Beejay

CONTRIBUTING AUTHORS

Chapter XVII Infertility in the Bitch and Queen

Donald H. Lein, DVM, Ph.D. Assistant Director Veterinary Diagnostic Laboratory, Associate Professor, Dept. of Pathology and Dept. of Clinical Sciences, New York State College of Veterinary Medicine, Cornell University, Ithaca, N.Y.

Chapter XIX Artificial Insemination

Robert H. Foote, Ph.D. Jacob Gould Shurman Professor of Animal Physiology, Dept. of Animal Sciences, New York State College of Agriculture and Life Sciences, Cornell University, Ithaca, N.Y.

Chapter XX Embryo Transfer

Maarten Drost, DVM, Professor of Reproduction, Department of Reproduction, College of Veterinary Medicine, University of Florida, Gainesville, Fla.

CONTENTS

PART I—OBSTETRICS

	Page
INTRODUCTION	1
CHAPTER I—OBSTETRICAL ANATOMY	
The Pelvic Bones and Ligaments	3
The Ovaries and Female Genital Tract	5
Embryology of the Female Reproductive Tract	12
CHAPTER II—EXAMINATIONS FOR PREGNANCY	
Pregnancy Diagnosis in the Cow	14
External Indications	14
Rectal and Vaginal Examination	15
Differential Diagnosis	22
Pregnancy Diagnosis in the Mare	24
Rectal and Vaginal Examination	25
Biologic Tests	30
Pregnancy Diagnosis in the Ewe	31
Pregnancy Diagnosis in the Sow	32
Pregnancy Diagnosis in the Bitch and Queen	32
CHAPTER III—GESTATION PERIOD—EMBRYOLOGY, FETAL MEMBRANES AND PLACENTA—TERATOLOGY	
Periods of the Embryo and Fetus	38
The Development of the Nervous, Digestive, Circulatory Systems	39
The Development of the Urogenital System	41
The Fetal Membranes	41
The Placenta	44
The Umbilical Cord	48
Anomalies of Development, Teratology	51
Inherited Anomalies	52
Noninherited Anomalies	68
CHAPTER IV—PHYSIOLOGY OF THE GESTATION PERIOD	
Shape and Location of the Pregnant Uterus	93
Position of the Fetus in the Uterus	94
Number of Fetuses in the Uterus	94
Twining and Multiple Births in Unipara	95
Immunogenetics	96
Freemartins	97
Sex Parity	102
Bacterial Flora of the Pregnant Uterus	103

VETERINARY OBSTETRICS

Length of Pregnancy	104
Hormonal Control of Gestation	107
Duration and Rate of Reproduction	110
Abnormalities in Fertilization and Gestation	111
The Mammary Gland and Lactation	113

CHAPTER V—DISEASES AND ACCIDENTS DURING THE GESTATION PERIOD

Abortion	123
Abortion in Cattle	125
Abortion in Horses	162
Abortion in Swine	180
Abortion in Sheep and Goats	192
Abortion in Dogs	206
Abortion in Cats	210
Mummification of the Fetus	213
Fetal Maceration	218
Prevention of Conception and Induction of Abortion	220
Extra-uterine "Pregnancies" and Fetuses	222
Dropsy of the Fetal Membranes and Fetus	223
Abdominal Hernias Resulting in Hysterocele	228
Torsion of the Uterus	230
Vagino-cervical Prolapse	233
Paraplegia of Pregnancy	240
Miscellaneous Accidents During Pregnancy	242

CHAPTER VI—PARTURITION

Symptoms of Approaching Parturition	245
The Initiation of Parturition	247
The Induction of Parturition	248
Stages of Parturition	251
Involution of the Uterus	256
Artificial Interferences in Normal Parturition	259
Diseases and Care of the Newborn	262
Care of the Postpartum Dam	272

CHAPTER VII—THE CAUSES OF DYSTOCIA

Incidence	277
Basic Causes of Dystocia	277
Immediate Causes of Dystocia	282
Common Forms of Dystocia in Domestic Animals	283

CHAPTER VIII—PROCEDURES PRELIMINARY TO THE HANDLING OF DYSTOCIA

History of the Case	287
General Examination	287
Specific Examination and Restraint	287
Prognosis	290
Obstetrical Equipment and Anesthesia	290

CHAPTER IX—OBSTETRICAL OPERATIONS FOR RELIEVING
DYSTOCIA

Mutation	298
Forced Extraction	301
Fetotomy	307
Cesarean Section and Hysterectomy	314

CHAPTER X—DIAGNOSIS AND TREATMENT OF THE VARIOUS
TYPES OF DYSTOCIA

Pathological Presentations, Positions, and Postures of the Fetus	326
Abnormal Size of the Fetus, Monsters, or Twinning	333
Uterine Displacements, Including Uterine Torsion	337
Obstruction or Stenosis of the Birth Canal	344
Uterine Inertia	347
Postmortem Changes in the Fetus	349

CHAPTER XI—INJURIES AND DISEASES OF THE
PUERPERAL PERIOD

Postpartum Hemorrhage	353
Lacerations and Contusions of the Birth Canal and Adjacent Structures	354
Rupture of the Uterus, Vagina, and Perineum	357
Prolapse of the Abdominal or Pelvic Viscera, Including Uterine Prolapse	360
Metabolic Diseases of the Postparturient Period	368
Postparturient Infections and Diseases	373
Retained Placenta	373
Septic Metritis	384
Infections of the Cervix, Vagina, and Vulva	390
Postpartum Paraplegia	393

PART II—GENITAL DISEASES

CHAPTER XII—PHYSIOLOGY OF REPRODUCTION (FEMALE)

Reproductive Hormones	398
Anterior Pituitary Hormones	399
Posterior Pituitary Hormones	402
Ovarian Hormones	403
Other Reproductive Hormones	406
Other Endocrine Glands	408
Puberty	409
The Estrous Cycle	411
Coition	415
Oogenesis (Ovogenesis)	417
Ovulation	419
Fertilization and Transport of the Ovum, Sperm and Zygote	422
Reproductive Table	427

VETERINARY OBSTETRICS

CHAPTER XIII—INFERTILITY IN THE COW

Reproductive Physiology	434
Infectious Diseases	447
Trichomoniasis	447
Vibriosis (Campylobacteriosis)	456
Brucellosis	467
Granular Venereal Disease	468
Infectious Pustular Vulvovaginitis	474
Miscellaneous Infections of the Bovine Female Genital Tract	475
Hormonal Disturbances Resulting in Infertility	478
Cystic Ovaries or Nymphomania	478
Failure of Estrum or Anestrus	495
Miscellaneous Conditions	511
Nutritional Causes	514
Congenital or Hereditary Causes	520
Other Pathological Causes—Ovary, Oviduct, Uterus, Cervix, Vagina, and Vulva	533
The “Repeat Breeder” Cow	559
Postpartum Period	572
Management Problems	575

CHAPTER XIV—INFERTILITY IN THE MARE

Reproductive Physiology	582
Irregularities of the Estrous Cycle and Anestrus	588
Nutrition and Infertility	598
Genital Infections	599
Other Infectious Diseases of the Genital Organs	618
Miscellaneous Pathological Factors	619
Evaluation of a Mare for Fertility	623
“Repeat Breeders”	625
Breeding Farm or Stud Management	627

CHAPTER XV—INFERTILITY IN THE SOW

Reproductive Physiology	636
Anatomical, Congenital, and Genetic Abnormalities of the Genital Tract	642
Pathologic Lesions or Diseases of the Reproductive System	643
Infections of the Genital Tract	643
Hormonal or Endocrine Disturbances	644
“Repeat Breeders”	647
Nutritional Deficiencies	647
Reproductive Management in Swine Herds	648

CHAPTER XVI—INFERTILITY IN THE EWE AND DOE

Infertility in Ewes	654
Reproductive Physiology	654
Pathology of the Ovine Reproductive System	660
Infections of the Genital Tract	661
Nutrition and Fertility	662
Fertilization and Embryonic Deaths	663
Infertility in Does	669
Reproductive Physiology	669
Pathology of the Caprine Reproductive System	671

CHAPTER XVII—INFERTILITY AND REPRODUCTIVE DISEASES

IN BITCHES AND QUEENS (by D. H. Lein)

Reproductive Physiology of the Bitch	675
Reproductive Physiology of the Queen	698
Anatomic and Congenital Defects, Intersexes	709
Nutritional Aspects	711
Hormonal Disturbances—Anestrus, Ovarian Cysts, Hypothyroidism and Others	712
Pathology of the Genital Tract	718
Developmental Anomalies and Cystic Embryological Remnants	718
Neoplasia	721
Infections of the Genital Tract	728
Specific Infections	728
Miscellaneous Infections	732
Cystic Hyperplasia, Endometritis, Metritis and Pyometra	734
Miscellaneous Disorders of the Genital Tract	740
Subinvolution of Placental Sites	742
Breeding Soundness Examination	745

CHAPTER XVIII—INFERTILITY IN MALE ANIMALS (ANDROLOGY)

Anatomy and Embryology of the Male Reproductive Tract	752, 759
Physiology of the Male	760
Frequency of Service	774
Coital Injuries	775
Vices of the Male Animal	776
Nutrition and Infertility	782
Hormonal Causes of Infertility	784
Forms of Infertility in the Male	786
Reduced Sex Drive	786
Inability to Copulate or Complete Coitus	786
Incapacity or Reduced Capacity to Fertilize	813
With Normal Semen Production	813
With Defective or Abnormal Semen Production, Testicular Hypoplasia, Degeneration and Orchitis	815
Hereditary or Congenital Sperm Cell Defects, Male Intersexes and Cryptorchidism	818
Acquired Testicular Pathology or Degeneration and Testicular Neoplasms	826
Pathological or Functional Disturbances of the Epididymis, Vas Deferens and Accessory Glands	841
Diagnosis of Infertility in the Male and Evaluation of Breeding Soundness	857
Semen Collection	861
Semen Examination and Fertility Assessment	872

CHAPTER XIX—ARTIFICIAL INSEMINATION (by R. H. Foote)

History	894
Advantages and Disadvantages	895
Artificial Insemination of Cattle	896
Handling and Extending of Semen	897
Frozen Semen	900
Shipping Semen, and Insemination of the Cow	904
Artificial Insemination in the Horse	911

VETERINARY OBSTETRICS

Artificial Insemination of Swine	916
Artificial Insemination of Sheep and Goats	920
Artificial Insemination of Dogs	923
Artificial Insemination of Cats	925
Artificial Insemination of Other Species	926
 CHAPTER XX—EMBRYO TRANSFER (by M. Drost)	
History	927
Embryo Transfer in Cattle	927
Embryo Transfer in Horses	934
Embryo Transfer in Sheep and Goats	935
Embryo Transfer in Pigs	937
Embryo Transfer in Dogs and Cats	938
 ADDENDUM—CURRENT (1983–1985) SELECTED SUPPLEMENTAL REFERENCES (By Chapter)	
INDEX	942
	955

TABLES

Number	Page
1. Approximate Diameters of the Female Bony Pelvis	5
2. Undifferentiated Genital Structures in the Embryo and Their Adult Male and Female Counterparts	12
3. Size and Characteristics of the Bovine Fetus and Uterus During Pregnancy ..	19
4. Size and Characteristics of the Equine Fetus and Uterus During Pregnancy ..	27
5. The Diploid Chromosome Number of Domestic Animals	51
6. Sex Ratios in Domestic Animals	102
7. Duration of Pregnancy in Animals	105
8. Composition of Milk in Domestic Animals	117
9. Summary of Causes of Abortion in Cattle	127
10. Summary of Causes of Abortion in Horses	163
11. Summary of Causes of Abortion in Swine	180
12. Summary of Causes of Abortion in Sheep and Goats	193
13a. Summary of Causes of Abortion in Dogs	207
13b. Summary of Causes of Abortion in Cats	211
14. The Differential Diagnosis between Hydrallantois and Hydramnios in Cattle	225
15. Relative Incidence of Fetal Monstrosities	335
16. Developmental States in the Maturation of the Ovum	418
17. The Reproductive Cycle of Domestic Animals	427
18. Cultural Characteristics of Common Vibrios	457
19. Summary of Reports of the Manual Removal of the Corpus Luteum in Nonpregnant Cows	505

VETERINARY OBSTETRICS

Number	Page
20. Incidence of Gross Lesions of the Uterine Tubes	535
21. A Frequency Distribution Graph of the Monthly Percentage of Ovulation in Mares	583
22. Outline of Spermatogenesis in the Bull, Boar and Ram.....	765
23. Semen Characteristics in Domestic Animals	772
24. An Approximate Guide to the Frequency of Service and the Number of Females Allotted to Male Domestic Animals	775
25. Summary of Reports on the Comparative Incidence of Testicular Tumors in Dogs	835
26. Sperm Cell Concentration and Semen Color in Bulls and Rams	874
27. Superovulation Treatments in the Cow	928

FIGURES

Number	Page
1. Pelvices of Domestic Animals	4
2. Nonpregnant Uterus of the Cow	7
3. Uterus of the Cow	7
4. Genital Organs of the Mare	7
5. Nonpregnant Uterus of the Mare	7
6. Bovine Ovaries	8
7. Equine Ovary	8
8. Equine Ovaries	8
9. Porcine Ovaries	8
10. Genital Organs of the Sow	10
11. Uterus of a Cow 60 to 70 Days Pregnant	17
12. Twin, Bicornual Bovine Pregnancy	17
13. Uterus of a Cow 60 to 70 Days Pregnant	18
14. Two-Months-Old Bovine Fetus in Its Membranes	18
15. Uterus of a Mare 60 Days Pregnant	28
16. Diagram of the Fetal Blood Circulation	40
17. Placentome of the Ewe	45
18. Placentome of the Cow	45
19. Normal Placenta of a Cow	46
20. Adventitious Bovine Placentae	46
21. Zonary Canine Placenta	46

22. Diagramatic Modification of Grosser's Classification of the Placenta of Domestic Animals (after Bjorkman)	47
23. Brachycephalic Hereford Dwarfs	54
24. Spastic Syndrome, "Stretches," in a Holstein Cow	55
25. Syndactyly in a Holstein Calf	55
26. Spastic Paresis in a Holstein Calf	55
27. Congenital Dropsy and Anasarca in an Aborted Ayrshire Fetus	55
28. Congenital Dropsy or Edema in an Ayrshire Calf	56
29. Cerebral Hernia in an Overtime Holstein Fetus	56
30. Skulls of a Normal Calf and One with a Cerebral Hernia	56
31. "Bulldog," Achondroplastic Ayrshire Fetus	57
32. Hypotrichosis Congenita in a Guernsey Calf	57
33. Guernsey Fetus with Adenohypophysial Hypoplasia	57
34. Epitheliogenesis Imperfecta in a Pig	58
35. False Masculine Porcine Hermaphrodite	73
36. False Masculine Bovine Hermaphrodite	74
37. False Masculine Equine Hermaphrodite	74
38. Diphallus or Double Penis in a Bull	75
39. Hydrocephalus in a Feline Fetus	76
40. Anasarca or Edema of a Canine Fetus	76
41. Cyclopia or Cebocephalus in a Holstein Calf	77
42. Skulls of Normal and Cebocephalic Calves	77
43. A Bovine Schistosomus Reflexus Monster	78
44. A Bovine Perosomus Elumbis Monster	79
45. A Bovine Perosomus Horridus Monster	79
46. A Porcine Double Monster	79

Number	Page
47. Amorphus Globosus on a Cow's Placenta	80
48. Yolk Sac Remnant on a Mare's Placenta	80
49. A Bovine Amorphus Globosus	80
50. A Holocardius Bovine Monster	80
51. A Parasitic Limb Attached to a Calf	81
52. Ectopia Cordis in a Calf	81
53. An Ovine Monster	81
54. Amelia in a Jersey Calf	82
55. A Freemartin Genital Tract	98
56. Clinical Diagnosis of a Freemartin	98
57. XX and XY White Blood Cells from a Chimeric Bull, Cotwin to a Freemartin	99
58. Udder and Subcutaneous Edema in a Heifer	114
59. Embryonic Death of One of Twin 35-Day Zygotes	137
60. Fetal Resorption 60 Days Postconception	137
61. Pustular Vulvovaginitis in a Heifer Due to IBR-IPV Virus	138
62. Nodular Chronic Lesions of the Fetal Liver in Epizootic Bovine Abortion . . .	139
63. <i>Aspergillus fumigatus</i> Mold on the Skin of an Aborted 7-Month Bovine Fetus	146
64. <i>Aspergillus fumigatus</i> Mold Infection of the Equine Fetal Placenta	147
65. Chronic Ergot Poisoning of a Pregnant Jersey Cow	147
66. Torsion of the Umbilical Cord of a Bovine Fetal Cadaver Undergoing Early Mummification	147
67. Lesions of the Liver and Lung from an Aborted Equine Fetus with Herpesvirus Infection	167
68. Intranuclear Inclusion Body in an Equine Fetus Aborted Due to Herpesvirus	167
69. Torsion of the Umbilical Cord Causing Death and Abortion of an Equine Fetus	168

VETERINARY OBSTETRICS

Number	Page
70. <i>Toxoplasma gondii</i> Abortion in Ewes: Toxoplasma Bodies in the Fetal Cotyledon	168
71. Mummification of Twin Bovine Fetuses	214
72. Removal by Cesarean Section of a 7-Month Bovine Mummified Fetus	214
73. Mummification of a Bovine Fetus Due to Displacement of the Umbilical Cord	214
74. Porcine Fetal Death and Mummification	215
75. Maceration of a 4-Month-Old Bovine Fetus	218
76. Bones of a 6-Month-Old Macerated Bovine Fetus in the Uterus	218
77. Hydrops Allantois in a Jersey Cow	224
78. Rupture of the Prepubic Tendon in a Cow	224
79. Impending Rupture of the Prepubic Tendon in a Mare	229
80. Rupture of the Prepubic Tendon in a Mare	229
81. A Massive Hematoma Cranial and Dorsal to the Bovine Udder, Resembling a Rupture of the Prepubic Tendon	229
82. Prolapse of the Vagina in a Heifer	235
83. Prolapse of Vagina, Including the Bladder, in a Cow	235
84. Prolapse of the Vagina, Cervix and Rectum in a Cow	235
85. A Technique for the Control of Chronic Prolapse of the Vagina	239
86. Normal and Abnormal Presentations, Positions and Postures in Bovine and Equine Births	284
87. Bovine and Equine Obstetrical Instruments	292
88. Procedures Followed in Mutation of Deviated Fetal Extremities	302
89. Dystocia Due to a Transverse Presentation in a Bitch	327
90. Normal Dorso-Pubic Position of an Equine Fetus Late in Gestation	327
91. Ascites and Anasarca in a Bovine Fetus	334
92. An Anasarcous Bovine Fetus	335

Number	Page
93a. Diagram of a Normal and Twisted Bovine Uterus and Vagina	339
93b. The Schaffer Method for Correction of Uterine Torsion	339
94. Bilateral Peroneal Nerve Injury and Paralysis	356
95. Rupture of the Gastrocnemius Muscle	357
96. Rupture of the Rectum, Vagina and Perineum of a Mare	358
97. Transverse Rupture of an Isolated Uterine Horn Containing Canine Fetuses . .	358
98. Uterine Prolapse in a Hereford Cow	362
99, 100. Surgical Technique for Amputation of a Prolapsed Uterus in a Cow	366
101. Dislocation of the Sacroiliac Articulation in a Cow	395
102. Diagram of the Neuroendocrine Control of Reproduction in Female Animals	400
103. Heifer in Standing Estrum	411
104. Normal Genital Tract of a Heifer in Estrum	411
105. Granular Venereal Disease in a Heifer	469
106. Bovine Genital Tuberculosis	473
107. Cysts of the Bovine Ovary	479
108. Cystic Ovaries (Follicular Cysts) in a Cow	479
109. A Central Luteal Cyst in a Bovine Ovary	479
110. Bovine Luteal Cysts Associated with Superovulation	480
111. A Bovine Cystic Corpus Luteum	480
112. A Chronic Cystic Ovary Associated with a Unilateral Mucometra	484
113. Cystic Endometrial Glands Caused by Cystic Ovaries	486
114. A "Sterility Hump" in a Cow Associated with Chronic Cystic Ovaries	486
115. A Steer-Like Appearance of a Cow with Chronic Cystic Ovaries	486
116. Anestrus Associated with Segmental Aplasia of the Bovine Uterus, Mucometra, Mucocervix and a Retained Corpus Luteum	496

VETERINARY OBSTETRICS

Number		Page
117.	Congenital Absence of Endometrial Glands in a Heifer with Anestrus and a Retained Corpus Luteum.....	496
118.	Bilateral Total Hypoplasia of the Ovaries in a 3-Year Holstein Cow	510
119.	A "Smooth" Inactive Ovary Seen Bilaterally in Debilitated, Anestrous Heifers or Cows.....	511
120.	Uterus Didelphys with Unilateral Cystic Dilation of the Left Cervix and Mucometra of the Left Uterine Horn	522
121.	White Heifer Disease with a Marked Aplasia of the Vagina, Cervix and Uterus.....	523
122.	Segmental Aplasia of the Cervix with Secondary Hydrometra in a Heifer	523
123.	Double External Os of the Cervix Due to the Persistence of the Median Wall of the Paramesonephric Ducts	524
124.	White Heifer Disease with an Imperforate Hymen Causing Mucovagina, Mucocervix and Mucometra	524
125.	Uterus Unicornis in a Cow	524
126.	Uterus Unicornis with a Cystic Apex Containing Bodies of Inspissated Mucus.....	525
127.	Segmental Aplasia of the Base of the Right Horn Resulting in an Accumulation of Inspissated Mucus.....	525
128.	Segmental Aplasia of Both Uterine Horns and Cervix in a Heifer	526
129.	Cystic Gartner's or Mesonephric Ducts in the Floor of the Vagina	529
130.	Bilateral Granulosa Cell Tumors of the Ovaries in a Cow.....	534
131.	Bilateral Hydrosalpinges with Adhesions Around the Left Ovary	534
132.	Ovarian Adhesions and Hydrosalpinx in a Cow	536
133.	Intramucosal Cysts or Cysts of the Diverticula of the Bovine Oviduct.....	536
134.	Some Common Instruments Used in the Treatment of Infertility in the Cow and Mare	542
135.	Chronic Postpartum Metritis and Pyometra Due to Inspissated Necrotic Cotyledons and Caruncles.....	546
136.	Extensive Perimetritis and Ovaritis with Adhesions Following a Severe Metritis After an 8-Month Abortion.....	548

Number	Page
137. Abscess of the Uterine Wall	548
138. Ectropion of the External Cervical Os	549
139. Lymphosarcoma of the Bovine Uterus	549
140. Adenocarcinoma of the Bovine Uterus	550
141. Atresia of the Internal Os of the Bovine Cervix Secondary to an Acute Cervicitis	553
142. A Horizontally-Tipped Abnormal Vulva Causing Pneumovagina in a Cow ...	553
143. Carcinomas of the Vulva of a Cow	554
144. An Anomaly or Wattle Present on the Vulva of a Heifer	554
145. Ovaries of a 5-Month-Old Equine Fetus	599
146. Appearance of the Perineal Region of a Mare with Pneumovagina.....	600
147. Coital Vesicular Exanthema or Genital Horse Pox in a Mare	618
148. Granulosa Cell Tumor of the Mare's Ovary	619
149. Squamous Cell Carcinoma of the Vulva of a Mare	619
150. Persistent Hymen in a Filly	623
151. Parovarian Cysts in a Ewe	660
152. Pyometra in a Bitch.....	719
153. Segmental Aplasia of the Uterine Horns with Mucometra in a Bitch	719
154. Segmental Aplasia of the Right Horn with Mucometra in a Queen	719
155. Uterus Unicornis in a Bitch	719
156. Cystic Ovaries from a Bitch	720
157. Cystadenoma of a Feline Ovary	720
158. Granulosa Cell Tumor of a Canine Ovary	721
159. The Genital Organs of the Bull	754

PREFACE

This third edition has engendered in the author a sense of enormous humility and gratitude. Humility in the realization of the great efforts, expenditures, honesty, study and research of innumerable persons who have contributed to all aspects of this broad interdisciplinary subject of reproduction in animals and man. The number and breadth of the selected references reviewed by the author has been an enriching experience and attests to the willingness of those in this field to share and advance the accumulated and new knowledge. As one of my former professors remarked, "Everything I know has been built on research and knowledge of other persons."

