. The satisfactory use of 9 percent homogenized sterilized cream was reported.¹ Skim milk powder, if of a good grade, may be used in preparing a satisfactory extender.¹⁸ The toxic fraction in milk is apparently the lactenin that is destroyed by heating.³ The protective fraction is composed of the phospholipids. It is easier to view sperm in skim milk but whole homogenized milk often is used.

Controlled fertility trials reported by various workers using egg yolk buffer and milk extenders have been summarized.^{8,13} The results with both extenders on the same ejaculates of semen were similar.

Antibiotics added to semen extenders have been shown to increase the viability of spermatozoa and to eliminate *V. fetus* organisms in the extended semen.¹⁷ It was found that 1,000 units of penicillin and 1,000 micrograms of streptomycin per ml of extender had no adverse effect on the spermatozoa and effectively con-

trolled bacterial growth in the diluted semen.² The addition of antibiotics to semen of low-fertile bulls improved their conception rates 10 to 15 percent.^{11a} Foote et al.^{11a} compared the combination of penicillin, streptomycin and polymyxin with individual antibiotics and obtained the best results with the combination. This is still the presently recommended combination of the National Association of Animal Breeders. This definite improvement in conception rates was possibly due to better control of vibriosis found to be present in the semen in many older bulls^{17,20} (see Chapter XIV). Five hundred units of penicillin and 500 micrograms of streptomycin per ml were found to be as satisfactory as the higher concentrations if semen was extended at least 1:25 times and held for 6 hours before use.¹⁷ Non-contaminated buffer solutions containing antibiotics for the egg yolk extender may be stored for one week at 5° C. For liquid semen extenders sulfanilamide may be added at a concentration of 0.03 gms per ml. Sulfanilamide should **not** be used for extenders for frozen semen. Excessive levels of antibiotics in semen may be toxic to spermatozoa and amounts above those recommended have no additional beneficial effect.

It should be noted and emphasized that although antibiotics will eliminate some bacteria in semen such as *V. fetus*¹⁷ and reduce the numbers of certain susceptible bacteria such as streptococci and staphylococci it will not eliminate such organisms as *C. pyogenes*, *Brucella* spp., *Trichomonas fetus*, *Leptospira* spp., mycoplasma, *Mycobacterium tuberculosis*, *Pseudomonas*, *Listeria*, and viruses such as IBR-IPV, *Chlamydia*, epivag, and others. Freezing of semen to which antibiotics have been added will further preserve nearly all of the above organisms for long periods of time.

Other antibiotics have been tried in semen extenders,^{8,13,6,7,27} and some are definitely harmful while others were no better than the penicillin and streptomycin combination. Currently many others are under test, particularly those which may control mycoplasma.²⁴ The addition of antibiotics to semen cannot be a substitute for the careful, sanitary collection of semen with a low bacterial content from healthy disease-free males.

Modifications of the above egg yolk buffer and milk extenders that have shown possible advantages include the addition of:

Catalase, at a level of 20 to 100 mg per ml,¹⁴ affords protection to extended semen, especially in yolk citrate buffers. Catalase prevents the formation of hydrogen peroxide due to the effect of light⁹ and agitation on semen, but its effect on fertility was not significant.¹⁵

Enzymes (with the possible exception of amylase), hormones, tranquilizers, vitamins, glucose, fructose, and other substances have been added to extenders without

noticeable success in improving the fertility rate. Amylase added to semen has been reported to increase conception rate, but its possible beneficial effects were not repeatable in other trials.^{11b}

VanDemark and co-workers^{25,26} described a modified egg yolk buffer semen extender in which carbon dioxide was bubbled through the buffer solution until the pH reached 6.3. The diluted semen was sealed in ampules and stored in the dark at room temperature. Although the results were inconsistent, some workers reported good conception rates for up to 7 days.

Foote et al.¹⁵ described an improved semen extender called C.U.E. (Cornell University Extender) that contained one part egg yolk to four parts of a special buffer containing sodium bicarbonate, potassium chloride, glucose, glycine, sodium citrate and antibiotics. This gave 66% pregnancy rates. However this extender is not good for freezing semen.

Extending Semen

The extension rate of semen is designed to give the optimal sperm per insemination dose. In practice this usually is the minimum number consistent with maintaining maximum fertility. By determining the volume of an ejaculate of semen and sperm cell concentration per ml., one can calculate the number of ampules or straws that can be filled with a standard number of sperm cells per breeding unit. The percentage of motile spermatozoa also is considered. Good quality bull semen, as ejaculated, should have at least 50% motile sperm and a concentration of 500 million sperm per ml.

Work by Foote and others^{11,13,14} indicated that 5 million motile sperm per ml. was about the minimum insemination dose when one ml was used for insemination. The 60 to 90 day nonreturn rate was 75 percent, with a pregnancy rate about 10 percent lower. If a sample of semen was 7.0 ml, had 60% motile sperm and a sperm concentration of 1,500 million sperm per ml., this would be enough to inseminate 630 cows with 10 million sperm per cow. With 5 million sperm per cow the total possible number would be 1260. Extension rates with liquid semen as high as 1 part of semen to 200 parts of extender were common. In New Zealand the cows are inseminated with about 2.5 million freshly collected sperm in the short breeding season.

Excessive light should be avoided during semen processing. This can cause photooxidation which is harmful to the sperm cells whether they are to be used with or without freezing.⁹

When numbers of spermatozoa per insemination decreased from 10 to 6 million there was a 0.5 percent drop in conception rate per each million decrease.²⁸ When one

breeding unit (one ml) of extended semen contained fewer than 6 million spermatozoa there was a decrease of about 2.6 percent for each million decrease in spermatozoa. When not all of the semen is needed for use, the dilution rate to control vibriosis should be at least 1:25 and the semen should be in contact with the antibiotics for at least 6 hours.¹⁷

After the gradual cooling period, the semen is extended by adding a calculated amount of extender, also at refrigerator temperature, 35 to 45° F or 3 to 8° C, to bring the amount of previously slightly diluted semen to the final volume needed. The semen and extender are gently mixed by tilting the container back and forth.

Nearly all bull semen today is processed for freezing. However, when liquid semen was used the extended semen often had colored coal-tar dyes added to aid in identification of breeds.⁴ Each bull was carefully identified on labeled tubes and the semen was packaged and kept at 3 to 8° C until used or discarded. Best fertility was obtained within 48 hours of collection.

A veterinarian could prepare his own egg yolk-citrate, egg yolk-tris or more conveniently boiled milk. This can be frozen in aliquots and stored.¹⁶ Selected references to the earlier literature on liquid semen are included to indicate the variety of combinations of balanced ingredients that were used successfully.^{8,12,13}

Thus, on an average farm, a semen sample would be collected, 1 ml of semen would be added to 25 ml of diluter, or 1/2 ml semen to 12 1/2 to 15 ml of diluter. Even if the sperm cell concentration were only 500,000 per ml, this would still provide over 10 million spermatozoa per ml if only 60 percent were actively motile. Proper antibiotic concentrations may be added to this small amount of prepared extender by making a stock solution of 100,000 units of crystalline penicillin and 100,000 micrograms (100 mg) of dihydrostreptomycin in 10 ml of a citrate buffer solution. To obtain a final concentration of 500 units or micrograms of each antibiotic per ml of egg yolk buffer or milk extender, 0.5, 1.25 or 2.5 ml of the antibiotic stock solution should be added to 10, 25, or 50 ml of extender, respectively. To obtain a final concentration of 1,000 units of each antibiotic in the extender the amounts of the added stock solution should be doubled. Although it is possible for a dairyman to manage his or her own A.I. program, they must be very skillful in estrus detection and all aspects of reproductive management.⁸

Frozen Semen

For many years frozen semen has largely supplanted liquid semen for artificial insemination of cattle in the U.S. and around the world.¹

The chief advantages of frozen semen are:

1. More efficient year round use can be made of semen from proven or injured sires.
2. Selected matings can be made at any place at any time to a large number of available proven sires. Custom freezing of semen makes frozen semen available from farmer-owned bulls. The latter also can be a disadvantage when bulls are not carefully screened genetically or for disease.^{4,5,6,65}
3. Semen can be stored for months to many years at -320° F (-196° C) in liquid nitrogen as a refrigerant. Frozen semen has been reported to have a slight decline in fertility^{38,70} after long-time storage. This was probably due to problems of handling in the field, as semen kept continuously at -196° C does not decrease in fertility for years.^{18,25}
4. Shipping costs are reduced from the bull stud to the technician in the field because semen supplies and liquid nitrogen supplies only need replenishment about once a month. Semen may readily be shipped anywhere in the world.²³
5. Great care is taken by major suppliers of frozen semen to insure that each package of frozen semen is carefully labeled and controlled.²⁰

6. Sperm cell output, percentage of morphologically normal spermatozoa and percentage of motile sperm after freezing was lower in bulls 6 to 12 years of age than in bulls 3 to 6 years of age.³⁰ Thus semen quality was highest in bulls not yet old enough to complete the progeny test. It might be desirable in certain young bulls with lower quality semen to freeze a supply before it reached an older age and the semen becomes relatively infertile. Banking of semen¹⁸ is followed on some bulls, particularly those breeds with few cow numbers.

The major disadvantages of frozen semen are:

1. Semen from about 10 to 20 percent of the bulls does not freeze well. These are often bulls with poor semen quality and low fertility even if semen was used in liquid form.

2. In the freezing process about 40 to 50 percent of the spermatozoa are killed so increased numbers of spermatozoa per insemination are required.^{23,28,64} When a proven sire is in great demand fewer cows can be bred compared to extended liquid semen. However, 6 to 8 million motile sperm after freezing are sufficient per insemination.^{16,17,54,55}

3. If proper bull health is not maintained, frozen semen has great potential for the spread of viral and bacterial diseases. Major bull studs are under continuous health tests.³³

4. Heavy use of frozen semen could limit the number of sires used, and possibly result in narrowing the genetic base of a breed. However, the actual increase in exchange of semen possible with frozen semen also has increased the number of sires used to produce sons, so this has not happened generally.

History

In 1949 Polge et al.⁶² reported that spermatozoa of several species, including cattle, could be treated with glycerol and survive at a temperature of -79°C . They showed that the protective action of glycerol, by modifying the type of crystal formed during freezing, resulted in less harm or injury to the cells and thus survival of spermatozoa could be greatly improved by the slow cooling and freezing process which they perfected. In 1951 the first calf was reported born from insemination with frozen semen. Thereafter interest in the application of frozen semen spread rapidly. Additional calves were born in England the following year. The first calf in the United States resulting from the use of frozen semen was born in May, 1953. The early work with frozen semen used solid carbon dioxide ("dry ice") as a refrigerant at -79°C . Extensive studies by American Breeders Ser-

vice resulted in the development of liquid nitrogen storage units which were very efficient and prolonged the storage life of spermatozoa.⁶¹ Details of the development of frozen semen and other associated historical events have been published.³⁴ Today it is clear that genetic material may be preserved in the form of properly frozen sperm cells for a lifetime, probably for centuries and perhaps for milleniums.

Extenders for Freezing Bull Semen

Bull semen for freezing is usually processed in an egg yolk-citrate, or an egg yolk-tris or milk extender.^{8,19,23,28,73} The milk can either be skim milk or homogenized whole milk. These extenders are prepared the same way initially as for liquid semen (see previous section). However, before freezing glycerol is added in various ways (described later) so that this cryoprotectant is present during freezing. Also, in a few countries where semen is processed in pellets, a sugar solution (lactose or raffinose) is combined with 20% egg yolk by volume plus 4 to 5% glycerol for freezing semen.^{49,50}

Extending and Cooling Semen

When semen is collected it is about 38 to 40°C in the collection tube. It is protected against the cold and usually brought into the semen processing laboratory at about 37 to 38°C . The semen is placed in a water bath at 35 to 37°C . Raw semen has antibiotics added in concentrated form at this point to provide maximum effect against microorganisms which may be present. The recommended concentrations of antibiotic are added in a volume of .02 ml to each ml of raw semen—so as to give 1,000 IU of penicillin, 1,000 ug of streptomycin and 500 ug of polymyxin B per ml.

Then the raw semen is mixed about 1 part of semen with 3 to 4 parts of any of the extenders listed previously. Whatever extender an A.I. organization has had most experience with they should continue to use under normal circumstances. However, one study indicates that much less than 20 percent egg yolk may be necessary.⁷³ It is important that the semen and extender be the same temperature when they are combined. The two parts should be mixed thoroughly by gentle swirling or inversion of closed tubes. This mixture often is referred to as the Pre-X (pre-extended semen). It is placed in a water jacket at the same temperature to protect against rapid cooling. The unit is placed in the coldroom at about 5°C where cooling takes place over a period of about 2 hours. After this time it is brought to one-half of the final volume with the same extender as used previously, excepting the antibiotics sometimes are reduced to about 500 units of penicillin, 500 ug of polymyxin B and 500

ug of streptomycin per ml. Up to this point no glycerol normally has been included, except in extenders containing tris buffer.

One-half the final volume without glycerol provides an opportunity to add glycerol slowly using a similar extender containing double the final concentration of glycerol by adding a volume equal to the first half. The actual volume of extender required depends upon the number of sperm cells available in the collection. This collection may represent more than one ejaculate from a bull. For example, two ejaculates collected the same morning may be combined after cooling and processed as one collection.

Supposing there are 10 billion motile cells in the collection from a particular bull and it is estimated that 50% of these cells will survive freezing and thawing. Thus, we would expect this collection to have 5 billion motile sperm after freezing. If the goal was to have 10 million motile sperm cells per breeding unit (straw, ampule or pellet) this would make potentially 500 breeding units. Of course, a small percentage is lost in processing, so the actual number of breeding units would be slightly less.

Assume that semen is being processed for the 0.5 ml straw. This is very common in the U.S.A., although there also are straws holding about 0.25 and 0.3 ml of semen.^{35,48,57} When packaging in 0.5 ml straws the 500 straws represent 250 ml of extended semen. So the first half of the extended semen without glycerol would be 125 ml. Then 125 ml of extender, usually containing about 14% glycerol by volume, would be added dropwise or stepwise over a period of about 30 minutes.

Another way of calculating the straws that could be filled with 0.5 ml and the volume of extender required would be as follows: Supposing the 10 billion motile cells, to start with, was made up of two ejaculates combined as one collection totaling 10 ml. This collection had 70% motile sperm with a sperm concentration of 1.428 billion cells per ml. This would be 1.000 billion motile sperm per ml. If freezing will kill 50%, there will be 500 million motile cells after freezing. Each straw with 0.5 ml has 10 million motile sperm per straw packaged at a concentration of 20 million motile sperm per ml. The arithmetic is quite simple, as 500 million divided by 20 million is a 25-fold dilution. Then 10 ml of semen diluted $25 \times$ gives 250 ml, one-half of which is without glycerol and the final one-half added with glycerol.

The actual number of sperm per ml varies with organizations and demands for semen from particular bulls. Usually it is desirable to extend semen at a rate to give 6 to 12 million motile sperm per breeding unit.^{16,23,54,55,60} High extension rates also reduce numbers of contami-

nating microorganisms, reducing the chances for infection.

Equilibration time is the period needed before freezing for the sperm cells to become adjusted to the extender so that upon freezing excessive loss of sperm cells does not occur. This time varies greatly between species. It is not necessary that bovine sperm cells equilibrate with or be in the presence of the glycerol for a period of time before freezing. Recent experiments, including fertility trials have indicated that the semen should be in the extender with or without the glycerol for about 4 hours at refrigerator temperature. Because of the adverse effects of glycerol on antibiotics, equilibrating for at least 4 hours in glycerol-free extender is desirable.¹⁰ The second half of the egg yolk extender should contain about 14 percent glycerol by volume, making a final dilution rate of 7 percent. If sterilized milk is used as the extender the second half of the extender should contain 14 to 20 percent glycerol so the final concentration will be 7 to 10 percent. Glycerol should be added gently by dripping or in small increments, usually in the cold room. The diluted semen is then placed in 1 ml amounts of glass ampules or more commonly in 0.5 ml straws that are sealed after being filled. Freezing should be accomplished within 4 to 20 hours of collection of the semen. A recent study¹⁰ reported on bull spermatozoa from 10 bulls exposed at 5° C to extenders containing glycerol for 6 hours, 30 minutes and 10 seconds before freezing. The latter very short equilibration time resulted in a highly significant improvement in sperm motility following freezing and thawing. More study is obviously indicated especially since the Milk Marketing Board in England reported that 6 highly fertile bulls whose semen following freezing had poor conception rates could be improved by a shorter equilibration time.

Freezing Semen

Freezing rates vary depending upon the kind of extender used. The principle is to freeze as rapidly as possible to avoid the osmotic shock of water freezing out (thereby increasing the salt concentration), but **not** so fast as to cause marked thermal shock with intracellular ice formation.^{28,64}

Freezing is usually done in liquid nitrogen freezers. The temperature is lowered from +5° C to about -100° C in 8 to 10 minutes by controlling the flow of nitrogen vapor over the straws or ampules. Ampules freeze a little more slowly than do straws. Anytime after the semen reaches -100° C it can be placed directly into the liquid nitrogen for storage at -196° C.

This storage temperature was preferable to dry ice at -79° C⁶¹ so liquid nitrogen is used almost universally.

Semen can be stored for years at -196°C .²⁵ Normally there is no point in storing semen longer than necessary to use it for insemination. An exception is to preserve certain banks of germ plasm. However, frozen embryos may be used for this purpose.

It is very important to keep frozen semen immersed in liquid nitrogen. This way there is no chance that semen will be warmed at all during storage. This aspect, along with thawing will be discussed further, under shipping and handling.

Ampules and Straws

The first sealed packages for freezing semen were ampules which held 1.0 ml of extended semen. These have been largely replaced with straws holding from 0.25 to 0.5 ml. The advantage of the straw over the ampule is that the sperm cells can be frozen more uniformly, and less storage space is required. In fact storage is greatly increased with the .25 ml straw. A typical field unit which would hold 1,512 1 ml ampules will hold up to 3,000 0.5 ml straws. Also, fewer sperm are left in the straw than in the ampule upon insemination.

All major suppliers of semen run quality control checks on semen after freezing. If it has been stored for a long time they check it again for the percentage of progressively motile cells. Normally semen must have 25% or more progressively motile sperm cells to be shippable.

Some sperm cells are killed in freezing and the general viability of sperm when incubated after freezing is not as good as before freezing. Nevertheless the conception rates with frozen semen are only slightly below those achieved previously with liquid semen. A 60 to 90 day nonreturn rate of 74.5 percent was reported¹⁷ with control liquid semen. Frozen semen stored 1 day and 103 days at -79°C resulted in nonreturn rates of 72.7 and 71.0 percent, respectively. Semen frozen, thawed and subsequently shipped for use 24 to 60 hours later averaged only 51.7 percent nonreturns. Most bull studs today are averaging just a little under 70 percent 60- to 90-day nonreturn rates with sperm frozen in straws and stored continuously in liquid nitrogen at 196°C . A comparison of ampules and straws with about 8 million motile sperm per insemination dose showed the nonreturn rates for straws was slightly higher than for ampules, but the difference was not significant.⁵⁴ A review of the fertility of semen packaged in straws and ampules⁵⁷ slightly favored the straw.

Freezing in Pellets

The extender for the pellets is composed of lactose, 11 percent, or raffinose, 18.5 percent in distilled water and 20 percent egg yolk, 4 to 5 percent glycerol, and

antibiotics.^{49,50} About 3 parts of warm extender are added to semen at 35°C and cooled to 5°C in about 1.5 hours. Three or four hours are provided for equilibration. About 0.1 to 0.2 ml of the extended semen containing 12 to 30 million spermatozoa is put directly in depressions made in a block of dry ice for 5 minutes to freeze. Then the pellets are transferred to storage tubes and put directly into liquid nitrogen. The pellet usually is thawed just before use in 1 ml of 3.2 percent sterile sodium citrate solution at 35°C . Then it is handled for insemination as liquid semen.

The advantages of such techniques are: the obvious savings in cost of storage and sometimes better survival of sperm from bulls whose semen freezes poorly otherwise. At present these methods lack automation and are slightly cumbersome. Sanitation is questionable and contamination in the liquid nitrogen is theoretically possible with pellets of semen. Identification methods for the semen are not as good as with ampules and straws. However, techniques have been developed for freezing the code number of the bull printed on thin paper as a part of the pellet.

Antibiotics added to semen to be used in the liquid or frozen form has limited value against most pathogenic organisms often present in the semen. As mentioned previously, penicillin at levels of 500 to 1,000 units and streptomycin at levels of 500 to 1,000 micrograms per ml. of liquid semen extended 1:25 or more times and stored for 6 hours before use controlled *V. fetus* present in the sheath and semen of bulls. Semen from infected bulls when treated with penicillin and streptomycin, extended, frozen in the usual manner and stored for one week before use was unable to produce infection in susceptible cows.^{39,44} Later it was shown the addition of polymyxin B sulfate (see previous section on use with liquid semen) at a level of 500 units per ml of extended semen along with 50 units of penicillin and 2,000 micrograms of streptomycin controlled *V. fetus* in the semen.²¹ The extended semen was incubated at 37°C for 30 minutes before cooling and freezing. The protozoan, *Trichomonas fetus* can remain viable and infective especially in liquid extended semen, but also in frozen semen containing antibiotics. The chances of survival of the organism are markedly reduced in semen containing glycerol and experiencing a long equilibration period before freezing. *Br. abortus*, *Listeria monocytogenes*, *C. pyogenes*, *L. pomona* and other such organisms are not affected by the antibiotics at levels that can be used in either liquid or frozen semen.^{40,42,47} Of course the viral agents of disease that may be in semen such as IBR-IPV and others are not affected by antibiotics added to the semen. Therefore, it is imperative that bull studs main-

tain bulls free of brucellosis, tuberculosis, trichomoniasis, leptospirosis, vibriosis (campylobacteriosis), and virus diseases. All major artificial insemination organizations carry out extensive disease control programs. New antibiotic combinations² are being tested to assist in controlling the presence of possible organisms such as mycoplasma.⁷⁷ For the individual owner of purebred bulls, used both naturally and artificially, and employing custom-freezing and for persons using such semen, the problems of disease control are complex. They are difficult to overcome even with highly competent veterinary and laboratory service.

Freeze-drying of bovine spermatozoa, as is employed extensively for the storage of bacteria at room temperature has been attempted by a number of workers but without reproducible success.⁴⁶

Shipping and Handling Semen

This discussion is limited to frozen semen as so little semen is shipped in any other form. The only exception is the use of highly extended liquid semen during the short breeding season in New Zealand. Also, if a specimen is obtained for diagnostic purposes it could be extended, cooled to 5° C, packed with a bottle of ice at 3 to 5° C and brought to a Diagnostic Laboratory. Frozen semen can be transported by car, truck, bus, railroad or airplane. Most A.I. organizations have trucks carrying frozen semen and liquid nitrogen. They resupply distributor or inseminator tanks, or on-the-farm units about every 4 weeks. Some of the newly engineered tanks will hold liquid nitrogen for several months, depending upon the model and conditions of use.

Semen handling in the field is very important.^{12,58,69} The tank should always contain several inches of liquid nitrogen. Preferably it should be filled whenever the nitrogen tank is half empty. The semen should be organized with a well arranged inventory.⁷¹ This avoids having to pull canes of semen out far enough to check the bull number and possibly damage the semen. **Never pull a canister or cane of semen above the edge of the liquid nitrogen tank** to remove a breeding unit of semen. Never take more than 15 seconds to remove the unit wanted. If possible, keep the goblets containing straws filled with liquid nitrogen so that they will be surrounded by the nitrogen even in the neck of the tank. Always return the canister back to the lower level position in the tank as soon as possible. Never thaw out more ampules or straws than will be used within 15 minutes of thawing. Most problems with poor semen quality result from improper field handling of semen. Large A.I. organi-

zations have extensive quality control procedures and a reputation they protect by insuring that all semen leaving their premises is of high quality.

Thawing of semen for insemination is very important.^{58,68,69} The optimal rate depends upon the kind of extender used for freezing. One should follow the recommendations of the semen supplier in thawing the semen. Some who use milk extender recommend a pocket thaw. Thawing time is the time required to thaw frozen semen in a water bath at about 30° C. Most organizations recommend a thaw bath of 35 to 40° C. Automatic thawing devices that plug into cigarette lighters in cars have been developed. Straws will thaw in less than one minute. Ampules take several minutes to thaw.

Once the semen is thawed it should not be loaded into a very cold gun in a cold barn. The inseminating gun can be warmed slightly with the hand under cold conditions before covering with a sterile sheath. Then insemination should proceed promptly. This avoids any possible freezing of the semen after thawing which would be damaging to the sperm cells. A slight amount of cooling does not seem to be detrimental. Nevertheless it is always good practice to avoid warming, cooling and re-warming frozen-thawed semen.

If there is any doubt about how well the semen has been stored, it should be checked microscopically for the proportion of motile sperm cells. If fertility is poor this check is most important. Some semen from individual bulls may have passed through the storage tanks of several distributors. It is especially important to check the quality of this semen, particularly if it has been purchased at a premium price.

In countries or areas where liquid nitrogen is available, several manufacturers¹ provide excellent insulated tanks at a cost of \$300 to \$700 which hold up to several thousand breeding units. Smaller tanks are used for shipping frozen semen. Old tanks require refilling with liquid nitrogen every 4 weeks, depending on their size and frequency of use, and some newly designed tanks may be safe for 4 months between refills. Thus, semen may be shipped long distances by air or other means of transportation over a period of several days.

Semen is a living biological product and could carry such diseases as foot and mouth disease and other cattle diseases.^{3-6,40,42,65} Health regulations have been established in certain states and in most countries regarding the importation of semen.^{3,4,33} For those desiring to import or export semen, information and permission should

1. Cryogenic Engineering Co., 4595 Bannock St., Denver, CO 80216; Linde Co., Div of Union Carbide Co., 270 Park Ave., N.Y.C. 10017; Minnesota Valley Engineering, Inc., New Prague, MI 56071.

be requested from either the Animal Inspection and Quarantine Division, Agricultural Research Service, U.S. Department of Agriculture, Washington 25, D.C. or from the Federal or State Veterinarian located in each state. Each semen shipment must be accompanied by the proper official health charts to comply with the regulations of the country of its destination. Semen shipped intrastate usually has no restrictions placed on it unless the herd is under quarantine for an infectious disease.