This current field of reproduction has a strong heritage going back over 60 years to studies by W. L. Williams, Nils Lagerlof, E. C. Amoroso, F. Benesch, C. G. Hartman, A. S. Parkes and L. E. Casida. In more recent times the tradition of excellence has been carried on by: K. McEntee, M. G. Fincher, R. Zemjanis, Wm. Hansel, H. H. Cole, P. T. Cupps, L. E. McDonald, O. J. Ginther, G. H. Arthur, M. Vandeplassche, J. Hughes, W. B. Pickett, R. H. Foote, W. R. Allen, D. A. Morrow, E. S. E. Hafez, L. Ball, E. L. Squires, M. Drost, and many others to whom we all owe a sincere and continuing debt.

In this third edition the author is pleased to be able to include the reviews and insights of his colleagues, Donald H. Lein, R. H. Foote and M. Drost who have contributed Chapters XVII, XIX and XX on Infertility in Bitches and Queens, Artificial Insemination, and Embryo Transfer, respectively. With my retirement from Cornell University in 1972 and entering a busy general practice with my brother James F. Roberts in Woodstock, Vermont, it was impossible to keep fully abreast with the progress and literature within these three fields so graciously and competently reviewed by these contributing authors.

For the rest of the text the author takes full responsibility for its shortcomings in English grammar and exposition. His primary concern was the organizing, documenting and abstracting of new and pertinent knowledge and fitting it into the framework of his first and second editions. "The printed word is not the truth nailed down,

it is the author."* At the suggestion of my professional colleagues, the author has removed nearly all individual names of researchers and reviewers from the text and replaced them with reference numbers. He hopes this will improve the readability of the text without detracting from the importance of the individuals' contribution.

This third edition was a challenge and a goal that nearly overwhelmed the author by the enormous increase in published material. Fortunately his health and eyes have remained excellent due to his wife's food, ministrations and understanding that have enabled him to spend the many hours of necessary reading, filing and writing.

The author has purposely not tried to simplify, eliminate controversial material, or omit any phase of the subject that concerns itself with veterinary obstetrics or genital diseases of domestic animals. This book was written for veterinary undergraduates and those practitioners who are still students. The layman was not considered, as to do so would make the text less satisfactory for its intended readers. The author has stressed diagnosis and physiology throughout the text because he feels these phases are of greatest concern for veterinarians. An accurate diagnosis often requires an extensive knowledge of the field and of all the possible conditions that may be responsible for certain symptoms. As Bertillon, the famous French detective said, "One can only see what one observes, and one observes only things which are already in the mind." Students might prefer a streamlining of information such as befits a core course. But each case in practice is different and a breadth of specific knowledge, skill and the art of its applications are essential.

This text would not have been possible without access over the years to the outstanding Flower Veterinary Library at Cornell and its skilled, pleasant and cooperative librarians. The author must also extend his appreciation to Dr. Kenneth McEntee, his respected colleague, who was a source of knowledge in reproductive pathology,

* From Fischer, M. H., Professor of Physiology, University of Cincinnati.

and also a source of illustrative material both of which were freely offered. My brother Jim and his wife, Dot, must be thanked for graciously and at a sacrifice allowing him extended "sabbatics" to work uninterruptedly at the New York State College of Veterinary Medicine at Cornell in the winters of 1981-1982 and 1982-1983. Ms. Joyce Reyna deserves grateful recognition for her secretarial services and help, as does his printer of the past 30 years, Edwards Bros., Inc., Ann Arbor, Michigan.

My past 10 years in veterinary practice in Woodstock, Vermont, has been very rewarding in personal satisfaction and in the realization of the many facets necessary to provide a needed service "out where the action is." It has given me great moments of pleasure and gratifi-

cation to combine my "ivory tower" knowledge and associations with practical on the farm and in the office transmittal and application of this knowledge. This interface is the ultimate area where veterinary knowledge serves animals and man. I am grateful to have lived and worked in the veterinary profession during what may have been the "golden age" of veterinary medicine and scientific progress. It has been inspiring, fascinating and challenging to keep abreast of many of these advances. However it has also provided rewarding satisfaction and opportunities for service.

Woodstock, Vermont
January, 1986

Part I

INTRODUCTION

Veterinary obstetrics has in the past been defined as that branch of surgery dealing with the oversight of the female animal during pregnancy and parturition. However, with our increased knowledge of genital diseases of female and male animals, the study of veterinary obstetrics has expanded to include the latter highly important field. The livestock industry depends upon reproduction. Any disease or pathological condition causing sterility or infertility in our domestic animals, whether it be a sporadic or enzootic condition, must be the concern of veterinary practitioners. The recent introduction and rapid growth of artificial insemination, and its inherent problems, require the modern veterinarian, especially in cattle practice, to be well acquainted with this field of obstetrics. The fields of reproductive physiology, endocrinology, immunology, nutrition, genetics, embryology, teratology, anatomy, virology, bacteriology, pathology, surgery, and medicine, all supply important necessary links in our chain of obstetrical knowledge. In the broad interdisciplinary field of veterinary obstetrics and genital diseases, as in any clinical field of study, the advances made in the basic sciences must be

studied, considered, and applied.

For the veterinarian entering practice the importance of this field of obstetrical and genital disease cannot be overestimated. The figures from the large New York State Veterinary College Ambulatory Clinic, in which 85 to 90 percent of the animals treated are dairy cattle, show that about 25 to 30 percent of the cases treated were obstetrical or dealt with the reproductive system. These include such common conditions as dystocia, retained placenta, pregnancy examination, sterility examination and treatment, abortion, metritis, blood testing, vaccinating for brucellosis and other abortion diseases and the treatment of many other genital conditions. From a purely business viewpoint, the volume of obstetrical work in a large animal or small animal practice is considerable. One must realize that the average layman or farmer places an undue amount of importance and significance on the successful handling of obstetrical cases and breeding problems. The young or inexperienced veterinarian may make or ruin his chances for success with a certain farmer or in a certain territory by the way in which he handles a single obstetrical case or problem.

Chapter I

FEMALE GENITAL ANATOMY AND EMBRYOLOGY

The bony and ligamentous structures comprising the pelvis are of particular interest in obstetrics. The bony pelvis is composed of the **sacrum**, the first to third **caudal vertebrae** and the two **ossa coxarum**, each formed by the ilium, ischium and pubis.

The **sacrum** is composed of five fused vertebrae in the cow. It is somewhat triangular in form with the base articulating cranially with the last lumbar vertebra and caudally with the first caudal vertebra. The ventral face of the sacrum is smooth and concave. The dorsal surface exhibits the sacral spine. The wing of the sacrum articulates or fuses with the ilium laterally as the sacroiliac joint. In older animals the first caudal vertebra may fuse with the sacrum in the horse, cow and pig.

The **ilium** is irregularly triangular in shape. The broad, flat, dorsal part of the ilium is called the wing. The medial portion of the wing is called the tuber sacrale and its ventral medial aspect articulates with the sacrum. The external portion of the wing of the ilium is called the tuber coxae, hip bone, or "hook" bone. Dorsally the wing of the ilium in the horse, cow, sheep and pig is concave, providing attachment for the gluteal and back muscles. Ventrally the wing is convex. In the dog and cat the wing of the ilium is rotated laterally so it lies nearly parallel to spinal column. The narrow, ventral part of the ilium is called the body. This bone fuses ventrally with the ischium and pubis at the acetabulum. Its medial or pelvic surface is smooth and is grooved for the obturator vessels and nerve.

The **ischium** forms the caudal part of the ventral floor of the pelvis. Its dorsal surface is smooth and rather concave. The caudal border of the ischium slopes inward and forward to join with the opposite ischium to form the ischiatic arch. The caudal lateral portion of these bones is called the ischiatic tuberosity or "pin" bone. The ischiatic tuberosity in the pig is largely cartilaginous in nature and the symphysis does not undergo complete ankylosis until 6 or 7 years of age. The cranial border of the ischium forms the caudal margin of the obturator foramen. Dorsally the ischium bears the ischiatic spine, cranial and caudal to which are the greater and lesser sciatic notches respectively. These notches become fo-

ramina when the sacrosiatic ligament completes their boundaries. The ischiatic spines are prominent in the sow and cow. Medially the ischium and pubis fuse to form the pelvic symphysis. In the cow and ewe the portion of the pelvic floor formed by the two ischia is deeply concave from side to side.

The **pubis** is the smallest of the three bones of the os coxae and forms the cranial portion of the pelvic floor. The dorsal or pelvic surface is smooth and usually concave in females, while in males it may be convex. Occasionally in the young cow a sharp tuberosity projecting into the pelvic canal is present on the cranial portion of the pubic symphysis. This prominence may rarely cause contusion or even laceration of the birth canal during a difficult birth. The cranial medial border of the pubic bone provides attachment for the prepubic tendon. The caudal border forms the cranial border of the obturator foramen.

The **acetabulum** is formed by the fusion of the ilium, ischium, and pubis. These bones form a cotyloid cavity lodging the head of the femur. The acetabulum consists of articular and non-articular portions. The acetabular notch is made into a foramen by the transverse ligament and transmits the accessory ligament to the head of the femur in the horse. The ligament of the femoral head is a short, strong band between the head of the femur and the acetabulum.

There are three, single or paired, **pelvic ligaments** that maintain the relationship of the pelvis to the spinal column. (1) **The dorsal and lateral sacroiliac ligaments**, which are attached to the medial wing of the ilium and lateral portion of the sacrum and the summits of the sacral spines. This articulation is very firm and rigid and is further maintained and supported by the sacrosiatic ligament and prepubic tendon. (2) **The sacrosiatic ligament** is an extensive quadrilateral aponeurosis that completes the lateral wall of the pelvic cavity. The ligament extends from the lateral border of the sacrum and the transverse processes of the first two caudal vertebrae to the ischiatic spine and tuber ischii. It furnishes attachment for the large gluteal muscles and the vulva. In the dog this ligament, called the sacrotuberous ligament,

Pelvis of Mare

Pelvis of Bitch

Pelvis of Queen

Figure 1. Pelves of the domestic animals.

is a narrow strong band extending from the caudal part of the lateral margin of the sacrum to the tuber ischii. (3) The **prepubic tendon** is essentially the tendon of insertion of the rectus abdominis muscle. It is attached strongly to the cranial border of the pubic bones.

The pelvic cavity is somewhat cone-shaped, with the base of the cone located cranially. This base is formed by the bony pelvis. The pelvic inlet is roughly oval in shape in all species, with the largest diameter being sacro-pubic. The size of the pelvic inlet varies greatly within a species due to breed, age and size. The sow and cow have the most elliptical pelvic inlets; while the mare and some dogs have nearly round inlets. (See Figure 1) The approximate diameters of pelves of domestic animals are given in Table 1.

Table 1. Approximate Diameters of the Female Bony Pelvis

Species	Sacro-pubic cm	Iliac cm
Mare	20.3–25.4	19.0–24.1
Cow	19.0–24.1	14.6–19.0
Sheep	7.6–10.8	5.7– 8.9
Sow	9.5–15.2	6.3–10.2
Bitch	3.3– 6.3	2.8– 5.7

In our larger domestic animals the cross section of the fetal chest or hips may be greater in diameter than the maternal pelvic inlet but birth is possible by the displacement and realigning of the fetal parts at the time of parturition. The caudal portion of the pelvic cavity is smaller than the cranial portion formed by the bony pelvis but the caudal portion at the time of parturition dilates markedly to allow the passage of the fetus. This ability to dilate is brought about by the relaxation of the pelvic ligaments, especially the sacrosciatic ligament. This relaxation in the cow is an obvious indication of approaching parturition.

The pelvis of the male domestic animal differs from the female in a number of definite points. The diameter of the pelvic inlet is smaller in the male and the ischiatic arch is usually narrower. The pelvic cavity is smaller and less roomy than in the female. The obturator foramen is smaller in the male. The cranial floor of the pelvis is more apt to be convex in the male while it is usually concave in the female. The bones of the pelvis are thicker and heavier in the male. The pelvis of the male castrated at an early age resembles that of the female. These differences are most noticeable in the larger domestic animals.

The comparative differences, other than size, between

the pelves of the various animals should be noted. In the mare the transverse or iliac and sacro-pubic diameters are nearly alike, making the pelvic inlet almost spherical. The coxal tuberosities are large and prominent and the wings of the ilia are nearly perpendicular to the long axis of the body. In the cow the ischial tuberosities are prominent and high. The ilia and coxal tuberosities are smaller than in the mare. The pelvic inlet is more elliptical than in the mare. The pelvis of the ewe is similar to the cow in the shape of the inlet but the wings of the ilia are more nearly parallel to each other and the tubera ischii are relatively much smaller. In the sow the pelvic inlet is long and narrow. The wings of the ilia are not prominent and large, as in the cow and mare. The symphysis pubis in the sow is thicker and does not undergo complete ankylosis. The tubera ischii are not completely ossified. In the bitch the wings of the ilia are small and nearly parallel with the median plane. The ischium has a twisted appearance, since the caudal part is nearly horizontal. The pelvis of the queen is similar to that of the bitch but has a relatively larger obturator foramen.

The **coxo-femoral articulation** is a ball-and-socket joint with the head of the femur fitting into the acetabular fossa made deeper by the cotyloid ligament. This is a fibrous band circling the acetabular fossa. The transverse acetabular ligament crosses the acetabular notch. The ligament of the femoral head extends from the subpubic groove in the acetabulum to the head of the femur and is intra-articular. In occasional cases this ligament may be small or absent.

The increased frequency of hip joint or coxo-femoral dislocation in the cow is due to the shallowness of the acetabulum, lack of bulky muscle around the joint, the small, or occasionally absent, ligament of the femoral head, absence of the accessory ligament present in the mare, the awkward gait, excessive relaxation of the pelvic ligaments in advanced pregnancy and with cystic ovaries, and the large size and weight of the abdomen in advanced pregnancy, twin pregnancy and hydrops of the fetal membranes.

The Ovaries and Female Genital Tract

The generative organs of the female consist of the ovaries and the tubular portion of the reproductive tract including the oviducts or uterine tubes, uterus, cervix and the cranial portion of the vagina arising from the primitive Mullerian or paramesonephric ducts. The vulva, vestibule and the caudal portion of the vagina develop from the urogenital sinus.

The **ovaries** consist of a stroma or network of con-

connective tissue and blood vessels surrounded by a covering of peritoneum except at the attached border or hilus where the vessels and nerves enter. Within the ovary are interstitial cells, primitive ova, developing or secondary ova or follicles, maturing or mature Graafian follicles, atretic or degenerating follicles, and developing, mature or degenerating corpora lutea. The ovary is supported and attached by the portion of broad ligament called the mesovarium dorsally and laterally and by the proper ligament of the ovary medially. Ovaries increase in size as the animal becomes older. The blood supply to the ovary is from the ovarian artery. Varying degrees of anastomoses between the ovarian and uterine arteries as well as the close apposition of the tortuous ovarian artery and the utero-ovarian vein in most domestic animals, except the mare, result in a local venoarterial pathway for prostaglandins from the endometrium to induce luteolysis.^{2,8} The nerve supply is the autonomic nerves from the ovarian plexus that arises from the renal and aortic plexuses.^{7,12}

In the **cow** the ovaries are oval in shape and vary in size from 1.3 to 5 cm. in length, 1.3 to 3.2 cm. in width and 0.6 to 1.9 cm. in thickness. The right ovary is usually slightly larger than the left, since it is physiologically more active. Ovarian weight varies from 5 to 15 gm. per ovary with the average weight of both ovaries in cattle of all ages being 19.5 gm.⁶ The size of the ovary varies depending upon the structures present either corpora lutea or follicles. The bovine ovaries are located on the cranial border of the broad ligament, occasionally under it, on the ventral lateral floor of the pelvis near, on, or slightly cranial to the pelvic inlet and slightly cranial and lateral to the internal os of the cervix. The pocket formed by the proper ligament of the ovary and the mesovarium is called the ovarian bursa. In the dog the mesosalpinx forms the bursa. The mature Graafian follicle is usually about 1.0 to 2.0 cm. in diameter and smooth, convex, thin-walled, and fluctuates on palpation. The corpus luteum is usually about 1.9 to 3.2 cm. in diameter and may comprise up to three-quarters of the size of the ovary. The corpus luteum of pregnancy and the mature corpus luteum of the estrous cycle weigh from 3 to 9 gms. or an average of 5 to 6.5 gm. Its consistency is liver-like. It is usually, but not always, irregular in outline with a protrusion or crown that may be variable in size, from 0.5 to 1.5 cm. in diameter extending 0.5 to 1.0 cm. above the surface of the ovary. About 3 to 5 days after ovulation the corpus luteum can be recognized by rectal palpation. About three days before the next ovulation the corpus luteum begins to regress in size, gradually atrophies and is replaced by connective tissue, the corpus albicans. The corpus albicans replacing the

corpus luteum of pregnancy is large, 2 to 5 mm., and persists indefinitely. These structures tend to make old cows' ovaries feel quite fibrous and roughened. The position of the ovary in the cow varies with the stage of pregnancy or with the size and contents of the uterus. During pregnancy the ovary tends to be drawn downward and forward into the abdominal cavity. In older, pluriparous cows the ovaries and non-pregnant uterus often lie over the brim of the pelvis on the caudal floor of the abdominal cavity. Usually by the fourth or fifth month of pregnancy the ovaries are drawn forward out of reach of the hand on rectal palpation. (See Figures 2, 3 and 6).

In the **mare** the ovaries are bean-shaped and vary in size from 4 to 8 cm. in length, 3 to 6 cm. in width and 3 to 5 cm. in thickness and weigh 30 to 90 gm. They are suspended in the abdominal cavity by the mesovarium or cranial portion of the broad ligament. The ovaries are 5 to 7.5 cm. dorso-lateral to the uterine horns and joined to them by the proper ligaments. A few or several developing follicles 1.3 to 6.3 cm. in diameter may be present in one or both ovaries. Occasionally follicles may reach a size of 7.5 to 10.0 cm. in which case the ovary is temporarily greatly enlarged. The corpus luteum in the mare is about 2 to 3 cm. in diameter within the substance of the ovary. It can be palpated several days after ovulation as a small protrusion in the region of the ovulation fossa and for about 7 days as a pear-shaped structure, liver-like in consistency. It does not project above the surface of the ovary because of the dense, thick tunica albuginea investing the ovary of the mare. The free border or concave portion of the ovary in the mare is spoken of as the ovulation fossa. (See Figures 4, 5 and 7).

In the **ewe** the ovaries are almond-shaped, about 1.3 to 1.9 cm. long resembling those in the cow.

In the **sow** the ovaries are oval in shape about 4 to 5 cm. long, weighing 3.5 to 12 gm., but in maturity having a mulberry-like appearance due to multiple follicles, and/or corpora lutea. Porcine ovarian follicles are normally about 7 to 8 mm. and corpora lutea about 12 to 15 mm. in diameter. The location of the ovaries in gilts is approximately the same as in the cow. Due to the long broad ligament, the location of the ovaries in the abdominal cavity in older sows is variable. The sow's ovaries are almost completely covered in the ovarian bursae by the mesosalpinx.

In the **bitch** and **queen** the ovaries are oval in shape, 1.0 to 3 cm. in length, 0.7 to 1.25 cm. in width and 0.5 to 0.75 cm. in thickness and firmly fastened just beneath the third and fourth lumbar vertebrae, 1 to 4 cm. caudal to the corresponding kidney. The ovaries are concealed in the ovarian bursae which have a 0.6 to 2.0 cm. slit-

Figure 6. Bovine Ovaries—The right ovary contains 2 corpora lutea and an atretic follicle. Left ovary is small since a double ovulation occurred in the right ovary about 6 days ago.

like opening medially.⁵ The wall of the ovarian bursa in the bitch usually contains fat. The ovary in the bitch and queen, like that of the sow may be mulberry-like in appearance due to multiple follicles or corpora lutea. The corpora lutea contain no pigment.

In the queen, the ovaries are similar to the bitch but are suspended more ventrally in the abdominal cavity. The ovarian bursa contains no fat.

The tubular genital tract develops from the primitive paramesonephric (Mullerian) duct system. These primitive ducts, two in number, unite caudally in the region of the vagina, cervix and body of the uterus to form a long tube with various constructions that is modified in structure and function to protect the developing fetus.

Figure 7. Equine Ovary—The corpus luteum is protruding into the ovulation fossa. Note depression over CL due to loss of follicular fluid at the time of ovulation about 48 hours ago.

Figure 8. Ovaries of a mare bisected—Note pear-shaped follicles with narrow portion toward the ovulation fossa.

The **uterine tube** or **oviducts** are about 20 to 30 cm. long and about 1.5 to 3.0 mm. in diameter in the mare and cow. They are tortuous, wiry and hard, feeling nearly cartilaginous when rolled between the fingers. They may be imbedded in fat in the mesosalpinx, a portion of the broad ligament supporting the uterine tube. The oviducts or uterine tubes are difficult to palpate on rectal examination. Bimanual vaginal and rectal examination often is of assistance in palpating the uterine tube. Another technique in the cow is to slip several fingers into the ovarian bursa or ventricle and palpate the uterine tube between them and the thumb. The distal or caudal, short segment, 1 to 3 cm. in length, attached to the tip of the uterine horn is called the isthmus; while the major portion of the uterine tube from the isthmus to the infun-

Figure 9. Ovaries of a sow—Note mature corpora lutea and small follicles.

dibulum is called the ampulla. The diameter of the uterine tube at the ovarian end becomes larger, 4 to 8 mm. and the uterine tube becomes funnel-shaped, the infundibulum. From this funnel-shaped end of the uterine tube arises the fimbriated portion of the tube. This has a partial attachment to the lateral side of the ovary and to the proper ligament of the ovary medially. The uterine end of the uterine tube in the bitch and mare opens into the uterine lumen through a small slit on a mound or papilla. In the cow and ewe there is a marked flexure at the transition of the isthmus with the elongated curving end of the uterine horn. The latter has a very narrow lumen. In the sow and bitch the mucosa of the uterine tube projects into the uterine lumen as folds well-supplied with blood.^{10,11} The uterine tube of the sow is 15 to 18 cm. long; that of the bitch and queen is 4 to 9 cm. long and has a slightly tortuous course around nearly the entire circumference of the ovarian bursa. The blood supply of the uterine tube is from the uterine and ovarian arteries. The nerve supply is the same as that of the uterus and ovary.

The **uterus** is a muscular membranous structure designed for the reception of the fertilized ovum, for the nutrition and protection of the fetus, and for the initial stage of its expulsion at parturition. The form of the uterus in animals varies with the degree of fusion of the paramesonephric ducts. The endometrium of the uterus in domestic animals is the only structure that can form sufficient placental attachment to result in normal development of the embryo and fetus. In uniparous animals the placenta lies against the cervix, while in multiparous animals the placenta does not touch the cervix. The muscular coat of the uterus is composed of smooth muscle in circular and longitudinal layers. The uterus receives its blood supply from the uterine artery, the ovarian artery and a branch of the urogenital artery. Nerve supply to the uterus consists of sympathetic fibers from the lumbar and lower thoracic region forming the uterine and pelvic plexuses. Nerve filaments from these plexuses supply the uterus, cervix, and proximal portion of the tubes. Parasympathetic fibers originate from the first to third sacral nerves and reach the plexus by way of the pelvic nerves or nervi erigentes.

In the **cow** the uterus is cornuate in shape, with the two uterine horns leaving the internal os of the cervix at an acute angle and lying nearly parallel to each other. The "uterine body" or proximal portion of the fused uterine horns with a single lumen is about 2.5 to 4 cm. long. Depending on the age and breed of the cow the horns are 20 to 40 cm. long and from 1.25 to 5 cm. in diameter in the nonpregnant state. The horns are joined by the dorsal and ventral intercornual ligaments for about

one-half their length. The uterus is located either on the floor of the pelvis, on the pelvic brim, or most commonly in parous cows over the brim on the caudal floor of the abdominal cavity. The uterus is usually dorsal or lateral to the bladder and is attached dorso-laterally by the broad ligament and the mesometrium. During pregnancy the uterus enlarges greatly and becomes located further cranially and ventrally in the abdominal cavity.

In the **mare** the nonpregnant uterus is cruciform or T-shaped with the horns perpendicular to the body of the uterus. The body is about equal in size to each horn, 15 to 20 cm. long, 4 to 7.5 cm. wide and 2 to 5 cm. thick. The uterus is suspended in the pelvic and abdominal cavities dorsal to the bladder by the broad ligaments. In the mare these ligaments are attached dorsally to the sublumbar region. The uterine horns in the mare lie ventral to the intercornual ligament. Unless gravid, the uterus usually does not lie on the floor of the pelvic or abdominal cavities.

In the **ewe** the uterus is shaped like that of the cow and located similarly. Each horn is 10 to 12 cm. long.

In the **sow** the uterine body is about 5 cm. long with long tortuous horns that are freely movable because of the long broad ligaments. In pregnant animals the horns may be 1.2 to 1.8 m. long.¹⁵

In the nulliparous medium-sized **bitch** and **queen** the uterus has a short body, 1 to 3 cm. long with straight horns 12 to 15 cm. long and 0.5 to 1.0 cm. in diameter that diverge at an acute angle toward the poles of each kidney. Suspended from the sublumbar region by the broad ligaments, the uterus lies entirely within the abdominal cavity.

The **cervix** (cervix uteri) is a tubular sphincter muscle between the vagina and uterus. Its wall is harder, thicker, and more rigid than are the walls of either the uterus or the vagina. This is more noticeable in uniparous than in multiparous animals. The blood and nerve supply are the same as those of the uterus and vagina with the exception of the ovarian artery.

The cervix in the **cow** is about 5 to 10 cm. in length by 1.5 to 7 cm. in diameter, the larger of the measurements occurring in pluriparous animals. In some Brahman or Brahman-cross, pluriparous cows the cervical dimensions may greatly exceed these averages. The cervix is located caudal to the uterus either in the pelvic cavity, on the pelvic brim, or in the abdominal cavity. During pregnancy the cervix is drawn forward into the abdominal cavity. The cervix of the cow is composed of 3 to 5 muscular fibrous transverse annular folds that have an almost cartilaginous consistency. The external os of the cervix does not protrude into the vagina, although prolapsed cervical rings in pluriparous cows may present

such an appearance. The cervix of the cow is difficult if not impossible to dilate manually. It dilates slightly during estrus.

The cervix of the **mare** is 5 to 7.5 cm. long and 2.5 to 5 cm. in diameter. It is suspended in the pelvic cavity caudal to the uterus and is characterized by numerous small low longitudinal folds of mucous membrane. The caudal os of the cervix extends into the vagina 2.5 to 5 cm. carrying with it a frenulum of vaginal mucous membrane below the external os. The cervix of the mare is relaxed, soft and easily dilated during estrus and tightly constricted and firm during diestrus.

The cervix of the **ewe** is about 2.5 to 5 cm. long and is similar to that of the cow. Its external os is located in the cranial ventral portion of the vagina and is partially covered by a projecting "hood" of mucosa.³

The cervix of the **sow, bitch and queen** is poorly defined, being characterized by a thickened wall with transverse folds. The sow's cervix is about 10 to 20 cm. long and is directly continuous with the vagina (See Figure 10). The cervix or neck of the uterus in the bitch is very short, 0.5 to 1 cm. in length and caudally the cervix projects into the vagina.

The **vagina** is a muscular membranous structure lying mostly retroperitoneally in the pelvic cavity dorsal to the bladder. It acts as a copulatory organ and as a passage for the fetus at the time of parturition. The vagina is capable of great dilation. Its caudal extremity is just cranial to the urethral opening in the region of the hymen or vaginovesibular junction. This junction is characterized in the mare, cow and sow by a slight constriction and annular folds.¹² A degree of persistence of the hymen, where in the embryo the paramesonephric ducts join the urogenital sinus, may occasionally occur. This may vary from a thin vertical central band to a completely imperforate structure. About 10 to 15 percent of heifers have hymenal remnants. These usually disappear after copulation or parturition. Prominent hymenal folds are present in the mare. A true hymen is lacking in the bitch and queen. The blood and nerve supply of the vagina arises from branches of the urogenital artery and autonomic nerves from the pelvic plexus. It is surrounded by loose connective tissue and varying amounts of fat.

The vagina of the **cow** is about 25 to 30 cm. long in the nonpregnant animal. The recto-genital pouch of peritoneum extends caudally about 12 cm. on the dorsal cranial surface and 5 cm. on the ventral cranial surface of the vagina. On the ventral floor of the vagina beneath the mucosa and running the length of the vagina, the two Gartner's ducts 0.25 cm. in diameter, remnants of the primitive mesonephric (Wolffian) ducts, are frequently

Figure 10. Genital organs of the sow. 1. Ovarian Bursa, 2. Ovary, 3. Uterine horn, 4. Uterine body, 5. Cervix, 6. Vagina, 7. Vestibule, 8. Clitoris.

present. Cysts of these structures may occasionally be observed.

The vagina of the **mare** is about 18 to 28 cm. long and 10 to 13 cm. in diameter when dilated. Most of the vagina, except a small dorsal cranial portion, is retroperitoneal. Mesonephric duct remnants are only occasionally present.

The vagina of the **ewe** is 7.5 to 10 cm. long and similar to the cow's vagina.

The vagina of the **sow** is 7.5 to 11.5 cm. long. It is small in diameter with a thick muscular coat. Mesonephric ducts are occasionally present.

The vagina in the **bitch** is long, 10 to 14 cm. and narrow, 1.5 cm. The muscular coat is thick, and mesonephric ducts are usually absent. A large dorsal median postcervical fold blends caudally into lesser dorsal longitudinal folds. The configuration of this fold and the lateral and ventral vaginal walls, when viewed through a speculum, simulates the external uterine ostium. This configuration of the vagina and vaginal portion of the cervix prevents or makes difficult, intrauterine cannulation.¹³ However, if the cervix is relaxed introduction

of fluid into the cranial portion of the vagina propels the fluid through the cervix and into the uterus. In the queen the vestibule and vagina are the same length.

The **vestibule**, located between the vulva and the vagina, and the **vulva** comprised of the two labia, the dorsal and ventral commissures and the clitoris, form the caudal termination of the genital tract. These two structures do not arise from the primitive paramesonephric ducts but rather from the ventral portion of the primitive cloaca. The ventral commissure of the vulva is pendulous and always lies ventral and caudal to the ischiatic arch.¹² The urethra opens into the cranial ventral portion of the vestibule. The vestibule has several circular or sphincter-like muscles that close the genital canal to the outside. These muscles are attached to the perineal body and the sphincter muscle of the anus and the caudal and last sacral vertebrae. Thus during parturition the vestibule acts as the point of attachment for the entire genital tract to contract upon when expelling the fetus. The clitoris is about 3 to 6 cm. long in the larger animals, but practically all of it is hidden in tissues between the vulva and the ischiatic arch. In the mare, bitch and sow the glans of the clitoris is well-developed and lies in a true fossa. The vulvar lips normally come together evenly, do not gape, and vulvar opening normally lies at a 90° angle to the pelvic floor. The vestibule and vulva are supplied with blood from the urogenital and the external and internal pudendal arteries and have the same autonomic innervation as the vagina. They are well-supplied by the sensory nerve fibers of the pudendal and caudal rectal nerves. The vulva and vestibule are the only reproductive organs of the female well-innervated by sensory nerve fibers.

The vestibule of the cow is about 10 to 12.5 cm. long on the ventral floor and 7.5 to 10 cm. long on the dorsal wall. Beneath the urethral orifice is the suburethral diverticulum, which is about 2.5 to 4 cm. long. The external visible portion of the clitoris in the cow is small in size. The major vestibular or Bartholin's glands, are two in number, one on each side, located in the constrictor muscles of the vestibule. They are about 1.5 to 3 cm. in diameter. These glands in the cow each open by a single duct in the lateral wall of the vestibule about 2.5 cm. caudal to the vagina.¹⁴

The vestibule of the **mare** is similar in size to that of the cow. Eight or 10 ducts from the minor vestibular glands open through its dorso-lateral wall. The external visible portion of the glans of the clitoris of the mare is large and prominent, 2.5 to 5 cm. long and 2 to 2.5 cm. wide. It is composed of erectile tissue similar to the penis. The clitoral fossa and sinuses of the mare are homologues of the preputial folds, and fossa glandis of the

stallion. The clitoral sinuses are 3 in number with the central sinus being the largest, located on the dorsal aspect of the glans clitoridis. The narrow openings of these sinuses are hard to detect unless the clitoris is partially extruded and held downward thus drawing them clear of the thin fold which separates the clitoral fossa from the vestibule.¹⁶ Contractions of the vestibular and vulvar sphincter muscles elevates the clitoris and protrudes it between the vulvar lips. This is called "winking."

The vestibule and vulva in the **ewe** are similar to that of the cow, but the suburethral diverticulum is very small. Minor, but not major, vestibular glands are present. The vestibule is about 2.5 to 3 cm. long. The clitoris is short, with the glans concealed in a fossa.

The vestibule in the **sow** is fairly long, about 7 to 9 cm. The labia are thick. The minor vestibular glands are variable in number. The clitoris is located about 2 cm. cranial to the ventral commissure. On either side of the cranial portion of the floor of the vestibule there is a cul-de-sac.

The vulva in the **bitch** and **queen** has thick labia. The vestibule is 2.5 to 5 cm. long. The urethral orifice opens on the urethral tubercle, which is elevated above the floor of the vestibule. There are small depressions on either side of the urethral orifice. Minor vestibular glands are present in the bitch but not in the queen which has two major vestibular glands. The clitoris in the bitch has a small, 0.6 cm. long by 0.2 cm. diameter, pointed glans and lies in a fossa. The dorsal commissure of the vulva is 8 to 9 cm. below the anus.

The anatomy of the perineal region of the cow and mare has been well-described.⁹

EMBRYOLOGY OF THE FEMALE REPRODUCTIVE TRACT

The urogenital system is formed mainly from mesodermal tissue that in the early embryonic period forms the nephric and genital regions. The ovaries develop from the undifferentiated gonads that form late in the embryonic period in the genital or gonadal ridge located between the dorsal mesentery and the mesonephros. The

primordial germ cells from the wall of the yolk sac in the region of the hind gut have migrated into the gonads by the early fetal period. The surface epithelium of the female gonad gives rise to cortical cords that contain primitive germ cells, later called oogonia. The surrounding epithelial cells from the surface epithelium form the follicular cells. Thus secondary cortical cords are characteristic of the early female gonad. The ovaries remain in the abdominal cavity suspended by the mesovarial portion of the broad ligaments.

In both the male and female during the embryonic period, two pairs of genital ducts are formed that enter the cloaca, the mesonephric (Wolffian) tubules and ducts and the paramesonephric (Mullerian) ducts. The mesonephric duct development is described in the section on embryology of the male reproductive tract. The paramesonephric ducts arise as longitudinal invaginations of the coelomic epithelium in the same region as the mesonephric tubules and ducts. The cranial portion of the paramesonephric ducts differentiate in the female to form the uterine tubes while the caudal portions of the ducts unite or fuse to form the uterus, cervix and the cranial two-thirds or more of the vagina. The septum initially present between the two ducts in the caudal region disappears early in the fetal period. The caudal one-third or less of the vagina is formed by evaginations from the wall of the urogenital sinus. The hymenal region and annular folds are formed by the junction of the fused paramesonephric ducts and the urogenital sinus. In the male the paramesonephric ducts degenerate but portions may persist as remnants, the appendix testis, near the head of the epididymis, and the uterus masculinus be-

Table 2. Undifferentiated Genital Structures in the Embryo and Their Adult Male and Female Counterparts

Embryological Structure	Adult Female	Adult Male
Gonad	Ovary	Testis
Mesentery	Mesovarium	Mesorchium
Gubernaculum	Round ligament of the uterus and proper ligament of the ovary	Proper ligament of the testis
Paramesonephric duct (Mullerian duct)	Uterine tubes Uterus Cervix Vagina (cranial portion)	Appendix testis Uterus masculinus
Mesonephric tubules and duct (Wolffian duct and body)	Epoophoron Paroophoron (Parovarian or mesonephric duct or cysts) (Gartner's) ducts	Efferent ducts Epididymis Ductus (vas) deferens (ductuli aberrantes, appendix epididymis, paradidymis)
Genital tubercle	Clitoris	Penis
Genital folds	Vestibule	Penile urethra
Genital swellings	Vulva	Scrotum

tween the ampullae near the prostate gland. Portions of the mesonephric tubules and ducts may persist as remnants in the female forming the epoophoron on the cranial pole of the ovary, the paroophoron or parovarian cysts, and (Gartner's) ducts in the vaginal floor. (See Table 2).

Early in the fetal period the external undifferentiated genitalia become modified so the genital tubercle forms the clitoris, the genital folds, failing to unite as in the male, become the vestibule and the genital swellings enlarge to form the vulvar lips.

Chapter II

EXAMINATIONS FOR PREGNANCY

An accurate, early diagnosis of pregnancy (cyesagnosis) in the cow, mare and sow has become essential for a successful, profitable breeding program. In recent years the owners of sheep and goats are recognizing the benefits of the early diagnosis of pregnancy. These benefits in the above herds of animals include a prompt assessment of the breeding efficiency of females, males or semen, and the management to maintain an acceptable parturition interval or to reduce the economically costly interval from parturition to conception. Pregnancy diagnosis increases the percentage of pregnant animals in a herd by the prompt treatment or culling of nonpregnant animals. An accurate pregnancy diagnosis is necessary in female animals bred, or possibly bred, either naturally or by artificial insemination prior to treatment for suspected failure of estrus. Most effective treatments would usually cause the expulsion of the conceptus in pregnant animals.

Pregnancy Diagnosis in the Cow

External or presumptive indications for pregnancy include:

(1) **Service by a bull or artificial insemination**—This information may not be known either through error, lack of records, lack of observation or accidental breeding.

(2) **Cessation of the estrous cycle and periods**—This is a moderately accurate means of diagnosis of pregnancy if the herdsman observes animals closely. It is not infallible since the herdsman may not see the signs of estrus or the animal may not exhibit signs of estrus ("silent" heats). About 15 to 30 percent of cattle not observed in estrus after service were not pregnant when examined rectally several months later.^{5,35}

After conception early embryonic death occurred in an estimated 10 to 25 percent of cattle based on the analysis of milk progesterone studies.^{7,33,34} Also uterine pathology such as pyometra and ovarian pathology such as cysts may occasionally cause cessation of estrous cycles in serviced but nonpregnant cows.

Conversely 3 to 6 percent of pregnant cows, especially

the first trimester of gestation, may occasionally exhibit signs of estrus.^{8,9,11,31} As in mares this estrus during pregnancy was apparently associated with follicular growth.

(3) **Radioimmunoassays (RIA) and enzyme immunoassays for determining progesterone levels** in blood plasma and milk have been developed in recent years and have proven helpful in monitoring the reproductive status, including pregnancy of cows. When the time of the prior estrus and breeding is known samples may be taken 21 to 23 days later. Milk samples are easier to obtain than blood samples and potassium dichromate can be added to milk samples as a preservative before shipping or long term storage.^{3b,14,15,29,26a,32}

Based on rectal palpation at 40 to 60 days after service, these tests for progesterone levels have proven to be 65 to 85 percent accurate for predicting pregnancy at 3 weeks post-service.^{6,15,17b,18,24,42} At this time a pregnant cow has a functional corpus luteum and a high level of milk and blood progesterone. When progesterone concentrations are low indicative of estrus and the absence of a functional corpus luteum and pregnancy, these tests have proven to be 94 to 100 percent accurate.

An enzyme immunoassay that may be an alternative to the radioimmunoassay for milk progesterone analysis for pregnancy diagnosis in cows has recently been described.^{26a} This test is simple, reliable and practical and with further refinement could replace the radioimmunoassay.

Each laboratory performing progesterone assays follows different procedures and thus different diagnostic levels of progesterone are reported. Progesterone is closely associated with the butter fat in milk so milk with high butter fat content will have a higher progesterone level than low fat milk. Thus procedures for sampling and interpretations of test results recommended by each laboratory should be followed.^{14,28,29,32,42}

The inaccuracies or high percentage (15 to 20) of false positive results of this test limits its value as a diagnostic test for pregnancy. Further confirmation of pregnancy by manual examination per rectum at a later date is indicated. Causes for this high incidence of error include: prior service of the cow at a time other than estrus; per-

sistence of the corpus luteum due to pyometra, presence of a luteal cyst, a sampling error, or possibly most frequently, early embryonic death from 15 to 50 days post-service. This test cannot detect failure of fertilization or early embryonic death prior to 10 to 14 days of pregnancy. When milk progesterone from cows of unknown pregnancy status was determined at three 7-day intervals, 97 percent of 88 pregnant cows and 98 percent of 83 non-pregnant cows were diagnosed correctly.²⁸

Manual rectal palpation of the genital tract of a cow by a skilled veterinarian at 20 to 23 days after service to detect the presence or absence of a functional corpus luteum or follicle, the turgidity of the uterine horns and the presence or absence of a clear or bloody vaginal mucus is equal to or more accurate than the progesterone assay in the detection of either pregnancy or the absence of pregnancy.

(4) **The presence or absence of postestrous bleeding**—"Menstruation" from the cow's vulva 24 to 48 hours after service is believed by some herdsmen to indicate conception. Careful studies have indicated that about 50 to 60 percent of cows and 75 to 85 percent of heifers exhibited some bleeding after estrus. There is no relationship between postestrous bleeding and conception.³⁹

(5) **Changes in the udder size of heifers and the size of the abdomen** in advanced stages of pregnancy—

In heifers increased development of the udder is noticeable about 4 months of gestation. In pluriparous cows enlargement and edema of the udder only occurs the last few weeks or month of gestation. Increased size of the abdomen is quite variable depending on the parity of the gestation. Young cows exhibit increased abdominal size after the sixth month of gestation and older cows after the seventh month of gestation. Progressive relaxation of the pelvic ligaments becomes evident the last month of gestation as does relaxation and edema of the vulva. Similar, but lesser, signs of relaxation of pelvic ligaments and edema and relaxation of the vulva may occur in cows with cystic ovaries.

(6) **Ballottement of the fetus or observation of fetal movements** after the sixth month of pregnancy. Occasionally in some thin animals where the fetus lies close to the abdominal wall, ballottement may be done as early as the fifth month of gestation. In fat animals this may not be possible until the eighth month of pregnancy. Depending upon the size of the fetus, the condition of the cow and the size and degree of fullness of the abdomen, the fetus can be ballotted in 5 percent or less of pregnant dairy cows at 5 months of gestation, 10 to 50 percent at 6 months, 70 to 80 percent at 7 months, 80 to 90 percent at 8 months and over 90 percent at 9 months. Abdominal ballottement of the fetus is easy in the cow

because of the relaxed, flaccid abdominal walls. The fist is pushed in an intermittent manner in a dorsal medial direction deeply into the lower right abdominal wall. If the fetus is ballotted, it is felt as a large, hard, solid object suspended or floating in the softer structures of the abdomen, such as the uterus, uterine contents and the abdominal viscera. The more advanced the pregnancy or the larger the fetus, the more dorsally in the right flank region the fetus may be ballotted.

(7) **Auscultation of the fetal heart** may be performed from the sixth to seventh month of pregnancy to term only with great difficulty due to the thick abdominal walls and viscera and the difficulty of obtaining a sufficiently quiet location. **Fetal electrocardiography** has been used to study the fetal heart and as an aid in the diagnosis of twin pregnancy and fetal mummification after the fifth month of pregnancy in cows.^{22,23,38}

(8) **Ultrasonography or the use of ultrasound to detect pregnancy** has only recently been developed to detect pregnancy in cattle^{1a,25a,b} (see Pregnancy Diagnosis in the Mare). Further research and improvement of the technique is necessary. Early pregnancy diagnosis with ultrasonography is more difficult in the cow because of the elongated rather than the oval blastodermic vesicle present in the mare, bitch and queen. Presently errors in diagnosis, especially in detecting nonpregnant cows, are too great for routine use of this technique when compared with the accuracy and lower costs of rectal palpation for pregnancy.

Internal indications of pregnancy in the cow

The rectal palpation of the uterus, ovaries, and uterine vessels is the most practical and accurate, as well as the earliest means of accurately diagnosing pregnancy in the cow. Prior to the actual rectal examination, the breeding history of the cow should be studied, including the date of the last calving, the dates and number of services, and information on any pathologic or disease condition previously affecting the reproductive organs. Complete breeding and reproductive records are very helpful for an accurate and rapid pregnancy or sterility examination of a cow or herd. Unfortunately many herds, especially range beef herds, do not have this information.²⁰

If a herd is to be examined it is helpful if someone is available to record notes on the results of the examination. The operator should wear proper protective clothing, consisting of rubber boots, a pair of clean, short-sleeved coveralls, or rubber pants, and a short-sleeved cloth jacket, and a thin rubber surgical, or disposable plastic glove and obstetrical sleeve. The sharp sealed edges of the plastic sleeve and glove often irritate and lacerate the rectal mucosa and anal skin. The glove and sleeve

is essential to protect the examiner's arm from chafing, infection, feces, and odor. It also protects the cow's rectum from irritation due to the examiner's hair and fingernails. No rings, especially rings with settings, should be worn on the examining hand. The fingernails should be short. Either hand may be used for the examination, but if many examinations are to be made it is usually desirable to use the stronger arm. Many prefer to do examinations with the left arm, so that the right is free for writing and for the manipulation of instruments or pipettes. The cow should be fastened or held securely to prevent forward or lateral motion. If many cows are to be examined it is helpful for an assistant to hold the tail away from the examiner's arm. Caution should be exercised when examining cows near posts or other obstructions that might cause the examiner injury if the cow moved suddenly. Cows seldom kick when being examined rectally but an excitable cow may occasionally kick backwards and injure the operator. When beef or range cows are in a chute a bar should be placed behind the cow above the hocks. Applying a nose lead or forcing the cow's tail dorsally and cranially in a firm manner may be necessary to restrain certain cows.

The arm should be well-lubricated with a non-irritating agent. The fingers and the hand are inserted into the rectum in the form of a cone. They are advanced into the rectum beyond the organ or structure to be palpated. Do not introduce the hand and arm a short distance into the rectum and push the rectum forward, thus stretching and irritating the rectal wall. With the arm well-inserted, bring a portion of the rectum caudally as a fold upon the hand and arm, thereby giving more freedom to the hand and producing greater relaxation of the rectum. It is usually necessary to remove most of the fecal material from the rectum before a thorough examination can be made. This can be done by raking the feces from the rectum with the hand, palm uppermost, or by stimulating peristaltic contractions and defecation by massaging the rectal wall just anterior to the anus and by allowing some air to enter the rectum. In the older, larger dairy cows one can leave the arm and hand in the rectum when a peristaltic wave is passed backward. However, in heifers and small beef cattle such a practice occasionally results in a laceration of the mucosa or even the rectal wall. In some cases, particularly where cattle have been on lush pasture and the feces are thin and loose, the rectal mucosa is easily irritated and the cow will suck air into the rectum, making examination nearly impossible through the dilated, tense rectal walls. Stimulating peristalsis, as mentioned above, will result in evacuation of the air. This may be aided and hastened by hooking the fingers cranially into a peristaltic contraction ring and pulling it

gently caudally. The cow's back should not be pinched down, since this tends to fill the rectum with air. Examinations of certain cows under epidural anesthesia may be desirable, however, ballooning of the rectum with air is a complication of this technique. All rectal examinations should be done with care, gentleness, and patience to avoid traumatizing the mucosa, rupturing the rectum, or irritating the anus.

The presence of free blood, or a fresh blood clot, in amounts of 15 to 30 ml. or more, not mixed with the feces, is highly indicative of a rectal rupture. If a rupture of the rectum occurs in the cow, examinations should cease immediately. Supportive treatment with penicillin and streptomycin, tetracyclines or sulfonamides and atropine are indicated. If the cow is not valuable, immediate slaughter may be indicated. If recovery follows rectal trauma with perforation, adhesions of the rectum to the genital tract, occasionally associated with abscesses, may occur.