Successful insemination of the cow depends upon (1) the quality of the semen used, (2) proper storage and handling of the semen, (3) a cow being reproductively healthy and in estrus and (4) use of proper insemination procedures.²⁷ Following is a discussion of the latter two points, as the first two were discussed previously.

The **optimal time to inseminate** a cow is from the middle to the end of estrus.⁷⁶ This is about 6 to 24 hours before ovulation, as discussed in Chapter XIV. With good detection of estrus near optimal conception rates were found by Foote²⁶ following the so-called A.M.-P.M. rule. Cows first seen in estrus in the morning were best inseminated the afternoon of the same day. Cows first seen in estrus in the evening should be inseminated the next morning. Conception rates were lower when cows first seen in estrus in the evening were not inseminated until the next afternoon or cows first seen in estrus in the morning were not inseminated until the next morning. In another study²⁹ cows were inseminated when first seen in heat versus a delay of 12 hours when the next heat check was made. This did not result in a statistically significant difference in conception rate. However, the pregnancy rate at the early insemination was 48 percent versus 53 percent for the insemination 12 hours later. Cows still in estrus 12 hours after insemination had a 57 percent conception rate as compared to 48 percent for those not in estrus 12 hours later. Pregnancy rates for heifers and cows in first, second, third or fourth and more lactations were 59, 51, 49, 48 and 38 percent, respectively. Ambient temperatures below 10° C or above 23° C at the time of insemination were associated with a decline in pregnancy rates. As sperm live in the cows reproductive system for 30 hours^{8,13} there does not seem to be a specific optimum time to inseminate. Also, in practice the exact time of onset of heat usually is not known. Nevertheless, with frozen sperm which do not survive as long in a test tube after freezing and thawing, it is thought that a slightly late insemination may have better chances of initiating pregnancy than an earlier one. Semen placement also affected fertility.^{41,78}

There is no doubt but what the whole aspect of cow management at insemination is important. Increased pregnancy rate occurred in beef cattle by applying cli-

toral massage immediately after insemination.⁶³ This has been confirmed with other studies in beef cattle. The technique did not affect fertility in dairy cows.⁴³

Many diarmen inseminate their own cows. If professional insemination service is not available this may be desirable. The diarmen feels that the insemination can be better timed.⁷⁹ However, it is then important for the owner to perform large numbers of inseminations and keep in practice, because many studies reveal that this is essential for best semen placement. Also, it is important that the semen inventory and liquid nitrogen level in the semen tank be carefully maintained.^{71,72} Under these circumstances the tradeoffs of convenience or inconvenience of doing one's own inseminations and conception rates that may be achieved probably balance out. But if herd fertility is low and a person on the farm is doing the inseminations, one of the possible problems is insemination techniques or improper storage of semen. This is much less likely to be the case with a professional full-time inseminator, especially if good results are being achieved in surrounding herds serviced by the same person.

Regardless of who does the insemination, the procedure is very important. One should be well-organized and have all equipment ready when thawing the semen. Thaw the semen according to the directions of the supplier. This usually will be at a temperature around 35° C. Then proceed carefully. NAAB has a checklist for new inseminators.

A comfortable clean place to restrain the animal for insemination also is important. An atmosphere of calmness is important. Sanitation also is important.³⁷ By carrying out hygienic procedures the inseminator protects the semen, the cow and himself or herself. One should not allow any contaminating materials to come in contact with the inseminating gun. The cow should be approached gently.

At the present time nearly all cows are being inseminated by the operator inserting one hand and arm encased in a rubber or plastic glove and sleeve into the rectum and grasping the cervix. Excess fecal material is paddled out. The vulva and vulvar lips are carefully wiped or, if necessary, washed and then wiped dry with cotton or a paper towel, precautions being taken to make certain that no feces are wiped between the vulvar lips. An inseminating pipette, such as the Cassou gun for straws, is inserted through the vulva dorsally and forward through the vagina and into the external os of the cervix. If folds of the vaginal wall interfere, the cervix is pulled or pushed forward to straighten the lumen of the vagina. If the external os is hard to locate, the cervix may be held by the fingers and the thumb placed over the external os; the

Ver-ebooks.com
 pipette is manipulated to touch the thumb and then into the cervix. By a combination of gently inserting the pipette and working the cervix over the pipette, it is usually readily passed one-half to two-thirds of the distance through the cervix, or into the uterine body on first services. The semen should be deposited slowly over a period of about 5 seconds. The body of the uterus is very short, so the objective is to deposit the semen on first service just through the cervix.

There has been general acceptance of the placement of the forefinger over the cranial end of the cervix on first service. As soon as the tip of the inseminating gun touches the finger, stop. Most technicians tend to inseminate too deeply. A variety of studies with dye placement and x-rays have been carried out. In one study only 42 percent of the inseminations were in the anterior cervix or body of the uterus, 42 percent were in the right horn and 4.4, 7, and 3 percent were in the left horn, posterior cervix and anterior vagina, respectively.^{57a}

Although there was no significant difference in the conception rates between the cervical or uterine body deposition of semen, semen deposition should be in the cervix when cows appear to be in diestrus, pregnant, or the cervix is otherwise difficult to pass. Intrauterine insemination could result in endometritis and a shortened cycle (Chapter XIV). If insemination occurred during the luteal phase of the cycle it could cause pyometra. Furthermore if non-motile organisms such as *Br. abortus* are placed in the cervix they do not readily become established in the uterus.⁴² The endometrium of the uterus may be injured by the pipette causing an abscess of the uterine wall. The intrauterine deposition of semen could result in abortion in pregnant cows.^{66,74,75} As many as 10 percent of pregnant cows, especially the first three months of pregnancy, show estrus.⁷⁴ Lastly, intracervical deposition of semen is more easily and quickly accomplished than is intrauterine deposition.

If semen is deposited into the uterus on first service it should be placed in the body or in both horns, or the ovaries should be examined to detect the location of the mature follicle and semen placed in the corresponding horn. This latter procedure requires great care not to rupture the follicle manually as this is usually followed by a failure to conceive. Most inseminators require about 2 to 3 months to become adept at inseminating cows. Each person should inseminate at least 500 cows to achieve high competence under different conditions. There is a significant difference between technicians and their insemination results. Conception rates may vary from 15 to 20 percent between technicians depending on their attitudes, methods of handling the cow, timeliness of insemination, care of handling semen, their techniques of

insemination and the method of record keeping.⁵⁸

Traumatization of the cervix is unnecessary and dangerous. If the pipette will not pass readily into the cervix due to its small size in virgin heifers or due to pathologic lesions or defects, the operator should make certain that the animal is in estrus, and, especially if it is a heifer, the semen should be deposited as far into the cervix as the tube can be gently or readily passed. In such instances it is probably desirable to use larger amounts of semen as some may be lost into the vagina. Using a pipette of smaller diameter might be helpful. The straw inseminating gun is smaller in diameter than the older plastic rods. Complete obstruction of the cervix or uterine horn is characterized by mucometra. It has been reported that penetration of the cervix with a pipette was not possible in 1.1 percent of 11,112 cows and 11.7 percent of 1,711 heifers, but conception on A.I. service occurred in 36.5 percent and 54 percent of these animals, respectively.⁵²

For good conception rates in herds bred artificially close cooperation and consultation is necessary between a competent veterinarian, a good herdsman, owner or manager, and the A.I. technician. If the herdsman, owner and A.I. technician are the same person then one has fewer people observing the animal. The herd should be placed on a routine reproductive examination program accompanied by good records that are reviewed periodically. Regular prebreeding or postpartum examinations of cows, pregnancy examinations, twice daily careful heat checks and records, prompt treatment of reproductive abnormalities of the estrous cycle and genital tract, and insemination of cows at the proper time of estrus with highly fertile semen are all important parts of a complete reproductive health program. With increasing herd size this becomes even more important. A good manager will find that no other program will pay greater dividends.

Measurement of the success of the insemination, such as regular pregnancy diagnoses, are important for the dairyman, inseminator and veterinarian in herd health and A.I. programs. It is also important for the semen supplier to be able to evaluate fertility of bulls and compare A.I. technicians they employ. Pregnancy results (palpation per rectum) are usually not available for this purpose. A nonreturn rate has been developed in A.I. to provide a regular basis for evaluating the reproductive efficiency of bulls and technicians.⁷ This nonreturn rate measures the proportion of cows inseminated which have not been resubmitted (returned) for another insemination within a certain time. For cows inseminated in a particular month, the nonreturn rate after two to three months (two months from the end of a particular month and three months from the beginning) is known as a 60- to 90-day

nonreturn rate. A faster cutoff in time at 30- to 60-days after insemination or with a fixed cutoff interval can be programmed easily with the high speed computers used today. Typical 60–90 day nonreturn rates with liquid semen for first services were in the low 70's and with frozen semen run just below 70.¹³ Second service cows have about the same nonreturn rate and pregnancy rate as first service cows, but conception rates decline with successive services in repeat breeders. There has been some concern that repeat inseminations with a foreign protein, such as egg yolk could cause immune reactions and infertility. However, studies⁵⁵ indicate that this is not a problem.

The submission of breeding records to an A.I. organization is essential for calculating nonreturn rates and this can provide relatively accurate information.⁵³ Nonreturn rates are higher than true pregnancy rates resulting from a particular insemination.^{7,45,53} This is because some cows are sold that are not pregnant, cows are rebred to a bull or some other source of semen is used. Because more and more semen is sold directly to herds and distributors, where there is no feedback, the fertility of semen used and general success rate achieved by an organization in the field is less well established. A.I. organizations do a rigorous quality control on semen, and this becomes more important as less reporting of fertility occurs. A.I. organizations that continue to employ their own full time inseminators have an advantage in this regard. They can maintain accurate records to compare bulls and inseminators.

Special fertility testing may also be done. Various experimental procedures are being researched to evaluate the fertility of bulls in highly efficient designs requiring fewer cows. One of the techniques is to use competitive fertilization.⁵¹ In this test semen from 2 to 3 sires is mixed and the proportion of progeny from each sire is determined later. Either color markings or blood type must be used to identify which sire produced the sperm that resulted in the calf. These types of tests require special followup and are not used with registered cattle. Some *in vitro* tests, using zona-free hamster eggs, to estimate the fertilizing ability of bull sperm or sperm from other valuable males of domesticated species are promising.

Artificial insemination in range beef cattle, if it is to be successful, requires excellent management and following practices to which many ranchers are unaccustomed. The principles are the same as for dairy cattle. Cattle in the herd are usually bred artificially with frozen semen for a period of 24 days, slightly longer than one normal estrous cycle, or preferably 45 days, two estrous cycles, with semen from a proven beef bull. The technician must be experienced. The cows or heifers to be

bred must be placed in a fairly level lush pasture confined area, free of bushes and trees and gullies so cows in estrus can be easily observed. Cows must be well fed during the last part of the previous pregnancy as well as after calving. Heifers nursing calves may require added grain or forage so that estrus will occur regularly. At least 3 pens large enough to hold 5 percent of the herd in each pen should be built near the water supply or where cattle are accustomed to feed. Connected to these pens should be a chute to hold 6 to 8 cows with a step-in gate to allow the technician access to the cows. Well-trained and experienced ranch hands who will handle cattle quietly should examine the herd carefully early in the morning when the cows first move about and again in the late afternoon or early evening. Otherwise many heats will be missed. One rider can usually observe about 200 cows in a good pasture arrangement. During the middle of the day beef cows are usually rather inactive.

Beef cows in estrus are much more quiet than dairy cows and ranch hands should observe that cows in heat tend to group together, may be nervous and walk around, tails may be slightly elevated, and mucus may be present at the vulva which may be edematous. They tend to stand behind other cows. Mounting in beef cows is much less frequent than in dairy cattle so it is harder to note cows standing to be ridden. Often the periods of estrus in the southern states and in Brahman or Zebu cattle are shorter than the estrous periods in the English beef breeds in the more northern states. Cows in estrum should be hazed slowly into the corral and holding pens for breeding. Cows must be identified and records maintained of the dates of service and the bull used. Long hard hours plus careful attention to details are highly important to good conception rates in beef cattle.^{13,14}

The use of "teaser" or vasectomized bulls has not generally been very satisfactory although some ranchers have reported success with them. The presence of a bull can increase sexual activity among cows and increase heat detection.⁹ Some use young 3- to 5-month-old beef bull calves; others use vasectomized bulls; while others use bulls with the penis truncated or deviated by various procedures which prevents copulation but does not interfere with libido. Also, a "Pen-O-Bloc," device has been used by some with variable results for detecting estrum. This device in the sheath (which is designed to block protrusion of the penis) is later removed to use the bull as a "cleanup" bull. These bulls are most effective if not allowed to run continually with the herd, but are turned out in the morning or evening whenever heat checking is done. Some ranchers use commercial "heat detector" patches ("Kamar") that may be glued to the sacrum. If the cow is mounted by another cow a dye is released

that can be easily observed. With such detectors on the rump of a cow it is desirable to run heat checking bulls or testosterone-treated steers with the cows continuously to detect cows in estrum at times cows are not observed directly. After two inseminations about 80 to 85 percent of the cows should be pregnant and one "clean up" bull for every 100 head should be turned in to breed the remaining unbred cows.

Estrous cycle regulation, with the objective of inducing animals to ovulate at a preset time has been investigated extensively.^{24,31,32} Many products have been approved for use in recent years. These include the natural prostaglandin $F_{2\alpha}$ (Lutalyse, The Upjohn Company) and analogs of prostaglandin such as "Estrumate." Various progestational agents are available. These include a silastic coil impregnated with natural progesterone (progesterone releasing intravaginal device, PRID), and a synthetic progestogen, "Norgestomet," which is combined with estradiol valerate in a commercially available product called "Synchro-mate B" (Ceva Labs.). There are many other combinations which have been tested.^{24,31} These hormonal treatments are not cures for infertility. However, the progestational agents tend to increase the proportion of suckled beef cows which will be induced to ovulate in the normal postpartum breeding period of about 50 to 100 days. Removing the calf from the mother for 48 hours has been studied extensively by Wiltbank,⁸⁰ and this increases the synchrony and number of cows that can be impregnated in a short period of time. It is very important that animals be well-fed and managed for synchronization to be effective. Recommendations of the manufacturer of each product must be followed carefully. When this is done recent studies indicate that conception rates can be as high as breeding cows and heifers at naturally occurring heats. This is in contrast to the first 20 years of work with estrous cycle regulation, when conception rates in treated groups of animals often were 10 to 20% below controls. As a consequence of current technology it is possible to group beef cattle into a tighter calving pattern and use semen from genetically superior sires by careful application of drugs to synchronize ovulation. These same techniques work especially well with dairy heifers.

Artificial insemination organizations. The large number of 100 or so small A.I. organizations in the U.S. which developed as A.I. first grew in the 1940's and 1950's have decreased due to many mergers.³⁴ Most of the semen today (outside of custom freezing) in the U.S. and Canada is supplied by about 10 large organizations. The proportion of registered cattle resulting from A.I. has increased over the years so that this technology predominates in producing dairy cattle that are registered.

The A.I. organizations and various colleges have intensive training programs to train full-time inseminators as well as herdsman's schools to train farm personnel to inseminate cows. The latter have been increasing, so a substantial part of the semen produced by these few large A.I. organizations is sold for direct service. In the high concentration areas of dairy cattle of the northeastern, midwestern and western parts of the U.S. there are still many full-time inseminators. The development and current status of organizations affiliated with the National Association of Animal Breeders (NAAB) has been described recently.³⁴

A full-time inseminator may inseminate between 2,500 and 4,500 cows per year, depending upon the density of the cow population in the area and the inseminator's reputation as a top performer. Charges for insemination service vary from about \$8 to \$10 per cow, and a second or third service may be free. However, the semen must always be purchased. This cost usually ranges from about \$5 to \$30. Semen from a few bulls highly sought because of pedigree and type, as well as production may be priced considerably higher.

At large bull studs complete uniform and regular health tests and procedures are carried out under the supervision of a competent veterinarian. The National Association of Artificial Breeders in the U.S. has adopted a Health Code of Minimum Standards³³ (obtainable from NAAB), that requires bulls to be negative to the following tests: tuberculosis, once or twice annually; brucellosis, blood tests and semen plasma tests twice annually; trichomoniasis, twice annually; and leptospirosis, twice annually. All bulls should be tested before coming from the farm to the stud; and should be placed in isolation for 4 to 8 weeks on arrival and retested. Many bulls are purchased as calves. If the bull is of breeding age six negative sheath tests for trichomoniasis are requested. For vibriosis control all studs must add the proper amounts of penicillin, dihydrostreptomycin and polymyxin B to the extended semen. Vibriosis should be eliminated from the stud since practical methods have been devised.³⁹ All A.I. studs in the U.S., Canada and several European countries are free of vibriosis (Campylobacteriosis). If a bull develops a blood titer for leptospirosis he should be isolated for 4 months and treated with parenteral dihydrostreptomycin and his blood titer should be stabilized before his semen is used. Many other diseases, particularly viruses are of considerable concern (See Chapter XVIII) to A.I. studs, regulatory officials, cattle farmers, and veterinarians. Many purebred breeders use artificial insemination within the herd to control genital disease and to be able to offer for sale semen from valuable sires. Often this is coupled with embryo transfer to produce

sons for sale and daughters for herd replacements or sale. There is an increasing demand for veterinarians to provide or advise on this type of service.

Further health requirements include general recommendations as to sanitation, investigation into the disease problems of herds of origin of newly purchased males, and elimination of bulls found to harbor genetic recessive defects. As newer knowledge concerning older diseases becomes available and new disease entities that might be spread by semen are reported, steps must be taken by the bull studs to incorporate and use this information to further protect the health of their valuable bulls and the herds of patrons using their semen. This is under continuous investigation. Monoclonal antibodies against viral diseases currently are being studied. In the U.S., custom freezing and uncontrolled sale of semen from bulls in private small herds provides a potential for wide-spread dissemination of infectious diseases. Such bulls are seldom subject to the rigid, continuing health standards enforced in most of the large A.I. studs.

With the growth of the large A.I. organizations and their major investments in genetic testing and disease control programs, the small bull rings have largely disappeared. The large organizations have highly trained personnel, well-equipped laboratories and careful quality control procedures. Thus, these are sources of semen which represent known quality. Another valuable service of the large central breeding units is the detailed recording of the fertility rates of bulls, and the collecting of data on the proof of production and the type transmitted by the bulls, so that intelligent selection of known proven sires can be made. In the large organization this makes possible the development of proven bulls and rapid improvement of the genetic makeup of cows sired by them, providing that participating members recognize the need and value of this service and cooperate with it. For further information on artificial breeding organizations the reader is referred to several of the general references listed earlier.

Blood typing of all bulls used artificially is required by the purebred beef and dairy cattle associations. There are about 70 known antigens in bovine blood of which about 50 are used routinely for blood typing. The combinations of blood antigens possible are so great that no two animals are similar unless they are identical twins. In questionable parentage cases the cow's and her calf's blood are typed. Then by a check of the blood types of the two bulls in question, one of the bulls can usually be excluded. Based on parentage tests 20 percent of cows bred artificially to two different bulls within an eleven day period conceived on the first service, while only 1 percent of cows bred to two different bulls at an 18 to

24 day interval conceived to the first service.⁶⁶ This study suggested that parentage tests are indicated when cows are bred to different bulls on consecutive heat periods, when the intervals between service dates are less than 16 days or when the gestation length from the last service for normal sized calves is shortened 8 to 10 days or more. Blood typing assures the accuracy of pedigrees and the maintenance of the purity of purebreds and has been an important factor in the growth and confidence in artificial insemination of cattle.

Artificial Insemination in the Horse

Although the horse was one of the first animals successfully inseminated by Ivanov on Russian stud farms early in this century, the practice has not become widespread because of difficulties in storing and shipping liquid or frozen stallion sperm as compared to the sperm of bulls. Also freezing stallion semen reduces fertility considerably, and most importantly there is the problem of detecting and breeding the mare at the proper stage of estrus to obtain a high conception rate. Only a few of the purebred equine breed registries recognize artificial insemination.¹ The Thoroughbred association does not permit or recognize artificial insemination except as it immediately follows a natural service to the same stallion. The Standard Bred Association and American Quarter-Horse Association permit artificial insemination on a farm with fresh unfrozen semen but do not permit transport of semen. Much work over a number of years will be necessary to develop artificial insemination of horses to its full potential. It is not likely to reach the level practised in cattle because of the scattered small horse farms, and the difficulties posed by a long estrous period and in the detection of estrus. Mares do not exhibit homosexual activities during estrus as do cattle. Detection of estrus in mares is best and most easily accomplished by teasing with a stallion.

Artificial insemination has been used to control diseases such as dourine and equine infectious anemia. Other advantages include (1) reduced chance of injuring the mare, (2) correction of bad breeding habits in stallions, (3) the possibility of evaluating each ejaculate of semen, (4) preventing overuse of the stallion (5) aiding in identification of reproductive problems, (6) permitting more mares to be bred to a particular stallion and (7) permitting use of valuable old stallions.¹⁸ If frozen semen can be improved, to have a good supply all the time, mares can be inseminated at the time to yield maximum fertility. Also, mares that have certain physical problems, and whose resistance to infection is low, may be inseminated with semen containing added antibiotics.

Semen collection has been described previously. Stai-

lions can be trained to mount a phantom²⁴ as well as a mare in estrum or one injected with estrogen. Thorough teasing of the stallion and scrubbing of the penis and sheath during the teasing period are important.²⁶ This removes smegma and other debris. Any residual water and soap should be removed with a clean dry towel. The artificial vagina (A.V.)^{11,22} is the best device for semen collection. This equipment, its assembly and use has been described in a preceding chapter and in the general texts cited previously.^{5,8,11,12}

Semen evaluation also was described previously. Care should be taken to protect the sperm from major changes in temperature or exposure to sunlight during examination and while holding until it is used for insemination. The semen may be collected with a strainer or filter, nylon preferred,^{1b} in the A.V. If this is not used the semen should be strained and volume with and without gel recorded. Also, any gross contamination should be noted. In addition the percentage of motile spermatozoa and concentration of sperm per ml should be determined. This information is needed in calculating the volume of semen required to provide sufficient sperm for insemination. In addition, sperm morphology should be noted. However, in contrast to normal bull semen stallion semen often contains more than 20 to 30 percent abnormal cells, even from fertile stallions.

Handling, extending and storing semen should be done gently, avoiding shaking and rapid changes in temperature. Normally, if semen is collected for insemination on the premises it should be collected just before the mares are ready for insemination. Fresh semen then can be used quickly without the necessity of preparing semen extenders and fertility is high.²³ If the semen is to be stored for several hours it should be mixed with an extender and kept in the dark. Sperm in raw semen held at room temperature or higher for 8 hours loses its motility.¹⁵ By mixing semen with extenders at various rates and cooling slowly to 5° C sperm has been used for several days. It was reported that 67 percent of 218 mares inseminated with extended semen conceived while 79 percent of 199 mares handled similarly, but bred naturally, conceived.¹³ The composition of the extender as well as storage time markedly affect conception rates. The number of spermatozoa inseminated also is an important factor. In one study^{9b} the mares were inseminated with (1) "fresh semen" held less than 1 hour at 39° C in a cream-gel extender, (2) semen cooled to 5° C for 2 hours in cream-gel extender, (3) semen cooled as before, but with 7 percent glycerol added and (4) semen held at 5° for 24 hours in cream-gel extender. The pregnancy rates (18 mares per group) at the first cycle were 56, 39, 6 and 28 percent, respectively. After 3 cycles the cor-

responding values were 94, 83, 44 and 56 percent, respectively. While the number of mares per group is too small to pinpoint accurately the conception rate due to each treatment, it is clear that both glycerol and storage for 24 hours were detrimental. Because cream-gel has been reported to be one of the better extenders for preserving unfrozen stallion sperm³³ this decline in conception rate emphasizes the desirability of using unfrozen semen in a relatively short period of time. There are many anecdotal accounts of using unfrozen semen after prolonged storage, but these lack controls and sufficient numbers and information to verify the success rate. This emphasizes the need for substantial research on the preservation of the fertilizing ability of stallion semen so that the most judicious use of desired stallions can be made to obtain maximum pregnancy rates in the mares.

Stallion sperm are sensitive to centrifugation.^{7,9a,25} Under certain circumstances it may be desirable to concentrate the sperm for storage or for freezing. Care should be taken to use low centrifugal forces and it was reported²⁵ that 10% seminal plasma should be retained to preserve maximum motility and fertility.

Also, care should be taken to avoid shaking and agitation of liquid semen that is to be transported or shipped. Tubes should be filled and sealed tightly to avoid agitation and leakage. Plastic bottles of ice in an insulated container should be provided to insure a temperature of approximately 5° C when extended semen is to be shipped long distances.

Equine semen extender—Horse semen, as noted in the previous chapter, is high in electrolytes and low in sugar, and sperm cells survive only a relatively few hours in the seminal plasma. Most recommended extenders that have proven satisfactory have generally supplied sugar and other protective substances. Some recommended extenders for equine liquid semen include:^{13,14,18,27,28,33}

- (1) Sterile skim milk or sterilized mare's milk prepared in a manner similar to bovine sterilized skim milk extender by heating in a double boiler to 92° C for 10 minutes. This extender can be stored frozen.
- (2) Distilled water or sterilized skim milk, to which 7 gms of glucose and 0.8 gms of egg yolk have been added per 100 ml.
- (3) Homogenized sterilized, 9 percent, cream, 400 ml, to which one-half ounce of plain gelatin in 40 ml of water heated to 145° F is added with gentle stirring while both were warm to prevent the lumping of the gelatin. Penicillin (1000 I.U.) and 1000 micrograms of streptomycin per ml are added. This extender can be frozen and stored for several weeks or more.

- (4) Hughes and Loy¹³ used a boiled skim milk diluter for extending semen and inseminating mares up to 24 hours after collection. For storing semen from 24 to 96 hours they used an extender in which "half and half" cream was heated to 95° C in a double boiler for 2 to 4 minutes. The scum was removed and the hot cream was added to 1.3 gm of Knox gelatin which had been autoclaved with 10 ml of distilled water, to a final volume of 100 ml. After cooling these two extenders, 1000 units of crystalline penicillin, 1 mg of dihydrostreptomycin and 200 units of Polymyxin B sulfate were added per ml of diluter. These diluters can be made up in advance and stored frozen in a freezer.
- (5) A dried skimmilk-glucose extender that is quite widely used for storage of stallion sperm for several hours consists of the following: 2.4 gm of "Sanalac" dried skimmilk, 4.9 gm. of glucose, 92 ml. of sterile distilled water, 2 ml. of 7.5% sodium bicarbonate and 2 ml of gentamycin sulfate.
- (6) A cream-gel extender can be simply prepared¹⁸ by adding 1.3 gm. of Knox gelatin to 10 ml. of distilled water, autoclaving and adding to 90 ml. of "half and half" cream which has been heated to 92° C. for 10 minutes in a double boiler. This can be frozen.
- (7) A Tris-egg yolk extender, modified from the bull semen extender, has been used, but fertility was lower than with cream gel.²³ However, all of the Tris-egg yolk extenders contained glycerol, which in several other studies has been found to be detrimental to stallion spermatozoa. Contrary to these earlier reports another study placed centrifuged stallion spermatozoa into a Tris-egg yolk-glycerol extender to remove the seminal plasma.¹⁰ Fertility of semen stored at 5° C was maintained for 2 to 6 days in a limited trial.
- (8) In Germany¹⁷ extensive use has been made of lactose extender modified from the Japanese lactose extender developed originally for pelleting bull semen.¹⁹ The extender has several modifications but consists basically of lactose, egg yolk, sodium citrate, EDTA, sodium bicarbonate, a detergent, glycerol, water and antibiotics (penicillin and streptomycin). It is used primarily for frozen semen packaged as pellets or large volume (4 ml) straws. Best results were obtained when the semen was centrifuged in extender, rediluted and frozen. Twelve of 19 mares conceived on a single insemination.
- (9) There have been many other extenders^{14,20,30} and references can be found listed in those cited. Many

of the reports are based on preliminary laboratory studies without fertility information.

Antibiotic additions to stallion semen have not been studied thoroughly. This is surprising in view of the potential contamination of stallion semen and the use of artificial insemination in mares which appear to be especially susceptible to infection. Equine spermatozoa appear to tolerate antibiotics commonly used for bull spermatozoa,³ such as penicillin, streptomycin and polymyxin B. In addition gentamicin is used widely. Recently amikacin² has been found to be innocuous to stallion spermatozoa. This antibiotic is especially effective against *Pseudomonas* and several other gram negative organisms. It can be combined with selected other antibiotics. It was used successfully to infuse mares before insemination.⁵ Some clinicians report that they infuse mares with extender containing antibiotic a few hours before insemination. This treatment does not seem to have been tested experimentally, but likely has the same effect as other solutions of antibiotics.

Freezing horse semen was first reported in 1957⁴ when epididymal spermatozoa were frozen in sterilized milk containing with 10 percent glycerol. One mare, of seven bred, conceived with frozen semen stored for 30 days. In 1963⁷ a technique of layering equine semen over an extender of sterilized skim milk containing glucose, fructose and egg yolk and centrifuging at 1200 rpm for 7 minutes at 30° C followed by and pouring off the supernatant seminal plasma after 95 percent of the sperm cells had been spun into the extender was reported. Further extender was added and the extended semen was cooled to 4°. Then equal parts of 20 percent glycerol in more extender was added slowly over a period of one hour. The semen was poured into 10 ml. vials, equilibrated for 5 hours and then frozen. Two of 11 mares inseminated with the frozen semen conceived. A similar technique resulted in about 70 percent recovery of sperm motility after freezing but no fertility trials were conducted.²⁸

During the 1960's experimental work with stallion semen was in progress in Pennsylvania, New York, Wisconsin (American Breeders Service) and particularly at Colorado State University, along with studies in Germany. Support for this research has been surprisingly minimal, considering its importance.

The importance of centrifugation is still controversial. If one wishes to store frozen semen in small volumes then concentration is important, and centrifugation is a convenient means of concentrating sperm. Low speed centrifugation is necessary, and possibly the retention of at least 10 percent seminal fluid during freezing is desirable. However, this may depend upon the extender

and method of freezing.^{10,17} By freezing and storing in larger volumes one can avoid concentrating the sperm at all, or it can be partly concentrated by collecting only the sperm rich fraction.⁶ This procedure also has been used by others.²⁹

The amount of cryoprotectant seems to be very important as a detrimental effect occurred in cream-gel within 2 hours of storage.^{9b} In another study¹⁰ 7.5% glycerol did not reduce fertility with unfrozen semen stored in a Tris-fructose egg yolk extender. However, with frozen semen only 1 mare out of 16 conceived during the first cycle versus 70 percent for mares inseminated with unfrozen semen. Only 7 of 16 mares had conceived after 4 cycles when inseminated with the frozen semen. Perhaps glycerol in the freeze-thaw process was more damaging than it was protective. In other studies^{14,17} 5 percent (v/v) of glycerol has been used.

Recently¹⁴ stallion semen extended with a dried skim-milk based extender with 5 percent (w/v) glucose was used to extend stallion semen to 250×10^6 sperm per ml. A portion of the semen was frozen in the lactose-egg-yolk-glucose-ETDA formula.¹⁷ Over one hundred mares were inseminated daily starting at day 2 of estrus, assigned alternately to control or frozen semen. Only 29 percent of the mares inseminated with frozen semen conceived, compared with 66 percent for the controls.

Sperm numbers may have been limiting in the trial just described, as frozen semen contained about half of the number of motile cells compared to the control. Many studies have been done to compare the number of motile sperm inseminated.^{12,21,27,33} In some studies as few as 80×10^6 motile spermatozoa produced as high a pregnancy rate as more spermatozoa. However, with frozen semen 500×10^6 sperm per insemination usually produced a higher pregnancy rate than 50 to 100×10^6 sperm per insemination. Obviously the fertility of the mare and timing of insemination may alter the response obtained with different sperm numbers inseminated. Volume of semen inseminated is believed by some to be important and generally 5 to 10 ml of semen are inseminated. However, when smaller volumes containing adequate sperm numbers are inseminated, fertility is not affected. There is great variation in the fertility of sires^{14,31,32} with frozen semen. Thus, stallions used in fertility testing with frozen semen usually are selected for the freezing quality of their semen. At the present time 300 to 500×10^6 sperm are recommended as an optimal insemination dose. Earlier studies had indicated that a billion or more sperm cells were needed in a volume of 10 to 50 ml.^{1,3,8,9,11,12} With proper detection of estrus and multiple inseminations during estrus, 500×10^6 sperm cells appear to be satisfactory. With skilled management the optimal

number of spermatozoa may be less. For convenience in insemination and to be sure sufficient volume is deposited in the uterus 5 to 20 ml is usually inseminated. With fresh undiluted semen, as is often used on Standardbred and Quarter horse farms, 5 ml of raw semen should have a sufficient number of sperm ($\geq 500 \times 10^6$ sperm) to impregnate the mare.

Insemination of mares. The mare should be in estrus. The characteristics of mares in estrus have been described many times and their quantification relative to the stage of estrus summarized.³² Winking of the vulva, crouching and urination in the presence of a teaser stallion all are positive signs of estrus. Because mares are not homosexual mares will not attempt to mount each other.

Insemination is performed on the second to fourth day. If the mare is still in estrus on the fifth or sixth day, insemination should be performed again. If the stallion semen is of good quality and fertile, insemination need only be performed every 48 hours, because spermatozoa may retain their fertilizing capacity for up to 4 to 6 days in the mare.⁸ By careful teasing, speculum examination of the cervix or rectal palpation of the follicle on the ovary and the cervix, insemination may often be performed when ovulation is expected in 12 to 24 hours. Summarized data indicated that conception rates increased in mares bred from 48 hours to within 6 hours before ovulation but declined in mares during ovulation and decreased markedly in mares bred 2 to 10 hours after ovulation.¹³ A few mares may conceive if bred or inseminated 6 to 14 hours after ovulation. There is less danger of introducing infection if insemination is performed only once, and at the most twice, during an estrus.

The administration of 2000 to 5000 I.U. of chorionic gonadotropin parenterally on day 2 of estrus usually results in ovulation in the estrous mare within 48 hours and this shortens the estrus and reduces the need for multiple inseminations. One insemination 24 hours after 3,300 I.U. of HCG gave 61 percent pregnancies in one study.³³ Under field conditions insemination every second day is common.

The mare should be suitably restrained. After bandaging the mare's tail with sterile gauze or a bandage, the buttocks, perineal region, and external genitalia are thoroughly scrubbed with mild soap and water, wiped and rinsed with clear water.

Most mares are presently inseminated with a 14 to 16 inch or 35 to 40 cm bovine plastic disposable insemination or uterine infusion pipette attached to a sterile 10 to 40 ml glass or plastic syringe. The tip of the pipette is guided alongside the index finger into and through the

cervix of the mare, which is normally relaxed at estrus. The semen or extended semen is slowly deposited into the body of the uterus. A vaginal speculum and a syringe attached to a long catheter or plastic pipette may be used to inseminate mares but it is more difficult to pass the pipette through the cervix. The cervix and uterus may be injured if too much force is used to insert the pipette or if the mare suddenly moves. Because insemination takes place directly into the uterus, great care is essential to insure that a clean source of semen is used and that a sanitary technique of insemination is followed to prevent genital infections.

In former times semen sometimes was placed in a gelatin capsule. The capsule was held in the hand encased in a disposable glove and sleeve and inserted through the cervix. This is seldom done currently. Another procedure, called "impregnation" was the placement of fresh semen into the uterus of the mare by means of a capsule or inseminating pipette and syringe after its collection from a stallion as he dismounted from the same mare after a service.¹⁶ This has been a long-established custom, done largely because of the wishes of the owners, and also to make certain that the stallion actually ejaculated as determined by microscopic examination of the dismount semen sample for the presence of spermatozoa. There is no evidence that "impregnation" or "capsuling" is of any value and there are several good reasons for not performing this operation. It is one of the most futile things done in the breeding of horses.¹⁵ The last portion of the ejaculate has relatively few spermatozoa; and there is a great risk of introducing infection. There might be a few occasions when "capsuling" or "impregnating" might be indicated, such as a small stallion on a large mare where a "good" cover was not possible.¹⁶

Artificial Insemination in Swine

Application of artificial insemination in swine is highly variable in different regions of the world.^{3,4,20,25,30,32} Substantial numbers of sows and gilts are inseminated in Russia, Hungary, Germany, France, Holland, Norway, Sweden and Denmark.² For example, in Holland and Denmark over 300,000 sows are inseminated (about 20%) and in East Germany 85% of the 1,200,000 sows are inseminated. Most of the semen used is unfrozen. In the United States there is one main supplier of boar semen for artificial insemination. About 20,000 sows are inseminated annually with commercially available semen in addition to boars collected on farms and semen used directly for insemination.

The main advantages of using artificial insemination in swine are similar to those in cattle. The first is the use of genetically superior boars that have been performance and progeny tested for such traits as rate of gain, efficiency of gain, litter size of female progeny, dressing percentage and carcass quality. One boar has the potential of siring up to 1,500 litters per year or 15,000 progeny, although they seldom achieve this potential.

The second advantage of A.I. in swine is disease control. If the boar stud is carefully tested for diseases of importance the semen may be used to introduce new ge-

netic material into specific pathogen-free herds. These include diseases such as virus pig pneumonia, leptospirosis, brucellosis, pseudorabies, tuberculosis, etc. Another advantage of A.I. is the ease with which cross-breeding can be done. A three-breed rotational cross can be used and the owner need only to select females to inseminate with semen from a different breed.

There are several disadvantages of A.I. The first is that the number of sperm cells required and volume of semen used for insemination requires that more boars be kept for the sow population than is necessary in cattle. Secondly, the price of a good boar usually is low enough that swine breeders may find it more economical to buy reasonably good boars and use natural service. Thirdly, as the value of each animal is not high, the cost of insemination may be relatively high compared to the value of the animal. This is especially true where labor costs are high, making the cost per sow expensive. Therefore, most of the inseminations, excepting where the density of pigs is high, are done by farm personnel. It is very important that swine breeders be well trained in heat detection. Thorough training of personnel in detecting estrus accurately is an essential component of a successful A.I. program in any species.

With the present economic climate it is doubtful that A.I. in swine will increase substantially in the U.S., although the use of superior boars can be shown to be profitable. The largest application appears to be either in countries where labor is cheap or herd size is small. With the improvement of conception rates when frozen semen is used it is surprising that more advantage is not taken of the gene pool available through frozen semen. The actual insemination of a sow is easily done and semen can be stored frozen in the same type of liquid nitrogen tank used for bull semen. However, the cost of boar semen is high and fertility results tend to favor natural service.^{7,11,34,38}

Collection of semen from boars for artificial insemination is done by the use of a simple artificial vagina or by the gloved hand grasping the penis¹³ as described in the previous chapter. Young boars are the easiest of the farm animals to train to mount a dummy, especially if other boars have mounted the dummy previously and the urine, smegma and semen odor is present on the dummy. Occasionally young boars may require a gilt or sow in estrus for stimulation. Older boars that have been used in natural service are more difficult to train. Collections are made at 3 to 6 day intervals or 2 to 3 times per week for best results.^{9,20,24,39,40} Some boars can continue to produce satisfactory ejaculates when collected every 48 hours.

Depending on his age and other factors³⁹ a boar will

ejaculate 125 to 500 ml of semen. The presperm fraction, which is usually heavily contaminated with bacteria due to preputial debris and fluid, should be discarded. The extirpation of the preputial diverticulum to reduce the bacterial contamination of semen at the time of collection has been recommended.² This also reduces the boar odor. Douching the sheath and preputial diverticulum and washing the skin around the external preputial orifice will help in reducing the large number of bacterial contaminants in boar semen such as *E. coli*, *Aerobacter* sp., *Proteus*, *Corynebacteria*, *Pseudomonas*, *Staphylococci*, and *Bordetella*. The gelatinous fraction should be discarded during collection or removed by straining through sterile cheese cloth. Either the sperm-rich fraction or the entire ejaculate minus the presperm and gel fractions should be used for insemination.

Using great care to prevent cold shock the semen is examined for concentration, motility and morphology.^{12,18,34} Either a hemocytometer or the photoelectric method⁹ can be used to determine sperm cell concentration in porcine semen. Most authors agree that the numbers of actively motile spermatozoa should be about 65 to 80 percent for best fertility but the relationship between fertility and motility is not high. Fertile boars, especially those in heavy use, may have up to 20 percent or more proximal protoplasmic droplets, but a high percentage of proximal protoplasmic droplets may be associated with infertility. Occasional sterile boars may have a very high percentage of acrosomal defects. Although this defect is usually considered to be hereditary, it might be acquired.²⁰ A typical ejaculate of boar semen would have 200 ml of gel-free volume, 250×10^6 sperm/ml, 70% motile sperm and 15% total sperm cell abnormalities.

Extension of boar semen is based, as in cattle, on the number of actively motile spermatozoa required for optimum conception rates. According to a number of authors³² this varies from 1 to 10 billion actively motile spermatozoa per insemination. Most recommend 5 billion or more. Fairly satisfactory conception rates occurred with 2 to 5 billion per insemination. Thus 10 to 20 sows may be inseminated per ejaculate. During the past several years International Boar Semen, in 10,000 semen collections, has averaged 120 billion sperm per week on a schedule of 2 ejaculates per week. With their recommended dose of 4 billion sperm per week one boar can produce enough semen to inseminate 30 sows per week. Conception rates including size of litters are also influenced by the volume of the extended semen inseminated and the length of storage time before insemination.⁶ Most authors recommend 50 to 100 ml of extended semen per insemination.

Extending boar semen. Boar semen is usually extended from 1 to 1 up to 1 to 8 times, depending on the concentration of motile spermatozoa and the volume of the ejaculate, with warm extender at 37° C immediately after collection. Slow cooling and the addition of phospholipids to the semen protects the sperm cell and aids survival. For use in a liquid semen program the extended semen is cooled gradually to 12 to 20° C (54° to 65° F), which is the optimal storage temperature for boar semen. This temperature requires special packaging for field use. Others cool the ejaculate slowly to 12° to 20° C and then add the extender at the same temperature. When boar semen is cooled to 4° to 5° C within 1 to 2 hours, many sperm cells lose their motility even if extenders have been added. In sperm-rich fractionated semen this harmful effect of cooling is much less pronounced. The addition of egg yolk or milk to boar semen prevented injury to sperm cells at 5° C.⁴ Temperatures of 35° to 38° C are definitely unfavorable to porcine sperm cell survival.

A variety of different types of egg yolk or heated milk extenders have been used to store boar sperm in the liquid state.⁸ Because of the relative difficulty of freezing boar spermatozoa the majority of inseminations are with liquid semen. This semen is useful for up to 3 days of storage.

Frozen boar semen for insemination was given considerable impetus in 1970 when it was reported³³ that a high fertilization rate could be achieved by surgical insemination into the oviducts. For freezing boar semen it is desirable to concentrate the semen by centrifugation in order to have enough sperm cells in a small volume. Several procedures were developed in the early 1970's which produced moderately successful conception rates.^{7,10,15,22,24,26,34,42} In Minnesota^{10,34} the sperm rich fraction was collected and slowly cooled to 22° C. It was determined that exposure to seminal plasma was beneficial to the survival during freezing so the semen was held at 22° C for 1 hour. Thereafter an organic buffer, glucose, sodium citrate, egg yolk and 0.5% of a detergent were added. Semen was cooled to 5° C and pelleted. Considerable attention also was given to thawing.^{8,16,35,36} In the Minnesota studies pellets were initially thawed at 65° C. In Sweden a similar procedure was developed. The final concentration of glycerol was 2.5% (v/v). Sperm were frozen in 0.1 ml pellets. Thawing is done with seminal plasma or other thawing extenders. Thawing media are at 65° C initially but the addition of many pellets results in a final temperature of thawed pellets of about 32 to 34° C.

A series of Beltsville extenders has been developed. One tested widely in the field is BF5.^{11,34} This extender contains Tris, Tes, dextrose, 20% egg yolk and 0.5 per-

cent Orvus Es Paste (a detergent). The semen is held at 22 to 24° C for two hours, centrifuged at $300 \times g$, extended in BF5 to a sperm concentration of 1.2×10^9 sperm/ml. Semen is cooled to 5° C over a period of two hours. Then BF5 containing 2 percent (v/v) of glycerol is added in equal amounts, giving a final sperm concentration of 0.6×10^9 /ml and 1 percent (v/v) glycerol. The semen is then frozen directly by placing 0.1 ml in predrilled dry ice to produce pellets.

It is clear that there are many variations in freezing procedures. All involve certain principles.¹⁰ First, boar semen develops resistance to coldshock by being exposed to seminal plasma. Secondly, seminal plasma is removed before final cooling to concentrate the sperm and cooling must be done slowly. Third, the concentration of electrolytes in the extender should be kept low. Fourth, low glycerol concentrations assist in protecting sperm during freezing, but the glycerol level must be kept low as it is harmful to boar sperm.²³ Finally, by concentrating the sperm the number required for insemination can be frozen in small packages (pellets) for rapid thawing.

Antibiotics should be used to control the large number of bacteria in boar semen stored at near room temperatures.^{29,37,41} Usually 500 to 1,000 I.U. of crystalline penicillin G and 500 to 1,000 micrograms of dihydrostreptomycin per ml of extended semen are recommended. Neomycin, polymyxin B and sulfadiazine are also of value. Improved conception rate and litter size was reported when antibiotics were added to extended boar semen.³² Recently, several of the newer antibiotics such as amikacin and gentamicin have been reported to inhibit bacteria in semen stored at 15° C for many days.³⁷

Detection of estrus and timing of insemination are of critical importance in obtaining good conception rates and litter size in artificial insemination of female swine. Gilts and sows should be observed for estrus twice a day separate from the time of feeding. In this regard the owner's or herdman's and inseminator's judgement, and experience and skills of observation are highly important. Swelling and slight reddening of the vulva in sows and gilts persist for 2 to 3 days of proestrus, 2 to 3 days of estrus and for about 2 days of postestrus, with maximum swelling generally seen at the onset of estrus. The degree of swelling of the vulva alone is unreliable. At the proper time for insemination the vulva is less swollen and more wrinkled and a clear or creamcolored flecked mucus is usually present in the lower vulvar commissure. The gilts and sows often become more restless and noisy during estrus. A method to aid in heat detection consists of approaching the female quietly, placing the flat of the hands on the loins and exerting moderate

downward pressure.¹⁹ If the sow moves away the hands and arms are placed between the hind legs and the rear parts are lifted off the ground, simulating the action of a boar toward a sow in estrus. After a few minutes some sows will stand in a saw-horse attitude (lordosis) when back pressure is applied. If possible the owner, herdman or technician should mount the female and sit astride the loins and remove the feet from the ground. Clawing the shoulders, digital manipulations of the clitoris or inserting the insemination pipette into the vagina will induce the state of sexual receptivity if the sow is in estrus. At this time most sows will stand very quietly and may be nearly insensible to extraneous stimuli. If sows do not show the above signs of estrus, insemination should not be performed as conception rates are apt to be low and litter size reduced due to faulty timing in relation to ovulation. Sows and gilts inseminated during the period of standing reflex, indicating the peak period of estrus, had conception rates of 73 and 61 percent compared to 41 and 46 percent in those sows not showing a good standing reflex.⁷ Sows and gilts should be bred without restraint.

The presence of a boar is very helpful in heat detection. Both the preputial odor of the boar and his vocalizations evoke external behavior signs of estrus in the sow that can be confirmed by hand pressure on the back. A vasectomized boar may be used as a aid in detection of estrus. Also, a boar in a pen adjacent to where the females are being checked for estrus will help evoke signs of estrous behavior.

Lactating sows in good physical condition when weaning their pigs should be watched closely for estrus starting about the third day postweaning. Most sows come into estrus about four to seven days after their pigs are removed. Synchronization of breeding sows can be accomplished by weaning a group of sows at the same time. For best results in insemination of gilts they should not be bred until they have been in estrus twice or more, weigh 280 pounds, or are 8 months of age.

Reports,^{4,24} indicated that the duration of estrus proper averaged 55 hours for gilts and 70 hours for the sow. The time of ovulation was 25 to 36 hours after the onset of estrus. Spermatozoa in the sow retained their fertilizing ability up to 25 to 30 hours. The best time for insemination with unfrozen semen was about 12 hours after the onset of estrus with a second insemination 12 hours later, if the sow or gilt was still in estrus. With frozen semen, it is recommended that gilts be inseminated 16–20 hours after onset of estrus and sows 22 to 26 hours after onset of estrus. A second insemination 12 hours later is recommended. Although under research conditions one well-timed insemination may be sufficient, 2

inseminations under field conditions improve conception rates 15 to 20 percent and litter size by one pig per litter.⁷ This procedure is costly and not necessary if close careful observations and tests for estrus are made.

Three types of insemination catheters and techniques used for inseminating swine have been described.⁸ One type was designed to seal the sow's cervix so no semen flows back into the vagina as the semen is infused. This type is made of rubber about 1.0 to 1.5 cm in diameter and 45 to 50 cm long. The anterior end may be tapered, end in a pear-shaped bulb, or have a corkscrew configuration,²¹ that is pressed with gentle pressure or rotated or twisted counter-clockwise into the cervix. In the latter case the catheter is not easily dislodged. A 7 to 8 mm diameter catheter with an inflatable cuff about 4 to 5 cm posterior to the tip has been devised.¹ The second type of pipette is designed to penetrate through the cervical canal and into the uterus. The diameter of this plastic or nylon tube with a bent tip is 4 mm. It is rotated with gentle pressure to negotiate the cervical canal. The third type is a combination of the two types, consisting of a double plastic tube. The outer tube is 1 cm in diameter and engages in the cervix while the smaller inner catheter is rotated to the left as it is pressed forward from the larger tube. All types of insemination catheters should be inserted dorsal-cranially through the vulva to avoid entering the urethra.

Presently most containers for holding and transporting extended boar semen are plastic bottles and bags that can be attached to the insemination pipette and used to expel the semen. The larger volume of extended semen is squeezed gently over a period of 3 to 5 minutes into the cervix and uterus of the sow. Most workers reported that after a minute or so the semen goes into the sow very rapidly without resistance.

Miscellaneous factors. The results of artificial insemination in swine were more successful in sows than in gilts. Most workers presently report a 50 to 70 percent farrowing rate on first service using single inseminations of fertile semen inseminated correctly at the proper stage of estrus. Conception rates for a single natural services are 80 to 90 percent. With 2 inseminations in one estrus 70 to 80% will conceive.

There are many factors affecting fertility in A.I. Differences among boars is one of the major ones. Frozen sperm are believed not to survive as long in the female reproductive tract. Therefore, timing of the insemination and expert detection of estrus are critical.¹⁴ Finally, the deposition of most sperm into the uterus with minimal loss also is important.

Estrus and ovulation synchronization in swine has been the subject of much research in recent years be-

cause of many desirable features in swine management possible if this could be successfully employed.⁵ The only natural synchronization observed and practiced in swine is that achieved by weaning pigs from sows. Estrus usually follows weaning by 4 to 7 days. One study reported 2 percent of sows were in heat before the fourth day, 12 percent on the fourth day, 35 percent on the fifth day, 16 percent on the sixth day, 16 percent on the seventh day, 6 percent on the eighth day and 13 percent on the ninth to fourteenth day, or 79 percent from 4 to 7 days post-weaning.¹⁹ When young pubertal gilts are transported and placed in a new environment, estrus may develop in up to 70 percent of the gilts within 5 to 10 days due to the induced stress. Early studies on hormonal control of estrus in gilts and sows with gonadotropins, estrogens and progesterone or progestational agents have not been very satisfactory, often because of the production of cystic ovaries.

At one time an excellent synchronizing compound known as I.C.I. 33828 or "Aimax" was available and provided excellent synchronization. However, it was discovered that if this compound was inadvertently administered to pregnant sows early in gestation fetal anomalies were produced. Thus, this compound was hastily withdrawn from the market.

Prostaglandins are not as useful in swine as most other species because the corpora lutea of sows seem only to be susceptible to luteolysis on days 11 to 12 or 14 to 15. One way to overcome this is to administer PMSG or HCG to induce accessory corpora lutea and postpone estrus. Then 12 days later the administration of prostaglandin often will cause regression of the corpora lutea and induce a fertile estrus.