A regular routine for examining the female genital tract should be developed and followed at each examination so no structure or portion of the tract will be overlooked. In making a rectal examination the hand is introduced cranial to the pelvic inlet or bony pelvis and is passed or swept from one side downward, across, and up the other side. If no structure is palpated the uterus is in the pelvic cavity. Usually the cervix or uterus is palpated on the brim of the pelvis in older cows. The hard, firm cervix is relatively easily located on the floor of the pelvis or cranial to it. The uterine cornua can be palpated in nonpregnant cows or in early pregnancy. The ovaries may be palpated lateral and slightly cranial to the cervix. As pregnancy develops they are drawn forward, especially the ovary corresponding to the horn containing the fetus, until by the fourth to sixth month of pregnancy they are out of reach. The uterus may be located laterally in the pelvic cavity if held there by a full bladder or a short broad ligament. The normal non-pregnant uterus in the heifer and pluriparous cow vary greatly in size. The uterus is normally soft, pliable and relaxed with a slight amount of tonicity in early pregnancy. A completely flaccid atonic uterus is characteristic of true anestrus and chronic cystic ovarian disease. At the time of estrus or following vigorous massage the uterus may become quite erect and turgid. In late estrus and early diestrus, 1 to 2 days after ovulation, the uterus may be thick-walled and edematous. Often about 20, 40 or 60 days post-conception the uterus may be quite tonic with a normal corpus luteum and an occasional follicle in the ovary.

The technique for manual retraction of the nonpregnant or one- to three-month pregnant bovine uterus into the pelvic cavity from the abdominal cavity to facilitate

its examination may be helpful.^{5,3} This involves caudal traction on the cervix, then further caudal traction on the ventral intercornual ligament. The cranial border of the broad ligament medial to the ovary may also be retracted. In particularly difficult cases the application of Knowles cervical forceps to the external cervical os will aid retraction of the uterus. The ovary may be grasped and slid between the middle and third fingers and held there while it is carefully palpated by the thumb and index finger.

Taking into consideration a number of factors including the age of the cow, rectal examination to diagnose pregnancy can be made quite accurately from about 35 days after conception. It is easier to detect early pregnancy in heifers than in cows. After 45 to 55 days of gestation, pregnancy diagnosis is usually easy for the experienced veterinarian. An accurate early pregnancy diagnosis is an important, economic necessity for the progressive cattle owner.

Veterinarians should be cognizant of the fact that the incidence of death of the early zygote, embryo and fetus in cows is highest during the earlier stages of gestation and declines rapidly after 60 to 90 days of gestation.^{5,21,33}

Early embryonic deaths occur whether rectal palpation of the uterus and its contents of fluids, membranes or amniotic vesicle, for confirmation of early pregnancy is performed or not. Recent studies on early pregnancy diagnosis using assays of progesterone in milk 21 to 23 days after service and continuing for 75 days have dem-

Figure 11. Uterus of a cow. 60 to 70 days pregnant.

Figure 12. Twin, bicornual bovine pregnancy, 60 days pregnant. Note CL in each ovary and lymphocytomas in the vagina. (Courtesy K. McEntee)

onstrated an incidence of early embryonic deaths of 7.2 to 14.5 percent in cows not subject to early rectal palpations of the uterus. These embryonic deaths were confirmed by a late return to estrus 28 to 60 days after service and rectal examinations at 55 to 75 days.^{7,21,33,34}

Vigorous, intense and prolonged rectal examinations for early pregnancy diagnosis, especially between 30 and 50 days of gestation, by certain, inexperienced examiners can result in an increased incidence of embryonic death and a return to estrus usually within 30 days but occasionally not until 50 to 90 days later.^{1,3,4,27,40} Palpation of the amniotic vesicle and slipping of the membranes were potentially more damaging to the developing embryo than palpation for the enlargement of the gravid uterine horn by fetal fluids or "fluctuance." The incidence of embryonic deaths were 4 to 9 percent in cows examined per rectum at 30 to 45 days of gestation compared to 2.5 to 4 percent when examinations were performed after 40 to 45 days of gestation.^{1,3,27,33,34} Since the "natural" embryonic death rate may be augmented by early pregnancy diagnosis per rectum, it behooves veterinarians to be particularly gentle and careful if early diagnostic examinations are made and possibly to reexamine and reconfirm the pregnancy diagnosis after 55 to 60 days of gestation.

As mentioned earlier under the use of progesterone

Figure 13. Uterus of cow 60 to 70 days pregnant. Note CL in the left ovary and large follicle in the right ovary.

assays for diagnosing pregnancy, rectal examinations of the cow's genital tract by a skilled veterinarian 19 to 23 days after service would be equally as accurate, about 75 to 90 percent, in assessing pregnancy at such an early date. If the cow failed to conceive estrus signs should be detectable including an erect, tonic uterus, an involuted, firm, small corpus luteum, a developing follicle, about 1 cm. in diameter, or a depression on the ovary where ovulation occurred. A vaginal examination by speculum should reveal the presence of an excess of clear, stringy mucus, possibly tinged with blood if ovulation has occurred, associated with a moderately hyperemic vaginal mucosa and a slightly relaxed external cervical os. If the cow conceived 19 to 23 days before the rectal examination one should detect a mature functional cor-

pus luteum, the absence of a maturing or ovulated follicle, and a uterus that is somewhat flaccid and lacking the tone of a uterus under the influence of estrogens. A vaginal examination will reveal a pale mucous membrane, a closed cervical os and only a small amount of tenacious, thick mucus.

The definite or certain signs of pregnancy in the cow as determined by a rectal examination are: (1) The palpation of the enlarged horn containing the fluctuating placental fluids from 30 to 90 days of gestation. (2) The careful, very gentle palpation of the amniotic vesicle in early pregnancy from 30 to 50 days. (3) The slipping of the fetal membranes including the allantois chorion and its blood vessels upon gentle pinching of the uterus with the thumb and forefinger in early pregnancy from 40 to 90 days. (4) The palpation or ballotement of the fetus in the enlarged uterus containing fetal membranes and placental fluids after about 80 days. (5) The palpation of the placentomes after 100 days and (6) The palpation of the enlarged, thin-walled, "whirring" uterine arteries after 90 days of gestation. Less definite signs of pregnancy include the increase in size of the uterus and a thinning and distension of its walls, its location in the abdominal cavity, the location, size and persistence of the corpus luteum and vaginal changes.

Uterine changes during pregnancy: During early pregnancy, the uterine horns, especially the horn containing the embryo or fetus, increase in size due to the distention of the horn by the amniotic vesicle, placental fluids, the membranes, and the conceptus. This increase in the diameter of the uterine horns is characterized by a thinning of the uterine wall and a fluid, watery, "alive" fluctuating feeling on palpation of the uterine horn. The uterine horns have a fair amount of tone due to their tenseness and distention. From 40 to 90 days of pregnancy, the uterus feels somewhat like a thick rubber balloon nearly filled with water. The approximate size of the horn containing the fetus during the first 5 months of pregnancy is given in Table 3.

Since the size of the fetus is small during the early stages of pregnancy the amount of fluid in the uterine horn largely determines its size or diameter. The volume of fluid increases rapidly the first 5 months of pregnancy but increases more slowly after the fifth or sixth month (Table 3). In cattle there is a marked increase in the allantoic fluid volume between 40 and 75 days and 6-1/2 and 7-1/2 months of gestation and a marked rise in amniotic fluid volume between 3-1/2 and 4 months of gestation that is not reflected in the total volumes of placental fluids given in Table 3.²

The size of the amniotic vesicle varies as noted in Table 3. The amniotic vesicle is spherical in outline up

Table 3. Size and Characteristics of the Bovine Fetus and Uterus during Pregnancy*

Days of Gestation	Diameter of the Horn Containing the Fetus	Amount of Fetal Fluid	Diameter of the Amniotic Vesicle	Length of the Fetus (C-R)	Weight of the Fetus	Diameter of the Placentomes	Diameter of the Uterine Artery	Fetal and Placental Characteristics
30	2-4 cm	30-60 ml	1.0 cm (pea size)	.8-1 cm	.3-.5 gm			Head and limb buds recognizable, placenta not attached.
40	3-6 cm	75-100 ml	2.5-3.0 cm (size of plum)	1.75-2.5 cm	1-1.5 gm			
50	5-7 cm	90-200 ml	3.5-5.0 cm (1-1/2-2")	3.5-5.5 cm	3-6 gm			
60	6-9 cm	200-450 ml	6-7.5 cm	6-8 cm (mouse size)	8-30 gm			Claw buds and small scrotum recognizable, palate and sternum closed, placenta attached and lens-sized cotyledons present.
70	7-10 cm	350-650 ml		7-10 cm	25-100 gm	0.5-0.75 cm		
80	9-12 cm	500-800 ml		8-13 cm	120-200 gm	0.5-1.0 cm		
90	10-13 cm	750-1400 ml		13-17 cm (rat size)	*200-400 gm	1-1.5 cm (size of dime)	0.3-0.5 cm	Hair on lips, chin and eyelids, scrotum present.
120	12.5-18 cm	2000-3500 ml		22-32 cm (small cat size)	1000-2000 gm	1.5-2.5 cm (size of quarter)	0.5-0.8 cm	Fine hair on eyebrows, claws developed and yellow-colored, epithelial plaques present on amnion, horn pits present.
150	18-23 cm	4000-5000 ml		30-45 cm (large cat size)	3000-4000 gm	2.5-4 cm (size of 1/2 dollar)	0.6-1.0 cm	Hair on eyebrows and lips, testes in the scrotum, teats developing.
180		4000-7500 ml		40-60 cm	5-10 Kg.	4-5 cm	0.9-1.25 cm	Hair on inside of ear and around the horn pits, tip of tail and muzzle.
210		6300-10,000 ml		55-75 cm	8-18 Kg.	5-7.5 cm	1.25-1.5 cm	Hair on metatarsal, metacarpal and phalangeal region of extremities and beginning on the back, long hair on tip of tail.
240		8000-12,000 ml		60-85 cm	15-25 Kg.	6-9 cm	1.25-1.7 cm	Fine short hair all over the body. Incisor teeth not erupted.
270		12,000-20,000 ml		70-100 cm	20-50 Kg.	8-12 cm	1.5-1.9 cm	Hair coat complete and long, fetus large, incisor teeth erupted.

*Richter & Goetze, Fraser, Bongso and Basrur, Swett, Matthews and Fohrman, Gier and Marion, Zemjanis, Arthur, Winters, Green, Comstock, Ball, Evans and Sack and Eley et al. These are all approximate figures as there is much individual variation especially between heifers and cows.

to about 40 days, at which time it becomes oval. The palpation of the amniotic vesicle in the free most distended portion of the horn at 30 to 65 days of pregnancy is helpful in diagnosis because of its fairly tense spherical to ovoid shape. If the vesicle is not palpable or is small or collapsed the embryo may have died and is macerating. If the operator is experienced, skillful and gentle early embryonic death may be detected at 30 to 40 days of gestation by palpation of the amniotic vesicle.^{3,36} These embryos are probably resorbed. Palpation of the amniotic vesicle should be performed very carefully and gently to avoid damaging or rupturing it or the heart or other friable organs of the embryo. The fingers and thumb gently palpate the gravid horn and as they are moved slowly back and forth the vesicle can be felt to slip between them. If such an examination cannot be done skillfully and gently it is best to omit it as it is not necessary for an accurate pregnancy diagnosis.

Slipping of the fetal membranes is another aid to early pregnancy diagnosis in the cow that is best performed from 35 to 90 days of gestation. Prior to 40 days of gestation slipping of the fetal membranes is difficult to detect because the membranes are thin and fragile. The technique consists of gently picking up and pinching or compressing either horn of the uterus and feeling the fetal membranes, the allantois chorion and its vessels slip between the thumb and the fingers before the uterine wall escapes from between the fingers.^{3,5,13} The entire horn may be grasped and let slip through the fingers so that the connective tissue band and allantoic vessels on the lesser curvature of the uterus, which are three to four times thicker than the chorioallantoic membrane, can be palpated. Excessive or rough pinching of the uterus, particularly over the amniotic vesicle is to be avoided, to prevent damage to the embryo or fetus. This technique of slipping the membranes is especially valuable in the differential diagnosis of pregnancy from uterine diseases characterized by fluids causing uterine distention, such as pyometra or mucometra.

Location of the pregnant uterus in older cows, since the uterus in the nonpregnant state lies on or over the brim of the pelvis, the pregnant uterus is found in the abdominal cavity as early as at the time of conception to the second to third month of pregnancy. In all ages of cattle the uterus lies on the floor of the abdominal cavity after the fourth month of pregnancy. In uteri that hang forward in the abdominal cavity the allantoic fluid tends to gravitate to the apices or pendant portions of the uterus frequently out of reach of the operator unless he retracts the uterus into or towards the pelvic cavity. In heifers or young cows 2 to 3 months pregnant, the uterus often lies in the pelvic cavity and the horn containing the fetus exhibits a typical dorsal bulging or terracing

because of its location. By the fifth to sixth month of pregnancy in all cows the uterus is drawn well-forward and downward in the abdominal cavity so that in some cases only the cervix and uterine vessels can be palpated per rectum. By the sixth to seventh month the fetus becomes large enough so that it can again be palpated on rectal examination in nearly all cows; and by the eighth or ninth month the fetus may, in a few cows, actually extend caudally so that the nose and feet are resting in the pelvic cavity. As the uterus drops forward into the abdominal cavity during pregnancy the mesometrium stretches and thickens and the ovaries are also drawn ventrally and cranially. The ovaries can usually be palpated through the fourth month of gestation and occasionally during the fifth month. During the latter month the ovary on the side of the uterine horn containing the fetus is usually drawn out of reach of the hand in the rectum.

Fetal size and characteristics at various stages of pregnancy:

The statistics of bovine fetal, length, and weight have been recorded by a number of authors. The average figures and records given by these workers are noted in Table 3. The author estimates that the fetus may be palpated per rectum in over 95 percent of cows at 3 to 4 months of gestation, about 40 to 70 percent of cows at 5 and 6 months of gestation, about 80 percent of cows at 7 months and about 95 percent or more of the cows at 8 to 9 months of gestation. Palpation of the fetus before 60 to 70 days of gestation is not possible because of the tense, distended amniotic vesicle and the small size of the embryo or the fetus. Between 70 to 120 days fetal crown-to-nose or head size measurements are 1.5 cm. at 70 days, 5.5 cm. at 90 days and 9.0 cm. at 220 days.³

The larger and deeper the abdomen of the cow and the longer the mesometrium the greater the difficulty in palpating the fetus per rectum during midgestation. Thus in heifers the fetus can often be palpated per rectum the entire gestation period. If the fetus cannot be felt, pregnancy diagnosis is based on the position of the uterus, the size of the uterine arteries, the palpation of the placentomes and the slipping of the fetal membranes. After the sixth month of pregnancy one can elicit or cause fetal movements by pinching the claws, grasping and pulling a fetal leg, pinching the eyeballs, or grasping the nose of the fetus either through the rectal or vaginal wall. The latter is possible only during the last month or so of pregnancy. If the bovine fetus can be secured and measured an approximation of its age, especially up to 6 months of age, as thereafter there is too much variation between breeds, may be obtained by doubling the crown-rump

length in inches and taking the square root of the result which is equal to the months of gestation.⁴

Palpation of placentomes Although the placentomes are forming by 60 to 70 days of pregnancy, they seldom can be palpated as definite structures until 75 to 80 days. At this time they can be palpated in the uterine wall at the level of the intercornual ligaments of the horn containing the fetus as ovoid thickened areas. They increase in size as the fetus develops (see Table 3). Inexperienced examiners may mistake a placentome for the ovary between 110 and 180 days of gestation. In general the placentomes in the middle of the horn containing the fetus and nearest the attachment of the middle uterine artery are larger than those placentomes in the cervical or apical end of the horn or in the opposite nongravid horn. Thus the largest placentomes from the fifth month of pregnancy to term are usually out of reach of the rectal hand.

The development and enlargement of the uterine artery is closely associated with the size of the fetus and the duration of pregnancy. The artery supplying the greatest amount of blood to the uterus is the uterine artery. Palpation of changes that occur in the size of this artery and the character of its pulse are of diagnostic value. The uterine artery arises from the internal iliac artery close to its origin at the aorta. In the nonpregnant cow it curves caudally in the broad ligament over the dorsal part of the shaft of the ilium into the pelvic cavity and then downward and forward over the pelvic brim to enter the concave aspect of the uterine horn near its center. As pregnancy progresses the artery is pulled more cranially as the uterus drops forward in the abdominal cavity until in the latter half of pregnancy it may be located 5 to 10 cm. cranial to the shaft of the ileum. One should not confuse the internal iliac artery which is securely fastened by fascia to the shaft of the ileum with the uterine artery in the broad ligament which is movable for a distance of 10 to 15 cm. In heifers a change in the size of this artery to the horn containing the fetus may be noted as early as 60 to 75 days of pregnancy, when it may be 0.15 to 0.3 cm. in diameter. In older cows the change in size of the middle uterine artery to the horn containing the fetus can be noted at 90 days, when the artery is about 0.3 to 0.45 cm. in diameter. The approximate size of the artery at different stages of gestation are noted in Table 3. The uterine artery to the nongravid horn also enlarges but the changes are not so great as those in the artery to the gravid horn and they occur later. With the enlargement of the artery the arterial wall becomes thinner, so that instead of feeling a pulsation in the artery a characteristic "whirr," "thrill" or fremitus is felt. This is first recognized at about 80 to 120 days of pregnancy, but the time may be variable.

By the fourth to fifth month of pregnancy it is always palpable. If the uterine artery is pressed too tightly this fremitus may stop, so that only a pulsation is felt. In advanced pregnancy this artery, when palpated lightly, feels much like a stream of water surging intermittently through a thin rubber hose. Aneurysms producing localized fremitus of the uterine artery in the cow may rarely be present. This change in the size of the artery and the character of the pulse is helpful in diagnosing pregnancy about the fifth and sixth months, when the uterus is forward in the abdominal cavity and the fetus cannot be palpated. It is of value and aid in determining the stage of pregnancy. If both uterine arteries are equally enlarged, twin bicornual pregnancy should be suspected. The characteristic fremitus of the pulse is often of value in determining whether or not a normal pregnancy with a viable fetus is present.

Determining the stage of gestation up to 120 days by rectal palpation when the date of service is unknown is quite precise, to within a few to 10 days but as gestation progresses it becomes less precise due to individual and breed variations in the size of the uterus and fetus.

The horn of the pregnant bovine uterus not containing the fetus may vary greatly in size. In most bovine pregnancies a portion or usually all of the non-gravid horn takes part in the placental attachments. There is a progressive enlargement of the nongravid horn, its uterine artery, and placentomes but these changes are not as great as those of the gravid horn. In possibly 10 to 20 percent of cows, some or most of the caruncles and cotyledons in the nongravid horn fail to develop normally or may be absent, in which case this horn is smaller than normal or even is nonfunctional. As a result an excessive burden may be placed on the gravid horn, with an hypertrophy of the placentomes causing them to become 15 cm. in diameter in some cases.

Examination of the ovaries. The ovary may be gently grasped between the first and second or second and third fingers and palpated with the thumb. The ovary following ovulation develops a corpus luteum at the site of the ruptured follicle. If fertilization and development of the ovum and embryo proceed normally this corpus luteum persists throughout pregnancy in the cow. The corpus luteum of pregnancy, or corpus luteum verum, is slightly larger, 2.46 cm. in diameter and 6.5 gms. in weight, than the corpus luteum of the estrous cycle, 2.3 cm. and 5.7 gms., respectively. These small differences are of no diagnostic value.¹⁰ However, as pregnancy progresses the corpus luteum tends to develop a darker golden-brown color and its projection above the surface of the ovary is less prominent due to a heavy layer of epithelium and stroma that covers it. It remains essentially the same size until near parturition.

With few exceptions the corpus luteum of pregnancy is on the ovary corresponding with the horn of the uterus containing the fetus. Less than 1 percent of the corpora lutea of pregnancy were in the ovary opposite the horn containing the fetus.^{1,2,5a,12} Thus, more than 99 percent of cows have the corpus luteum of pregnancy on the ovary corresponding to the horn containing the fetus. The possible reasons for the presence of the corpus luteum being on the ovary opposite the horn containing the fetus might include: (1) External migration of the ovum across the peritoneal cavity. This is highly unlikely. (2) Internal or transuterine migration of the early embryo through the uterine body, which is rare in the cow.^{32b} (3) Regression of the corpus luteum of pregnancy and the development of another corpus luteum on the opposite ovary. This has been observed by the author during the first trimester of pregnancy in 3 cows.

If a rectal examination of a cow 20 to 24 days after service reveals a normal corpus luteum on one ovary and no signs of estrum, the examiner can be reasonably sure that conception has taken place. These early diagnoses are about 80 to 90 percent accurate. This can be confirmed on re-examination at 40 to 50 days by the presence of the corpus luteum in the same site on the same ovary with typical changes occurring in the gravid uterine horn. The manual removal of a bovine corpus luteum of pregnancy or the administration of a prostaglandin the first 5 months of gestation will invariably result in abortion.

Vaginal changes during pregnancy as determined by examination with a vaginal speculum and light or manually may be of some diagnostic value but are of only secondary importance to the uterine changes. During pregnancy the vagina usually develops a pale, dry, sticky mucous membrane similar to that observed in diestrus. The external os of the cervix is closed and pale. Since milk or serum progesterone levels and vaginal electrical resistance correlate closely, a commercially-produced instrument to measure the latter as an estrus-detection aid may be of value for early pregnancy diagnosis.^{24a} In about 60 to 70 percent of the cows the cervical seal which forms after conception increases in size until it protrudes or covers the external os and is visible and palpable between 40 to 120 days of pregnancy. In the rest of the cattle it is present in the cervical canal but does not become visible. The seal is a translucent, whitish mucus that is very tough, adhesive, and tenacious. This seal may remain after the fetus has died in such diseases as mummification of the fetus and trichomoniasis with fetal maceration. Occasionally there may be a normal pregnancy with a cervicitis of the external os and a purulent vaginitis. In such an instance, the cervical canal and internal os have a normal cervical seal present. There is

in rare cases a condition characterized by a cervical seal of large proportions called mucocervix. This is noted by a cervix with a diameter of 7.5 to 10 cm. filled with tenacious mucus and accompanied by a persistent corpus luteum or luteal cyst and a failure of estrum. Just prior to parturition and abortion the normal cervical seal breaks down and is discharged in strings. The vaginal mucous membrane becomes more moist and hyperemic, and the cervix relaxes and dilates. Thus a vaginal examination is of value in diagnosing impending abortion or parturition. Passing a catheter or insemination pipette through the sealed cervix in a pregnant cow may introduce infection into the uterus and cause the death of the fetus the release of prostaglandin and subsequent abortion. In advanced pregnancy a manual examination of the vagina frequently reveals the presence of a portion of the uterus and fetus in the pelvic cavity dorsal or lateral to the vagina. The cervix is pulled forward by the weight of the gravid uterus causing a lengthening of the vaginal cavity.

Biologic tests for the diagnosis of pregnancy in the cow have been reported but are not as accurate as the rectal diagnosis of pregnancy by a competent veterinarian. Presently the only practical biologic test for pregnancy in the cow is the radioimmunoassay (RIA) test for determining the levels of progesterone, produced by a functional corpus luteum, in the milk or blood plasma as described previously.

Differential Diagnosis in Pregnancy Examinations

Anatomically there is no reason for confusing a pregnant uterus with such structures as the **bladder**, the pendulous **left kidney** or the **rumen**. Careful rectal examination, consideration of the anatomical structure and relationships of these organs and their consistency, will prevent erroneous diagnoses.

Tumors may be confused with pregnancy in the cow if a careful examination is not performed. The tumors most commonly confused with pregnancy are lymphocytoma, granulosa cell tumor of the ovary, and fat necrosis in the mesentery. Other tumors of the uterus or genital tract of the cow such as leiomyomas and fibromas that might be confused with pregnancy are rare.

Mummification of the bovine fetus characterized by the death of the fetus from 3 to 8 months of gestation, failure of abortion, absence of estrum or parturition, absorption of the fetal and placental fluids, contraction and thickening of the uterine walls, resorption of the placentomes, and the presence of the hard, firm fetus and

membranes in the closely applied uterine horn lying deep in the abdominal cavity may be confused with pregnancy. The history of apparent conception but failure of udder development, failure of an increase in the size of the abdomen or fetus, and failure of parturition should cause the examiner to suspect the presence of this condition. On rectal examination the uterus is usually drawn forward into the abdominal cavity and may require caudal traction on the cervix or lifting of the ventral abdominal wall to bring it within reach of the rectal hand. The typical "whirring" or fremitus in an enlarged uterine artery is absent. If palpable, the ovary on the side of the horn containing the fetus has a corpus luteum of pregnancy. Mummification of the fetus has not been associated with rectal palpation of the uterus for pregnancy diagnosis even when the examinations have been vigorous and prolonged.

Pyometra or accumulation of pus, from 200 to 20,000 ml. in amount, in the uterus is characterized by failure of estrum and may be confused with pregnancy. Pyometra may occur either postpartum or post-service. In most cases pyometra follows a retained placenta and postpartum metritis, in which case there is frequently an intermittent discharge of pus from the vagina. In trichomoniasis or other infections early pregnancy may occur and the fetus may be killed by the organisms. The fetus and fetal membranes then macerate with pyometra resulting. In these cases the cervical seal may remain intact in the cervix for long periods. In pyometra the uterine walls are usually thick and heavy and lack tone. The fluid in the uterus may be watery, syrup-like or viscous. The uterine horns are usually unequal in size as in pregnancy. The pus tends to gravitate and collect in the pendant portion of the horns and there is no dorsal bulging of the horn as in often palpated during early pregnancy. The fetus or placentomes cannot be palpated and the fetal membranes cannot be slipped. The uterine arteries are usually contracted and the fremitus is absent. If the diagnosis is uncertain, reexamination in one to two months is indicated. In normal pregnancy progressive development of the fetus and uterus occurs, whereas in pyometra the condition remains essentially the same. As in mummification of the fetus the corpus luteum remains in the ovary.

Maceration of the fetus exhibits signs similar to those of pyometra with the exception that death of the fetus after the fourth month of pregnancy results in the presence of fetal bones in the uterus causing crepitation when palpated. Occasionally the cervical seal breaks down and a vaginal discharge is observed.

Mucometra or hydrometra may occur secondarily to an imperforate hymen, in the defective horn of a cow with uterus unicornis, in other anomalies of the devel-

opment of uterus, cervix, or vagina, segmental aplasia, and in long-standing cases of cystic ovaries causing a cystic degeneration of the uterine wall. This condition is variable in its manifestation. Anomalies of the development of the paramesonephric duct system may not be characterized by failure of estrum, whereas in cystic ovaries failure of estrum is common. The mucus varies in consistency from a thin, watery secretion seen in cystic degeneration of the uterine wall, to a heavy mucus secretion in heifers with imperforate hymens, to a gummy and inspissated type of mucus that might be confused with a mummified fetus in certain defects including segmental aplasia of the uterine horn. The uterine wall in most of these conditions is fairly thin but in cystic degeneration of the uterine wall it may be so extremely thin that it is difficult to palpate. These conditions differ from pregnancy based on the history; and on rectal examination by a failure to "slip" or feel fetal membranes, by the absence of the fetus and placentomes, lack of fremitus or increase in size of the uterine artery, and a failure of the progressive development of the uterus as in a normal pregnancy.

Embryonic or early fetal death with abortion or possible absorption. Death of the embryo or fetus prior to 70 to 90 days of gestation may be followed by immediate or occasionally delayed abortion.⁴ In early pregnancy the fetal membranes may continue to grow and develop for several weeks after fetal death before showing degenerative changes. Thus a positive diagnosis of fetal death and absorption can only be made late in the absorptive process when the signs of pregnancy do not correspond with the breeding history, a diminished amount of fetal fluids are in the uterus, the membranes feel collapsed and wrinkled upon slipping between the fingers and thumb, the amniotic vesicle may be atonic and flaccid or be absent, and the uterine wall is thick and somewhat contracted. These cases when detected or suspected should be brought to the attention of the owner so that he can watch the cow closely for a recurrence of the estrous cycle or if this is not observed the cow can be reexamined two to four weeks later. Probably in most of these cases, expulsion or abortion of the degenerated partially macerated embryo and its membranes occurs and is unobserved.

Careful rectal examination may reveal abnormalities or pathology of the pregnant uterus and fetus in such conditions as hydrops amnii and allantois, fetal monsters, twins, torsion of the uterus, adhesions of the pregnant uterus to other abdominal structures, rupture of the uterus with an extra-uterine fetus, metritis characterized by lack of tone of the uterus and gaseous crepitation within the uterus that occasionally precedes bacterial abortion.

The diagnosis of twins may be based on the findings

of equal enlargement of both uterine horns or uterine arteries, the presence of two amniotic vesicles, or the presence of two fetuses—usually one in each horn, but occasionally two in one horn. In most cases there are two corpora lutea, usually one on each ovary, as bicornual twins are by far more common than unicornual twins. Dizygotic bovine twins are much more common than monozygotic twins.

There is ample evidence to indicate that in the dairy cow the right ovary is slightly more active.^{1a,5a,12,13} About 60 percent of pregnancies occur in the right horn and 40 percent in the left horn. In beef cattle these percentages are more nearly equal.¹²

PREGNANCY DIAGNOSIS IN THE MARE

The external indications of pregnancy in the mare are similar to those in the cow. Since the breeding season for most mares is short, early and accurate pregnancy diagnosis is essential in a good breeding program. Following service the mare should be teased regularly by a stallion or an aggressive, or testosterone-primed gelding every one to two days to determine the end of estrus, and continuing for 18 to 21, and even to 40 days to determine if conception has apparently occurred. It is not unusual for up to 10 to 15 percent of pregnant mares to exhibit some or all the signs of estrus, especially the first several months of gestation.^{20,50} These signs are usually weak and short, lasting for only one or two days. They are probably due to developing ovarian follicles that regularly occur in mares the first 90 days of gestation. Other mares may show no signs of estrus after breeding and yet have failed to conceive. Post-estrous bleeding as seen in cattle after estrus does not occur in the mare.

Diagnosis of pregnancy in the mare based on an increase in the size of the abdomen is hazardous even though most mares in advanced pregnancy show a marked increase in the size and a characteristic shape of the abdomen. The pregnant mare's abdomen after the fifth to sixth month of pregnancy is usually pear-shaped with the greatest width in the ventral third. In fat mares or mares fed large amounts of roughage the abdomen is large but round with the greatest width in the middle third. The last month of pregnancy the mammary glands begin to enlarge. Distention of the teats with colostrum occurs the last 3 to 4 days of gestation and in most mares "waxing" of the teats due to the expression of colostrum occurs 4 to 48 hours before foaling. This may be absent or in a few mares may occur for three to ten days before foaling. Edema of the abdomen just anterior to the udder

may occur in advanced pregnancy. Relaxation of the pelvic ligaments occurs in late gestation but is not as evident in the mare as in the dairy cow.

Ballottement of the fetus in the mare in advanced pregnancy is difficult due to the thick abdominal wall and because the mare will tense the abdomen. Ballottement in the mare, however, is occasionally possible on either or both sides of the abdomen. Fetal movements may be observed through the abdominal wall the last months of pregnancy especially after the mare has ingested cold water. Prior to parturition the vulva becomes enlarged, flaccid, and edematous.

Plasma and milk progesterone values, determined by radioimmunoassay techniques, as in the cow, have been shown to be helpful in determining the reproductive status of mares, including the stages of the estrous cycle and the diagnosis of early pregnancy. However several days are usually required for transporting and laboratory procedures on the samples. Progesterone levels are probably more reliable than behavioral patterns toward a teaser stallion in assessing ovarian activity in certain mares. This test would be of value for bred mares when no stallion was available for teasing or for mares exhibiting poor estrous behavior. Plasma samples from all mares were more easily obtained and processed than milk samples from lactating mares and produced equally accurate results. In a limited study over 90 percent accuracy was obtained in the diagnosis of pregnancy by the presence of high levels of plasma progesterone 16 to 17 days after bred mares went out of estrus. These diagnoses were later confirmed by rectal palpation. Low levels of plasma progesterone indicated non-pregnancy and the presence of estrus at this time.^{24b,29} Persistence of the corpus luteum without pregnancy is not uncommon in the mare and could cause an occasional inaccurate early pregnancy diagnoses when large numbers of mares are examined.^{3b,24b,28,29}

Ultrasonography or ultrasonic echography of the genital organs of the mare shows definite promise of being very useful in the detection of early pregnancy.^{8b,34b,40,44a,b,49b,c,56a,57a} Although this technique involving the use of a rectal probe or transducer, requires further study and refinement and the equipment is very costly (\$13,000 to \$28,000) (see footnotes 1–5), research has shown that pregnancy diagnosis for the presence of a chorionic vesicle or conceptus may be per-

formed without damage to the embryo with an accuracy of over 95 percent from 15 to 50 days of gestation. Repeated examinations at 5 to 10 or more day intervals greatly reduces the possibility of error as the size of the normal viable vesicle grows at a steady rate from about 1.5 to 2 cm. in diameter at 15 days of gestation to 2.75 cm. at 20 days, to 3.25 cm. at 25 days, 3.6 cm. at 30 days, 4.45 cm. at 35 days, 6.0 cm. at 40 days and 8.85 cm. (range 7–10 cm.) at 50 days. The viable embryo increases in size from about 1 cm to 3.5 cm from gestation day 15 to 50.^{34b,49c,56a} In early pregnancy diagnosis errors may be due to scanning near the tip of the uterine horn and locating an ovarian follicle or in older mares finding an endometrial cyst or enlarged lymphatic lacunae in the uterus.^{34b,56a} In one study^{49c} 11 of 67 mares (16.4%) had a resorption or death of the embryo between 15 and 50 days of gestation. This ultrasound instrument has also proven valuable in the detection of twin embryos early in gestation when treatment is best accomplished.^{34b,56a} Presently many veterinarians are using this instrument on horse farms in England, France and the U.S. Further controlled studies are indicated to assess its value and possible harmful effects, which presently are negligible, and to obtain needed data on the incidence and fate of early twin embryos and early embryonic deaths in mares. Fetal pulses are visible at 24 days. Ultrasound is useful in the diagnosis of pregnancy and fetal monitoring in dogs, cats, sheep, cattle and goats as well as the mare.^{43b}

The accuracy of an ultrasonic pregnancy detector with the transducer applied to the external abdomen of the mare was unsatisfactory.^{49b,57a}

Fetal electrocardiography has been found to have some technical limitations for the diagnosis of early pregnancy and twinning. Further studies will be necessary if this technique is to become practical.^{12,27,33,34}

Internal examination for pregnancy in the mare.

Before the internal examination for pregnancy in the mare is performed, a good breeding history should be obtained if possible. The foaling and breeding dates, dates of estrum, the frequency and efficiency of teasing before and after breeding, and knowledge of the regularity of the mare in her estrual cycles and past foalings are helpful.

The rectal diagnosis of pregnancy in the mare by an experienced veterinarian is presently one of the earliest and most accurate methods available. In performing a rectal examination of a mare the same equipment, dress, and mode of procedure is used as for examinations of the cow, with the following exceptions. Restraint is more essential in mares. Since most horses are more accustomed to being handled on the left or near-side, the author prefers to perform rectal examinations with the right

arm and make the initial anal penetration while standing lateral to the left hip of the mare. Thus both the operator and the man on the twitch or halter are on the same side of the mare. Many mares require the application of a nose twitch to control and make them stand quietly and prevent them from kicking the operator. Some veterinarians have the mare's tail forced firmly dorsally and cranially over the sacrum as a further form of restraint. Certain excitable mares that object to restraint must be handled gently and quietly if a rectal is to be performed. Often these mares may be examined by having only a foreleg elevated. In some mares tranquilization or even sedation may be required as well as application of a twitch. If breeding hobbles are used to restrain a mare, kicking is prevented but the hocks may be raised suddenly and injure the operator if he is standing too close to the rear quarters. A mare can be examined in stocks, around a stall partition, or by being backed up to a manger or several bales of hay or straw. If a mare is in stocks, the rear rope or board should be low so that if the mare drops her hind quarters suddenly the examiner's arm will not be injured. It may be desirable to bandage the mare's tail and have it held upward and to one side by an assistant so the long tail hair does not irritate the anus and rectum at the time the arm is inserted and the tail does not become soiled. A bland, nonirritating lubricant should be used on the arm. The rectum of the mare is drier than that of the cow and the operator's arm requires frequent liberal lubrication. The author favors a bucket of soapy water made with bland soap and applied to the arm with a sponge. Nonirritating obstetrical lubricants such as K-Y Jelly or a low-cost lubricant of 500 grams of Na carboxymethyl cellulose (Hercules) mixed with 8 gallons of water and 100 ml of chlorhexidine (Novalsan) as used at the Univ. of California^{57b} are also satisfactory. The preparation of this latter lubricant requires careful control of temperature and mixing procedures. The peristaltic waves in the mare are stronger than in a cow. The hand and arm should be withdrawn from the rectum when a peristaltic contraction occurs. Trauma to the rectum is more easily produced than in the cow and has more serious and sometimes fatal consequences because of the mare's increased susceptibility to peritonitis. Lacerations of the rectum have become a serious malpractice problem not limited to younger inexperienced veterinarians. Of 54 cases of rectal tears over 90 percent resulted in the death of the horse. Of a total of 720 equine malpractice cases from 1968 to 1981 these rectal lacerations represented 13.4 percent.⁵⁰ The need for prompt vigorous surgical treatment of such tears of the rectum is imperative.^{57b} Even with such treatment the prognosis is guarded to poor. Rectal examinations should therefore

be made with quiet restraint, care, and gentleness. Daily or every other day palpation of the mare's genital tract and ovaries during estrus, especially by inexperienced operators to detect a mature follicle and predict the time of ovulation, caused a delayed and lowered conception rate.⁵⁶

After entering the rectum of the mare and locating the bony pelvis, it is easier to locate one of the ovaries, until with more experience the uterus can be readily found. The distinct fibrous bean-shaped ovary, 4 to 8 cm. long by 3 to 5 cm., in thickness is located about 10 to 20 cm. cranial to the shaft of the ilium and about 5 to 10 cm. below the lumbar vertebrae in the nonpregnant mare or mare in early pregnancy. The operator who uses his right hand can more readily locate the left ovary of the mare and vice versa. After locating one ovary the hand is passed down the proper ligament of the ovary to the uterus. The uterus is cupped in the hand between the fingers and thumb and palpation of the cranial border, ventral, and dorsal portions of the nonpregnant or early pregnant uterine horns, the opposite ligament and the opposite ovary is performed. The nonpregnant completely-involuted uterus during estrus or/aneustrus is pliable, soft, flat, and rather flaccid, 4 to 7 cm. wide and 2 to 5 cm., thick. In the maiden or young mare the nonpregnant uterus is suspended above the floor of the pelvis and abdomen. In older mares, especially the first month after foaling, the uterus may be located more ventrally and be hanging cranial to the pelvis in the abdominal cavity. In circumstances where the uterus was located well-forward and downward in the abdominal cavity, traction on the broad ligament, or bimanual examination, with the other hand in the vagina grasping and exerting traction on the cervix, could be helpful.²⁰

Uterine changes during pregnancy. A presumptive diagnosis of pregnancy may be made at 18 to 22 days after service by the absence of signs of estrus in a mare with a normal behavioral pattern. On rectal palpation at this time the uterus is firm and tubular, the cervix is also contracted and firm, and 1 or 2 follicles of small to medium size may be present in the ovaries. Possibly a thinning of the uterine wall usually near the bifurcation over the conceptus often can be palpated. The accuracy of rectal palpation at this time varied from 80 to 93 percent.^{5,26,35,48,52} These signs, together with those revealed by a speculum, of a pale rather dry vaginal mucosa and a closed, nonedematous external cervical os are highly indicative of pregnancy. Confirmation of this presumptive diagnosis should be performed by rectal palpation, and/or biologic tests for pregnancy at 30 to 45 and 90 days after service.

In most mares rectal palpation of the uterus to diag-

nose pregnancy can be performed by an experienced operator with accuracy from 30 to 40 days of gestation. Diagnosis usually is easier for the less experienced veterinarian from 40 to 50 days of pregnancy. Pregnancy diagnosis is easier in maiden mares or primigravidae, and barren, nonfoaling mares than in mares conceiving on foal estrus when the uterus has not completely involuted. Highly skilled veterinarians may accurately diagnose pregnancy as early as 20 to 30 days of gestation. Care must be used not to injure the embryo, the chorionic or blastodermic vesicle or the rectum.

Careful repeated early pregnancy examinations by rectal palpation of the uterus were not detrimental to fertility by causing an increased abortion rate.^{7,30,56,57} The rectal examination for the diagnosis of early pregnancy in mares consists mainly of gentle palpation of the oval chorionic vesicle in a localized area of the uterine horn and doesn't involve the procedures of direct palpation of the amniotic vesicle and manual slipping of the membranes as practiced in the cow. This may account for the much lower incidence of embryonic damage after rectal palpation in the mare. It is often desirable to reexamine the mare once or twice at 60 to 120 days of gestation to make certain embryonic death and resorption did not occur.

In the mare, as in the cow, early embryonic deaths are not uncommon with an incidence of 2 to 20 percent or greater between early pregnancy diagnosis and 110 days of gestation.^{11,42,46,60} A survey of 100 equine practitioners revealed that 5 to 6 percent of mares abort after having been diagnosed pregnant early in gestation.³¹ Early embryonic deaths with absorptions or probably abortions from 25 to 30 days of gestation was reported in mares on a low plane of nutrition.⁵³ In a preliminary study using ultrasound to diagnose pregnancy and early equine embryonic deaths from 20 to 50 days of gestation, embryonic deaths occurred at all intervals with peaks around 20 and 35 days.^{56a} The cause of the deaths was not determined. "Spurious" conceptions may follow a normal service in a healthy cycling mare in which further estrous cycles are not exhibited on regular teasing, and on rectal examination at a later date the mare is not pregnant. Some of these are undoubtedly due to early embryonic death, resorption, unobserved abortion or persistence of the corpus luteum. In a few instances one of a pair of twin embryos in mares may die early, the dead embryo and its membranes may undergo maceration and absorption of mummification and the normal embryo survives to term.

The thickness and tone of the uterine wall increases slightly in both pregnant and nonpregnant mares from days 10 to 16 after the onset of the estrus. From day

Table 4. Size and Characteristics of the Equine Fetus and Uterus During Pregnancy*

Days of Gestation	Size and Shape of the Chorionic Vesicle	Amount of Fetal Fluids in ml.	Diameter of the Horn Containing the Fetus	Weight of the Fetus	Length of the Fetus (C-R)	Fetal and Placental Characteristics
16	2-4.0 cm. Bantam's egg (round)				0.32 cm.	
20	2.5-4.5 cm. Small Hen's egg (slightly oval)				0.66 cm.	
25	2.5-4.5 cm. Small Hen's egg (slightly oval)	30-40			0.6-0.85 cm.	
30	2.5-5.0 cm. Hen's egg (oval)	40-50	4-1/2-5 cm.	0.2 gm.	0.9-1.0 cm.	Eye, mouth and limb buds visible, chorionic vesicle present only in the uterine horn.
35	3.5-6.5 cm. Goose's egg (oval)	60-90	4.5-6.5 cm.	0.8 gm.	1.5-2.0 cm.	
40	4.5-7.5 cm. Small orange (oval)	100-150	7-8.5 cm.	1.6 gm.	2.5-4.0 cm.	Eyelids and pinnae have appeared.
45	6-10 cm. Large orange (oval)	150-200	7.5-10 cm.	3.0-4.0 gm.	2.6-4.5 cm.	
50	12 × 7.5 cm. Small melon (oval)	200-350	8.3-10 cm.	5.5-6.5 gm.	3.0-6.0 cm.	
60	13.3 × 8.9 cm. Melon (oval)	300-500	8.9-10 cm.	10-20 gm.	4-7.5 cm.	Lips, nostrils, and beginning development of feet observed, eyelid partially closed. Placenta not attached but beginning to go into the body of uterus.
90	14 × 23 cm. Football (oval)	1200-3000	12.5-15 cm.	100-180 gm.	10-14 cm.	Villi of placenta present but without firm attachment, mammary nipples and hoofs visible, body and horn of uterus both involved and enlarged.
120		3000-4000		700-1000 gm.	15-25 cm.	External genitalia formed but scrotum is empty, placenta attached, ergots and orbital areas prominent.
150		5000-8000		1500-3000 gm.	25-37 cm.	May or may not have fine hair on orbital arch and tip of tail, prepuce not yet developed.
180		6000-10,000		3-5 Kg.	35-60 cm.	Hair on lips, orbital arch, nose, eyelashes and fine hair on mane.
210		6000-10,000		7-10 Kg.	55-70 cm.	Hair on lips, nose, eyebrow, eyelids, edge of ear, tip of tail, back and mane.
240		6000-12,000		12-18 Kg.	60-80 cm.	Hair on mane and tail, back and distal portion of extremities.
270		8000-12,000		20-27 Kg.	80-90 cm.	Short fine hair over entire body.
300		10,000-20,000		25-40 Kg.	70-130 cm.	Body completely covered with short hair, prepuce developed, hair in mane and tail increased.
330		10,000-20,000		30-50 Kg.	100-150 cm.	Complete hair coat and hair coat gets its final color, testes descend.

*1c, 4, 9, 10, 18, 20, 21, 23b, 36, 44b, 52, 54, 55, 59, 60.

16 to 21 there is a 3-fold increase in thickness in the uterine wall in pregnant mares while in nonpregnant mares the thickness of the uterine wall declines to a low point at the onset of the next estrum. The tone of the uterine wall follows the same pattern, with a definite increase in the tone of the uterine wall of both the pregnant and nonpregnant mares to day 16 followed by a decline in tone in nonpregnant mares to a soft flaccid state about one day before the next estrum. In pregnant mares the uterine tone continues to increase after day 16 with the uterine horn becoming round and tubular about 5 days later.^{7,26,35,43,44a,b,52}

Palpation of the chorionic or blastodermic vesicle.

During early pregnancy a portion of the uterine horn enlarges. (See Table 4). The earliest this can ordinarily be detected is 20 to 30 days. This enlargement is characterized by a circumscribed, **ventral** bulge or distention and thinning of the uterine horn just to the right or left of the center or bifurcation of the horns. The enlargement of the uterus produced by the ovoid conceptus in mares is localized and not diffuse as it is in the cow that has an elongated blastodermic vesicle. Rarely the embryo and its membranes may develop more laterally in either horn or in the body of the uterus. The spherical bulge or swelling is caused by the chorionic or blastodermic vesicle in early gestation and later by the oval chorioallantoic vesicle containing the enclosed amniotic sac and embryo, the vitelline or yolk sac and the allantoic sac. From 3 to 6 weeks the vitelline or yolk sac is large and the amniotic cavity around the embryo is small. The allantoic cavity grows rapidly from 5 to 7 weeks of gestation when it contains much fluid.^{22,55} This chorionic vesicle at first is oval and then as it enlarges it assumes a more ovoid, tubular or sausage-shaped outline and extends into the body of the uterus about 60 to 90 days of gestation. The uterine wall during this early stage of pregnancy is more tubular in shape, has a more tonic, firm consistency, and is thinner, especially over the ventral bulge. As in the cow these changes are primarily due to the localized distension of the uterine horn and body with fetal membranes and fluid, imparting the feeling of heavy, water-filled rubber balloon.

By 60 to 70 days the chorioallantoic vesicle is so large it is difficult to delineate its extent and the early uterine tonus is less evident. Slipping of the fetal membranes is not performed in the mare because it is difficult, possibly damaging to the embryo and not necessary because the discrete, localized oval area of the uterus occupied by the conceptus in early pregnancy readily differentiates pregnancy from pyometra or mucometra. The thicker, more tonic, equine rectal wall also makes this technique hazardous.