For sows nursing pigs, several can be weaned at the same time after about four weeks of age. Most sows will be in estrus within 2 to 3 days of each other. Then at the other end of pregnancy experimental work with prostaglandin and relaxin may synchronize farrowing so that most pigs can be scheduled to be born Monday through Friday. Further studies are indicated and if synchronization becomes feasible then practical management factors such as the number of boars available for A.I. or natural service, problems of heat detection if A.I. is to be used, the size of the farrowing house, and other factors must be considered.

Artificial Insemination in Sheep and Goats

In the United States artificial insemination in sheep and goats has not generally passed from the experimental to the practical stage, although technically it has been

feasible for a long time.^{18,23,27,30} Artificial insemination with frozen goat semen has been used in a few goat dairies. In Russia, sheep have been artificially inseminated on a large scale for many years. In Australia, Argentina, Peru, France, East Germany and several countries it has been successfully practiced on a large scale. The advantages and the disadvantages of artificial insemination in sheep are much the same as in cattle. Probably the greatest disadvantages are its high cost when compared to natural service and the difficulties associated with detecting and separating estrous ewes for insemination. With the current success in synchronizing ewes and the development of frozen semen, A.I. could make economical use of the best rams if sheep producers were properly trained to collect semen and inseminate ewes.

It is very important that rams and bucks used for artificial insemination be highly fertile in order to provide the maximum number of inseminations with a high conception rate. Collection of semen by means of an artificial vagina is the preferred method. For rams not trained to the artificial vagina, electroejaculation can provide a satisfactory semen sample.³ Usually a fertile ram or buck can be collected 2 to 6 times or more daily to provide an adequate number of spermatozoa. There is only a moderate decrease in the number of sperm per ejaculate as the ram only ejaculates a limited volume of highly concentrated sperm. A typical ejaculate would contain 0.5 to 1.0 ml of semen with a sperm concentration of about 3 billion cells per ml.

Much of the artificial insemination of ewes is done with freshly collected semen.^{23,25,27,30} Semen should not be chilled if it is to be used immediately. In warm weather (above 20° C) the semen can be allowed to cool to ambient temperature or it can be maintained in warm water at 35° to 37° C. Excellent fertility can be obtained with ram semen used within a few hours as long as sufficient sperm (at least 100×10^6 sperm) are used in well-timed inseminations. This requires only 0.05 to 0.1 ml of normal fresh ram semen to provide this many sperm cells.²¹

If unfrozen semen is to be held for several hours before use,^{19,31} it can be extended at low rates of 1:1 up to 1:10 with heated skimmilk, heated homogenized milk or various combinations of 5 to 20 percent egg yolk with 2.9 percent sodium citrate dihydrate. Sometimes 0.5 to 1.0 percent glucose is added to this solution. Also Tris-yolk extenders, similar to those used for bull spermatozoa, have been used successfully. In glucose-saline buffers best results were obtained with only 1.5% egg yolk or less.³² Storage was at 5° C. When semen is to be stored for several hours it is especially important to use a large number of spermatozoa for insemination. In one study in which 25×10^6 versus 100×10^6 sperm cells were used for insemination fertility had declined

after 5 hours of storage at 5° C, with the greatest decline when only 25 million sperm cells were used. Storage for 48 hours resulted in near zero fertility. However, Salamon²³ compared the fertility of semen extended with a 300 mM Tris, 27.8 mM fructose, 95 mM citric acid plus 14 percent egg yolk when used fresh versus storage for up to 8 days. Then sperm were deposited surgically into the uterine horn. The inseminating dose was 200×10^6 sperm. The percentages of cleaved eggs when semen had been used after 0, 2, 4, 6 and 8 days of storage at 5° C were 95.5, 94.4, 91.3, 75.0 and 52.9. Corresponding samples inseminated normally (into the cervix) after 0, 2 and 4 days of storage at 5° C resulted in 62.5, 40.0 and 0% cleaved eggs. Thus, it is clear that the fertilizing ability of ram sperm can be maintained for many days at 5° C, but the ability for these sperm cells to pass the cervix and be transported to effect normal fertilization is lost rather rapidly during storage.

There has been considerable success with **frozen semen**.^{4,20-23} Again, part of the disappointing results with early frozen semen tests was the greater difficulty in frozen sperm passing the cervix as compared with unfrozen sperm cells. It has been recommended that ewes be tested for the possibility of intrauterine semen deposition via the cervical canal before expensive frozen semen is used. The repeatability of penetration was 0.745.¹³

The extenders used for frozen semen are similar to fresh semen with the addition by glycerol.⁸ Pellets have been found to give good results with raw sperm frozen in a lactose or raffinose extender (166 mM raffinose, 68 mM sodium citrate, 15 percent by volume egg yolk and 5 percent by volume glycerol). After five years of storage at -196° C the lambing rate was 53 percent compared with 54 percent for frozen semen stored for two weeks.²⁸ Maxwell *et al.*²⁰ used a triscitric acid-glucose-egg yolk extender with 6 percent glycerol. Lambing rate with unfrozen semen was 83 percent compared with 55 percent for semen frozen in pellets. In another experiment comparing semen frozen in pellets versus straws the lambing rates were 52 and 29 percent, respectively.

It is apparent that the fertility obtained with A.I. depends upon the extenders used, whether semen is used fresh, cooled and stored or frozen, how it is frozen and thawed,⁴ the number of sperm cells inseminated and the season and fertility of the ewes. Optimal insemination time is 12 to 24 hours after the onset of estrus. With fresh semen 100×10^6 sperm are recommended. With stored or frozen sperm 300×10^6 motile sperm are recommended. If the timing of the insemination is ideal one insemination is sufficient,²⁴ but many studies,¹⁶ particularly in the field result in marked increases in fertility with a double insemination.

The most difficult problem to solve in artificial insemination

ination of sheep is the handling of large numbers of ewes under flock conditions, while still detecting and sorting for breeding the ewes that come into estrus. Rams with aprons, or vasectomized teaser rams may be turned in with the flock of ewes or led through the flock once or twice daily. Vasectomized rams remaining with the ewes can be painted on the brisket or wear jackets holding different colors of paint or chalk to mark the rump of the ewes that are in estrus. Marked ewes are sorted from the flock daily for insemination. This latter procedure has proven most satisfactory for large flocks. Ewes and does in estrus will often bleat, switch their tails rapidly, have an edematous vulva, seek out the ram or buck and stand to be mounted. Does in estrus only occasionally mount each other. Normally estrus lasts about 30 to 36 hours in the ewe and possibly a little longer in the doe. Ovulation occurs late in estrus.

Insemination should take place the last half of estrus. If insemination is to take place only once in a heat period, this should be about 12 to 18 hours after the onset of estrus. Spermatozoa survive about 30 hours in the ewe's genital tract. For insemination the ewe should be placed in a crate that holds her securely and makes examination and insemination easy for the operator. Insemination is accomplished by lubricating and inserting into the ewe's vagina a pyrex glass speculum about 18 cm. (7 inches) long, and 2 cm. (7/8 inch) in diameter. By means of a head light, flashlight, or speculum light the cervix is located and a graduated pipette attached to a syringe is introduced into the cervix and the semen deposited. A speculum with a built in light source is very convenient. Plans and procedures for the artificial insemination of large numbers of sheep have been outlined^{8,12} as management is highly important for saving labor and for good conception rates. It has been demonstrated that if artificial insemination of sheep and goats is carefully conducted during the natural breeding season the results will compare favorably with those produced by natural mating.

Synchronization of estrus has been discussed elsewhere and descriptions can be found.²¹ It is equally important with synchronized ewes to have all conditions optimal, including insemination with at least 200×10^6 sperm.¹⁶ Under proper management conditions ewes can be synchronized and a large number inseminated successfully with semen from high quality rams. Under the usual conditions on farms, natural breeding with good quality rams has been more successful.

Goat A.I. can be carried out in a manner almost identical to sheep. It has one distinct advantage for the owner of a small flock of does with close neighbors. The strong buck odor can be eliminated if the owner desires to use

A.I. to impregnate the does. There are many recent publications on artificial insemination in goats.^{10,11,14,29,30} Results can be very successful. In Norway Fougner^{10,11} reported that buck sperm frozen in Tris-citric acid-yolk extender developed for cattle gave a 63.4 percent conception rate when 3,240 does were inseminated in utero with 75×10^6 sperm. A similar extender has been used in Australia.²⁶ There is a lysolecithin compound in goat seminal plasma which may cause coagulation in egg yolk extenders containing sodium citrate, but this may not be a problem with Tris-buffered egg yolk. Corteel⁶ has eliminated this problem by centrifuging the semen and removing of the seminal plasma. This procedure is generally recommended. He also used milk extender containing 100 gm of skimmed milk powder, 0.194 g. of glucose, antibiotics and 100 ml. of distilled water in the final extender. This extender is heated to 85° C for 10 minutes and cooled. Semen should be extended prior to centrifugation to remove the seminal plasma and then extended again so that there will be 100 million motile sperm per insemination dose. Convenient packages for freezing semen are the 0.5 ml or 0.25 ml French straws manufactured for freezing bull spermatozoa.

For insemination the doe should have the hind quarters elevated over a bale of straw. Or one person can grasp the doe by the hind legs, hold the head down between ones legs and elevate the hind quarters. This provides an ideal position for a second person to insert the semen through the cervix, if possible. The use of a speculum and head lamp is useful in locating the cervix. Experienced inseminators achieve a higher penetration of the cervix and a higher kidding rate (Aamdal).² The insemination should be performed 12 to 24 hours after the onset of estrus.

Does can be synchronized when cycling during the breeding season with progestagens¹⁵ or prostaglandin. The most thoroughly tested method is to insert intravaginal sponges which release a progestagen for 16 days. Administration of 400–600 IU of PMSG at the time of sponge removal brings most animals into estrus within two or three days. A discussion of the various procedures for does both during and outside the breeding season is given by Smith.^{29b}

Artificial Insemination in Dogs

Artificial insemination is performed most commonly in dogs for reasons that prevent or interfere with copulation.¹³ These include: shyness or fright on the part of either the male or female in the presence of their partner, lack of libido often associated with sexual inexperience in the male or for pathological reasons, including premature erection preventing intromission, phimosis due to a small preputial orifice, painful lesions such as arthritis, spinal lesions, acute prostatitis, and exhaustion especially in obese, young or old, inexperienced dogs on hot humid days. It may also be used for the control of infectious diseases such as caused by *Brucella canis*. The American Kennel Club has not encouraged the practice of artificial insemination, but will allow it to be performed under certain restrictions and stipulations, including the issuance of an affidavit by the sire's owner certifying that he witnessed the collection of semen and the insemination by a licensed veterinarian, and another by the veterinarian certifying that he performed the collection and insemination in the presence of the sire's owner. The male and female dogs are identified and the time and place of insemination is indicated. Relatively

little controlled experimental work has been done with artificial insemination in the dog but the techniques of semen collection and insemination are fairly simple^{1,6,9,10,12,13} and the procedure is often employed by veterinarians.

The favored method of semen collection is by digital manipulation of the penis, with or without the presence of a teaser bitch, to produce ejaculation.^{6,10,12} Semen may also be collected by means of the artificial vagina. A special vagina has been designed with a closed balloon in the space between the liner and casing attached to a bulb which, when squeezed, caused a pulsating pressure on the penis simulating the contractions of the vulva of the bitch.⁹ This artificial vagina could be used with or without a teaser bitch. In contrast to the good results reported with this A.V., another study¹ reported poor motility in the semen collected with the artificial vagina possibly due to overheating of the spermatozoa in the vagina. Digital manipulation is simpler and requires less equipment and produces as good or better semen samples. Dogs may be collected every other day without loss of semen quality. Good quality canine semen should have 70 to 90 percent actively motile sperm cells, less than 10 to 20 percent abnormal cells and a concentration of 90 to 300 million or more spermatozoa per ml, depending upon the amount of prostatic fluid collected.

Semen should be collected in a warm funnel and a 20 ml warmed test tube or a 20 to 30 ml warmed syringe from which the barrel has been removed. Immediately after collection the semen should be placed in warm water at 35° C. if it is not to be used promptly. Undiluted semen, *in vitro*, usually survives about 20 hours. Spermatozoa in extended semen remains viable and capable of fertilizing ova for 4 to 5 days if stored at 5° C. or 40° F.^{9,12} Harrop⁹ preferred heating pasteurized homogenized milk to 92° C. for 10 minutes. The albuminous scum was removed and 500 µg of streptomycin per ml was added. This extender was used at an extension rate of about 1 to 8, with the semen and extender both at either body temperatures, room temperature or refrigerator temperature when added together to avoid cold shock. Foote⁴⁻⁷ reported that the best extender for canine semen was 20 percent egg yolk in a buffer solution composed of 1.45 gm of sodium citrate dihydrate, 0.93 gm of glycine, and 1.25 gm. of glucose per 100 ml of distilled water. The extension rate was 1:10 to 1:20. Each ml of buffered-egg yolk extender contained 1000 units of crystalline penicillin G. and 1 mg of dihydrostreptomycin. This extended liquid semen could be stored at 40° F. or 5° C. for 24 hours before insemination. Good motility was still present after 4 days but no fertility trials were made. Subsequently,⁸ use of the same tris-buffered

egg yolk with glycerol, as is used for cattle, resulted in high pregnancy rates when semen was stored for 24 hours at 5° C. From 100 to 200 × 10⁶ motile sperm per insemination were required. There were no pregnancies with frozen semen. It has been demonstrated that milk extended liquid semen may be shipped over long distances and produce conceptions.⁹

The first successful pregnancies from frozen canine semen was 1969.¹⁷ There have been several reports since that time.^{13,14} Some have used a lactose-egg yolk method devised for pelleting bull semen.¹⁷ Others have used the tris-fructose-citric acid egg yolk extender also developed for bull semen. Semen can be packaged in 0.25 or 0.5 ml straws. After cooling the semen, it can be frozen similar to bull semen. Considerable research still is needed because there is little quantitative evidence of the success rate with frozen canine semen.

Insemination should be performed with undiluted or extended semen 24 to 48 hours after the onset of the estrus. That is the time when the bitch will accept coitus by the dog. A second insemination given one to two days after the first may increase conception rate. Usually at this stage the vulva is still swollen, the vulvar discharge is frequently clear instead of hemorrhagic as in proestrus, and vaginal smears reveal many cornified epithelial cells and few red blood cells. The bitch usually ovulates by the second or third day of estrus, but the ova require several days to mature and shed the polar bodies. Spermatozoa survive 4 to 6 days or more in the female genital tract.² Conception is less likely late in estrus or early in postestrus when many leucocytes are present in the vaginal smear. Vaginal smears may be taken with a cotton swab on a six inch applicator stick, placed on a slide and stained with Wright's or other stain.

A sterile plastic inseminating tube, or pipette, about 20 cm. (8 inches) long and 6 mm. in diameter is fixed to a syringe and the semen is drawn into the syringe. A bovine plastic inseminating pipette broken in half makes a good canine inseminating tube. Most bitches in true estrus stand quietly to be inseminated even though previously they may have resisted normal mating. They should be placed on a table of proper height and held by an assistant. The external genitals are washed and dried. Some veterinarians use a lubricated vaginal speculum and light to locate the cervix, and the insemination tube is placed at or into the cervix where 5 to 10 ml or more of undiluted or extended semen containing about 200 million actively motile spermatozoa should be deposited. Most operators insert the insemination tube without a speculum. In this technique the insemination tube is inserted between the vulvar lips and directed in a dorsal direction until it passes into the vagina. It is then di-

rected horizontally and gently pushed to or into the cervix. It is desirable to elevate the rear parts of the bitch for 3 to 5 minutes after insemination to prevent the possible loss of semen. A finger covered with a sterile finger cot may be inserted into the vagina and the dorsal wall gently stroked or "feathered." This appears to promote the passage of the semen into the uterus. Usually 60 to 80 percent conception rates are realized by artificial insemination with fertile dogs using unfrozen semen. A technique for intrauterine insemination has been described.¹³

Artificial Insemination in Cats

Studies on the reproductive physiology and insemination of cats has been very limited because of their general economic value, and the belief that cats are difficult to handle, especially during mating. Sojka *et al.*¹⁸ described successful procedures for the insemination of cats. Donor toms were selected on the basis of their libido and temperament when a "teaser" queen was placed in the tom's cage. Teaser queens were either normal females in estrus or ovariectomized females that had been given 1.25 mg. **Repositol** diethylstilbesterol subcutaneously every 10 days to produce estrus and acceptance. The selected toms required about 2 weeks of training by a technician to get them to ejaculate routinely into an artificial vagina.

The artificial vagina was made by cutting off the bulb end of a 2 ml rubber bulb-pipet and fitting a 3 × 44 mm test tube into the cut end of the bulb to make a water tight system. The artificial vagina is then placed in a 35 × 75 mm (60 ml) polyethylene bottle filled with water at 52° C. to maintain a temperature of 44 to 46° C. at the time of collection. The rolled end of the rubber bulb-pipet is stretched over the rim of the bottle and the opening of the vagina is sparingly lubricated with K-Y jelly. The artificial vagina is slipped over the penis of the tom as he mounts the teaser female and develops an erection. The technicians other hand is used to steady the tom and queen.

The volume of the ejaculate varied from 0.01 to 0.12 ml, with an average of 0.04 ml.¹⁸ The sperm cell numbers per ml of ejaculate varied from 100 to 5,100 × 10⁶ with an average of 1730 × 10⁶. The total sperm numbers per ejaculate varied from 3 to 143 × 10⁶ with an average of 57 × 10⁶. The motility varied from 35 to 100 percent with an average of about 80 percent. Collection of the semen takes about 1 to 4 minutes with a trained tom. Toms could be collected 3 times a week on a regular basis or daily for short periods and maintain good semen quality. Methods of electroejaculation have been re-

ported.¹⁵ The average volume for 303 ejaculates from 17 toms was 0.23 ml, with a mean of 28 × 10⁶ sperm per ml ejaculate and 60 percent of the sperm being motile. The toms were anesthetized with ketamine hydrochloride (33 mg/kg of bodyweight). Thus, semen collected with the electroejaculator had a higher volume, much lower sperm concentration and fewer sperm per ejaculate, than semen collected with an artificial vagina.

Females bred by artificial insemination can be checked for estrus daily by stroking them on the neck and down the back to the base of the tail and by gently rubbing the perineal region. A queen in estrus will crouch on its sternum, elevate the pelvis, raise and laterally deflect the tail, extend the hind legs, tread with the hind feet and press against the hand when it is held over the pelvic region. Estrus can be confirmed by vaginal smears which contain only large, cornified cells during the height of estrus. Queens are induced ovulators. Queens in full, natural estrus were stimulated to ovulate by the intramuscular injection of 50 I.U. of HCG.¹⁸ The queen was also inseminated at this time by placing 0.1 ml of the saline-diluted semen containing 50 × 10⁶ spermatozoa into the anterior portion of the vagina with a 20 gauge needle, 9 cm long, bulbed at the end with silver solder to make it blunt and attached to a 0.25 ml syringe. A second insemination 24 hours later increased the conception rate.

These authors¹⁸ found that all queens in estrus would ovulate 26 to 27 hours after the injection of HCG. Successful matings occurred up to 49 hours after HCG injection. The queens would accept toms up to 55 hours after the injection. It was also reported that queens in full estrus could be stimulated to ovulate by probing the cervix with a glass rod. This, and the act of artificial insemination at the time the rod or pipette contacted the cervix, often resulted in a characteristic yowl followed immediately by an attempt to lick the perineal region. Thus, the spines on the penis are probably not the cause for this postcoital reaction in the female.

Conception did not occur in queens inseminated with less than 1.25 million spermatozoa. The conception rate was 54 percent (14/26) with 5 to 50 million spermatozoa per insemination. In these insemination experiments¹⁸ the gestation periods ranged from 65 to 72 days, which is nearly a week longer than the 56 to 63 day period that follows natural matings. This should receive further study. Thus, by artificial insemination outstanding toms could be used to breed 12 to 15 queens per ejaculate, compared to natural mating conditions where one tom is usually kept per 15 to 30 females.

There are limited data on freezing feline spermatozoa.¹⁶ Semen was collected 6 months by electroejacu-

lation followed by 6 months with an artificial vagina. The extender was composed of the one used frequently for pellets, containing 20 percent egg yolk by volume, 76 percent of a 11 percent (w/v) solution of lactose and 4 percent by volume of glycerol. Semen was pelleted. Subsequently 56 queens were inseminated in estrus with 50×10^6 or 100×10^6 motile sperm. Six became pregnant, one from semen obtained by electroejaculation and 5 from semen collected with an artificial vagina. Pregnancies lasted 65 to 71 days, with 1 to 4 kittens per litter.

Other Species

Semen collection and artificial insemination has been reported for many other species.^{2,3} One ruminant of considerable importance in many countries is the buffalo.¹ Many of the techniques developed for cattle are useful in buffaloes. However, libido may be less and there are many problems associated with collection of semen from males and detection of estrus in females. Part of the latter problem is associated with the small group of females and their general management in areas where buffaloes are kept. When A.I. is properly carried out, semen can be preserved and females impregnated successfully.

Artificial insemination has been used by geneticists for multiplying stocks of chickens for decades. This technique is standard practice in the turkey industry where selection for extensive breast meat has resulted in difficulty in natural mating. There are hundreds of references in this field. To date most of the inseminations involve freshly collected semen as fertility declines rapidly with storage. Fertility is reduced by freezing the sperm cells.

Currently, the information on artificial insemination is very fragmentary for most non-domestic species. There is great interest in using this technique to perpetuate endangered species. It has been used quite successfully in several species. One of the problems in mammals, even when semen has been collected and apparently frozen successfully, is to be able to detect estrus in the female. One of the species of great interest which has been reproduced by artificial insemination in China is the great panda. Experiments with this species and many others have been initiated in recent years at several of the large zoos around the world and preliminary success has been reported in the popular press.

Chapter XX

EMBRYO TRANSFER

By Maarten Drost, DVM*

History

Nearly a century has passed since Sir Walter Heape in 1890 successfully transferred the first fertilized ova between rabbits.²² A number of viable transfers were subsequently reported for laboratory animals such as guinea pigs, mice, rats and rabbits, but it was not until 1932 that Warwick, Berry and Horlacher made the first successful transfers in domestic sheep and goats in the United States.⁴⁰ Then in 1951 Willett, Black, Casida, Stone and Buckner in Wisconsin reported the first successful ovum transfer in cattle using surgical technics.⁴² Rowson and coworkers firmly established the surgical technic as a research tool in cattle, sheep and goats during the 1960's. Rowson and his colleagues were also the first to produce a calf after the 11-day blastocyst had been frozen prior to transfer.⁴³ The introduction of "exotic" (European) breeds into North America in the early 1970's precipitated a major impetus of the application of the technic. By the end of the decade the approach had shifted from surgical to nonsurgical technics in cattle. As with artificial insemination 25 years earlier, embryo transfer has found its widest application, for economic reasons, in cattle.

In livestock the technic of embryo transfer permits the transfer of embryos from genetically superior animals in a population to the less desirable ones. In research, the application of embryo transfer is perhaps limited only by the imagination, and has already provided insight into the causes of early embryonic death, early maternal recognition of pregnancy, maternal-fetal interrelationships and inter-species crosses. The process of embryo transfer is a factorial one whereby each step may limit the number of offspring born, and whereby the end result is the product of the various probabilities involved.

Embryo Transfer in Cattle

Donor Selection

The owner selects his donor animals on the basis of performance and genetic merit, criteria which are gen-

erally more readily available for the older dairy cow than for the beef cow, and preferably would include data for a proven sire she produced. The role of embryo transfer in cattle improvement programs has been reviewed and placed in perspective elsewhere.^{9,24}

Criteria applied by the owner do not automatically make the donor a good prospect for embryo transfer. The donor cow or heifer must be in good body condition and preferably gaining weight. She should be free from underlying disease, a minimum of 50–60 days postpartum and cycling regularly. Generally, cows with a history of reproductive problems do not make good donor animals. Donors are evaluated further by rectal and vaginoscopic examinations. Vaccinations should be current for infectious bovine rhinotracheitis, bovine viral diarrhea, leptospirosis (five types) and clostridial diseases.

Brucellosis and tuberculosis tests should be performed and in the event of export, additional tests for blue tongue virus, leukemia and anaplasmosis. Bloodtyping of the donor for subsequent identification of offspring is required by some breed associations and must be done before embryo transfer. Accurate heat detection methods are also intensified.

Donor Treatment

Single embryos or multiple embryos may be collected from naturally ovulating or superovulated cows respectively. For optimal efficiency 2 to 4 donors should be treated and synchronized with their recipients for each attempt, this allows the sharing of the recommended potential 8 to 10 recipients per donor.

Superovulation remains the least predictable step in the process of embryo production. Tremendous variation in response occurs with age, breed, lactational status, nutritional status, season and stage of the cycle at which treatment is initiated. The most commonly used superovulatory regime for cows in North America involves the use of follicle stimulating hormone (FSH). The short half-life of FSH necessitates twice-daily injections over a period of 4 to 5 days (Table 27). Treatment is begun during the mid-luteal (day 8 to 14) phase of the donor's cycle and employs the use of prostaglandins (PGF2alpha)

*Professor of Reproduction, Department of Reproduction, College of Veterinary Medicine, University of Florida, Gainesville, Florida.