Palpation of the changes in the size of the horn and body containing the fetus has been outlined in Table 4. Since the size of the round and later oval chorionic or chorioallantoic vesicle is closely correlated with the size of the uterine horn, the diagnosis and duration of early pregnancy may be ascertained.

The pregnant uterus in the mare is usually suspended above or on the level of the floor of the pelvis until the third to fourth month of gestation, when it drops enough to rest on the abdominal floor and the ventral surface of the uterus can't be palpated. In older mares it may rest there by the third month. If the mare is more than 3 months pregnant it will be difficult or impossible to retract the uterus, due to its weight; whereas if the mare is not pregnant the uterus can be retracted and palpated. By the fifth to sixth month of pregnancy the uterus is well-forward in the abdominal cavity and the broad ligament is under definite tension. The ovary may be 20 to 25 cm. below the lumbar vertebrae and is moved with difficulty because of the stretching of the mesovarium.

Palpation of the fetus through the rectal wall can usually be performed from 90 to 120 days of gestation when the fetus feels like a small, heavy, submerged but floating object as the hand by a patting motion ballots it. It is usually possible in most mares to palpate the fetus per rectum from the third month throughout the rest of the gestation period. The size and weight of the equine fetus during the various stages of pregnancy are noted in Table 4. In a few deep-bodied older mares palpation of the fetus may be difficult from the fifth to seventh month of gestation. In these mares the location of the uterus, the position of the ovaries, and the palpation of

Figure 15. Uterus of a mare, 60 days pregnant.

the enlarged, whirring uterine artery will aid or confirm a diagnosis of pregnancy.

The ovaries of the mare during early pregnancy, differing from the cow, are of no value in determining the uterine horn containing the fetus. The corpus luteum is only palpable for a few days to a week after ovulation before it is covered by the dense fibrous ovarian tunic. A number of reports indicate that the incidence of ovulation may be slightly higher from the left ovary, 51 to 60 percent. The early embryo, up to 30 or possibly more days of gestation can migrate within the uterus resulting in slightly more pregnancies, up to 60 percent, in the right horn.^{1,3,8,13,25,38}

The gestation period can be divided into four periods based on the changes that occur in the ovaries.¹⁹ The first period, from ovulation to 40 days, is characterized by the presence of a single corpus luteum of pregnancy and a number of various-sized follicles on both ovaries. Great follicular activity occurs between 17 and 30 days after conception and before the secretion of gonadotropin by the endometrial cups.^{6,19,52} The second period, from 40 to 150 days, is characterized by marked ovarian activity many follicles over 1 cm. in diameter and the formation of accessory corpora lutea. Ovulation occurs during this period.³ Usually 3 to 5 or more accessory corpora lutea are present in each ovary. This ovarian activity with follicle and corpora lutea formation is probably caused by the high FSH and LH levels in the mare and not the high PMSG secreted by the endometrial cups from 40 to 120 days of gestation. Mares' ovaries apparently are unresponsive to PMSG (pregnant mare serum gonadotropin). The third period, from 150 to 210 days, is characterized by a regression of the corpora lutea and the absence of large follicles. The fourth period from 210 days to foaling no corpora lutea or follicles are present. During these latter two periods, gestation is maintained by steroid hormones produced in the placenta.⁴⁷

The vaginal examination as an aid in pregnancy diagnosis may be helpful but is not as accurate as the rectal examination of the uterus. By 30 days of pregnancy the normal equine vagina and cervix, on examination with a speculum, are very white and pale. They are more white and pale than at any time during the estrual cycle and resembles a mare's vagina in anestrus during the winter months. The mucous membrane is very dry, sticky, and gummy. There is less tendency for the vagina to balloon when the speculum is inserted than during the estrual cycle. More gummy mucus is present on the mucous membrane of the vagina during pregnancy than during the anestrus period. About 75 percent of pregnant mares show these characteristic vaginal changes.²⁰ The other pregnant mares may show a more hyperemic or con-

gested mucous membrane with less mucus. In rare cases a vaginitis with a mucopurulent exudate may be seen. The cervix in pregnant mares is usually tightly closed and small with a puckered external os. It is usually pulled downward and to one side. The external os of the cervix usually becomes covered with gummy, sticky mucus. In advanced pregnancy it may be easier to palpate the fetus through the vagina than through the rectum, as the mare objects less to the vaginal examination.

Differential diagnosis in pregnancy examinations should be considered by the inexperienced examiner. Occasionally a large endometrial cyst or lymph lacuna of the uterine wall may be mistaken for early pregnancy. From 70 to 110 days a distended bladder may be confused with pregnancy. Pneumovagina or a uterus filled with air might be mistaken for pregnancy. From 90 to 120 days an enlarged or distended right colon or pelvic flexure of the colon might rarely be confused with a pregnant uterus. Pyometra and mucometra associated with endometritis and focal cystic degeneration of the endometrium are occasionally found in the mare. The uterine wall and the fluid contents of the uterus may be heavy and thick. Tumors of the uterus and ovaries are uncommon in the mare. Mummification of a single fetus has not been observed in the mare. Fetal maceration is also uncommon.

Double ovulation occurs in 18 to 25 percent of mares and twin pregnancies are quite commonly diagnosed. But the incidence of twin births is low, 0.5 percent, due to embryonic or fetal death and abortion of possible of one, or more often, both fetuses.^{4,38} Twin embryos may be detected early, 21 to 25 days, by the palpation of two chorioallantoic vesicles or ventral bulges, often with one in each horn. If both vesicles lie close together producing a ventral bulge of the horn 10 to 30 percent greater in size than that of a single pregnancy, diagnosis is difficult, especially after 60 days.³⁵ Later, twin fetuses might be palpated and both uterine arteries might be enlarged.

Embryonic deaths in mares may be diagnosed at 35 to 45 days or more of gestation by a loss of fluid and tone in the chorioallantoic vesicle and a marked reduction in the size of the ventral bulge. These affected mares may not return to estrus and a regular estrous cycle for 40 to 80 days or more because of the presence of endometrial cups and the elevated secretion of PMSG.^{1,2,53} Douching the uterus with 500 ml. of warm saline or an injection of 10–15 mg. of prostaglandin (PGF_{2a}) or a prostaglandin analogue if performed before 40 days of gestation, usually results in a return to estrus within a few days in these mares. If early embryonic death is suspected, repeated examinations per rectum may be needed to confirm it.

The Biologic Tests for Pregnancy in the Mare

The tests are practical and nearly as accurate as pregnancy diagnosis per rectum. They are particularly indicated in highly nervous or vicious mares and small ponies in which rectal examinations would be highly dangerous for the operator or impossible because of the size of the animal. Veterinarians not experienced in the techniques of pregnancy diagnosis per rectum frequently employ these tests. The gonadotropic hormone, present at high levels during the early stages of the equine gestation period, is the principal hormone utilized for pregnancy testing.

The gonadotropic hormone (pregnant mare serum gonadotropin (PMSG) or equine chorionic gonadotropin, (ECG) from the endometrial cups in pregnant mares is first found in mare serum from 38 to 42 days of gestation. It reaches its maximum levels between 50 and 80 days and then gradually declines and is absent after 120 to 150 days. Ten ml. of blood should be drawn from the mare's jugular vein into a sterile tube. After clotting and separation of the serum at room temperature, the serum should be removed and refrigerated. Overheating of the sample should be avoided. This test may be conducted with accuracy from 40 to 120 days of pregnancy. Tests before 40 days and after 120 days of gestation in the mare may be inaccurate due to the low level of circulating gonadotropins in the plasma.

The hemagglutination-inhibition test is highly accurate, over 90 percent, in mares.^{14,32,41,49} The hemagglutination inhibition test utilizes the principle that PMS gonadotropins inhibit the agglutination of horse erythrocytes coated with PMS gonadotropin in the presence of PMS gonadotropin antiserum. This test, the Mare Immunological Pregnancy (MIP) test is sold commercially in the U.S. by Diamond Laboratories, Des Moines, Iowa. A recently developed radioreceptor assay test^{22b} and the possible commercial development of an ELISA test^{56a} for the presence of PMSG or ECG may be more accurate than the MIP test at 35 to 45 days to 100 to 150 days of gestation. Further studies should be conducted on these promising tests even though the former requires carefully controlled laboratory techniques.

The tests for gonadotropic hormone in pregnant mare serum are based on the development of endometrial cups in the region of the junction of the horn containing the embryo and the body of the uterus at about 30 to 40 days of gestation. These endometrial outgrowths are closely invested by the chorioallantois. The endometrial cups enlarge and fill with a mucoprotein secretion very rich in gonadotropic hormone the amount of which parallels levels in the blood.¹⁵⁻¹⁸ At 40, 80 and 150 days of gestation the total gonadotropic secretory activity in the cups

and in the plasma of the mare were 21,000 I.U. and 0.1 to 6.0 I.U./ml.; 73,000 I.U. and 6 to 296 I.U./ml.; and 42,000 I.U. and less than 0.5 to 106 I.U./ml., respectively. The equine gonadotropin produced in the endometrial cups is formed by the apocrine glandlike cells from the early chorionic girdle. The endometrial cups and their associated structures begin to show very early desquamation and regression at about 80 days of gestation and have completely desquamated by 100 to 120 days²¹ but the high levels in the plasma of PMSG may require more time to completely disappear.

When a mare is carrying a mule fetus the MIP test is not accurate because the equine gonadotropin concentration of her serum is about one-tenth that associated with a horse fetus.¹⁶ Ponies have as much as 8 times the concentration of gonadotropin as the draft breeds.¹⁷ This might be a breed difference or due to a dilution factor. Mares with a twin pregnancy of 52 to 72 days duration usually had twice the level of gonadotropin in their plasma than mares carrying single fetuses.⁴⁵ This difference was apparently due to a double set of endometrial cups in mares carrying twins. Ovarian activity was not correlated to gonadotropin levels in the blood. Gonadotropins are not found in the urine of pregnant mares as they are in women.

False negative reactions may occur due to taking serum from mares at 35 to 38 days and from 110 to 150 days of gestation when the level of serum gonadotropin may be very low in some mares. False positive reactions in mares may be due to early embryonic deaths that may occur in 5 to 10 percent of mares between 40 and 120 days of gestation and in which PMSG is continued to be secreted by the endometrial cups.⁴¹ Because of these occasional false positive results when testing for equine gonadotropin, some owners rely on the rectal examination or ultrasonography by a skilled veterinary examiner for the most accurate determination of pregnancy in mares.

Pregnant mares in which spontaneous or induced embryonic deaths occur after 40 days of gestation, when endometrial cups secreting PMSG are present, enter a pseudopregnant or infertile period that persists until the endometrial cups have sloughed or desquamated and levels of PMSG have disappeared from the blood plasma at about 120 or more days after conception. Thoroughbred mares during this period are in anestrus and have small firm inactive ovaries while pony mares have irregular frequent but anovulatory estrus periods characterized by follicular activity and apparent premature luteinization of the follicles. Repeated douching of the uterus or injections of prostaglandins to cause involution of the corpora lutea failed to produce estrus, ovulation and conception in these mares.^{1,2}

Other tests for gonadotropin in the plasma of mares

include the Ascheim-Zondek or immature rat test, the Friedman modification of the A.Z. test or rabbit test, the male frog or toad test and the direct latex agglutination test. These tests are more difficult, costly and give slower results than the convenient, practical, rapid, cheaper hemagglutination-inhibition or MIP test.⁴³ The Cole-Hart modification of the A.Z. test or "mouse" test is currently considered to be more accurate than the M.I.P. test or manual pregnancy test in mares for insurance purposes in Australia.^{39b}

The Cuboni and other tests for detecting the presence of estrogenic hormone in the urine of pregnant mares are accurate when applied from 120 to 250 days of pregnancy.⁴³ These tests have not proven practical because horse owners want the results of pregnancy testing much earlier than 120 days of gestation.

Pregnancy Diagnosis in the Ewe and Doe

Pregnancy diagnosis in the ewe and doe has been based primarily on post-conception clinical observations of changes in the animal similar to those occurring in the cow and mare, such as: service by a male and cessation of the estrous cycle. The use of a marking harness on the ram with different colored chalk used every 2 to 3 weeks and keeping of breeding records with ewe identification is desirable.^{8,12,17} In a well-managed flock over 90 percent of the ewes were marked and apparently bred but 20 percent failed to lamb so embryonic death losses probably occur. In advanced pregnancy there is an increase in the size of the abdomen and udder. The latter is most evident in primipara. During gestation up to 20 to 30 percent of pregnant ewes exhibit an estrous period of about 18 hours' duration one or more times. These periods were most common during early pregnancy but also occurred even in the late stages of gestation.^{8,22} Ninety-four percent of ewes failing to return to estrus by 21 days after service were pregnant but matings must be closely supervised and observations recorded.^{8,17}

In the ewe and doe one can occasionally observe **fetal movements** in advanced pregnancy and **ballot the fetus** on the right side from 3-1/2 to 4 months of pregnancy to term. The latter is most readily accomplished in thin fine-wool breeds by placing them on their rump on a crate and ballotting of the lower abdomen.^{7,15,18,21}

A radiographic diagnosis of single or possibly twin pregnancy can be made in 90 percent of ewes and does from 75 to 90 days of gestation to term but it is rather expensive.^{7,17}

The use of the **fetal electrocardiogram** as reported in horses and cattle has not proven practical for pregnancy diagnosis in sheep and does.^{7,17} The use of an **ultrasonic Doppler instrument** by rectal insertion or application to

the abdomen was over 90 percent accurate in the detection of pregnancy in ewes and does from 65 to 135 days of gestation.^{3b,4,7,9,10a,10b,12,13,17} These Doppler instruments detect movements of the fetus, blood in the heart and the pulse in the large vessels of the fetus. The accuracy in detecting twins was about 50 to 60 percent. Using an ultrasonic device similar to that used in swine had an accuracy of 80 to 90 percent in does and ewes pregnant more than 65 days.^{1a} (See Pregnancy Diagnosis in the Mare)

A direct method of palpation of the uterus with the fingers through a small abdominal incision in the inguinal region between 5 to 8 weeks of gestation was described.⁸ **Progesterone levels in blood** plasma, milk or milk fat may be used in ewes and does, especially the latter for pregnancy diagnosis. Blood or milk samples taken at 16 to 21 days and 32 to 35 days after mating in ewes and 21 days in does are analyzed by radioimmunoassay. Progesterone levels in blood and milk fat were more accurate for pregnancy diagnosis in does than milk levels.^{1c} High levels of progesterone indicate pregnancy and low levels nonpregnancy. The results are about 90 or more percent accurate when correlated with lambing of kidding.^{3b,7,12,14,17,20}

A bimanual rectal probe-abdominal palpation technique for ewes has been described and illustrated that is over 90 percent accurate by 65 to 70 days post-breeding. It is simple, easy and practical. Thin and relaxes ewes are easier to examine than fat or straining ewes. This technique was quite accurate in diagnosing single or twin fetuses.^{5,6,19} However, careful manipulation of the rectal probe is essential to avoid injury. Occasional abortions and deaths due to laceration of the rectum have been reported. Skilled operators produced very few rectal perforations but rectal abrasion and bruising are common, especially in nonpregnant ewes. This rectal abdominal palpation technique has been evaluated in does and is accurate⁸ but the possibility of abortions and deaths occasionally produced by this procedure limits its usefulness.¹³ **Laparoscopy or peritoneoscopy** with an instrument inserted through the upper right flank area is an alternative to the laparotomy procedure.^{3,11}

The technique of vaginal biopsy after 40 days of gestation was over 90 percent accurate for pregnancy diagnosis but was of no value in determining twinning. Its accuracy in detecting non-pregnant ewes was about 80 percent. This technique required a laboratory and a skilled person to examine the slides prepared from the biopsy of the vaginal mucosa.^{12,16}

A variety of other techniques to determine pregnancy in ewes and does have been evaluated, such as palpation of the caudal uterine artery per vaginum, assay of blood levels of estrogen and others but they are either unsat-

isfactory, unreliable, too expensive or too time consuming.^{7,12,17}

About 10 to 20 percent of the embryos in sheep, especially with double ovulation, will undergo transuterine migration from one horn to the other. Sixty-two percent of single ovulations in ewes and 56 percent of multiple ovulation occurred on the right ovary.¹ Ovine fetal crown-rump length at various stages of gestation are as follows: 30 days, 1.5 cm.; 60 days, 5.0 cm.; 90 days, 15 cm.; 120 days, 27 cm.; and 150 days, 50 cm.

Pregnancy Diagnosis in the Sow

Clinical observations may be used to diagnose pregnancy in sows as in ewes, cows and mares. Although the incidence of ovulation from each ovary may vary in sows, transuterine migration and placement of embryos results in nearly an equal number of fetuses in both uterine horns.^{3,13}

Rectal examinations and palpation of the uterine artery for diagnosing pregnancy can be performed in most sows and large gilts with an accuracy of over 90 percent after 40 or more days of gestation. Diagnosis was based on the size, tone and fremitus in the uterine artery compared to the external iliac artery. The tone of the cervix was also considered.^{1,8} Testing blood plasma for elevated **estrone levels by radioimmunoassay** between 20 to 30 days after service could be used as a pregnancy test in sows and gilts.^{3b,2,6,10,13b} This elevated estrogen level produced by the blastocysts in the uterus, was first detectable at 15 days after service and resulted in the maternal recognition of pregnancy and persistence of the corpora lutea. **Laparoscopy techniques** have also been used in sows and gilts for a highly accurate diagnosis of early pregnancy.¹⁶

Ultrasonography or ultrasonic amplitude depth or fetal pulse analysis, despite the initial cost of the equipment, is rapidly becoming the method of choice for pregnancy diagnosis in swine. A number of commercial companies are selling these solid-state machines utilizing a transducer probe placed on the lower abdomen or flank region of the female just lateral to the nipples and caudal to the navel and directed toward the uterus. A water soluble gel or corn oil is placed on the tip of the probe before placing it on the skin to improve contact. This test has proven to be over 90 percent accurate between 30 and 90 days of gestation in both pregnant and non-pregnant sows or gilts. The test is rapid and safe and restraint is minimal.^{3b,3,5,9} Amniotic and allantoic fluids are largely responsible for the positive acoustical patterns. The allantoic fluid increases rapidly from day 23 to day 65 and amniotic fluid from day 30 to day 80 of

gestation. The proportion of conceptus volume, fluids vs. fetus, declines rapidly after 90 days coinciding with rapid fetal growth resulting in a decline in the reliability of this method (amplitude-depth) after 90 days of gestation. The fetal-pulse ultrasonic analysis is over 90 percent accurate after 55 days of gestation.⁵

The **vaginal biopsy technique** for early pregnancy diagnosis in sows or gilts is over 90 percent accurate from 20 to 90 days after service. A special biopsy instrument is inserted into the vagina when the females are eating and a portion of the vaginal epithelium is recovered. Frozen, unstained tissue sections or stained tissue sections are examined under a microscope. A pregnant animal has four or fewer layers of epithelial cells with no interpapillary pegs. While a nonpregnant female has a many layered vaginal epithelium with abundant interpapillary pegs.^{3,4,5,7,15}

The fetal crown-rump length of swine fetuses at various stages of gestation is: 30 days, 1.8 to 2.5 cm.; 60 days, 8 to 11 cm.; 90 days, 17 to 23 cm. and at farrowing, 23 to 29 cm.¹⁴

Pregnancy Diagnosis in the Bitch and Queen

During pregnancy in the bitch there is usually a marked progressive increase in abdominal size from 35 days to term due to the deposition of fat and the increase in size and weight of the uterus. The teats between 35 to 45 days of gestation become enlarged and turgid. After 45 days they soften and become still larger. The mammary glands become enlarged and edematous from 50 to 55 days of pregnancy. Since these changes are even present, but usually less apparent, in non-pregnant bitches following estrus due to the pseudopregnant state, one must be cautious in diagnosing pregnancy on the basis of the above signs. Pseudopregnancy in the bitch extends for approximately the same period of time as gestation and may be followed by lactation if suckling is allowed. In dogs abdominal distention may also result from ascites, splenic enlargement, abdominal tumors, pyometra, or other causes.

Palpation of the uterus through the abdominal wall is one of the best and earliest methods of diagnosing early pregnancy in the bitch.¹ The ease with which this is done will depend on a number of factors such as: the temperament of the bitch, size of the dog, the stage of gestation, the number of fetuses in the uterus, and the degree of obesity.¹ At 18 to 21 days the embryos and their chorioallantoic vesicles produce a series of round swellings about 1.25 cm. in diameter in the uterine horns which frequently may be difficult to palpate at this time through

the abdominal wall. From 28 to 32 days of pregnancy these round ping-pong ball-like swellings in the uterus are about 1.5 to 3.5 cm. in diameter and are usually readily palpable. After 30 days it is difficult to palpate the pregnant uterus since the swellings increase in size, elongate, become confluent, lose their tenseness and come to rest on the abdominal floor. In some cases abdominal enlargement is noticeable. At 40 days of gestation these uterine swellings are 5.4×8.1 cm. in pregnant bitches.⁵

It is easier to palpate the caudal portions of the uterus. Fecal material in the colon should not be confused with pregnancy. From 45 to 55 days of pregnancy the size of the uterine horns and fetuses increase rapidly. The caudal fetuses are about 7.5 cm. long in medium-sized bitches and may be palpated in thin bitches with a thin, relaxed abdominal wall. The horn, since it is greatly distended and elongated, is usually bent in the middle at the liver. The apical portion of the horn is bent caudal and lies lateral and dorsal to the cervical portion of the horn. From 55 to 63 days the size of the fetuses are such that they can readily be detected. Rectal palpation with the finger with the forequarters elevated often is successful if palpation through the abdominal wall is difficult. The crown-rump length of the canine fetus at various stages of gestation is: 21 days, 0.7 to 1.0 cm.; 30 days, 1.5 to 1.6 cm.; 40 days, 6.3 to 7.8 cm.; 50 days, 11 to 12 cm. and 60 days, 14 to 20 cm.^{6,12}

Radiography is a helpful diagnostic aid in the bitch and queen especially late in pregnancy since fetal bones calcify during the last 20 days of gestation.^{7,10} With careful technique and experience the introduction of air, 200 to 800 ml., depending on the size of the bitch, into the abdominal cavity producing pneumoperitoneum, may help delineate the swellings in the uterus as early as 30 to 35 days of pregnancy. In the feline fetus the radius and ulna at 41 days and the tibia, fibula, ilium, ischium and occipital bones at 43 days, metacarpals and metatarsals at 49 days, and the entire skeleton at 55 days is calcified and can be visualized radiographically.^{1,3,4} Radiographs prior to 25 days in bitch and queen should be avoided because teratologic effects may be produced in the embryos.

In the queen palpation of the implantation sites in the uterus through the thin abdominal wall is easier than in the bitch and possible from 14 to 25 days but best accomplished from 17 to 21 days of gestation when these sites are about 1 to 1.5 cm. in size and firm. The fingers and thumb are placed together through the abdomen beneath the transverse lumbar vertebrae. Slowly draw these ventrally feeling first the rectum and then the uterus. After this period the uterus enlarges rapidly, becomes much softer and doughy and is difficult to palpate. By 45 days

of gestation the abdomen has become enlarged in queens carrying four or more fetuses. This manual examination should be done carefully and gently at all stages of gestation to prevent possible death and abortion of the embryos or fetuses. Between days 45 and term, the fetus, especially the head, can be palpated.

Ultrasonography or ultrasound techniques have been utilized in pregnancy diagnosis in the bitch and queen from about 30 days of gestation to term.^{1a} It may also be used to detect fetal life in conditions in which radiography and auscultation of the fetal heart are difficult or not definitive. Further studies are needed to develop and make more practical this technique. Presently the cost of the equipment is nearly prohibitive. (See Pregnancy Diagnosis in the Mare.)

Laparoscopy has been developed and used for pregnancy diagnosis in the bitch and queen. It is accurate in early gestation from about day 15 to term.^{3,8}

Biologic tests for pregnancy diagnosis are not available in the bitch and queen. Vaginal cytology is also unreliable.^{3,10}

Chapter III

GESTATION PERIOD—EMBRYOLOGY, FETAL MEMBRANES AND PLACENTA—TERATOLOGY

The gestation or pregnancy period is the period from fertilization or conception, to parturition or the birth of the young. During this period single cells divide and develop into highly organized individuals. This antenatal period is the least understood and probably one of the most important periods of life. There is a separate and distinct physiology of the fetus and placenta that is being intensively studied. The mortality rate of the ovum, embryo, or fetus during this period is much greater than for any other period of equal length after birth. Because they are usually unrecognized, early deaths of the fertilized ovum, or the early embryo, with resulting resorption or abortion, are often considered as sterility or infertility. The expulsion of a dead embryo or fetus that has reached recognizable size is called an abortion. The expulsion of a live fetus is called a birth. Until birth has occurred the viable bovine or equine fetus should not be called a calf or foal. The antenatal bovine individual or fetus, not a "calf," is present in the uterus and may be balloted through the abdominal or rectal wall. Dead fetuses, not "calves," may be aborted, or expelled at term. Calves are only born alive and the term "born dead" is improper. Through common usage the fetuses expelled dead at parturition in swine and some other species are called stillbirths. Those born before the end of the normal gestation period are spoken of as premature calves, foals, pups and etc.

The gestation period can roughly be divided into two parts, based on the size of the individual and the development of its tissues and organs. These two periods in the gestation period of the cow are:⁶⁴ **The period of the early embryo, ovum or blastula**—Presently the designation of the period of ovum or blastula has been dropped because as soon as fertilization occurs embryogenesis begins. Unfertilized ova die within a few hours after ovulation. This period of about 10 to 12 days in the cow extends from the time of fertilization, that usually occurs within a few hours after ovulation, to the development of the zygote's primitive fetal membranes in the uterus. The size of the ovum in domestic animals, not including the zona pellucida or granulosa cells, is

about 120 to 180 microns at the time of fertilization and the shedding of the second polar body. During this period, division or cleavage of the fertilized ovum progresses in the region of the ampullary—isthmic junction of the uterine tube to the morula stage characterized by the inner and outer cell masses totalling about 16 to 32 cells. The morula enters the uterus on day 3 after fertilization in the sow and days 4 to 6 in the other domestic animals. By 8 to 11 days after fertilization the zona pellucida has fragmented and a blastocyst has formed composed of the embryoblast or inner cell mass and trophoblast or outer cell mass and fluid, probably absorbed from the uterine cavity. By 11 days in the ewe and 12 days in the cow the blastocyst is about 1 and 1.5 mm. in diameter, respectively. Elongation of the blastocyst has not yet occurred. During this period defective embryos die and are absorbed. The corpus luteum is developing and producing progesterone, a hormone necessary for the growth and preparation of the endometrium, so a favorable environment for the embryo will be present in the uterus. (See Chapter 20 on Embryo Transfer.)

Period of the embryo and organogenesis—This period extends from 12 to 15 days to about 45 days of gestation in the cow, 11 to about 34 days in the ewe and probably about 12 to 55 to 60 days in the mare. During this period the major tissues, organs and systems of the body are formed and changes in body shape occur so that by the end of this period the species of the embryo is readily recognizable. This usually coincides with the development of the eyelids.⁵⁴ Starting at 12 days of gestation in the ewe and 14 days in the cow the trophoblast elongates very rapidly so by 14 days in the ewe and 17 days in the cow it is 10 cm. to 30 cm. in length, respectively and maternal recognition of pregnancy occurs. By 18 to 19 days of gestation in the cow the trophoblast may extend into the opposite horn.^{33,41,52} In the sow during this same period, 13 to 17 days, the lengthening of the trophoblast and the migrating and positioning of embryos in the uterus occurs. By 24 days of gestation the trophoblasts in the sow are about 24 cm. long.^{1,3} In the mare, bitch and queen the trophoblast or blasto-

dermic vesicle does not elongate but remains oval during this period causing a localized enlargement in the uterus helpful in early pregnancy diagnosis. In the cow the amnion is completely formed and closed and somites are forming by 20 days of gestation, by 22 days the heart is crudely formed and beating, by 25 days the neural tube is closed and 25 somites are present, the allantois is well developed, anterior limb buds are formed and eye and brain development are well advanced.

In the cow, as in other animals, attachment of the fetal membranes is a gradual process that begins with the formation of the first villi about 30 days of gestation and progresses to a primitive attachment of the chorioallantois to the endometrium in the caruncular areas about 33 to 36 days of gestation.^{32,33} In the ewe attachment begins at about 17 to 20 days and is well-developed by about 28 to 30 days.¹⁹ While in the mare, attachment is delayed until 70 to 90 days when villi develop on the chorion and project into crypts in the endometrium.⁸ In domestic animals the term attachment is preferred to the term implantation or nidation. Implantation refers to the process in humans and rodents where the zygote erodes, penetrates and implants itself within the endometrium. Up until the time of the well-developed attachment of the chorion to the endometrium the nourishment of the early embryo is provided by the secretion of the uterine glands called "uterine milk," a yellowish or whitish, thick, opaque secretion, grossly resembling, and occasionally mistaken for, a purulent exudate.

During this period nearly all of the more severe teratologic defects or anomalies of development occur. Also during this period the embryo may die, be expelled unnoticed at the next estrus, or become macerated and absorbed without external signs.

The period of the fetus and fetal growth. This period extends from about 34 days of gestation in the ewe and bitch, 45 days in cows and 55 days in the mare to parturition. During this period minor details in the differentiation of organs, tissues, and systems occur along with the growth and maturation of the antenatal individual. Changes in the bovine fetus from 70 days to parturition are not radical. During this period caruncles and cotyledons develop and enlarge to supply nutrition to the fetus in the cow and ewe. The increase in size of the fetus is a geometric-like curve, with the weight of the bovine and equine fetus increasing very rapidly the last two to three months of gestation.^{8,22,24,27} From 210 to 270 days the increase in weight of the bovine fetus is equal to three times the increase from the time of fertilization to 210 days.

The prenatal development of the ovine and bovine zygote have been carefully described.^{18,31,58,64} The em-

bryology of swine has been reviewed.⁶ Recent valuable information on embryology in horses and dogs, has been provided.^{8,22,25,27}

Embryology

Embryology is the study of the physiological development and growth of the antenatal individual. **Teratology** is the division of embryology and pathology dealing with abnormal development and malformations of the antenatal individual. Teratologic studies are of value because they constitute important available records of injury and arrested or pathologic development of the embryo or fetus. These studies explain the nature of some of the teratologic abnormalities in the fetus that frequently result in dystocia as well as other defects of the reproductive and other body systems. The embryology of importance in obstetrics, excluding that relating to the male and female reproductive systems which are discussed in detail elsewhere, is as follows:

The nervous system. The hypophysis or pituitary gland is an important endocrine gland. It is composed of the anterior, intermediate, and posterior lobes. The former and latter are of greatest significance. The posterior lobe arises embryologically as a downward extension of the floor of the diencephalon, a portion of the primitive brain. The deep portion of Rathke's pocket loses its original connection with the stomodeal ectoderm and becomes closely applied to the infundibulum and forms the anterior lobe. Thus the posterior lobe of the hypophysis arises from neural tissue and the anterior lobe from ectodermal tissue. Teratologic defects or arrests in development of the nervous system may result in such conditions as: ankyloses, hydrocephalus, hypoplasia of the cerebellum, cerebral hernia, cyclopia, lack of optic tissue, and persistence of the anterior neuropore with failure of facial bones to fuse (*Schistocephalus bifidus*).²

The digestive system. This system is of little importance in obstetrical studies in animals. Arrested development at the terminal portion of the digestive system may result in atresia ani or the lack of a rectum. Occasionally a common cloaca is observed in the female or atresia ani is made less acute by the rectum emptying its contents into the vulva. Anomalous development of the gut may result in atresia coli. In the mouth region arrested development may result in a cleft palate or persistence of epithelial linings of the pharyngeal pouches, as seen by pharyngeal cysts in dogs.

The circulatory system. The heart, arising from the fusion of the primitive endocardial tubes, develops initially in the neck region caudal to the gill clefts or pha-

ryngeal arches and then descends into and is enclosed by the chest in the bovine embryo around the fifth to sixth week of gestation. If this fails to occur the condition of ectopia cordis results. When the heart descends, the aortic arches descend also and carry with them the laryngeal nerves. The left aortic arch persists and the right aortic arch disappears. In dogs and cattle and rarely in other animals, the right aortic arch persists and the left disappears. In these instances, if the left ductus arteriosus is present, a chronic stenosis of the esophagus occurs as it passes over the base of the heart. It is compressed between the trachea, the aorta, the ligamentum or ductus arteriosus, and the base of the heart.

The fetal venous circulation of blood consists largely of "arterial" blood rich in oxygen and nutrients coming from the placenta into the umbilical vein of the fetus. This vein passes through the umbilicus into the liver of the fetus where it anastomoses with the portal vein. In the fetal liver in most animals including the dog, cow, and sheep there is a direct shunt, called the ductus venosus, from the umbilical vein to the posterior vena cava. The blood that enters the portal veins goes through the liver tissue and into the posterior vena cava by means of hepatic veins. From the posterior vena cava, the blood then enters the right atrium where about 50 percent of it is immediately shunted through the foramen ovale into the left atrium.²⁰ The remainder passes into the right ventricle and is pumped into the pulmonary artery, where again a large portion of the blood is shunted through the

short ductus arteriosus into the aorta. A small amount goes through the pulmonary artery into the lungs as only a small blood supply is needed since the lungs are not functional in the fetus. Blood from the lungs is returned to the left atrium by the pulmonary veins. Blood that comes through the foramen ovale is mixed in the left atrium with blood from the pulmonary veins, passes to the left ventricle, and is pumped into the aorta and thence through the arteries to the various organs and tissues of the body. The aorta carries blood caudally to the rear quarters and in the region of the last lumbar vertebrae the two large umbilical arteries arise that carry largely "venous" blood down on either side of the bladder through the umbilicus to the placenta where waste products and carbon dioxide can be exchanged for nutrients and oxygen. More than 50 percent of the fetal cardiac output goes to the placenta.²⁰ In the fetal lamb at 130 days of gestation 48 percent of the blood volume was in the placenta; at near term about 26 percent of the blood volume was in the placenta.^{5,6} The effect of allowing the cord to remain intact for a short time after birth to increase the blood volume in the newborn is evident. Hemoglobin values and red blood cell numbers in the fetus are much higher than in the adult. These values rapidly drop to normal after birth. Fetal hemoglobin apparently has a greater affinity for oxygen and releases it more slowly than does hemoglobin in the adult. The fetus has a high heart rate, about twice that of a young animal, promoting a high cardiac output per unit of body weight necessary

Figure 16. Diagram of fetal blood circulation (arrows indicate the direction of the blood flow).

to compensate for the low oxygen content of the fetal blood.^{5,6}

Marked changes occur in the fetal circulatory system at the time of birth.^{20,29} The umbilical cord ruptures. The umbilical vein present in the umbilical stump apparently closes due to a smooth muscle effect. The remnant of this vessel from the umbilicus to the liver becomes in later life the round ligament of the liver. The ductus venosus is apparently closed by a smooth muscle sphincter within 30 minutes to several hours after separation of the umbilical cord. In later life it becomes the ligamentum venosus in the substance of the liver. The liver then has the entire volume of portal blood going through its lobules instead of about one-third the volume. The foramen ovale closes mechanically within 5 to 20 minutes after birth by the closing of its lumen with the thin fold of tissue lying in close apposition to the foramen. This thin membrane or valve is maintained by an increase in blood pressure in the left atrium over the right. Finally after a year or more a complete septum is formed, the ductus arteriosus is closed by the contraction of its smooth muscle within 4 to 5 minutes after birth. This closure is apparently associated with an increased supply of oxygen in the blood of the newborn. The ductus arteriosus atrophies and eventually becomes the ligamentum arteriosum. The umbilical arteries are stretched at the time the cord is broken and they contract into the abdominal cavity and are closed by smooth muscle contraction. These are similarly affected by an increased oxygen level in the blood. The umbilical arteries later become the round or lateral ligaments of the bladder. Concomitant with these changes after separation of the fetus from the placenta at birth is a marked rise in arterial blood pressure.^{5,6} Defects in cardiac development are occasionally seen in animals, especially calves, dogs and pigs, where they may be associated with weakness, hypoxia, signs of circulatory failure, and death soon after birth.

The urinary system. This system is formed mainly from mesodermal tissue. The earliest or most primitive urinary or excretory organ in the embryo is the pronephros with two pronephric ducts, one on each side in the body wall dorsal to the peritoneum. This organ soon degenerates, to be succeeded by the mesonephros or Wolffian body. This structure, using the earlier pronephric ducts now called mesonephric or Wolffian ducts opens into the common cloaca. Later in the development of domestic animals the mesonephros degenerates and the metanephros or true kidney develops more caudally as an outpocketing of the mesonephric ducts. These ducts become the ureters, which open into the bladder. This latter structure opens caudally by the urethra into the amniotic cavity and cranially by the urachus into the allan-

toic cavity. During most of the late development of the fetus, urinary wastes are discharged principally into the allantoic cavity and little passes through the urethra into the amniotic cavity. Occasionally in domestic animals anomalies of the urinary system are observed, with polycystic kidneys or dilations or stenoses of the ureter. In rare cases a horse-shoe kidney, *ren arcuatus*, in which both kidneys are joined, is observed. This condition is noted more frequently in fetal monsters. The embryology of the genital system of the male and female animals are discussed separately in chapters relating to the anatomy of the genital tract.

The physiology of the fetus is a fascinating study. It has been shown that contractions of the heart and circulation of the blood through the vessels occurs early in the embryonic period. During this period respiratory movements are present. Although they may occur intermittently at first, they become more frequent and occur continually during the period of the fetus. The principal carbohydrate circulating in the ovine, caprine, equine, porcine and bovine fetuses is fructose produced by the placental tissues while in the canine and feline fetuses it is glucose.³⁶ Fructose does not pass through the placenta into the dam's circulation. The fetus starts swallowing late in the embryonic or early in the fetal period. Undoubtedly large amounts of amniotic fluid are swallowed and absorbed. Some of the waste products are stored in the rectum and colon as part of the meconium. This swallowing reflex of the fetus may be associated with maintaining the proper amounts of amniotic fluid. In fetal monsters, where defects of the cranial portion of the fetus or alimentary canal are present, hydrops amnii often occurs.

Fetal movements begin early, at 90 days in the mare, and are more or less continuous in the form of paddling movements of the limbs and moving of the head and neck.³⁰ If these movements do not occur or are markedly restricted, ankyloses with such abnormalities as wry neck or ankylosed limbs may result.

The Fetal Membranes and Placenta

The fetal or extra-embryonic membranes serve as protection, a means of transmitting nutrients from the dam to the fetus, in caring for fetal waste products and synthesis of enzymes and hormones. The latter are necessary for the maintenance of pregnancy in most domestic animals. The fetal membranes are discarded at the time of parturition. The fetal membranes consist of the primitive yolk sac, the amnion, the allantois and the trophoblast or chorion which when combined with the allantois

forms the chorioallantois. The trophoblast is the most important single tissue of the fetal membranes and placenta as it has functions of absorbing, transmitting and handling nutritive and waste products. It has an erosive action on the endometrium mediating the attachment of the blastocyst; and it has a regulating function by being the site of the synthesis of enzymes and hormones. The needs of the embryo and fetus are supplied and cared for as follows: water, oxygen, and nutrients are taken from the maternal structures as the uterus and, after placental attachment has occurred, the maternal blood and carried to the developing embryo and fetus by the yolk sac, the amniotic chorion and the chorioallantois. The first two structures develop early in the life of the embryo of domestic animals and only function a short period of several weeks until the chorioallantois develops. Waste products from the embryo and fetus such as carbon dioxide and urea are eliminated by the same structures. The allantoic cavity stores much waste material from the fetal kidneys. The large intestine and rectum of the fetus store waste products from the digestive tract as meconium. The amniotic cavity may play an early role in the care of some waste products. The fetal fluids permit the growth and movement of the fetus by distending the uterine lumen. Protection of the embryo and fetus is performed principally by the amnion, although the allantois, uterus, and maternal body assist in this function. Heat and immunity to early diseases of the newborn are supplied by the mother's body. These immune bodies in domestic animals are mainly supplied by the colostrum. The fetal membranes and placenta have been well-described.^{1,2,10-14,55,61,63}

The **yolk sac** is a primitive structure developing early in the embryonic period from the endoderm and disappearing after a short period of time in ruminants and swine but persisting for 4 to 6 weeks in the horse before becoming a remnant in the fetal membranes.^{11-14,60} Prior to the formation of the amnion, the blastocyst or blastodermic vesicle and then the yolk or vitelline sac perform limited placental functions of providing nutrients and care of waste for the early embryo. The endometrial or uterine glands, under the influence of progesterone from the corpus luteum, produce a secretion called "uterine milk." This contains protein, fat globules, organic and inorganic solids, and possibly other nutrients.^{5,1,2} This uterine secretion is absorbed by the blastocyst and yolk sac for the nutrition of the early embryo and later by the chorioallantois for the early fetus. Its role in middle or late gestation is probably not important.

The **amnion** forms about 13 to 16 days after conception in the ewe and cow, probably about the same time in the mare, and slightly earlier in the sow, bitch, and queen. The amnion is an ectodermic vesicle that arises

from an outfolding of the chorion, or from a space in the inner cell mass of the blastocyst, as a double-walled sac that completely surrounds the fetus except at the umbilical ring. When this sac is completed it is filled with amniotic fluid which surrounds the embryo and thus is a mechanical protection to the fetus. There is a thin sheet of smooth muscle in the amnion that contracts producing a tense amniotic vesicle.³⁵ Amniotic fluid also prevents adhesions between the soft, developing tissues of the embryo and the surrounding membranes which might cause malformations. The inner layer of this double-walled sac is the "true amnion" and the outer layer is the "false amnion," amniotic chorion, or portion of the trophoblast or serosa over the true amnion. Until the allantois is formed and the external portion of it fuses with the chorion, the amniotic chorion acts for a very short period, as did the yolk sac, in providing for the transfer of nutrients and for the care of wastes for the embryo.

The amnion during the fetal stage of development is a rather transparent, tough membrane. It provides the outer covering of the amniotic portion of the umbilical cord. On the inner surface of the bovine amnion are small, 0.25 to 1.5 cm, irregular-shaped, flat, white, elevated epithelial thickenings, called amniotic plaques. They are most noticeable during the third to seventh months of gestation. The portion of the amnion covering the cord of the bovine fetus is also covered with these amniotic plaques but at this site they are coarse, elongated villi or papillary elevations. They vary widely in number and consist of edematous epithelial cells that sometimes are keratinized. These amniotic proliferations are also found to a lesser degree in mares, ewes and does but not in sows and carnivores. The etiology or significance of these amniotic plaques is not known. They apparently are not due to infectious agents, either bacterial or viral. There are no inflammatory lesions associated with these plaques.⁴⁷

The amniotic fluid is clear, colorless, and mucoid in nature. This fluid is present toward the end of gestation in amounts of 2000 to 8000 ml. with an average of 5000 to 6000 ml. in the cow, 3000 to 7000 ml. in the mare, 400 to 1200 ml. in the doe, 350 to 700 ml. in the ewe, 40 to 200 ml. in the sow, and 8 to 30 ml. in the bitch and queen.^{1,2,3,5,7,15,65} Amniotic fluid contains the following substances: pepsin, a diastatic ferment, a lipolytic ferment, protein, fructose, fat, and salts. It is bactericidal and prevents adhesions.⁴⁶ Concentrated bovine amniotic fluid has been recommended for the prevention of peritoneal adhesions following abdominal operations in humans. Changes in the biochemical constituents of amniotic and allantoic fluids in cows during gestation has been reported.⁶⁶

The source of the amniotic fluid in early to midges-

tation is probably from the amniotic epithelium and from the fetal urine as the fluid is quite watery. As gestation advances the allantoic fluid increases in volume while the amniotic fluid volume remains fairly static but becomes viscid and glairy because the bladder sphincter prevents the further release of urine into the amniotic cavity. The probable source of the mucoid amniotic fluid is then the saliva and secretions of the nasopharynx of the fetus. The volume of amniotic fluid is probably partially regulated by swallowing by the fetus.^{3,5,6,61} The normal fetus does not inhale amniotic fluid into the lungs. The amniotic fluid aids parturition because its slippery, mucoid consistency lubricates the fetus and birth canal.

Pathologically, especially in fetal monsters or certain types of fetuses carried overtime, the amount of amniotic fluid may be greatly increased up to 8 to 10 times. This condition is called *hydrops amnii*. Another abnormal finding in the cow and ewe is the presence of meconium in the amniotic fluid causing staining and smearing of the fetus. This is probably caused by perinatal asphyxia or hypoxia.^{19b} In rare instances hairballs may be found in the amniotic fluid, especially in prolonged gestations associated with fetal giantism.

The **allantois** arises the second and third week of gestation in bovine fetuses as an outpocketing of the hind gut almost as soon as the hind gut is formed. The allantois consists of entoderm covered by a vascular layer of splanchnopleuric mesoderm. The outer layer of the allantois is eventually richly supplied with blood vessels connected to the aorta of the fetus by the umbilical arteries and to the liver and posterior vena cava by the umbilical vein. As the allantois grows and enlarges it extends between the true and false amnion. The outer layer of the allantois fuses with the trophoblast, false amnion, or serosa to form the chorioallantois. The inner layer, largely devoid of blood vessels, lies against the amnion and invests the allantoic portion of the umbilical cord. The allantoic sac or cavity is filled with allantoic fluid. The allantois is completely formed in the larger domestic animals by 24 to 28 days after conception and extends the entire length of the fetal membranes except the undilated apices of the chorionic or blastodermic vesicle in the ewe, sow, and cow. Because they are not supplied with blood vessels, these undilated apices atrophy and become necrotic and are called the necrotic tips of the chorioallantois. The small amount of allantoic fluid present before the fetal kidneys are active probably comes from the allantoic epithelium or by absorption from the uterine lumen. A precipitation of calcium in the allantois chorion causing white streaks or mottling is commonly observed from 60 to 90 days of gestation in the cow after which time it is removed and disappears as it is deposited in the fetal bones. A similar calcium storage in the

allantois chorion has been reported in pigs between 20 and 46 days of gestation.⁴³

The allantoic cavity stores the waste products of the fetal kidneys, which pass to it from the bladder through the umbilical cord by means of the urachus. This fluid is clear, watery, and amber in color and contains albumen, fructose, and urea. In a number of animals such as the sow and ewe the amount of allantoic fluid rises sharply during early pregnancy, rises more slowly around midpregnancy and then rises sharply toward the end of gestation. The allantoic fluid in the sow may decline the latter half of gestation.⁶⁵ In all animals the amounts of amniotic and allantoic fluids are variable.^{2,1,2,3,15,22,24,53} Toward the end of gestation the volume of allantoic fluid varies from 4000 to 15000 ml. averaging about 9500 ml. in the cow, from 8000 to 18,000 ml. in the mare, 500 to 1500 ml. in the ewe and doe, 100 to 200 ml. in the sow, 10 to 50 ml. in the bitch, and 3 to 15 ml. in the queen.

Occasionally excessive amounts of allantoic fluid, 40,000 to 160,000 ml. or more, may accumulate in the allantoic cavity. This condition is called *hydrops allantois*. This excessive fluid has the specific gravity and characteristics of a transudate. The cause is most commonly due to a vascular disturbance in the allantois.

Amorphous, semisolid, amber-colored, soft, pliable, rubber-like, irregular-shaped masses or bodies, thinner at the edges and thicker in the center, 2.5 to 15 cm. in diameter and from 0.3 to 3.8 cm. in thickness are commonly found in the allantoic cavity floating in the allantoic fluid of the cow, mare, ewe, doe and sow. These bodies are called *hippomanes* (after hippo or horse and manes or manus, Latin for hand) In a few cases these masses, resembling fibrin in appearance, have been observed fastened to a fold of the allantois. Hippomanes have been described as allantoic "calculi" consisting of a central nucleus of desquamated cell debris upon which were deposited in a concentric manner a denatured mucoprotein complex and minerals, mainly calcium phosphate.³⁸ This allantoic "calculus" has a higher specific gravity than allantoic fluid and if free-floating will sink to the bottom of the allantoic cavity. The author has not observed the reported concentric deposits in the formation of hippomanes and still considers their etiology an enigma. Occasionally the allantois will become pathologically thickened and edematous, edema of the allantois chorion.