Table 27. Superovulation Treatments in the Cow

Day	Treatment I	Treatment II
-14	donors and recipients	25 mg PGF2alpha
-5	am 5 mg FSH pm 5 mg FSH	7 mg FSH 7 mg FSH
-4	am 5 mg FSH pm 5 mg FSH pm recipients 25 mg PGF2alpha	6 mg FSH 6 mg FSH recipients 25 mg PGF2alpha
-3	am 5 mg FSH am donors 35 mg PGF2alpha pm 5 mg FSH	5 mg FSH donors 35 mg PGF2alpha 5 mg FSH
-2	am 5 mg FSH pm 5 mg FSH	4 mg FSH 4 mg FSH
-1	am 5 mg FSH pm (5 mg FSH)	3 mg FSH (3 mg FSH)
0	Estrus, AI 8 hours after onset of estrus, repeated twice at 12-hour intervals.	

to synchronize the cycles of the donors and the recipients. Alternately, treatment may be initiated on day 16 or 17 (day 0 = estrus) of the donor's estrous cycle. Dose levels of FSH vary from decreasing levels of 7, 6, 5, 4, and 3 mg twice daily²⁶ to increasing levels, or a uniform 5 mg twice daily⁴⁴ injection schedule. Colorado workers¹⁶ reported more ovulations, embryos recovered and pregnancies after a superovulatory regimen with FSH and LH in a 5:1 ratio administered twice daily in decreasing doses for five days. Recent work²⁹ has indicated that an improved response could be obtained when LH was not used. Consequently, two superovulatory regimens with only FSH are used today (Table 27).²⁶ Prostaglandins (PG) (25–35 mg PGF2alpha or 500 mcg PGF-analog (cloprostenol) IM) are routinely given at the time of the fifth and sixth FSH injection which is then followed by estrus and ovulation in 2 and 3 days. This interval from PG to the onset of estrus is 12 to 24 hours shorter in superovulated animals than in naturally ovulating cows. Consequently, recipients should be injected with PGS 12 to 24 hours before the donors if this method of synchronization is used. The response to the foregoing FSH regimens ranges from zero to as many as 50–60 ovulations with an average of 8 to 12. None of the specific dose levels cited has shown a consistent advantage. When a donor has failed to respond to the superovulatory treatment, the second attempt to superovulate her with the same or a

similar regimen is also likely to result in failure. It is difficult to accurately assess the number of ovulations by palpation of the ovaries per rectum when the number exceeds 4 to 6 per ovary or when several anovulatory follicles are present. It is felt that an excessive number of anovulatory follicles in the presence of corpora lutea adversely influences the recovery percentage because of an unfavorable estrogen/progesterone ratio which allegedly affects gamete and embryo transport.

Pregnant Mare Serum Gonadotropin (PMSG) has also been widely used for superovulation. Food and Drug Administration regulations have severely restricted its importation from the traditional South American sources for disease control reasons. While PMSG has the advantage of requiring only a single injection, its half-life is perhaps too long as measurable levels could still be detected in the blood of cows 10 days after the administration of 1500 to 3000 IU PMSG.²⁸ The FSH/LH ratio of PMSG ranges from 1.9 to 95.5 and depends on the stage of gestation at which the serum was collected.²³ PMSG is a crude product and as such is difficult to standardize. It is a foreign protein that is antigenic, which may lead to a reduced response after repeated use.^{5,38} PMSG may be injected SC or IM on day 16 or 17 of a normal estrous cycle. Doses range from 1500 to 3000 IU, but 2000 to 2500 IU are most commonly used. When used in conjunction with PG, PMSG is administered between day 9 to 12 of an estrous cycle followed by PG 48 to 72 hours later. PMSG injections initially exert a luteotropic effect that has been related to its LH activity. LH is presumed to be responsible for the occasional premature ovulation of a large follicle present at the time of the PMSG injection. The precocious CL is believed to inhibit further ovulations, perhaps because it is not old enough to be lysed by PG given 2 days later, yet secretes enough progesterone to block endogenous LH release.

Equine Pituitary Extract and Human Menopausal Gonadotropin are infrequently used. Equine pituitary extract was used successfully to superovulate beef heifers.¹² A single daily injection for three days appeared to be adequate with 75 percent of the cows responding with 5 or more ovulations. In a trial involving 20 cows, Human Menopausal Gonadotropin (equal FSH and LH activities) when compared with FSH was found to be equally effective.¹¹

There is no need to give the donor GnRH or LH at the onset of estrus in an attempt to precipitate or to group ovulations. There is also no benefit from the injection of a physiological dose of estradiol (500 mcg) at the anticipated time of onset of estrus to intensify the expression of heat.¹⁰

Insemination of the Donor

In the presence of hormonally stimulated ovulations, fresh semen gives higher fertilization rates than frozen semen.²⁰ This probably reflects the number of viable spermatozoa in the inseminating dose. Donors should be artificially inseminated 2 to 3 times at 10 to 12 hour intervals beginning 8 to 10 hours after the onset of estrus, to cover the range of time over which the ovulations may occur. Depending on the quality of the frozen semen, it is common practice to use a double inseminating dose at each insemination.

Embryo Recovery

Embryo recovery technics have evolved from slaughter of the donor animals via surgical collection from the anesthetized live animal to nonsurgical embryo recovery from the standing animal. There are several detailed descriptions of the surgical procedures in the literature.^{13,14} The advantages of the surgical approach are that the patient is immobilized, that sterile technic is possible, that the uterus can be manipulated directly, that the ovarian response can be accurately evaluated, that only 20 to 50 ml of recovery medium are needed and that the procedure can be carried out prior to the fifth day after estrus. However, the major disadvantage is the formation of adhesions which limits surgical collections to 1 or 2 operations without lowering reproductive efficiency. The midventral surgical approach further requires operating room facilities and brings with it the risks of general anesthesia. It is difficult in lactating animals with large udders.

Nonsurgical embryo recovery on the other hand is repeatable with relative impunity, it can be performed on the farm, neither fasting nor surgical risk are involved and probably fewer assistants are needed. However, nonsurgical recovery does require considerable manipulative skill and can only be performed in animals in which the cervical canal is passable, and must be done after day 5.

Nonsurgical Embryo Recovery

Bovine embryos descend into the uterus around day 4.5 to 5 (estrus = day 0) and shed their zona pellucida ("hatch") around day 8.5 to 9. Consequently, most nonsurgical recoveries are made between days 6 and 8.

A 2-way or 3-way, roundtip Foley catheter (French size #12-20) with a 30 ml inflatable balloon is used. The 2-way catheter has one channel for inflation of the balloon plus a single channel for alternate inflow and outflow of flushing medium. The 3-way catheter has separate channels for inflow and return flow. A sterile stylet (such as the plunger of an insemination gun) is inserted

the full length of the device to render it sufficiently rigid to allow introduction into the uterus under guidance per rectum. The donor is restrained in a squeeze chute or, in the case of a tractable dairy cow, in a stanchion. The feces are carefully removed from the rectum to avoid aspiration of air, and an estimate is made of the number of ovulations (CL). Inadvertent air can be removed from the rectum with a small stomach tube attached to a "wet-vac" vacuum cleaner. Epidural anesthesia is administered (4 to 6 ml 2 percent lidocaine) to prevent defecation and straining. The vulva and perineal region are thoroughly washed and disinfected with 70 percent alcohol, and the tail is tied out of the way. If the cervix feels small or tortuous, a cervical dilator¹⁴ may be used to gently expand and straighten the cervical canal. The rigid, relatively sharp-pointed dilator should be used with extreme caution as it can readily perforate the uterine wall as it is "forced" through the tight cervical canal. The lips of the vulva are again parted and the Foley catheter, with the stylet in place, is inserted into the vagina and on into the lumen of the expanded cervix. It is then manipulated into the appropriate horn until the inflatable balloon is situated at the base of the uterine horn. The balloon is slowly inflated with 15–25 ml of air in cows and 10–20 ml of air in heifers. The endometrium is easily split by overdistension, resulting in hemorrhage and escape of the flushing solution into the mesometrium from which it cannot be recovered. After the catheter is in position, the stylet is removed and the inlet channel connected by sterile siliconized tubing to a 500 ml bottle of flushing solution. The outlet tubing channels the fluid directly through an embryo filter (75 μ m pore-Em-Con filter) placed well below the level of the uterus. When using the 3-way catheter, the flushing solution flows into the uterus by gravity with the bottle suspended one meter above the level of the uterus. The uterus is manipulated per rectum by alternately lifting and extending the tip of the horn and the intercornual ligament and by compressing the horn or pressing it against the pelvic wall. The out-flow tube may be clamped off periodically to allow build-up of the flushing medium in the uterus. In older cows with long pendulous tracts, manipulation of the cervix and uterus is facilitated by retracting the cervix into the vagina with cervical forceps. The flushing solution usually starts to flow back after 100 to 150 ml have entered the uterus of the cow, or 75 to 100 ml in the heifer. The filter should never be allowed to run completely dry leaving the embryos on the filter dish exposed to the air. A 1 cm layer of fluid can be maintained by manipulation of a clamp on the tubing attached to the bottom of the filter unit.

With the 2-way catheter a 60 ml catheter-tip syringe

may be attached directly to the catheter. The medium is gently introduced and then allowed to flow back into the syringe, if necessary aided by gentle pull on the plunger. This process is repeated 6 to 7 times. Alternately, a Y-connector with inflow and outflow tubes is attached to the 2-way catheter and used in a manner similar to the 3-way catheter by alternately clamping off the outlet and inlet tubing. During the final collection of the flushing solution 50 IU oxytocin may be given IV to aid in the recovery of the last residual portion of the solution. In superovulated cows the procedure is repeated for the opposite horn, using a separate sterile catheter. It is hazardous to re-insert the stylet into the Foley catheter while it is in the uterus because the sharp tip might come out one of the side openings. It is possible to pull the catheter back into the body of the uterus after partially deflating the balloon, until the expanded balloon is held by the cervix. With the catheter stretched by pulling on the extended end, the stylet can be re-inserted until it reaches the tip where it can be palpated. Once the stylet is safely in place, the balloon is deflated and the Foley catheter once again placed one-third of the way into the selected horn. Some operators prefer placement of the catheter with the balloon in the cervix and the tip in the body of the uterus which enables them to flush the horns simultaneously. Immediately after collection, dishes containing media and embryos are placed in an incubator at 39C, but may be kept at 20C without loss of viability. However, fluctuations in temperature must be avoided. Considerable dexterity, patience and practice are needed to achieve consistently satisfactory results.

Flushing Media

The most commonly used medium for nonsurgical embryo recovery is phosphate buffered saline (PBS). A modified solution is prepared by adding 1 percent heat-treated bovine serum^{1,39} and 100 IU sodium penicillin G, 100 mcg dihydrostreptomycin, 0.25 mcg fungizone and 1 mg glucose per ml PBS and .33 mM sodium pyruvate.^{26,41} All culture media are passed through a disposable 0.22 micron millipore filter prior to use. Fetal bovine serum is added at a 20 percent concentration to the flushing medium to make a holding medium. It would seem that the glucose and pyruvate are only necessary for longer term culture of embryos, for "on-farm" use, media need only contain PBS, antibiotics and 1 to 2 percent bovine serum. Bovine serum contains a thermolabile, embryotoxic factor which may be deactivated by heating to 56C for 30 minutes. The serum acts as a protein source for embryo growth and membrane stabilization, and renders the embryos less sticky.

Embryo Handling

Identification and evaluation of embryos is one of the more difficult aspects and requires considerable experience.

The work area must be clean and free from dust. Insecticide sprays should be avoided; some sprays are extremely toxic while the effect of others is unknown. Extreme temperatures are detrimental; stable temperatures are the key to success. The contents of the filter are poured into a (square 100×100 mm) grid searching dish and the filter disk is rinsed completely clean with plain PBS without serum by a forceful stream from a 35 ml syringe and a 22 ga needle. Then 5 to 7 ml of serum is added to the searching dish and stirred while clearing the bubbles from the edge of the dish.

After a brief settling period in the searching dish, the embryos are located as soon as possible so that they may be transferred to sterile holding medium containing 20 percent bovine serum. All dishes must be kept covered between searches to avoid contamination, and particularly evaporation, when placed in the incubator. Evaporation of the small volume of medium in a flat dish rapidly leads to hypertonic solutions.

Embryos are searched for and located at 10–15X magnification and evaluated at 70–100X using transmitting illumination (from below the stage). Embryos are picked up with a sterile, disposable Unipet attached with a short section of rubber tubing to a 0.5 ml syringe, or a shortened sterile tomcat catheter attached to a small syringe, and deposited in a small sterile disposable petri dish (35×10 mm) containing fresh holding medium. In this way the embryos are rinsed and undesirable debris is removed.

Formerly, recovery rates of embryos were improved by filtration after collection of the large volumes of nonsurgical flushes.³² The technic used a nylon plankton mesh of 56-micron pore size. After filtration was complete, the sieve was backflushed with fresh medium which was subsequently allowed to settle for another 30 minutes before examination.

Morphologic evaluation of embryos is the only practical method to determine the suitability for transfer. Such methods are subjective and depend very much on experience.³⁶ Diagrams of normal embryos at various stages of development are presented in Figure 206. The stage of development after fertilization must be appropriate for the day on which the embryo is collected.

Embryos that are of doubtful quality can be cultured for a few hours. An improvement in appearance will suggest that the embryo is a candidate for transfer. A practical grading system based on morphology places embryos in good, fair and poor categories which pro-

vides a basis for priority of transfer. A good embryo has a regular, round, symmetrical shape in contrast to a fair embryo which shows slight imperfections, an extraneous blastomere or has an odd shape, and a poor embryo which shows severe imperfections. Good embryos resulted in high pregnancy rates (65 percent) while fair and poor embryos resulted in a reduced number of pregnancies (45 and 33 percent respectively).⁴⁴ It is of interest to note that good embryos were less sensitive to exact synchrony between the cycles of the donor and the recipient than fair and poor embryos.

For optimal pregnancy rates, it is advisable to transfer embryos as soon as practical after collection. Enriched PBS allows embryo survival to remain constant for at least 7.5 hours. If embryos are not transferred within two hours from the initial rinse, they should be washed again by the same procedure.

Short-term storage of bovine embryos is possible without significant adverse effects on embryo survival and pregnancy rates whether at 37C for 24 hours³¹ or at 4C for 48 hours.⁶

For long-term storage embryos are frozen to -196C in liquid nitrogen. Mammalian embryos must be stored in a quiescent state to retain viability for a long time. To freeze embryos, a cryoprotectant like dimethylsulfoxide or glycerol is required and slow cooling (0.1 to 2.0C/min) and warming (1 to 50C/min) rates are used. Nucleation or seeding of the freezing medium is a necessity, and stepwise addition and removal of the cryoprotectant at room temperature seems to be beneficial. Using the above parameters, embryos have been frozen and stored at -196C for several years and upon thawing and transfer to a suitable recipient, viable offspring have developed.²⁷

Embryo morphology contributes to the success of the frozen-thawed technics: the presence of the zona pellucida protects³⁷ and the presence of a blastocoele appears to improve survival rates.

Possibly each embryonic stage has its own optimal freezing and thawing requirements.¹⁹ Despite the losses, freezing is used commercially when recipients are not available. Frozen embryos offer a unique advantage for the marketing and distribution of embryos, be it for export purposes or long distance transportation.

Microsurgical technics applied to embryos include removing embryonic cells from, or transferring them into a zona pellucida, biopsy, dividing the embryo in half, aggregating them, injecting nuclei and removing material or structures such as pronuclei. Such manipulations make it possible to analyze chromosomes for sex determination and to produce identical twins or multiplets. Eventually, it may be possible in livestock production to

produce chimeras and homozygous diploid females, to clone by nuclear transplantation and to introduce exogenous genes into pronuclei.³⁵

Recipient Selection and Synchronization

Recipients should be large-framed, healthy, mature heifers or young cows in good condition. A minimum of two normal cycles should have been recorded before use whether they are going to be synchronized with prostaglandins or just selected from a pool of cycling animals. It has been common in embryo transfer programs to overlook the quality of the recipients. Recipients and their maintenance represents the greatest single cost of running a commercial embryo transfer program. Culls from a breeding program, cattle in poor condition and early postpartum animals do not make suitable recipients. Recipients should not be fat and should preferably be gaining 0.1 to 0.2 kg per day. They should be officially calthood vaccinated for brucellosis.

Permanent (double) identification of each animal, meticulous record keeping, accurate heat detection, ample handling and quarantine facilities are all absolute essentials of reliable recipient management. Pregnancy rates are highest when the estrous cycles of the donor and the recipients are synchronized within 24 hours.⁴⁴ Reasonable success can be achieved if they are out of phase by plus or minus one day, but results are too poor to be usable when they differ by two days.

The availability of synchronous recipients can be achieved in three ways: 1) A pool of several hundred cycling females, which limits the number and times when donors can be collected. Five percent of the herd will be in heat on any given day. 2) Large commercial dairy farms can sometimes be persuaded to rent recipients which must of course not be inseminated. A fee will also need to be paid in the event a recipient is not used. 3) A relatively small number of recipients can be synchronized with PG to come in heat the same day as the donor. Animals with a palpable corpus luteum are injected with 25 mg PGF2alpha IM or 0.5 mg PG-analog and may be expected to come into estrus in 2 to 4 days with a peak on the third day. Alternately, all recipients may be injected with PG regardless of the presence or absence of a corpus luteum. The injection is repeated 11 days later and again estrus will peak on the third day after injection. Those recipients which did not respond on the first occasion because they were in the first 5 days of the estrous cycle, respond the second time as they are then in the mid-to-late luteal phase; while the recipients that did respond are in the early-to-mid luteal phase at the time of the second prostaglandin injection.

The average donor yields 7 transferrable embryos. Therefore, 8 recipients per donor is a reasonable number to prepare. When recipients are palpated for corpora lutea, about 20 are palpated in order to definitely identify 12 with corpora lutea on their ovaries. When 12 are injected with PG, 8 on the average will be suitably synchronized with the donor. Recipients must be injected with PG one day earlier than the donor. Due to prior gonadotropin treatment, the donor comes into estrus 48 hours after the PG, while the recipients which did not receive any gonadotropin treatment, will come into estrus three days after PG.

About 85 percent of fertile donors will respond to the superovulatory treatment on the first attempt. For optimal efficiency, 3 to 5 donors should be superovulated at the same time which permits the sharing of the prepared recipients and avoids the expensive failure encountered too frequently when only one donor is prepared at a time.

Transfer

Transfer of bovine embryos may be done either surgically or nonsurgically. The surgical approach seems to produce the most consistent results. Successful nonsurgical transfer requires an even higher degree of dexterity and skill than does the nonsurgical recovery procedure.

Surgical exposure of a uterine horn needs to be done via a midline incision if the recipient is a heifer with a short broad ligament or if she is to receive twin embryos. Halothane anesthesia provides excellent relaxation of the broad ligament. Single transfers are always made to the horn ipsilateral to the corpus luteum: twin embryos should be transferred to separate horns as uterine migration of embryos rarely if ever occurs in the cow. The horn is exteriorized by placing tension on the broad ligament over the distal portion of the horn.

In cows, the incision may be made in the flank on the side of the corpus luteum as far caudally as possible with the animal in the standing position. In both approaches a small stab incision is made along the greater curvature about 7 cm from the tip of the exteriorized uterine horn with a small, closed mosquito forceps. The instrument characteristically "pops" through the endometrium. Care should be taken not to pass through the lumen into the endometrium and submucosa on the other side. The embryo is deposited in the lumen of the uterus via the stab incision with a fine, modified Pasteur pipet. Closure of the abdominal incision following either approach is by routine surgical methods.

Nonsurgical transfers are made through the cervix similar to artificial insemination. It is important to minimize contamination of the uterus because it is more sus-

ceptible to infection during the luteal phase. Feces are evacuated from the rectum and the side of the corpus luteum is determined. Epidural anesthesia is induced to prevent defecation and to minimize straining. The perineal region is thoroughly washed and disinfected with 70 percent alcohol. The embryo is aspirated into a 0.25 ml French straw between two air pockets and two columns of culture medium. The straw is inserted into the AI gun and shortened to fit even with the end of the gun. A gas-sterilized 0.25 ml sheath is fitted over the AI gun and fixed in place. A second, sterile, large sheath which is closed at the distal end is fitted over the first to serve as a cannula and permits passage of the gun through the vagina without coming into contact with the vaginal flora. The tip is placed into the external os of the cervix and is then pushed through the sheath before it is guided as gently as possible through the remainder of the cervical canal and on into the uterine horn on the side of the corpus luteum. The embryo is deposited approximately one-third of the way up the uterine horn and the gun is withdrawn slowly. A negative correlation has been demonstrated between the time spent in the uterine horn and the pregnancy rate.³³ Success is related to dexterity and practice. Pregnancy rates achieved by most operators improve with experience. The pregnancy rate after nonsurgical transfer through the cervix is generally lower than that reported after surgical transfer. In the hands of some experienced embryo transfer practitioners, pregnancy rates following nonsurgical transfer equal those after surgical methods.

Pregnancy rates are higher (approximately 75 percent) after bilateral transfers to non-mated recipients or single transfers to mated recipients. The twinning rate of these recipients is 50 to 60 percent. As a consequence the embryo survival rate percent is not greater.²

Donor and Recipient Aftercare

It is common practice to treat the donor with PG immediately after the collection of ova. At this time the ovaries are generally greatly enlarged by the excessive number of corpora lutea. Such treatment will not only rapidly reduce the size of the ovaries, but also terminate any unwanted pregnancies should an occasional embryo not have been flushed out. It is best not to breed the cow on this induced heat 2 to 4 days later. Furthermore, like a spontaneous heat, the induced heat will have a salutary effect on uterine health should any contamination have been introduced at the time of the collection. Cows can be superovulated at intervals of two months for three treatments without any appreciable decrease in response.¹⁸ Single embryo collections may be made between these superovulatory treatments.

Pregnant recipients should basically be managed like other pregnant cattle. Mature cows should be fed to gain 0.25 kg per day through the seventh month and 0.75 kg per day during the last 2 to 3 months. Heifer recipients should be fed to gain 0.5 to 1.0 kg per day depending on age, size and condition. Overly fat recipients are undesirable. Pregnancy examinations are made at six weeks and confirmed at three months. Pregnancy loss after three months is less than 2 percent. Some recipients will be carrying large fetuses from breeds with a long gestation period and may—particularly when they are heifers—require delivery by cesarean section.

Results Obtainable

The following are average results for several large populations. Superovulation with FSH produces 8 to 12 ovulations per donor.^{18,34} Nonsurgical collections will yield 7 to 10 ova with 75 to 80 percent fertilization rates. Single embryos collected from nonsuperovulated cows tend to result in slightly higher pregnancy rates.^{18,34} Four to seven embryos are suitable for transfer.^{8,18,30,34} Surgical embryo transfer results in a 60 to 70 percent pregnancy rate, while nonsurgical pregnancy rates are 35 to 55 percent, a considerable attrition rate. The range of results varies a great deal from cow to cow; on the average, superovulation and embryo transfer results in four pregnancies per attempt and can be repeated three times per year for an annual total of about 12 offspring.

Cows With Reproductive Problems

Valuable, infertile cows are often presented for embryo transfer. Many of these animals are classical repeat breeders with regular cycles and no palpable abnormalities of the reproductive organs. After a thorough physical examination, nonsurgical embryo transfer techniques may be used for examination of uterine contents and collection of ova. Cases of endometritis not diagnosed by rectal palpation may be obvious when excessive amounts of cellular debris are observed in the sediment of the flushing medium. If aseptic techniques are used the sediment may be submitted for bacterial culture.

Cows with (a history of) cystic follicular degeneration must not be superovulated until after two normal estrous cycles have been observed. After the first observed estrus each problem donor should be subjected to a single ovum recovery to determine: a) the condition of the uterus (nature of the flushing medium); b) if ovum transport is occurring; c) if the ovum was fertilized and d) the stage of development of the embryo.¹⁷ Cows with cystic follicles had fewer corpora lutea after superovulation than cows with uterine infections (4.1 vs 10.1). Furthermore, only 7 percent of the possible ova released (based on the

number of corpora lutea) were fertilized, versus 60 percent in fertile donors. Also, significantly fewer ova and pregnancies per treatment were obtained from cows with cysts than from cows with adhesions.

If an infertile donor does not respond with more than two corpora lutea to either of two superovulatory attempts, it is unlikely that a favorable response will be obtained. Embryo transfer can be used as a refined, sophisticated technic for the diagnosis of infertility.^{3,21,25}

Embryo Transfer in Horses

Oguri and Tsutsumi in Japan reported the first successful nonsurgical recovery of equine eggs as early as 1972 and in 1974 the first successful nonsurgical transfer of 6 to 15 embryos.⁹ Allen and Rowson in England recovered 11 embryos from 30 mares in 1975 and produced 5 pregnancies after nonsurgically transferring 7 embryos.¹

Donor Treatment

The induction of superovulation in the mare has been very difficult. The mechanism of the marked resistance of the ovary of the mare to exogenous gonadotropic stimulation remains unknown. Prospects for induction of multiple ovulations and collection of multiple embryos in the mare have been reviewed.¹⁰

Pregnant mare serum gonadotropin, equine pituitary extracts with,³ and without, human chorionic gonadotropin (HCG)⁶ and porcine follicle stimulating hormone⁵ have all been tried with limited success. Single ovulations can be timed with HCG, 2000 to 3000 IU given intravenously on about the third day of estrus usually induces ovulation 24 to 72 hours later. Natural breeding or artificial insemination are used when ovulation is anticipated from palpation of follicles or following HCG injection.

Embryo Recovery

Surgical recovery techniques were described by Allen and Rowson in 1975,¹ and today are perhaps needed only for small ponies and experimental reasons. Nonsurgical techniques have been adapted from those used for bovine embryos recovery. The easily dilatable cervix and straight uterine horns make the technic of embryo recovery relatively easier than in the cow. Although the embryo arrives in the uterus on day 6, most embryo recovery attempts are not made until 8 or 9 days after ovulation. The large size of the equine blastocyst on day 10 (5–7 mm diameter) precludes transfer of the blastocyst intact.

An extended 2-way Foley catheter (French size 30) is used with simple in-out irrigation. The donor mare is confined in stocks and a thorough prebreeding prepara-

tion is done of the tail, perineum and vulva. The sterile catheter with a stylet in place is introduced per vaginam and passed through the cervix until it is approximately 5 cm into the uterine body. Its position is verified per rectum and the balloon is inflated with 75 ml air after which it is drawn back against the internal os of the cervix to form a seal preventing the escape of the flushing medium from the uterus. One liter of phosphate buffered saline containing 1 percent heat-treated bovine serum is infused into the uterus by gravity flow. Both uterine horns and the uterine body are flushed simultaneously. The return fluid is collected in a prewarmed, sterile, one-liter graduated cylinder or embryo filter placed well below the level of the uterus. The procedure is repeated twice for a total of three liters per collection attempt. Mares predictably return to estrus 3 to 5 days after the flushing procedure in response to the endometrial stimulation.⁷

Synchronization of the Recipients

Close synchrony of the times of ovulation of the donor mare and the recipient mare is desirable for maximal success.⁴

Synchronization of estrus in cycling mares may be achieved by a double prostaglandin treatment. All mares in a group are given a luteolytic dose of a prostaglandin (analog). Mares with a 4- to 13-day old corpus luteum will come into estrus on the third day after treatment and are given 2500 IU HCG IV on the sixth day. Those mares in estrus or with immature corpora lutea at the time of treatment will shortly become diestrous. Fourteen days after the initial injection of prostaglandin all mares are given a second luteolytic dose, and all mares are treated with 2500 IU HCG to synchronize ovulation.

Identification of the Embryo

The collection fluid is allowed to settle for 30 minutes before all but the bottom 100 ml are gently siphoned off, unless an embryo filter has been used. The day 8 post-ovulation blastocyst is 1 to 2 mm in diameter and can frequently be distinguished macroscopically. It can be readily transferred since it is not easily ruptured. Evaluation of its suitability for transfer, like that of bovine embryos, is based on morphological appearance and stage of development in relation to the day of collection. After the embryo is located it is picked up with a fire-polished Pasteur pipet and passed through three consecutive small petri dishes (35×10 mm) each containing a small amount of sterile phosphate buffered saline containing 20 percent heat-treated bovine serum. This procedure washes the embryo by the dilution of possible contaminants. The embryo is stored in a covered dish at 37C until transfer.

Nonsurgical Transfer

The recipient mare is prepared in a manner identical to the preparation of the donor. The embryo is aspirated into a sterile 55 cm insemination pipet in a 5 cm column of medium. The inseminator should wear a plastic palpation sleeve covered by a sterile surgical glove.

The pipet is aligned with the index finger and a second, gas-sterilized sleeve is put on over the pipet. The lips of the vulva are parted and the hand is inserted into the vagina until the index finger has entered the cervix. At this time the pipet is pushed through the outer plastic sleeve and inserted 5 cm into the body of the uterus. Next the embryo is slowly discharged into the uterus. Upon withdrawal of the pipet and the hand from the vagina, the lips of the vulva are held closed to prevent the aspiration of air into the vagina. The pipet is examined for the absence of the embryo by rinsing it with a small amount of medium into a petri dish.⁴ Although surgical transfer has been shown to yield higher pregnancy rates, practicality may dictate the use of nonsurgical techniques. The surgical approaches are analogous to those used in other species and have been well described.⁴

In its research applications, the technic has already contributed much to our understanding of the reproductive physiology and endocrinology of the estrous cycle, early development of the embryo and the early maternal recognition of pregnancy.

The commercial application of embryo transfer will be limited to obtaining offspring from proven infertile mares and the management of older broodmares of the more enlightened breed associations, until the equine industry shows a genuine interest in the propagation of genetically superior animals by relinquishing its restrictions on the use of artificial insemination and embryo transfer.

The meager results obtained in the early 1980's most likely relate to the ability to recover embryos from "problem" mares. At Colorado State University the recovery rate from normal, fertile mares is 70 percent compared to only 26 percent from "problem" mares, mainly due to poor uterine environment or failure of unfertilized ova to pass through the normal uterine tube. If 50 percent of these recovered embryos produce a pregnancy after surgical transfer, the overall chance of success is one foal from eight problem donor mares.

Embryo Transfer in Sheep and Goats

Sheep and goats were the first species of large domestic animals to be used in embryo transfer experiments. Interestingly, the technic was employed to achieve intergeneric and interspecies transfers between goats and sheep.^{9,10} None of the pregnancies endured beyond 55

days probably due to placental differences and diverging endocrine support of pregnancy. In the ewe the CL of pregnancy is no longer needed after 55 days of gestation⁷ while in the goat the CL is required throughout gestation.

Embryo transfer has remained an elegant research technic for the investigation of maternal-fetal interactions.² There has been little if any commercial application in either sheep or goats. In many breeds embryo transfer is limited to the natural breeding season.

Superovulation

The induction of multiple ovulations is principally the same for the (domestic) ruminants. Follicles are stimulated near the end of the luteal phase and early part of the follicular phase of the estrous cycle, be it the natural end or the progestogen- or prostaglandin-manipulated end of the cycle. In the ewe, pregnant mare serum gonadotropin (PMSG) is most commonly used. PMSG is administered IM in a single injection of 1200 IU (range 700–2000 IU) on day 12 or 13 of the cycle, and the ewes may be expected to come into estrus 2 to 4 days later.

Alternately, horse anterior pituitary extracts may be given as three daily doses (total 60 mg) beginning on day 12.⁴ Optimum responses were obtained with horse anterior pituitary extracts in ewes coming into estrus 24 to 48 hours after the end of treatment. The estrous cycle and the time of ovulation can be controlled with the use of either progesterone or prostaglandins which is of value in scheduling the procedure and the recipients.

Progesterone is administered daily by 12 mg per day IM injections or via progestogen-impregnated intravaginal pessaries. Progesterone treatment must be maintained for at least the lifespan of the CL, or 14 days, in the ewe.

Gonadotropin treatment is initiated on the day before the last progesterone injection is given or the day before pessary removal. The ewes generally come into estrus about 2 days after the cessation of progesterone treatment.

Prostaglandins may be given in combination with gonadotropin treatment when the latter has been initiated during the midluteal phase (day 5–10). Prostaglandin (10–15 mg PGF₂alpha or 100 mcg PG-analog) is given 1 to 3 days after the PMSG injection. The majority of the ewes will come into estrus within 36 hours after the administration of prostaglandins.

In the goat, 1000 IU PMSG are given IM on day 17 of the natural cycle. Intravaginal, progestogen sponges may be used to synchronize estrus. The sponges are left in place for 16 to 18 days, or the approximate lifespan of the CL in the doe. PMSG is administered two days

before sponge withdrawal or cessation of daily (12 mg/day) progesterone injections. Equally effective is a dose of prostaglandins (8 mg PGF₂alpha or 50 mcg PG-analog IM) administered between day 6 and 18 of the estrous cycle, two days after PMSG. Porcine pituitary FSH (18 mg in 8 divided doses for 4 days) and horse anterior pituitary extract (40–60 mg in three equal SC injections on consecutive days) have also given satisfactory results of 10 to 16 ovulations.¹

Insemination

The donor animals should be handmated at 12-hour intervals until they no longer accept the male. This approach aids in the timing of estrus and direct observation insures that actual mating took place. Alternately, artificial insemination is also done at 12-hour intervals with the help of a teaser male. An inseminating dose of 400 million or more motile sperm is used at each insemination. Fertilization failure is common in superovulated ewes, particularly in animals showing a high ovulatory response to treatment. This appears to be due to faulty transport of spermatozoa through the cervix and can be overcome by surgical insemination directly into the lumen of the uterus.⁸ The uterine horns are exposed via a midline incision under local anesthesia. Manipulation of the reproductive tract should be kept to a minimum. Fertilization rates in excess of 90 percent of ova recovered, were achieved by injecting 0.02 ml of semen into the tip of each uterine horn around the time of onset of estrus, or on the second day after discontinuing progestogen treatment in synchronized ewes.

In the doe fertilization failure following superovulation is not a severe problem, perhaps because the cervix is more patent in the doe than in the ewe, presenting less of a barrier to sperm transport.⁵

Embryo Recovery

Nonsurgical embryo recovery as described for the cow and the mare is not possible because of the tortuous nature of the cervix and the inability to guide the catheter per rectum. Collections are generally carried out under general anesthesia. This provides maximal relaxation of the broad ligaments and precludes movement of the donor during the procedure. The uterine tubes are cannulated via the infundibulum. A portion or all of the horn and the uterine tube are flushed by gentle expression of the flushing medium from the base of the horns through the uterine tubes.³ Recovery rates of 80 percent can be achieved. Embryos enter the uterus around the third to the fourth day after estrus. Embryos collected on day 3 or earlier (embryos of 8 cells or less) should be transferred to the uterine tubes and yield a 60 percent preg-

nancy rate. Embryos collected on or after day 4 must be transferred to the uterus and will have 70 to 75 percent survival rate.⁵

Luteal failure and early return to estrus occurred in the majority of superovulated does. This resulted in failure to recover embryos later than five days after estrus. By flushing uterine tubes and uteri between day 2 and 4, high embryo recovery rates could be achieved despite the premature luteal failure associated with superovulation in these does.¹ Repeated collections from individual animals have rarely been attempted and would be progressively hampered by the development of adhesions. As in cattle, phosphate buffered media are most commonly used and have the advantage over bicarbonate buffered media in that they do not have to be maintained under a gas phase to maintain pH.

Procedures for embryo handling and evaluation are the same as those already described for cattle.

Recipients

The requirements for synchrony of the cycles of the donor and the recipients in sheep is less exacting than that in cattle. While close synchrony is optimal, a variation of plus or minus two days is adequate in sheep. Critical data are not available for the doe, but there are indications that the doe may tolerate as much as 36 hours asynchrony. If a large pool of recipients is available, animals whose estrus occurs at the same time as that of the donor can be selected. About ten potential recipients should be available for each donor. Prostaglandins or progestogen administration may also be used. Progestogen treatment of the recipients should be discontinued one day earlier than that of the donor. Aftercare of the recipients is the same as that of naturally pregnant females. Nonreturns can be monitored with a teaser male.

Transfer

Transfer via the cervix is extremely difficult in small ruminants because of the tortuous nature of the cervix.⁶ Surgical transfer under local anesthesia via a midventral approach is rapid and economical. Each embryo is transferred with a Pasteur pipet in 0.01 ml of medium to the uterine tube prior to day 4, or to the distal portion of the uterine horn after day 4. Single embryos are transferred to the horn ipsilateral to the CL, twin embryos one to each horn or uterine tube.

Embryo Transfer in Pigs

Genetic progress in the swine industry will require and rely on embryo transfer. There is also considerable interest in the use of embryo transfer to reduce the disease risk involved in the introduction of replacement herd

sires.^{3,4} Embryo transfer has been a useful experimental technic for the study of uterine migration and the spacing of embryos,⁷ the local effect of the embryo on luteal function as well as the effect of a variable number of embryos on the maintenance of pregnancy and embryonic survival rates. Descriptions of embryo recovery procedures have been available since 1962.¹⁰

Donor Selection and Treatment

Sows should be reproductively sound and in good health for optimal results, especially since embryo recovery involves general anesthesia and surgery. Repeated embryo recovery is likely to be limited by adhesions of the uterine horns and ovaries which may have an adverse effect on egg transport and fertilization as well as on manipulation of the reproductive tract.¹²

Superovulation can be induced in sows at weaning by subcutaneous (SC) injection of 1200 IU pregnant mare serum gonadotropin (PMSG) on the day of removal of the pigs.¹⁴ Gilts can be superovulated by the SC injection of 1200 to 1500 IU PMSG on day 15 or 16 of the estrous cycle. Onset of estrus and the time of the LH peak are advanced by about one day, occurring 3.5 to 4.0 days after PMSG treatment in sows. As in other species tremendous variation in the ovulatory response occurs in sows and gilts of similar age, reproductive stage, breeding and management. An average of 20 to 30 ovulations may be expected with a range of 10 to 50.⁶ Donors are mated or inseminated every 12 hours after the onset of estrus. The most important single insemination is at 24 hours after the onset of heat. An inseminating dose of 100 ml diluted fresh semen containing at least 4 billion live spermatozoa is used.

Embryo Recovery and Transfer

Under general inhalation anesthesia, usually maintained by a closed-circuit system,⁸ the reproductive tract is exposed via a midventral incision. Embryos can be collected from the uterine tubes by means of a flared glass cannula inserted at the infundibular end or through the uterotubal junction. Uterine embryos cannot be flushed back through the uterine tubes due to the valve-like nature of the uterotubal junction.

Uterine embryos may be collected by first occluding the uterine horn 25 cm below the uterotubal junction with rubber-shod Doyen intestinal forceps, and then slowly introducing 25 ml of flushing medium into the uterine horn via the uterine tube. Next a cannula (e.g. a 12-French Foley catheter with 5 ml balloon or a flared glass cannula) is inserted through the uterine wall near the uterotubal junction while the fluid is trapped distally by digital pressure. The medium is then allowed to flow

back toward the cannula and an additional 25 ml is infused into the uterus at a point adjacent to the intestinal forceps. Blastocysts, up to day 10 of pregnancy, may also be collected via a catheter inserted through an incision in the isthmus of the uterine tube, through the uterotubal junction and into the uterine lumen. The catheter (ID 1.25 mm) should have two to four sideholes cut in the last 3 cm of the catheter and is inserted into the uterus to facilitate blastocyst recovery.² During the normal rate of development of pig embryos following fertilization,¹¹ cleavage from one to four cells takes place in the uterine tubes during the first 36 hours. They enter the uterus at this stage. Development is generally arrested at the 4-cell stage for up to 48 hours and 4-cell embryos are commonly still recovered as late as 70 to 80 hours after ovulation. When cleavage is resumed, there is roughly a 12-hour cell cycle. However, not all embryos resume cleavage at the same time, hence 4-cell embryos may be recovered in the presence of 8- to 16-cell embryos.¹⁶

Embryo transfer at the 4- to 8-cell stage is recommended primarily because embryos can be evaluated with less difficulty at this stage since normal cleavage is more apparent. A further reason for scheduling embryo transfer in the pig at the earlier stages of development is the sharply reduced embryonic survival rate and pregnancy rate obtained when the transfers are made more than 6 days after ovulation or 7 to 8 days after the onset of estrus.¹¹

The length and tortuosity of the cervix and also of the uterine horns in the pig virtually preclude the possibility of nonsurgical recovery of embryos.

Recipients

Estrus in the recipients should occur within 24 hours of that of the donor, and preferably, the donor should exhibit estrus about 12 hours before the recipient. This may be especially important when sows are used as donors since they tend to ovulate 10 to 12 hours later after the onset of estrus than gilts.⁵ The survival of embryos transferred from sows to already pregnant gilts has been reported.¹ Survival rates for transferred and native embryos were 51 and 35 percent (not significant), 56 and 20 percent ($p < .01$) and 72 and 3 percent ($p < .01$) when the sows were in estrus 12 hours before, at the same time or 12 hours after the recipient gilts.

Weaning may be used to synchronize sows. Prepubertal gilts may be injected SC with 750 IU PMSG followed 96 hours later by 500 IU HCG intramuscularly. The time of HCG injection is then considered as the onset of estrus for the determination of synchrony. The ef-

fective antigonadotropin, synchronizing agent methallibure is no longer available in the U.S.A. because of its teratogenic effects when fed to pregnant sows.

Prostaglandins are impractical in the pig because they are only luteolytic between days 11 or 12 and 14 or 15 in normally cycling animals. Prostaglandins may be used in combination with gonadotropins. PMSG and HCG are used to prolong the luteal phase by inducing accessory corpora lutea (CL) which postpone estrus in all animals. Twelve days after the administration of HCG, prostaglandins can cause all CL to regress resulting in a high degree of synchronization and normal fertility.⁹ A synthetic progestogen, allyl trenbolone or Regumate, shows great promise for estrus synchronization in swine. It is fed for 18 days and, upon withdrawal from feed, estrus occurs 4 to 7 days later with most gilts in estrus on days 5 and 6. Fertility of synchronized gilts was comparable to that for untreated gilts.¹³

Recipient gilts should be examined during surgery to determine that CL of normal appearance are present. Embryos are transferred with a fire-polished Pasteur pipet via a stab incision in the uterine wall about 10 to 15 mm from the tip of the horn. All embryos can be introduced at one site, since spacing within the uterus will occur by intrauterine migration.

Aftercare is routine for a surgical patient. Pregnancy may be diagnosed at 30 to 60 days of gestation with ultrasonic techniques.

Embryo Transfer in Dogs and Cats

The induction of estrus and ovulation in the bitch, and to a lesser extent in the queen, remains an obstacle to the ready application of embryo transfer in these species, although considerable information is available on the endocrinology of the estrous cycle of the bitch^{4,10} and the queen.^{8,9}

Preimplantation canine embryos have been described and illustrated.³ In addition to research applications, the technic of embryo transfer might be used for the genetic improvement of a breed or the preservation of an endangered species with the use of nonendangered and/or domestic canids or felids as recipients.² The difficulty of synchronizing estrus and ovulation of the donor bitch and her recipient(s) might be circumvented by collecting the embryos and freezing them. The embryos could then be transferred to a suitable recipient during her respective natural cycle. However, neither dog nor cat embryos have been successfully frozen and thawed to date. The domestic cat ovulates in response to a coital or hormonal (LH, GnRH) stimulus. Ovulation may be induced by daily

injections of 2.0 mg FSH until estrus is observed at which time she is mated.¹⁰

Embryo Recovery

The donor bitch is anesthetized and the abdomen and perineal region are prepared for surgery. The ovaries, uterus and cervix are exposed via a mid-ventral abdominal incision. The corpora hemorrhagica cannot be observed directly without surgically opening the ovarian bursae, but an impression may be gained by the overall size of the ovary and by direct palpation of the ovary during surgery. A roundtip Foley catheter (8 or 10 French size) made rigid with a stylet is inserted into the vagina. The tip of the catheter is identified at the external cervical os via the abdominal incision and manipulated through the cervix into the lumen of the uterus. The catheter is then directed into a uterine horn 2 cm cranial to the bifurcation. After the stylet is removed, the balloon of the catheter is distended with 3 to 4 ml of flushing medium or air. The ipsilateral uterotubal junction is occluded by digital pressure and a blunt 18-gauge needle is inserted into the lumen of the uterus approximately 4 cm from the uterotubal junction. Next the lumen is flushed with 10 ml of warm phosphate buffered saline solution. The opposite horn is then flushed in a similar manner. Each horn is flushed three times with a total of 30 ml. The flushings are collected via the Foley catheter in sterile petri dishes for examination under a stereomicroscope as described for cattle embryos.¹

In the queen, each horn is flushed separately by introducing recovery medium near the uterotubal junction with a blunt needle and a syringe, and collecting the phosphate buffered saline via a cannula inserted into the lumen near the bifurcation.

Results

Schriver and Kraemer⁵ recovered 47 feline embryos from 9 surgical collections 6 days after mating. Four pregnancies resulted from 9 transfers. Two litters of 3 and 1 males, respectively, were delivered naturally. A third pregnancy resulted in a stillborn male and the fourth pregnancy terminated in either an unobserved abortion or fetal resorption. A total of 72 canine embryos were obtained from 26 collections. Thirty seven of the embryos were transferred to 7 recipients. Three pregnancies were diagnosed and a total of 4 offspring was produced.^{6,7} These studies show that embryo transfer is biologically feasible in the dog and the cat. However, the efficiency must be markedly increased before embryo transfer will be useful in increasing the number of offspring from genetically valuable females, for production

of biomedical models, or for the presentation of endangered species.

INDEX

Abnormalities (see anomalies)

Abortion (also see mummification), 123–222, 705, 728–741

causes of, 123, 127, 162, 163, 180, 193, 207, 211, 705, 728–741

definition of, 38, 123

diagnosis of (causes of) 123–125, 153, 162, 180, 192, 208, 211, 212

due to abscesses and adhesions of uterus, 153

allergies or anaphylaxis, 153

anomalies of the fetus, 126, 152, 173, 201

arsenic, 148

campylobacteriosis (vibriosis), 134, 193, 194

chemicals, 147–149, 170, 188

chlamydiosis, 137

chlorinated naphthalenes, 148

chromosomal defects, 126, 152, 173, 174, 189, 202, 209, 213

douching of the pregnant uterus, 151, 173

drugs, 147–149, 170, 201, 209

endocrine deficiencies (mainly progesterone), 150, 171, 172, 201, 209, 212, 406, 438, 561–565, 673, 692, 715

endotoxins, 136

ergot, 148, 188, 201

estrogens, 149, 170, 188, 201, 209, 213, 404, 692

glucocorticoids, 149, 172, 173, 188, 201, 209, 408

hereditary or congenital disease of fetus, 123–222

hormones, 149, 150, 170–173, 201, 209, 213, 220–222, 248–251, 404, 407, 408, 691–694, 705, 707

inanimation, 151, 201, 202, 213

insemination during pregnancy, 151

ketosis in ewes, 202

lack of uterine caruncles and placenta, 153, 173

lack of progesterone (see due to endocrine deficiencies)

lead, 148, 201

manual trauma to amniotic vesicle, embryo or fetus, 151

miscellaneous bacteria:

cows, 135–137

mares, 162–165

sows, 183, 184

ewes, 197

bitches, 207, 208, 732, 735, 738

queens, 735, 738

mycotic or fungal agents, 145, 148, 170, 188, 199

nitrites, 147

nutritional deficiencies, 150, 151, 173, 188, 202

pediculosis, 146, 153

phenothiazine, 170, 201

physical causes, 125, 151, 152, 173, 188, 209

plant poisons, 147–149, 188, 201

poisons, 147–149, 170, 201

prostaglandins, 150, 171, 188, 201, 407, 438, 691–699, 707

protozoa, 146, 170, 188, 200

purgatives, 170

removal of corpus luteum, 151, 171, 172, 201, 209, 212

rickettsia, 136, 137

septic processes, 152, 188

shipping (stress), 136, 172, 188, 202

sodium iodide, 148

starvation, 157, 172, 201, 202

strangulation of uterus, 173

stress, 152, 172, 173, 188, 201, 202

surgical operations, 152

torsion of the umbilical cord, 152, 173

torsion of the uterus, 152, 173

trauma, 125, 151, 152, 173, 209

twinning, 99, 100, 152, 174, 175

vaccination, 187, 199

violence, 125, 152

viruses, 138–145, 165–170, 184–188, 197–199, 209, 211, 212, 729

yeasts, 170

enzootic in sheep, 138, 197, 198

epizootic in cattle (EBA), 137, 138

importance of, 123

in anaplasmosis, 146

animals, infectious for humans, 147

bovine virus diarrhea (BVD-MD) 142, 143, 199

brucellosis—of cattle, 126–131, 374

of horses, 163, 165

of sheep, 195, 196

of swine, 182, 183

of dogs, 206–208, 728, 729

cats, 210–213, 705, 741

cattle, 125–162

distemper (dogs), 209

dogs, 206–210, 728–740

dourine, 170

eperythrozoonosis, 188

hog cholera, 187

horses, 162–180

IBR-IPV, 138–142

ketosis in ewes, 202

leptospirosis: of cattle, 131–134

of horses, 165

of sheep and goats, 197

of swine, 180–182

listeriosis, 134, 135, 163, 165, 194, 195

panleukopenia in queens, 211

pasteurellosis in sheep, 197

pseudorabies, 144, 185, 186

salmonellosis, 135, 164, 196, 208, 210

sarcocystosis, 146

sheep and goats, 192–206, 673

shipping fever, 136

streptococcal infections in mares, 163, 164

- swine, 180–192
 - swine erysipelas, 184
 - tick-borne fever, 136, 137, 198
 - toxoplasmosis, 146
 - trichomoniasis, 146, 450
 - tuberculosis, 135, 136, 184
 - viral diseases: in cats, 211, 212, 705, 741

- uses of the, 149, 170, 188, 201, 209, 213, 404, 405, 505, 506
- Estrous cycle**, 411–415, 427, 434–442, 676, 699
 - body temperature during the, 436, 437
 - classification of animals by the frequency of their, 413
 - factors affecting the, 413–415
 - in bitches, 676–682
 - cows, 434–442
 - does, 669, 670
 - ewes, 654–657
 - mares, 582–597
 - abnormalities of the, 591–597
 - queens, 699–704, 714
 - sows, 636–639
 - induction of the, in bitches, 694, 695, 713
 - queens, 705, 706
 - length of the, 412, 413, 415, 434, 435, 565, 566, 584, 637, 656, 669, 700, 701, 713
 - onset of the, after parturition in the cow, 258, 438–440
 - stages of the, 411–413, 676, 699–701
- Estrum**, 411, 412
 - aids for detection of, 501–503
 - control of, or prevention of, in bitches and queens, 500–504, 582–586, 637–639, 680, 681
 - detection of, 500–504, 565, 566
 - by teaser (“gomer”) bulls, 502, 503
 - during the gestation period, 14, 24, 31, 435, 714
 - failure of (see anestrus) in cows, 412–415, 478–491, 495–512
 - 574
 - accompanied by a corpus luteum, 495–507
 - due to cystic ovaries, 478–491, 507, 712, 718–720
 - debility, 508, 509
 - luteal cysts, 478–491, 509, 737
 - miscellaneous causes, 509, 510, 712, 713
 - “retained” or persistent corpora lutea, 495–497
 - “silent” or subestrus, 497, 498, 499, 500–508, 530
 - unobserved estrus, 499–507
 - etiology of, 495–500, 507–510
 - treatment of, 500–507, 510–512
 - with no corpora lutea, 507–511
 - failure of in mares, 594–597
 - foal (heat), 584
 - in bitches, 676–682, irregularities of, 713
 - in cows, 435–442, 501–504
 - in does, 669, 670, 672, 706, 922
 - in ewes, 654–658, 921
 - in mares, 582–586, 588–597
 - examination for, 588–591
 - irregularities of, 581, 586, 591–597
 - teasing to detect, 588–590
 - in mules, 584
 - in sows, 637, 645, 646, 918, 919
 - onset of in days after weaning, 638, 918, 919
 - the production of, during lactation, 638, 919
 - prediction of time of in cows, 503, 504
 - signs of in cows, 435–437, 501, 503, 504
 - suppression of in bitches, 687–690, 706
 - synchronization of in cows, 405–408, 441, 442, 507, 908
 - does, 670, 671
 - ewes, 402, 405, 406, 655, 659, 660
 - mares, 593, 597, 598
 - sows, 638, 918, 919, 921, 922
- Eunuchoidism**, 817
- Eutocia**, 277
- Eversion of the bladder**, 361
 - uterine horn, 361–371
 - uterus, 361–367
- Evisceration of the fetus (see fetotomy)**, 310, 312
- Examination for breeding soundness**, 745
 - pregnancy, 14–33
 - of the bull, 857–861, 862–870
 - of the semen (see semen examination)
- Exanthema, coital vesicular in cattle (see IBR-IPV)**, 138–142, 474, 555, 556, 804
 - in horses, 618, 805
- Exercise for males**, 788, 790
- Exostoses of the vertebrae in bulls**, 792
 - multiple, 60, 65
 - pelvic, 344
- Expulsion of the conceptus (see abortion)**
 - fetal membranes, 255, 256
 - fetus (see parturition)
- Extenders for semen of the boar**, 912–918
 - bull, 897–899, 900–904, antibiotics in, 898, 903
 - dog and cat, 923–926
 - ram and buck, 921, 922
 - stallion, 615, 912–914
- Extractor, fetal**, 291, 292
- Eye, defects of**, 57–59, 61–63, 66
- “Fading pup” syndrome**, 732
- Failure of estrus (see estrus, failure of)**
- Fallopian tubes (see uterine tube or oviducts)**
- False entry (see coition)**, 416, 417
- “Fat cow” syndrome**, 393–396
- Fat necrosis**, 346
- Fat, perivaginal, prolapse of**, 233–236, 344, 346, 361
 - removal of, 236, 361
- “Feathering” of the vagina**, 348
- Feeding of orphan newborn**, 264, 265
- Feline panleukopenia**, 66, 211
- Fertility evaluation of the bitch and queen**, 745
 - of males, 786–890, 906
 - of mares, 623, 624
- Fertilization**, 422–424, 426, 559–569, 587, 639, 640, 658, 683, 704
 - failure of, in repeat breeders, 559–569, 647
 - due to abnormalities of ovulation 423, 564, 568
 - due to the inability of the ova or spermatozoa to fertilize, 422–428, 559–569

- due to failure of sperm transport in the female, 660
 due to obstructions in the genital tract, 562, 841–845
 number of spermatozoa required for, 425, 426, 587, 639
 fetal electrocardiography, 15, 25, 31
 fetal membranes, 41–44
 dropsy of the, 43, 223–228, 240
 eating of the, by the dam, 256
 examination of the, 48
 retention of the, 256, 373–384
 separation and expulsion of the, from the uterus after parturition, 255, 256
 slipping of the, in bovine pregnancy diagnosis, 18, 20
 tumors of the, 48
 weight of the, 48
 Fetal monsters, 335–337
 incidence, 80, 81, 335
 methods of handling, 335–337
 Fetatomes, obstetrical, 293
 uses of, 309–337
 Fetotomy operations, 307–313, 327–332
 advantages and disadvantages of, 307
 Feto-pelvic disproportion, 278, 279, 281, 305, 335, 344
 Fetus
 adjustment of the extremities of the, 300, 301, 326–332
 amputation of the forelimbs of the, 309, 310, 327–332
 head and neck of the, 309, 327, 328
 rear limbs of the, 311, 312, 330
 anasarca of the, 55, 63, 226, 278
 anomalies of the, 51–82
 antibodies in the, 124
 ascites of the, 226
 autolysis of the, 123
 ballottement of the, 15, 18, 24
 bisection of the pelvis of the, 311, 312, 329, 331
 bovine, 19, 20, 39
 breakdown of the ribs of the, 310
 breech presentation of the, 253, 312, 330, 331
 cephalotomy of the, 308
 changes in the size of the, during gestation, 19, 20, 27, 37
 characteristics of the, during the stages of gestation, 19, 27
 circulation of the, 39–41
 craniotomy of the, 308, 336
 death and postmortem changes of the, 38, 218–220, 337–343, 346, 348–351, 685
 decapitation of the, 308, 328
 detruncation of the, 310, 311, 330
 displacement of the, or extrauterine, 218, 219, 222, 223, 741
 dropsy of the, 43, 226, 278
 edema of the, 43, 226, 271
 embryotomy of the (see fetotomy)
 emphysema of the, 218–220, 328, 330–332, 346, 348–351
 equine, 27, 28
 evisceration of the, 310, 312, 328
 excessive size of the, 106, 107, 278, 329, 331, 333–337, 349, 350
 expulsion of the, during parturition (see abortion) 252–255
 extractor for the, 291, 303–305
 extrauterine, 218, 219, 222, 223
 fetotomy of the, 307–314, 326–337, 344, 349, 350
 forced extraction of the, 259, 301–307, 328, 329, 331, 343–350
 fractures in the, 271, 303–307
 fructose in the, 41
 giantism of the, 106, 107, 278, 333, 334
 growth of the, 20, 27, 39
 injuries to the, at parturition, 271, 272, 303–307
 killing of the, before fetotomy, 307
 maceration of the, 23, 218–220, 283, 338, 340, 349, 350
 methods of handling abnormal presentations, positions and postures of the, 298–303, 326–332
 methods of handling excessive size of the, 301–323
 methods of handling the severely deformed, 307–323, 335–337
 movements of the, 41, 113
 mummification of the, 22, 143, 153, 123–222, (213–218), 232, 346, 349, 351, 404, 407, 415, 496, 500, 642
 mutation of the, 298–301, 326–332
 number of, in the uterus, 94, 95, 110
 nutrition of the, 39–44, 45
 nutritional deficiencies in the, 150, 151, 173, 188, 202, 269
 ovine, 39
 period of the, 39
 physiology of the, 41, 113
 position of the, in the uterus, 94, 252, 253; 299, 300, 326–332
 postures of the, 252, 253, 300, 301, 326–332
 presentations of the, 94, 252, 253, 300, 326–332, 687
 protection of the intrauterine, 42
 repulsion of the, 298–301, 326–332, 335, 350
 respiration of the, 41, 262, 263
 rotation of the, 94, 252, 299–304, 326, 330, 341, 342
 size of the, as regulated by the sire and dam, 281, 282
 bovine, 20; canine, 33; equine, 27; ovine, 32; porcine, 32, 39
 time of intrauterine death of the, after the onset of parturition, 289, 290
 traction on the, 301–307, 326–331, 333–337, 344–350
 transverse presentation of the, 252, 300–332
 tumors of the, 334
 version of the, 300–332
 weight of the, at term, 19, 27, 106, 107
 withdrawal of the, 304–307, 326–331, 333–337, 344–350
 wryneck of the, 41, 280, 283, 327
 Fibroelastosis of the heart, 270
 Fibromas, vaginal, 723
 Fibropapillomas, infectious, on the vulva, 476, 557
 on the penis and prepuce, 557
 Fibrosis of the testes (see testicular degeneration)
 Fistula, recto-vaginal, 359, 614
 Flehmen stance or reaction, 409, 670, 787
 "Flora," bacterial of the uterus, 103, 104, 538, 539, 602, 728–739
 Flushing of ewes, 657
 Follicle, ovarian (see Graafian follicle), primordial, 417–419, 676
 Follicle-stimulating hormone (FSH), 399, 400, 420, 422, 584, 586, 694, 713
 Follicular atresia, 418, 421, 585, 645, 703
 Folliculogenesis, 419
 Foramen ovale, 40, 41, 55
 Forced extraction, 301–307, 326–337, 344–350
 Forceps, obstetrical, 291, 292
 Fracture of the fetal jaw, 271, 303, 347
 limbs, 271, 303
 ribs, 271
 pelvis, 241, 344, 394
 rear limbs, 241, 303, 304, 394
 spine, 241, 304, 394

 controlling the gestation period, 106–110, 149, 247–251, 399–409, 683–686, 704
 controlling lactation, 114–116, 399, 401
 corpus luteal, progesterone, 107–110, 405, 406, 437, 438, 491, 507, 585, 734, 740
 relaxin, 247–251, 406, 687
 deficiency as a cause of abortion, 150, 171, 172, 201, 209, 212, 406
 as a cause of impotency, 784, 785
 as a cause of reduced spermatogenesis, 764
 as a cause of skin and hair lesions, 115, 408, 512, 599, 763, 784, 790
 equine gonadotropin (see PMSG), 401, 402, 694, 705, 706, 760, 928
 estrogenic, 403–405, 438, 482, 547, 564, 585, 658, 692, 709, 710, 761, 762, 784, 785, 829
 feeding of, 404, 483, 564, 644, 662, 663, 852
 follicle stimulating (FSH), 399, 437, 584, 593, 598, 658, 694, 760, 928, 938
 glucocorticoids (see cortisone)
 gonadal, 403–406, 593, 708–711, 734–740, 760, 761
 gonadotropic, 30, 31, 108, 109, 399–402, 488–491, 512, 515, 584–586, 593, 597, 646, 658, 671, 677–683, 694, 760, 761, 762–764, 784, 785, 928, 934–938
 human chorionic gonadotropic, (HCG), 760
 releasing (GnRH), 399, 489–491, 500, 564, 586, 593, 760–764, 785, 938
 growth (somatotrophic) 114, 399, 717, 763
 hypothalamic (see gonadotropic releasing, GnRH)
 inhibin, 5, 947, 950
 in the female, 104–107, 247–251, 399–409
 in the male, 760–764
 in the therapy for impotency and infertility in the male, 691–694, 704, 784, 785
 initiating parturition and abortion, 248–251, 404, 407, 408
 lactogenic (prolactin), 108, 109, 114, 115, 399, 401, 691, 763
 levels in the plasma in pregnant mares, 30, 584–586
 lutinizing (LH or ICSH), 400–402, 405, 437, 438, 480, 482, 483, 488–491, 585, 658, 677–682, 703, 713, 760
 Müllerian-inhibiting substance, 760
 posterior pituitary, 116, 401–403
 oxytocin (pitocin), 116, 150, 248, 249, 253, 345, 348, 349, 401–403, 763
 pitressin (vasopressin), (antidiuretic, ADH), 401–403
 progestational (progestogens), 405, 406, 438, 491, 507, 585, 593, 594, 597, 598, 658, 688–690, 706, 709, 734–740, 936, 938
 prostaglandins, 438, 490, 491, 507, 547, 585, 594, 597, 614, 638, 659, 671, 672, 691–694, 928, 936, 938
 pulsatile release of GnRH, LH and FSH, 400, 437, 438
 relaxin, 247–251, 345, 406, 687
 “repositol,” preparations, 404, 406
 somatotrophic (see growth), 114, 399, 712, 763
 testosterone (see androgenic)
 therapy in “repeat breeders,” 564, 565, 569
 thyroid, 115, 408, 512, 599, 763, 784, 790
 thyrotrophic, 399
- Hyaluronidase, 426, 767
- H-Y antigen, 75
- Hybrids, 75, 76, 820
- Hydatid cysts of Morgagni, 621
- Hydrallantois (see hydrops of allantois)
- Hydramnios (see hydrops of amnion)
- Hydrocephalus, 54, 60, 62, 63, 65, 77, 278, 285, 308, 336
- Hydrocortisone, 149, 172, 173, 188, 201, 209, 247–251, 408
- Hydrometra (see mucometra)
- Hydrops allantois, 43, 76, 223–228, 334, 335, 395
- Hydrops amnii, 43, 77, 223–228, 334, 335, 395
- Hydrosalpinx, 535–538, 609, 621, 642, 643, 661
- Hymen, 10
 embryology of the, 12, 13
 imperforate (persistent) 346, 522, 528, 622, 623
- Hyperadrenocorticism, 716
- Hyperbilirubinemia, 62
- Hyperestrinism, in the dog and cat, 405, 714, 717, 718
- Hyperkeratosis, 551, 661, 845
- Hyperplasia, of the prostate gland, 785
- Hypertrophy of muscle (“double” muscle), 56, 61, 278
- Hypocalcemia, 241, 346, 348, 353, 357, 361, 362, 368–370, 372, 374, 380, 394
- Hypoestrinism, and incontinence in dogs, 716–718
- Hypomagnesemia, 241, 371, 394
- Hypophysis (see pituitary gland)
- Hypophosphatemia, 372
- Hypoplasia of the adrenal gland, 106, 107, 333, 334
 cerebellum, 54, 63
 ovaries, 521, 522, 621

- pituitary gland, 55, 106, 107, 333, 334
 - testes, 763, semen characteristics of, 815–818
- Hypothalamus, relation to pituitary gland, (releaser substances from), 399, 489–491, 500, 564
- Hypothyroidism, 712, 717, 718
- Hypotrichosis congenita (see alopecia), 53, 57, 61, 62, 64, 67
- Hypoxia, 270
- Hysterectomy, 596
 - causing persistence of CL, 496
 - in dystocia, 323, 324, 331, 348–351
 - fetal emphysema and maceration, 218–220, 232, 324, 331, 348–351
 - uterine prolapse, 363, 365
 - rupture, 359
 - torsion, 32, 233, 340, 343, 359
 - infections, 387
- IBR-IPV infection, in females, 138–142, 474, 555, 556
 - in males, 139, 775, 803–805, 813
- Icthyosis congenita, 53, 64
- Icterus of the newborn (see neonatal isoerythrolysis), 267–269
- Idiogram (see Karyotype)
- Iliocolonic aganglionosis, 59
- Ilium, 3
- Immunity, transfer of from the dam to the newborn, 47, 263, 264
- Immunodeficiency, combined and other, 59
- Immunogenetics, 96, 97
- Immunologic pregnancy tests, 30
- Implantation or attachment of the embryo, 39, 560, 561, 563–565, 683
- Impotency in males (see libido), 762, 772–774, 782–785, 786–808
 - acquired factors, 786–789, 792–808
 - due to cardiac disease, 808
 - due to pain (in peritonitis, orchitis, balanitis, prostatitis, arthritis and etc.) 792–808
 - due to respiratory disease, 792–808
 - environmental factors, 788, 789
 - hormones in, 787, 790, 791
 - inheritance of, 787, 807
 - psychic, 789, 790, 794
 - tests for, 790
- “Impregnation” of mares, 866
- Inanition, as a cause of infertility, 515, 516, 596, 598, 782
- Inbreeding, 52, 67, 68, 278, 530, 819, 820
- Incontinence, in dogs, 716
- Induction of estrum in ewes during anestrus, 402, 659, 660
 - in mares during anestrus, 583–592
- Inertia, uterine, 225–227, 278–281, 305, 306, 344, 345–349.
 - causing dystocia, 347–349
- Infections of the genital organs, in bitches and queens, 728–740
 - cows, 374, 447–476
 - ewes and does, 660, 661, 672
 - males, 803–806, 841–843, 886, 887
 - mares, 599–619
 - sows, 643, 644
- of the navel, 263
 - of the newborn, contracted in-utero, 266, 267
- Infertility, 398–870
 - associated with, “repeat breeders,” 559–569, 575–579, 625–627, 646, 647
 - caused by stress, 566, 567, 645, 646, 663, 664
 - caused by cytogenetic defects, 819, 820
 - incidence of, 434, 581, 582, 636, 654, 673
 - induction of, to control pet populations, 687–694, 706, 707
 - instruments for the treatment of, 540
 - in the bitch and queen, 675–745
 - due to anatomic or congenital factors, 709–711
 - genital infections, 728–740
 - hormonal factors, 712–718
 - nutritional factors, 711
 - pathological factors and tumors, 718–728, 734–745
 - in the cow, 434–579
 - due to anatomical or congenital factors, 521–530, 709–711
 - genital infections, 447–476
 - hereditary factors, 481, 482, 521–531
 - high ambient temperatures, 566, 567
 - hormonal factors, 478–491
 - management factors, 481, 496–512, 514–519, 530, 579
 - nutritional factors, 481, 514–519
 - pathological factors, 533–557, 814
 - twinning, 100, 481, 482
 - economic importance of, 434
 - in the ewe and doe, 654–664
 - due to anatomic and congenital factors, 660
 - genital infections, 660–662
 - nutritional factors, 657, 662
 - pathologic factors, 660–662
 - in the hybrids, 820
 - in the male animal, 752–870, 872–890
 - breeding soundness evaluation (BSE) (or diagnosis of), 857–870, 872–886, (see 885)
 - due to age, 789
 - anatomic, congenital and hereditary factors, 787
 - hormonal factors, 784, 785, 787, 790, 791
 - impotency or lack of libido, 784–792
 - inability or difficulty in copulating, 786–808
 - inability or reduced ability to fertilize, 813–815, 857–890
 - management factors, 789, 790
 - nutritional factors, 782, 783, 788
 - in the males twin to freemartins, 820
 - in the mare, 581, 582, 588–628
 - due to early embryonic or fetal death, 600–606
 - genital infections, 599–619
 - hereditary or congenital factors, 621–623
 - hormonal factors and irregularities of the estrous cycle, 591–597
 - management factors, 588–590
 - nutritional factors, 598
 - in the sow, 636–648, 814
 - due to anatomic or congenital factors, 642, 643
 - genital infections, 643, 644, 647
 - hormonal factors, 644–646
 - nutritional factors, 647, 648
- Infusions, intrauterine, 538–547, 612, 615, 616
- Inguinal canal, 754, 755
 - hernia, 59, 61, 65, 760, 822
- Inhibin, 5, 947, 950
- Injuries, at coitus (copulation), 416, 417, 644, 700, 711, 774–776
 - to the female during dystocia or parturition, 240–242
 - fetus and newborn, 271, 272, 303–307

INDEX

joints, tendons, muscles of the dam, 240–242
of the male preventing copulation, 792

penis and prepuce preventing copulation, 794, 796–799

spine of the male, 792, 793

insemination, artificial, 894–926

advantages and disadvantages, 895, 896, 900, 901, 911, 916, 922, 923

as a cause of abortion, 151, 906

blood-typing of bulls for parentage tests, 96, 97, 909

history of, 894, 901

"impregnation" in mares, 915

in bitches, 923–925

cows, 896–909

ewes and does, 920–922

others, 926

mares, 911–915

queens, 925, 926

sows, 916–919

organizations and health standards in, 895, 898, 903, 904, 908, 909, 911, 923

site of, in bitches, 924

cows, 567, 905–907

ewes and does, 921, 922

mares, 914, 915

queens, 925

sows, 919

time of, in bitches, 924

cows, 437, 566, 905

ewes and does, 921, 922

mares, 914

sows, 639, 918

Intrauterine devices, (I.U.D.), 221, 407, 659

Instruments, used in obstetrics and sterility therapy, 290–294

Interestrous interval in bitches, 676

Intersexes (see hermaphrodites), 72–75, 97–99, 671, 672, 673, 709–711, 715, 820

Interstitial cells, 753, 760, 764, 769

hypoplasia of the, 817, 818

tumors of the, 833–835

Intestines, prolapse of, 360, 362

Intrauterine migration of embryos, 38, 111, 588, 641, 642, 657

Intromission (see coition)

Invagination of the uterine horn, 353, 362, 366, 367, 382

Involution of the uterus, 256–259, 438–440, 544, 545

corpus luteum, 406, 407, 411, 436, 440, 441, 742

Iodinated casein, 115, 408

Irradiation, effect on testes, 828, 829

Ischiocavernosus muscle, 757, 770

Ischium, 3

Isoerythrolysis, neonatal, 267–269

Isoxsuprine, a tocolytic agent, 248, 296

Isthmus, of uterine tube, 8, 423, 424, 427

Joints, lesions of, 60, 65, 792, 793

malformations of, 57, 59, 60, 61, 64, 65, 69, 70, 78

Kartagener's syndrome, 819

Karyotype, 51, 70, 73–76, 96, 97, 529, 621, 709, 814, 815, 820

Ketosis, in cattle, 240, 370

ewes and does, 202, 240, 370, 371, 394

Kidneys, anomalies of the, 63, 66, 72

fetal, 41

Klebsiella pneumoniae genitalium infection in the mare, 165, 602, 605

Klinefelters' syndrome (XXY), 585, 815, 817, 820

Labor, 251–255

Laceration of the cervix, 314, 354

uterus, 354

vagina, 314, 344, 353, 354, 416

vulva, 259, 314, 354

Lactation, 113–117, 686, 704

artificial induction of, 115, 405

hormonal control of, 113–116, 401, 404–406, 686, 704

of milk "letdown," 116, 402, 403

suppression of, 116, 405

Lacuna, lymphatic, 25

Laminitis, puerperal, 389, 390, 394

Laparohysterotomy (see cesarean operation)

Laparoscopy, 681, 704

Laparotomy, for extrauterine fetuses, 222, 223, 359

rupture of the uterus, 359, 360

uterine infections, 387

prolapse, 363, 365

torsion, 233, 341

Leiomyomas, 723

Leptospirosis, as a cause of abortions, 131–134, 165, 180–182, 197

in relation to infertility, 471

Leydig cells (see interstitial cells)

Libido (see impotency), 762, 772–774, 782, 784, 785, 786–792

effect of frequency of service on, 772, 773

lack of, in males, 777, 782, 784–808

effect of hormones on, 762, 784, 785, 787, 791

Ligaments, accessory, 3, 4

broad, of the uterus (see mesometrium), 9

cotyloid, transverse, 5

dorsal apical, of penis, 795

dorsal and lateral sacroiliac, 3

pelvic, 3, 246, 484, 485

relaxation of, at parturition, 5, 246

round, of the bladder, 41

hip, 4

liver, 41

sacrosciatic, 3, 484–486

Ligamentum arteriosum, 41

venosum, 41

Light, effect of on breeding season in ewes, does, males, queens and

sows, 583, 592, 654–656, 669, 699

"Limber legs," in Jersey calves, 54

Lip and leg ulceration, in sheep, 661

Lipoma, strangulation of uterus by, 173

Lipomatosis, 58

Listeriosis, causing bovine abortion, 134, 135

ovine abortion, 194, 195

Lithopedion, 223

Litter size, 95, 101, 640, 641, 699

Liver, 40

Liveability or longevity tests for spermatozoa, 587, 877

Lochia, 257, 258

infection of the, 257

Losses of newborn, 270

Lubricants, obstetrical, 294, 299, 304, 305, 326, 334, 344–346, 349, 350

- Luteinizing hormone (LH), 400, 401, 402, 404, 437, 438, 593, 677–682, 703, 763
- Luteolysin or luteolytic factors (see prostaglandins and estrogens), 440, 594, 595
- Maceration of the fetus, 218–220, 232, 283, 338, 340, 349, 351, 415, 496, 500
- Major histocompatibility complex (MHC), 97
- Malformations (see anomalies, teratology)
- Malignerers, 395
- Malpractice, in relief of dystocia, 306
- Mammary gland, 14, 113–117, 402, 404, 405
 - anatomy of the, 113
 - artificial involution of the, 273
 - ectopic, 673
 - tumors of the, in the bitch and queen, 725–728
- Management, as a cause of dystocia, 278–280
 - infertility in cows, 481, 496–512, 514–519, 530, 575–579, 813
 - mares, 581, 582, 625–628
 - sows, 648, 814
 - diseases of the newborn, 269–272
- Mannosidosis, 54, 62
- Mastitis, 387, 388, 726
- Masturbation, 769, 776
- Meconium, 43, 72
 - retained, 265
- “Medusa heads,” 768, 882, 884
- Melanoma, 620, 621
- Melatonin, 409
- Menopause, 110, 419
- “Menstruation,” metrorrhagia in the bitch, 677–699, 742–745
 - in the cow, 15, 437
- Mesometrium, 7, 8, 9
- Mesonephric duct (see Wolffian duct), 11–13, 529, 535, 556, 621, 622, 709, 759, 843–846
- Mesorchium, 753
- Mesosalphinx, 8
- Mesovarium, 6
- Metabolic disease of the puerperal period, 240–242, 368–372
 - eclampsia, 240–242, 368–370, 372
 - grass tetany (hypocalcemia), 240–242, 368–372
 - ketosis, 240–242, 370, 371
 - parturient paresis (milk fever), 240–242, 346, 348, 368–370
- Metestrus, 412, 677
- Metritis, endo- in the bitch and queen, 734–740
 - cow, 218–220, 346, 348, 349, 350
 - mare, 382, 383, 538–546, 600, 601, 608
 - laminitis from, 382, 389, 390
 - metritis-mastitis-agalactia (MMA) syndrome in sows, 387, 388
 - peri- and para-, 219, 223, 351, 359, 535–538, 548, 549, 643
 - postpartum, 272, 353, 376–389, 538–550
 - sclerotic, 219, 550
 - septic, 384–386, 389, 394
 - of pregnancy, 218–220, 227, 228, 241
- Microphthalmia, 55, 62, 66
- Milk, composition of, in animals, 117
 - production of, 117
 - stimulation of the “let-down” of, 116, 402, 403
 - suppression of the let-down of, 116, 402, 403
 - uterine, (“milk”), 39, 42, 405
- Milk fever (parturient paresis) in the cow, 240–242, 346, 348, 368–370, 374
 - syndrome in the cow, 387, 388
- Minchev’s operation of vaginal fixation, 238
- Mineral deficiencies, 150, 151, 173, 188, 202, 518, 519
- M.I.P. test for pregnancy in the mare, 30
- Mismating, prevention of conception and abortion, 687–694, 705–707, 715
- Mitochondria of spermatozoa, 767, 768
- “Moles,” hydatiform of the fetal membranes, 48, 551
- “Monorchidism” (see cryptorchidism)
- Monotocus animals, 94
- Monsters, fetal (see anomalies and teratology), 69, 76–82, 278, 313, 335–337
 - campylorrhachis scoliosa, 78, 313, 335, 336
 - causing dystocia, 278, 313, 335–337
 - double, 81, 82, 313, 336
 - conjoined twins (diplopagus), 81, 82
 - dicephalus, 82
 - dipygus, 82
 - perosomus elumbis, 78, 335, 336
 - perosomus horridus, 78, 336, 337
 - schistosomus reflexus, 78, 313, 335, 336
- Morphology of spermatozoa, 763, 766–768, 814–819, 837, 877–885
 - in testicular pathology, 836, 837
 - primary abnormalities, 763, 814, 837, 879–882
 - secondary abnormalities, 818, 837, 879–882
- Morula, 38
- Mosaicism, 52
- Motility of spermatozoa, 768, 813–815, 818, 819, 836, 875–877
 - degree of, 875–877
 - determination of, 875–877
 - in testicular or genital pathology, 815–838, 874
 - percentage of, 875–877
 - rate of, 424, 425
- Mucocervix, 487, 554
- Mucometra, 23, 486, 487, 496, 500, 546, 550, 551, 642, 672, 720, 734
 - associated with cystic ovaries, 486, 487, 720
 - in white heifer disease, (segmental aplasia of the paramesonephric ducts), 41, 277, 346, 522–528, 642
- Mucus, from nose and mouth of newborn, 263
 - from vulva in estrus, 435, 436
 - pregnancy and cervical, 22
- Mules, 75, 76
- Mules’ operation on ewes, 661, 662
- Mullerian duct (see paramesonephric duct), 12, 13
 - agenesia of the, in the cow, 277, 346, 522–528
 - in the sow, 642, 643
 - persistence of the median wall of the, 277, 346, 526–528, 622, 642, 643
 - segmental aplasia of the, 522–528, 622, 642, 643, 660, 710, 721, 845
- Multipara, 94
- Multiple births, in unipara (see twinning), 95, 96, 335
 - incidence of in cows, 96
- Mummification, fetal (see abortion), 123–222, 213–218, 232, 346, 349, 351, 415, 496, 500, 642
 - hematic in cows, 214–217, 407, 496
 - papyraceous, in the mare and multipara, 214, 217, 218, 741
 - static fetal cadaver, 214
- Muscle, corpus spongiosum, 770
 - external cremaster, 764
 - hypertrophy (“double”-muscling), 56, 61, 278
 - relaxants for uterine, 248, 296, 299, 349

- rupture of the gastronemius, 357, 394
 Mutation of the fetus, 298–301, 326–333
 Mycoplasmas (see ureaplasma or T mycoplasma),
 in females, 135, 136, 164, 165, 184, 199, 469–471, 538, 539,
 661, 672, 730, 813
 in males, 469–471, 848, 849
 Mycotic abortion, 145, 148, 170, 188, 199
 Mycotoxins, 148, 188, 519, 644
 Myiasis, 661, 662
 Myoclonia congenita, 61
 Myositis, Zenker's, 241, 357, 394
 Myotonia congenita, 62
- Navel, care and disinfection, 255, 263, 265, 269
 infection of the, due to a persistent urachus, 265
 Necrosis, of the skin of the udder associated with edema, 114
 Necrospemia, 889
 Necrotic tips of the allantochorion in the cow, 44
 Necrotic vaginitis and vulvitis, 355, 379, 390, 391, 555
 Neonatal isoerythrolysis, 267–269
 Neoplasms (see tumors)
 Nerve, hemorrhoidal, 236–238
 gluteal, 355, 394
 obturator, 279, 306, 329
 pudendal, 236–240
 nerve block of the, 236–240
 Nervous system, embryology of the, 39
 in the physiology of reproduction, 398, 399, 400, 401, 403, 421,
 422
 Neurohypophysis, 402, 403
 Newborn
 anomalies of the, 51–82, 335–337
 antibiotics in diseases of the, 263, 265
 care and feeding of the, 262–265
 orphan, 264, 265
 infection of the, contracted in-utero, 266
 injuries of the, 259, 271, 272, 303–307
 due to a vicious dam, 259, 271, 272
 killing of the, due to avicious dam, 259, 271, 272
 losses due to chilling of the, 270
 need of the, for colostrum, 263, 264
 neonatal isoerythrolysis of the, 267–269
 neoplasms of the, 269
 nutritional diseases of the, 269
 parasitisms of the, contracted in-utero, 267
 stimulation of respiration in the, 262, 263
 Nitrate poisoning, as cause for abortion, 147–149
 Nodular venereal disease (see granular venereal disease)
 Nonreturn rates in AI of cattle, 560, 888, 906, 907
 Nullipara, 95
 Nutrition, deficiencies of causing abortion, 150, 171, 173, 188, 202
 causing dystocia, 278–280
 causing infertility in females, 508, 509, 514–
 519, 566, 598, 599, 647, 648, 657, 662,
 711
 causing paraplegia of pregnancy, 240–242
 of the dam, 240–242, 245, 711, 712
 of the orphan newborn, 264, 265
 overfeeding and obesity, 279, 882, 888
- cow, 478–491
 mare, 593, 596
- Obesity, as a cause of dystocia, 279
 infertility in females, 516, 599
 males, 782, 788
 Obstetrical operations (see operations, obstetrical)
 Obstetrics, definition of, 1
 Obturator nerve, paralysis of the, 279, 306, 329, 355, 356
 Occipital joint, dislocation of the, 304
 Odor, male (see pheromones), 398, 409, 410
 Onanism (see masturbation)
 Oocytes, 417–419, 676
 number of, 418, 419, 676
 Oogenesis (see ovogenesis)
 Oogonia, 417, 418
 Operations, obstetrical, 298–324
 cesarean section, 314–323
 in bitches and queens, 321–323
 in cows, 316–320
 in ewes and does, 320
 in mares, 314–316
 in sows, 320–321
 episiotomy, 347
 fetotomy, 307–314, 327–332
 advantages and disadvantages, 307–317
 amputation, of the forelimb, 309, 310
 of the head and neck, 309
 of the rear limbs, 311, 312
 bisection of the fetal pelvis, 311, 312
 breakdown of the ribs, 310, 312
 cephalotomy, 308
 decapitation, 308
 detruncation, 310, 312
 evisceration, 310, 312
 on monsters, 333–337
 forced extraction, 259, 301–307, 326–337, 343–350
 hysterectomy, 323, 324
 incidence of, 298
 mutation, 298–301
 extension and adjustments of the fetal extremities, 300, 301
 repulsion, 298, 299, 301
 rotation, 299, 300, 301, 303, 304
 traction, 301–307
 version, 300
 splitting of the pelvis of the dam (see symphysiotomy), 313, 344
 vulva-suturing (see Caslick's operation), 237–240, 346, 347, 355,
 556
 Orchitis (see testis, degeneration of the), 776, 829–832, 837, 838,
 841, 842
 in brucellosis, 829
 treatment of, 837, 838
 Orphans, adoption of by other dams, 264, 265
 feeding and care of, 264, 265, 323
 Os coxae, 3
 Os penis, dog, 757
 Osteoarthritis, 57
 Osteochondrosis dissecans, 60, 65
 Osteogenesis imperfecta, 53, 65
 Osteopetrosis, 53
 Ovariectomy, 400, 596, 713
 during pregnancy, 104–108

- Ovaritis, 504, 505, 534, 535, 610, 734
- Ovary, agenesis of the, 522
 - anatomy of the, 5–8
 - cysts of the, in bitches and queens, 712, 714
 - in cows, 402, 404–406, 415, 478–491
 - in sows, 644, 645
 - during pregnancy, 21, 22, 29, 93
 - dysgenesis of the, 621
 - effects of removal of the, on pregnancy, 104–108
 - hematoma of the, 620, 621
 - hormones of the (see estrogenic, progestational, relaxin, and inhibin), 403–406
 - hypoplasia of the, 419, 521, 522, 621
 - palpation of the, at estrum in the cow, 567, 568
 - in the mare, 587, 588, 591, 592
 - parovarian cysts of the, 535, 621, 645, 661
 - “smooth,” nonfunctional, 507–511
 - tumors of the, 533, 534, 620, 647, 661, 673, 722, 723
- Ovigenesis, 417–419, 676
- Oviducts (see uterine tubes), anatomy of the, 8
 - anomalies of the, 535, 643
 - embryology of the, 12, 13
 - pathology or disease of the, 535–538, 609, 610, 643
 - tests for patency of the, 537, 610
 - transport of ova and embryos through the, 422, 424, 586, 639, 640, 658, 670, 683, 704
 - transport of spermatozoa through the, 424–428, 587, 639, 658, 670, 680–683, 700–704
- Ovulation, 419–422, 565, 566, 584–588, 591, 637, 655–658
 - double in mares, 95, 585, 586, 588
 - endocrine control of, 399–401, 420–422, 584–586, 637, 639, 681–683, 694, 700–704
 - failure of, or delayed, 491, 492, 588, 645, 646, 670
 - follicular atresia, after or before, 418–420, 584, 586, 645, 703
 - fossa, in the mare, 6, 420, 585, 586
 - in bitches, 681–683
 - cows, 96, 432, 437, 565, 566
 - does, 670
 - ewes, 655–659
 - mares, 584–586
 - queens, 700–704
 - sows, 637, 639
 - induction of, in bitches, 694, in queens 703, 704
 - influence of the nervous system on, 421, 422
 - multiple, in unipara associated with infertility, 95, 96, 588
 - species with spontaneous and nonspontaneous, 421, 422, 585
 - super-, 101, 422, 492, 597, 598, 928, 936, 937
 - time of, 422, 435, 437, 491, 492, 566, 586, 639, 657, 669, 681–683, 700–704
- Ovum or early embryo, 36, 417–419
 - abnormal or defective, 562, 563
 - migration of the, 38, 111, 428, 588, 640–642, 657, 683
 - rate of transport of the, to uterus, 422–424, 586, 640, 658, 670, 683, 704
 - size of, 423
 - spacing of the, in the uterus of multipara, 111, 428, 588, 640–642
 - viability of, after ovulation, 423, 587, 639
- Oxygen, for the stimulation of respiration in the newborn, 263
- Oxytocin, 116, 150, 248, 249, 253, 345, 348, 349, 358, 364, 365, 383, 401–403, 440, 670, 686
 - in the male, 763, 768, 771, 772
- Palatoschisis, 39, 55, 60, 61, 67
- Pampiniform plexus, 753, 764
- Panleucopenia abortion in queens, 211
- Paradidymides, 759
- Paralysis, of the gluteal nerve, 355, 394
 - obturator nerve, 279, 306, 329, 355, 356, 394
 - penis, 802
 - peroneal nerve, 356, 357, 394
- Paramesonephric duct (see Mullerian duct), 12, 13, 41, 277, 346, 522–529, 535, 550, 621, 622, 709–711
- Paraphimosis, 619, 775, 800, 801, 802, 805
- Paraplegia, of pregnancy, 240–242, 353
 - postpartum, 353, 355–357, 393–396
- Parasite, 82, 267
- Paratyphoid (see salmonella) abortion in ewes, 196
- Parentage testing (blood), 96, 97, 909
- Paresis (see paraplegia)
- Paresis, spastic in cattle, 240–242, 346, 348, 368–370, 374, 394
- Parturition, 107–110, 245–276, 686, 704, 705
 - artificial interference in normal, 248–251, 259
 - cervical dilation in, 247, 248, 251, 252
 - double, 112
 - duration of stages of, 251–259, 687, 705
 - expulsion of the fetal membranes in, 255, 256, 687, 705
 - expulsion of the fetus in, 253, 255, 687
 - induction of, 248–251
 - initiation of, 108–110, 247–251, 333, 345, 686–687, 705
 - involution of the uterus after, 256–259, 742
 - lowering of the body temperature during the early stages of in the bitch, 109, 247, 252, 686, 705
 - nutrition of the fetus in relation to, 247
 - placental changes prior to, 255, 256
 - placental separation from uterus after, 255, 256, 687
 - postponement of, by tocolytic agents, 248
 - presentation, position and posture of the fetus at, 252, 253, 687
 - stages of, 251–259, 687
 - symptoms of, 245–247, 251–259, 687
 - time of day as related to, 246, 247
 - uterine contractions in, 251–259
- Parvovirus abortion in sows, 186, 187
- Patella, subluxation of, 59, 65
- Pavilionitis (see oviduct),
- Pederasty, 777
- Pelvis,
 - bisection of the fetal, 311, 312
 - comparative anatomy of the, 3–5
 - diameters of the, 4, 5
 - disproportion of fetal and maternal, 278, 279
 - ligaments of, 3–5
 - relaxation of the, 4, 107–110, 245–276
 - splitting of the, in the dam (see symphysiotomy), 313, 344
 - stenosis of the, causing dystocia, 278, 279, 344
 - withdrawal of the fetus through the, 303–307
- Penis,
 - adhesions of, 763, 796–799, 803, 806, 807
 - amputation of the, 800, 802, 803, 807
 - anomalies of, 793–795

- anatomy, comparative of the, 756, 757, 771
- arrested development of the, 793, 794, 807
- broken (see rupture of the)
- bulbus glandis of the, in the dog, 757
- chronic protrusion of the, in dogs, 802
- coiled or "corkscrewed," 771, 795, 807
- congenitally short, 793, 794, 807
- corpora cavernosa of the, 756, 770, 795, 799
- deviated, curved, bent or spiralled, 771, 795, 796
- double, 793
- edema of the, 802
- embryology, 12, 759
- erection of the, 756, 770, 771, 799, 807, 808
- excessive size of the, 807
- fibropapillomas of the, in the bull, 799, 800
- fistula of the, 776
- glans of the, 756, 757, 770, 771
 - "belling" of the, in stallions, 770
- hematoma of the, 770, 775, 776, 796–799
- hemorrhage from the, 770, 775
- hypospadias of the, 793, 794
- inability to protrude the, 793–798
- infections of the, 468–471, 474, 618, 661, 775, 794–807
- injuries and diseases of the, preventing copulation, 793–807
- injuries to the, at coitus, 775, 797
- loss of sensation to the glans, 771, 798, 807
- muscles of the, 757, 794
- os of, 757, 776, 795, 807
 - fracture of the, 776
- papillae or spines of the, in the cat, 758
- paralysis of the, 757, 802, 806
- persistent frenulum of the, 758, 763, 795
- prolapse and paralysis of the, 757, 802, 806
- rupture of the, 770, 775, 796–799
- sarcoma, infectious venereal, of the dog, 799, 800
- sigmoid flexure of the, 757, 763, 794, 796
- tumors of the, 775, 799, 800
- twisting of glans at ejaculation, 771, 795
- Perianal gland neoplasia, 854
- Perimetritis, 219, 223, 351, 359, 535–538, 547, 549
- Perineum, anatomy of, 11
 - rupture of, 259, 347, 359, 360
- Periods or stages of gestation, 38, 39, 104–107
- Peritonitis, 333, 338, 340, 343, 354, 357–359, 385, 547–549, 743
- Perivaginal fat, prolapse of the, 233, 236, 346, 361
 - removal of the, 235–240, 361
- Peroneal nerve paralysis, 356, 394
- Perosomus elumbis, 61, 78, 79, 329, 330, 335, 336
 - horridus, 78, 79, 336
- Persistence of the corpus luteum, in cows, 24, 214, 217, 407, 496, 497, 546
 - in does, 672
 - in mares, 587
- ductus arteriosus, 40, 64, 67
- urachus, 59, 265
- Pessaries, 237, 365, 597, 608
- pH of semen, 772, 874
- Phallocampsis, 795
- Phenocopies, 69
- Pheromones, 398, 409, 410, 680, 699, 761, 762, 785, 787

 scrotum, 835
 testes, 710, 761, 784, 833–836
 undescended, 710, 761, 784, 821, 822, 829, 834, 835
 transmissible venereal in the dog, 724, 799
 uterus, 550, 621, 647, 673, 723, 724
 vagina, 346, 556, 621, 723
 vulva, 557, 621, 661, 673, 724
 Turner's (XO) syndrome, 75
 Twins, 23, 25, 30, 79, 81, 82, 95, 96, 99–102, 335, 585, 586, 588
 causes of, 101, 102
 conjoined, 81, 82, 335
 differential diagnosis in pregnancy examinations, 24, 25, 30, 335
 dizygotic, 75, 95, 96
 "double" parturitions in, 112
 double (twin) ovulation in mares, 558
 dystocia due to, 95, 96, 100, 335
 incidence of, 95, 96, 585–588
 influence of nutrition on, 95, 101
 monozygotic, 79, 95, 96
 prevention of, 99–102, 173–175
 monsters, conjoined, "Siamese", 81, 82, 335, 336
 undesirability of, in unipara, 99–101, 335
 unicornual, 93
 Udder, (see mammary gland), 15, 113–117
 Ulcerative dermatosis of sheep, 661, 662, 805
 Ultrasonography, for pregnancy diagnosis, 15, 24, 25, 31, 683, 741
 Umbilical arteries, 40, 41, 49, 255
 cord, 40, 48, 49
 dangers of ligation of the, 263
 disinfection of the, 263
 dystocia due to the, 333
 pulsations in, in foal at birth, 254
 rupture of the, at parturition, 49, 255
 torsion of the, 49, 152, 174, 271
 hernia, 49, 57, 67, 343
 vein, 40, 49, 255
 Umbilicus, 49, 255, 259
 care of, after birth, 255, 259, 263
 Underfeeding (see inanition), 151, 172, 201, 202, 278–282, 515, 516, 782
 Unipara, 94
 multiple births in, 95
 Urachus, 41, 43, 49, 255, 265
 persistence of the, 59, 265
 Ureaplasmas (see T-mycoplasmas), 469–471, 538, 539, 661, 672, 730, 731, 813, 841, 848
 Ureters, 39, 63
 ectopic, 63, 72, 622
 Urethra, 11, 41, 755, 756, 757
 calculi in the, 776, 808
 diverticulum of the, in boars, 11, 607, 756, 757
 fossa of the, in stallions, 607
 embryology of the, 41
 process (filiform or vermiform) in stallion and ram, 757, 771
 Urethral glands, 756, 770
 muscle, 757
 Urethritis, 776
 Urinary calculi, 808
 Urine, in continence of bitch, 716
 pooling, in vagina (see urovagina), 440, 539, 555, 556, 609, 641, 642, 659
 Uro-genital system, embryology of, 12, 13, 39, 709
 Urovagina, 539, 555, 556, 609, 641, 642, 659
 Urticaria, 272
 Uterine artery, 8, 20, 21, 29
 lochia, 257
 "milk", 34, 405
 "sand" (in spissated plasma) 48, 376
 tube, (see oviduct)
 anatomy of the, 8
 embryology of the, 12
 incidence of diseases of the, 536, 621, 643
 pathology of the, 535–538, 621, 643
 vessels, rupture of, 353, 354
 Utero-ovarian pathway (see prostaglandins)
 Uteroverdin, 258
 Uterus
 abscess of the, 390, 549, 550, 608, 609
 adhesions of, 358
 amputation of the prolapsed, 363–365
 anatomy of the, 9
 anomalies of the, 522–525, 622, 660, 718, 719
 "bacterial flora" of the, 103, 104
 biopsy of the (see biopsy, endometrial), 540, 541, 591, 616–618, 624
 blood flow to, during pregnancy, 112, 113
 collagen increases in the, with aging and disease, 568
 contractions of the, during and after parturition, 251–259, 296, 299
 culture of the, 599–613, 616–618, 624
 evaluation of the, 602, 617, 624
 curetting of the, in the mare, 595
 cytology (smear) in the mare, 616–618, 624
 "degeneration" of the endometrium of the, 478–491, 616–618, 734–740
 didelphys, 526, 527, 642
 douching of the, to cause abortion, 151, 173, 221
 to cause luteolysis in the mare, 594
 embryology of the, 12, 13
 enlargement of the, localized in mare, 621, 622
 hemorrhage into the, 214, 216, 257, 353, 354, 720, 740

- inertia of the, or failure of uterine contractions, 225, 226, 227, 278–281, 305, 306, 344, 345–349, 599–613
 - infections or inflammation of the, (see endometritis, metritis, pyometritis, pyometra and retained placenta), 23, 257, 374–388, 538–550, 734–740
 - influence of hormones on the, 103, 734–740
 - infusion of the, 542, 544, 569, 614, 616
 - invagination of the apex of the horn of the, 353, 366, 367
 - involution of the, 256–259, 439, 544, 545, 584
 - laceration of the, 353–355
 - masculus, 12, 13, 756, 759
 - number of fetuses in the, 94, 95
 - position of the fetus in the, 94, 252, 253
 - prolapse of the, 361–367
 - retraction of the, to assist palpation of the, 16, 17, 26
 - rotation of the, in uterine torsion, 93
 - rupture of the, 218, 219, 222, 223, 233, 242, 314, 345, 353–355, 357–360, 737, 743
 - size and location of the pregnant, 8, 20, 28, 93
 - torsion of the, 93, 230–233, 337–343, 351, 354, 357, 738, 740, 741
 - incidence of, 337
 - tumors of the, 550–557, 620, 621, 647, 661, 673, 723
 - unicornis, 524, 525, 622, 710
- Vagina,**
- anatomy of the, 10
 - anomalies of the, 346, 528, 529, 720, 721
 - atresia of the, 346, 528, 529, 720, 721
 - biopsy of the, for pregnancy diagnosis, sows, 31, 32
 - cysts of the, 529, 556, 622, 710
 - cytology of the (see smears), 591, 677–679, 702, 712, 741
 - during pregnancy, 22, 29
 - edema of the, during estrus in the bitch, 679
 - embryology of the, 12, 13, 709
 - examination of the, 22, 29, 679, 721, 741
 - “feathering” of the, to promote oxytocin release, 348
 - Gartner’s ducts in the, 11–13, 529, 556, 622, 710
 - hematoma of the, 346, 353, 354, 355, 361
 - hymen of the, 10, 12, 13, 346, 622
 - hyperplasia (edema) and prolapse of the, 240, 679
 - inflammation of the, (see vaginitis)
 - lacerations of the, 314, 344, 416
 - prolapse of the, 233–240, 343, 344, 354, 355, 484, 679
 - reefing operation on the, 239
 - rupture of the, 314, 344, 346, 353–355, 357–359, 361, 416
 - septate, 278, 346, 526, 528, 622
 - smear of the, for cytology, 591, 677–679, 712, 702, 736, 741
 - stenosis or constriction of the, 277, 346, 529, 609, 741
 - tumors of the, 346, 361, 556, 621, 723
- Vaginal hysterotomy (trachelotomy),** 345
- smear in the bitch, 677–679
 - queen, 702
- Vaginitis,** 343, 468–472, 474, 475, 554–556, 672
- due to *C. pyogenes*, 472
 - due to IBR-IPV (infectious pustular vulvo-vaginitis) 138, 142, 474, 555, 556
 - in “epivag,” 474, 475, 555
 - in granular venereal disease, 468–471, 555, 729
 - in prolapse of the vagina, 233–240, 343, 679
 - in the bitch and queen, 33, 741
 - in the cow, 468–471, 475, 554–556
 - in the mare, 599, 600, 609, 614
 - in trichomoniasis, 449
 - necrotic, 355, 379, 390, 391, 556, 557
- Vaginoscopy,** 501–504, 582–591, 679, 733
- Varicocele,** 828
- Vas deferens,** 755, 759, 769
- ampullae of the, 755, 769
 - anatomy of the, 753, 755
 - anomalies of the, 843–845
 - inflammation and pathology of the, 845, 846
- Vasectomy,** 502
- Vasopressin** (antidiuretic hormone, ADH) 401–403
- Vein, umbilical,** 40, 41, 255
- Ventricle, ovarian** (see bursa)
- Version of the fetus,** 300, 331, 332
- Vertebrae, pathology of, in the male,** 792, 793
- Vesicle, amniotic,** 18
- blastodermic, 26–28
 - chorionic, 26–28
- Vesicular coital exanthema** (see IBR-IPV), 138–142, 165, 474, 555, 556
- Vesicular gland** (see seminal vesicle)
- Vestibular gland** (see Bartholin’s gland), 11
- Vestibule, (see vulva)**
- anatomy of the, 11
 - inflammation of the, (see vulvitis, vestibulitis)
 - pneumovestibule, 600
 - stenosis or constriction of the, 54, 277, 529
 - vestibulitis (see vulvitis), 554–557, 600, 609
- Viability, of ova, after ovulation,** 423, 587
- of spermatozoa in the female genital tract, 425, 426, 437, 565, 566, 587
 - tests on spermatozoa, 872–887
- Vibriosis, abortion in** (see campylobacteriosis), 134, 460, 462, 539, 813
- in cattle, 134, 456–465
 - in sheep, 193, 194
- Vices, in male animals,** 776, 777
- Viciousness in female animals, after parturition,** 271, 272
- in males, 777
- Villi, of the fetal placenta,** 39, 44, 45, 48
- Viruses, as a cause of abortion**
- in bitches, 209, 729
 - cows, 138–145
 - ewes and does, 197–199
 - mares, 165–170
 - queens, 211, 212
 - sows, 184–188
 - as a cause of anomalies, 70
 - as a cause of infertility in cows, 474–476
- Viscid rod infection** (see Klebsiella), 162–165
- Vitamin deficiencies, contributing to abortion,** 150, 151, 173, 188, 202, 374
- causing infertility, 517, 783
- Vitelline sac** (see yolk sac)
- Volume of semen at ejaculation,** 873
- Vomerian organ** (see pheromones), 409, 699
- Vulva** (vestibule)
- anatomy of the, 11
 - Bartholin’s (vestibular) gland, 11
 - cysts of the, 235, 557, 710
 - clitoris in the, 11, 604, 612, 709, 716
 - contusions and edema of the, 346, 347, 354, 355, 484

- depigmentation of the, 618, 619
- discharge (type of) from the, in dystocia, 350
- edema of the, 645, 646, 679
- embryology of the, 13
- episiotomy of the, 347, 355, 529
- "fish-hook", in hermaphrodite swine, 73, 643, 645, 821
- granular venereal disease of the, 468–471
- hematomas of the, 355, 361
- hemorrhage from the, 353, 354, 623, 742–745
- immature or juvenile, 346, 347, 529, 710, 721, 734
- infantile, 346, 347, 529, 710, 721, 734
- inflammation of the, (see vulvitis or vestibulitis)
- lacerations of the, 259, 303–306, 314, 346, 347, 354, 355
- rupture of the, 259, 303–306, 314, 346, 347, 354, 355
- stenosis of the, 304, 314, 346, 347, 529, 710
- suturing of the, in the cow, 237, 238, 347, 355, 365, 556
 - in the mare, 347, 609–612
- tumors of the, 361, 557, 621, 661
- Vulva-suturing operations, in the cow, 236–240, 347, 355, 556
 - in the mare, 347, 609–612
- Vulvitis
 - catarrhal, 556, 609, 661, 672
 - due to *C. pyogenes*, 472
 - in dourine, 618, 619
 - in granular venereal disease, 468–471, in bitches, 729, 734
 - in the bitch, 734
 - in the cow, 556, 557
 - in the mare, 609
 - postpuerperal, 390, 391, 392, 609
 - necrotic, 390–392, 473, 556
 - ulcerative, in bitches, 734
 - in ewes, 661, 662
- Vulvo-vaginitis in swine caused by moldy, estrogenic grain, 188, 234, 644
- Wattles, in swine, 60
 - in sheep and goats, 62
 - on the vulva, 557
- "Waxing" of the teats in mares, close to parturition, 24, 246
- Wharton's jelly, in the umbilical cord, 49, 255
- Wheat poisoning (hypocalcemia, hypomagnesemia), 371, 394
- Whipple's operation, for vaginal prolapse in the bitch, 238–240
- White heifer disease (see arrests in development of the Mullerian ducts), 522–529
- Windsucking, genital (see pneumovagina and pneumovestibule)
- Wobbles, genetic, in horses, 59
- Wolffian body (see mesonephric ducts), 12, 41
 - ducts, 12, 13, 41, 709
 - anomalies of the, 529, 535, 556, 621, 622, 709–711, 843–846
- Wry neck, of fetus, 41, 280, 283, 327
- Xxy or Klinefelter's syndrome, 815
- Yolk sac, 26, 42, 80
- Zearalenone, an estrogenic mycotoxin, 644, 785
- Zenker's degeneration (myositis) of the gastrocnemius muscle, 357, 394
- Zona pellucida, sperm cell penetration of, 426