The **chorioallantois** or **allantois chorion** is formed by the fusion of the outer layer of the vascular allantois and the trophoblast, chorion, or serosa. This structure, richly supplied with blood vessels communicating with the fetus and in intimate contact with the endometrium, is designed to carry on the metabolic interchanges of gases,

nutrients, and wastes between the fetal and maternal circulations. It actively begins this function with its formation and grows and develops as required by the needs of the fetus. The allantois chorion is the fetal placenta. Although liquids and gases may pass through the chorion to the maternal and fetal circulations, solids and most bacteria ordinarily cannot pass unless disease of the chorion is present. Certain bacteria, viruses, fungi, and parasitic larvae can penetrate the intact placental barrier.

In the cow, sow, and ewe the allantois is attached to the amnion at various points. This divides the allantois into a number of compartments. In the bitch, queen, and mare the amnion containing the fetus floats free in the allantoic cavity attached only by the umbilical stalk. In these latter animals the young are more apt to be born covered by the amnion or a portion of it. Unless it is promptly removed, they will smother if it lies over the nostrils and mouth. This rarely happens in the cow, sow, and ewe. The necrotic tips of the chorion, found at the apices of the chorioallantois, are observed in the ewe, cow, and sow, and are usually about 1 to 2.5 cm. long and about 0.3 cm. in diameter. In the mare an irregular bare spot in the diffuse placenta of the chorion is found over the internal os of the cervix and is called the "cervical star." Since the allantois chorion and endometrium are in intimate contact for most of the gestation period, disease or abnormalities of either is mirrored on the other. A careful examination of the fetal placenta after parturition will give an accurate index of the health of the uterine endometrium.

The Placenta

The placenta is composed of two parts: the fetal placenta, or allantois chorion, and the maternal placenta or endometrium. For a few weeks in the early embryonic period the yolk sac and amniotic chorion act as primitive placentae. During the first month or more of gestation, the blastocyst becomes attached to the endometrium, and the fetal membranes, including the allantois chorion, develop. At this time the villiform projections of the chorion and the maternal crypts in the endometrium, into which they extend, are rudimentary, small, and friable. During this early period in domestic animals much of the nutrients still are absorbed from the uterine secretions. Not until the end of the first third of gestation do the anatomical attachments of the maternal and fetal placentae become sufficiently intimate and complex to prevent the very easy separation of these two structures. Until this time the fetal membranes and embryo are held in place in the uterus by the accumulation of fluid within the membranes.

That a pregnant animal does not reject her placenta is an apparent biological paradox. With half of the genetic make-up of the fetus and placenta contributed by the sire there should be sufficient tissue incompatibility to induce an immune reaction in the dam and subsequent rejection of the conceptus. It has been postulated that the greater the trophoblastic invasiveness, as in man and rodents, the greater the necrosis of both chorionic and endometrial tissue.⁶⁶ This resulted in the development and deposition of a mechanical acellular barrier of acid mucopolysaccharide in those animals such as man and rats having a hemochorial placenta. In the epitheliochorial placentas of the mare, cow, sow, and ewe where the interdigitating microvilli of the chorion or trophoblast and endometrial epithelium are closely apposed, no extensive degeneration or deposition of fibrinoid is present. Therefore in the former an acellular mechanical barrier and in the latter the absence of trophoblastic antigenicity may offer reasonable explanations for retention of the placental homograft. The inability of immunologically active maternal cells to penetrate into the fetal circulation may also be important. Further immunological studies are needed to explain this failure of placental rejection.

Anatomically the placenta of animals may be divided into 4 general types based on their shape; the diffuse, the cotyledonary, the zonary, and the discoidal.

The diffuse type. In the mare and sow the entire surface of the allantois chorion is covered with microcotyledons, villi and microvilli that project into crypts or pockets in the endometrium. In the former these complex structures are completely formed by day 150 of gestation.⁵⁷ The entire endometrium and chorion take part in the placentation except over the openings of the uterine glands where the glandular secretion causes a separation of the two structures. These whitish structures are large and abundant in the pig placenta and are called areolae. In the mare the region of the internal os of the cervix is devoid of villi, the cervical star, as are occasional bare areas elsewhere due to placental folding. In the sow the apices or paraplacental zone of the placentas that abutt against the adjacent zone of the next placenta are free of villi and as pregnancy progresses the trophoblast and allantois in this area disappear and these areas fuse. The placental bed of each porcine fetus enlarges until nearly all of the endometrium is utilized.⁴ Uteroferrin, a glycoprotein, found in uterine secretions of sows and mares with a diffuse type of placenta is probably involved in iron transport to the embryo.⁶⁷

The cotyledonary or multiplex type. In ruminants, including the cow, ewe and doe, only a portion of the maternal placenta, or the endometrial caruncles, and portions of the allantois chorion, or cotyledons, which

closely appose each other to form the placentome, take part in the placental functions. In these structures the villi, secondary villi and microvilli of the cotyledon fit together closely with the maternal crypts and microvilli in a more complex arrangement than in the diffuse type of placenta. In the ruminant uterus the caruncles are arranged in 4 rows, 2 ventral and 2 dorsal, the length of each uterine horn. There are between 75 and 120 placentomes in the normal pregnant uterus of the cow, and about 80 to 90 in the ewe. Occasionally due to prior uterine disease or a failure of the horn opposite the one containing the fetus to form placental attachments, the numbers of placentomes may be reduced to one-half or less of the normal complement. In pregnant cows the convex uterine caruncle is elevated above the endometrium like a button, with the concave fetal cotyledon grasping it (See Figure 18). In the ewe and doe the maternal caruncle is also elevated above the endometrium but it is concave in shape, with the fetal cotyledon fitting into it (See Figure 17). The endometrium between the caruncles is called the intercaruncular endometrium and the fetal placenta between the cotyledons is called the intercotyledonary placenta. This area normally does not take part in placental functions once the placentomes are formed. Occasionally because of uterine disease or due to a lack of placentomes, primitive placental structures, simulating a diffuse placenta, develop in this area between the allantois chorion and the endometrium. These are called adventitious placentae, or "accessory placentomes."⁴¹ These may be few in number or they may involve a large portion of the intercaruncular endometrium and chorion. When these are extensive and numerous the pregnancy is usually insecure and the possibility of subsequent normal pregnancies questionable.

A confusion in nomenclature existed in the older American veterinary literature regarding the use of the term, cotyledon. American veterinarians formerly called the combined maternal and fetal placental structure palpated through the uterine wall of a pregnant bovine uterus

during a rectal examination as a cotyledon.⁷ Recent veterinary authorities stated that the cotyledon was the fetal placenta that produced villi which projected into the crypts of the maternal caruncle that had become greatly enlarged. These two structures, the maternal caruncle, and the fetal cotyledon in ruminants was termed a placentome. This latter nomenclature is preferred by the author.^{1,2,10-14}

The zonary type. In the bitch and queen the placenta forms a zonary band or girdle about 2.5 to 7.5 cm. in width around the circumference of the uterine lumen in the middle of the oval chorionic sac. It is a highly complex structure. In carnivores the placenta is of a labyrinthine, rather than a villous type that interlocks more intricately than does the maternal and fetal placentae in the larger domestic animals. The rest of the chorion is bare and devoid of villi and does not take part in placental functions during most of the gestation period. Placental hematomas or extravasations are observed as green and brown borders or margins of the zonary placenta in the bitch and queen, respectively. These are seen in the cow and ewe as multiple hematomas within the placentome at the base of the chorionic villi. They are considered to play an important role in the nutrition of the fetus because this stagnant maternal blood breaks down providing a source of iron that is utilized by the fetus.⁶³

The discoidal type. This type is not seen in domestic animals but is present in primates and rodents. There is a round to oval, disc-shaped placental area of the endometrium and allantois chorion. In these species the placental union is even more intricate and intimate than in the others.

Another method of classifying placental types is by the microscopic tissues, layers or structures that intervene between the maternal and fetal blood.^{1,2,34,48,63} The placentae of various animal species have recently been carefully examined with the electron microscope.^{10-14,66} Although the types of placentae were originally classified physiologically and anatomically, this classification

is used at the present time only as an approximate anatomical basis for the study of placental morphology or structure³⁴ (See Figure 22).

The epitheliochorial type of placenta is found in the mare, sow, cow, and ewe. In this type six structures of varying thickness: the endothelium, connective tissue, epithelium of the endometrium and the trophoblast or chorion, mesenchyme and endothelium of the fetal tissue separate the maternal and fetal blood.

The syndesmochorial type was formerly considered present in ruminants. In this type all the tissues of the preceding type are present with the exception of the maternal epithelium. The loss of uterine epithelium was previously considered to occur in the placentomes in this type by phagocytosis and cytolysis by the cells of the trophoblast.^{1,2,40,41} Syndesmochorial relationships are found

Figure 20. Adventitious placentae in a cow. (Courtesy of K. McEntee)

Figure 21. Zonary canine placenta.

in ruminant placentae when infections or other pathological disturbances have destroyed the maternal epithelium. At present it might be desirable to drop the term syndesmochorial, because of the great structural and functional similarity of the placentae between the mare, sow, cow and ewe.^{10-14,57}

The endotheliochorial type in the bitch and queen has the endothelium of the uterine vessels and the chorion, mesenchyme, and endothelium of the fetal tissues or 4 structures separating the maternal and fetal blood.

The hemochorial type present in primates and rodents has only the fetal tissues of the chorion, mesenchyme, and endothelium that lie or bathe in a "lake" of maternal blood since all maternal tissues have been eliminated. There is considerable difference in the structure of the hemochorial placenta in the different species.¹⁰⁻¹⁴

It was previously believed that the thickness of the placental membranes determined the efficiency of the barrier.³⁴ But the various cell layers in the placentae of the various domestic animals are not so regularly arranged. For example, in the epitheliochorial placenta capillaries migrate into intra-epithelial locations so fetal and maternal blood streams may at certain points be quite closely apposed.^{1,2} In the placenta there probably are definite transport mechanisms for most substances rather than a passive diffusion type of transport. Furthermore the inference that the epitheliochorial placenta is less efficient or more primitive than the endotheliochorial or hemochorial is not supported by the growth rates of fetuses in the various species and the type of placentalation found in both primitive and advanced species.^{1,2,10-14,63}

A third more general classification is made of the placental types of domestic animals into the **deciduate** or **conjoined**, and **indeciduate** or **apposed**. The deciduate

Figure 22. Diagrammatic modification of Grosser's classification of the placentae of domestic animals. (after Bjorkman)

type, or placenta vera, is that seen in primates and rodents and in a slightly modified form in the bitch and queen. In this type, the decidua composed of portions of the maternal epithelium or endothelium, submucosa, decidual cells and the fetal placenta are shed at parturition leaving a portion of the endometrium denuded. The **indeciduate** or **adeciduate** type of placenta is seen in larger domestic animals such as sows, mares, and also ruminants.¹⁰⁻¹⁴ In this type the fetal membranes and placenta are expelled at the time of parturition, leaving the endometrium intact except in ruminants in which only the surfaces of the caruncles are devoid of epithelium after the caruncle sloughs about 6 to 10 days following parturition.

The placenta is not only an organ for exchange. It can synthesize substances required by the fetus, produce enzymes necessary for the attachment of the trophoblast and intracellular digestion, and produce the hormones, estrogen and progesterone, to maintain pregnancy. It can store and catabolize other compounds. Because of the varied functions of the placenta it has some of the biochemical and even structural resemblances to adult organs such as liver, lung, kidney, small intestine and endocrine glands.

The **passive transfer of immunity** is necessary for the protection and survival of the newborn. To provide young mammals with a passive immunity against disease for a considerable time after birth, antibodies are transferred from the dam **in utero** or by the colostrum or first

milk after birth or both. The cow, ewe, doe, sow, and mare, transfer this immunity only by the colostrum.^{16,17} The human, guinea pig, and rabbit transfer immune bodies to the fetus only in the uterus through the placenta, or in the case of the rabbit through the yolk sac early in gestation by absorption from the uterine secretion. Bitches, queens and rodents pass small amounts of antibody through the placenta but the major portion comes from the early mammary secretion. In the newborn of domestic animals the intestine can absorb antibodies for only approximately 24 to 36 hours after birth. The concentration of antibody in the colostrum and the serum of the 3 to 7 day-old neonate equals and often exceeds that in the dam's serum.

Most fetuses may develop an active immunity if stimulated by certain antigens during gestation.^{44,56} The fetus doesn't develop immunologic competence simultaneously with respect to all antigens. This period may extend from early gestation to sometime after birth depending upon the antigen. This is a further defense mechanism for the fetus or newborn. Antibodies in the pregnant dam may be a factor in maintaining asepsis of the uterus to protect the fetus and placenta from infectious organisms. This study of the transfer of immunity is of great importance in treating hemolytic diseases of the newborn.

As is obvious in this discussion of placental types and the means of placental transfer of immunity, the number of layers of tissue between the maternal blood and fetal

blood have no relation to the manner in which the passive immunity is accomplished.^{16,17}

The procedures used in the examination of the placenta of the cow and mare are described because of the importance of this examination in valuable animals in providing an accurate picture of the health of the endometrium of the uterus at the time of parturition. The placenta should be examined as soon as possible after expulsion. If it is retained an excessively long period it will not be suitable for examination because of autolytic and putrefactive changes. If it cannot be examined at once it should be refrigerated. If possible the quantity, color, and nature of the fetal fluids should be noted. The membranes should be spread out to see if they are complete. Occasionally in the mare or cow the tip or apex or other portion of the fetal placenta may be torn off and left within the uterus where it may act as a focus of infection. In the mare the apices or tips of the placental horns are often edematous and if this edematous tip is incarcerated by the contraction of the uterine horn just proximal to the apex, tearing or retention of the placenta may occur.⁵⁰ The external surface of the placenta is examined for the presence of abnormal exudate or blood. The blood may be old, dark, clotted, dried, or fesh. It may rarely be in the form of dry, amber-colored, inspissated granules, called "uterine sand." Edema or necrotic leathery areas and rarely calcified portions of the allantois chorion should be noted as to their severity or extent. With the aid of a stream of water, dirt or loose material may be removed from the uterine surface of the allantois chorion and the size, nature, and uniformity of the cotyledonary villi may be observed. Evidence of clumping of villi, bare areas, necrosis, or calcification of villi are noted. Normal cotyledonary villi are uniform, smooth, and velvety. After incising the bovine allantois chorion between the dorsal and ventral rows of cotyledons and spreading it flat, the uniformity of the size of cotyledons may be checked. The presence of giant cotyledons, 15 cm. in diameter, usually indicates a lack of placentomes or a lack of placental areas or caruncles for attachment. The number in each horn is counted. There should be a total of between 75 and 120 cotyledons. Cotyledons are smaller in size in the horn opposite to the one that contains the fetus. The presence, location, number, and extent of adventitious placentae in the cow is noted. The size of the necrotic tips in the bovine placenta is observed.

Rectal examinations and slaughter-house examinations of uteri of dairy cattle from the third to eighth month of gestation frequently reveal the horn not containing the fetus to be much smaller than is normal. On examination of the uteri, fetal membranes, and placenta, there is found

a slight to complete lack of development of fetal membranes and placentae in this horn, often with a varying amount of necrosis of the membranes. The horn containing the fetus, the placenta, and the fetal membranes will appear normal. No studies have been made in the cow to determine the cause for this rather common failure for normal development of the placenta in the horn opposite to the one containing the fetus.

Evidence of thrombosis or disease of placental blood vessels is rarely observed. In placentae expelled after twin births in cattle the blood vessels should be examined for evidence of anastomosis. The amnion should be examined for evidence of disease and edema.

The fetal membranes should be weighed. In Thoroughbred mares the normal healthy placenta weighs about 10 to 14 lbs.³⁷ Mares having fetal membranes weighing more than 14 lbs. may have evidence of uterine and placental disease. The fetal membranes of cows should weigh between 6 and 18 lbs.^{1,59} with an average of 7 to 12 lbs. The weight of the foal and calf is about 6 to 10 percent of the postpartum weight of the dam. The weight of the afterbirth, or fetal membranes, is about 11 percent of the foal's weight and about 14 percent of the calf's weight. The total weight of the newborn young in the ewe and sow is about 5 to 10 percent of the dam's postpartum weight.

Tumors or anomalies of the placenta are very rare in animals. Cystic or hydatid, villous, and fibrous moles, tumorous placental growths or hyperplastic tissues and several other types that resembled hemangiomas or sarcomas have been reported in the placentae of animals.^{7,28,51} In animals they are usually benign and are shed with the fetal membranes after parturition. In dogs the hydatiform mole of the placenta was not a true tumor. The condition was due to cystic changes in the villi.⁹ They were very rare. Chorioepithelioma is rare and malignant and usually occurs after parturition from cells remaining in the endometrium.⁹

The umbilical cord connects the fetus and the placenta. In uniparous animals it is directed from the fetus toward the lesser curvature of the uterus and toward the uterine artery. In dogs and cats the umbilical stalk is attached to the zonary placenta on the opposite side of the uterus from the mesometrial attachment.^{25,26} It is composed of the allantoic and amniotic portions. The umbilical cord in the equine fetus is strong and averaged 45 to 60 cm in length, although the cord may occasionally be as long as 90 cm.^{1,62} The umbilical cord of the bovine fetus is 30 to 40 cm. in length. In the porcine fetus the cord is relatively long, about 25 cm.⁶ In the bitch and queen it is quite strong and short with a length of only 8 to 12 cm. In the cow, ewe, and usually sow, the cord

is ruptured as the fetus passes through the birth canal. In the bitch, queen, and mare the cord usually ruptures by the actions of the dam or the fetus after birth. In domestic animals it is safer from the standpoint of possible hemorrhage or infection to allow the cord to break naturally by traction than to ligate and cut it. The point of rupture in the foal and calf is about 2.5 to 5 cm. from the umbilicus at a constriction of the cord between the cord proper and the umbilical base or cutaneous navel. After rupture, the arteries retract into the body, the vein collapses, and the urachus shrinks and ceases to function. Possibly, due to the long umbilical cord and the fact that the fetus and amnion float free in the allantoic cavity, the umbilical cord in the mare is usually twisted spirally left to right or clockwise. Twisting of the cord in the mare may occasionally be severe and result in torsion and strangulation of the umbilical vessels, followed by the death of the fetus due to obstruction of the blood supply from the placenta.⁶² The umbilical cords of the other domestic animals are seldom twisted. Occasionally during pregnancy the umbilical cord may become looped around the head, neck, body, or limbs of the fetus and cause fetal death by the limitation of the blood supply.

During the early stages of development the intestines of the fetus rest partly in the umbilical cord because of their early rapid growth. Later the body walls enclose this area and the umbilical ring contracts, forcing the intestines back into the abdominal cavity. If this does not occur, an umbilical hernia results. A cross section of the umbilical cord in the amniotic portion reveals the amnion as the investing membrane. Fine granular villous elevations of the amnion occur over the umbilical cord in cows and to a lesser degree in mares, ewes, and does. Inside the investing amnion are two umbilical arteries and two umbilical veins. The latter fuse in the amniotic portion of the cord near the fetus to form a single vein. The urachus, the vestige of the yolk sac which can be seen only on histologic section, and Wharton's jelly which surrounds the above structures are also present within the amniotic membrane. The allantoic portion of the cord consists of a mass of branching vessels. The urachus expands just beyond the amniotic portion of the cord to open into the allantoic cavity.

Teratology

Teratology is the division of embryology and pathology dealing with the abnormal development and malformations of the antenatal individual. It has also been defined as the science concerned with the causes, mechanisms and signs of structural or functional developmental deviations.³⁸⁵ Teratologic, abnormal development or arrests in development of the embryo or fetus may result in death or malformations of the antenatal or postnatal individual. In recent years rapid developments and "breakthroughs" have occurred in the fields of genetics, embryology, pathology, virology and biochemistry resulting in the new and rapidly expanding fields of molecular and cellular biology and cytogenetics.

Teratogenic agents from the environment such as radiation; chemicals; infections, especially viruses; nutritional imbalances; temperature extremes; hypoxia and endocrine or metabolic imbalances can act on germ cells, embryos or fetuses in a variety of ways to cause mutations of chromosomes or nucleic acid integrity or function, altered metabolism or enzyme inhibition and other pathogenic influences to cause either death, anomalous development, growth retardation or a functional deficit of the zygote, embryo, fetus or postnatal animal.^{33,386}

Cytogenetics is the branch of genetics devoted to the study of the cellular constituents, chromosomes and genes, which are concerned in heredity. Since a new mammalian zygote originates by the combining of an ovum and a spermatozoa to form a single cell, all of the genetic information needed to form a new enormously complex animal is present in that cell. As stated by a recent popular press article, all these instructions, if written out in English, would require several 24 volume sets of encyclopedias. Yet they are packaged into two ten-trillionths of an ounce of DNA in the nucleus of the single-celled zygote!

Molecules of DNA, deoxyribonucleic acid, a nucleoprotein which are composed of nucleotides containing

four bases, adenine, guanine, thymine and cytosine in an enormous variety of sequences arranged in ladder-like, double rows in a coiled, spiral helix, form genes which direct and control the chemical processes of each cell along certain lines by means of messenger and transfer RNA, ribonucleic acid, another nucleoprotein. These complex protein units of DNA or genes are carried on structures called chromosomes. These are best seen in anaphase, or that stage of cell division in which the chromosomes have separated and are diverging toward opposite poles of the cell. About 100,000 loci or gene locations are present on each chromosome except the Y chromosome which has fewer. The usual procedure followed in the study of chromosomes is to culture leucocytes, skin, tissue of other organs, or cells from the amnion obtained by amniocentesis for a few days so mitoses develop and then add colchicine to arrest mitosis. After a few hours hypotonic salt solution is added to the cells to swell them. They are then prepared, fixed, stained and examined under a microscope.^{89c} Chromosomes consist of a pair of chromatids held together by a centromere the location of which together with the size of the chromosome aids in the identification of the chromosomes. Their systematized arrangement in pairs and groups is called a karyotype or idiogram. The latter is a diagrammatic or formalized karyotype. Each normal cell contains two sex chromosomes and the rest of the chromosomes are called autosomes. A metacentric chromosome is one with a median centromere (X). A submetacentric chromosome is one nearly the same as the former with a submedian centromere. A telocentric chromosome is one with a subterminal centromere. An acrocentric chromosome is one nearly the same as the former with a terminal centromere (Λ). Chromosome analyses in mammals have been used to provide increased understanding of possible species differences and their evolutionary relationships. Since chromosomes can now be examined and studied, cytogenetics is providing further insights into chromosomal or genetic aberrations

Table 5. The Diploid Chromosome Number of Domestic Animals*

Species	Chromosome Number	Chromosome Characteristics
Cattle	60	58 acrocentrics, 2 submetacentric sex chromosomes
Horse	64	38 acrocentrics, 26 metacentrics
Donkey	62	
Pig	38	12 acrocentrics, 26 metacentrics
Sheep	54	47 acrocentrics, 7 metacentrics
Dog	78	76 acrocentrics, 2 metacentric sex chromosomes
Cat	38	5 acrocentrics, 33 metacentrics
Man	46	11 acrocentrics, 35 metacentrics
Goat	60	59 acrocentrics, 1 metacentric y chromosome

*Hsu and Benirschke.

as they are related to teratologic defects. (See Table 5.)

The genetic make-up of cells may be altered at the time of meiosis in a number of ways. The normal process of segregation of chromosomes may fail to occur producing **nondisjunction** resulting in an extra chromosome, trisomy or polyploidy, or a lack of a chromosome, monosomy, in the new zygote. Excellent examples of nondisjunction with an extra chromosome is mongolism or Down's syndrome in humans characterized by trisomy of chromosome 21 resulting in a total of 47 chromosomes in the individual and Turner's syndrome due to a missing Y chromosome, monosomy, of the sex chromosomes resulting in a total of 45 chromosomes. Parts of two nonhomologous chromosomes of a germ cell at meiosis may break off and be relocated on other chromosomes resulting in **translocation**. Widespread distribution in cattle of the 1/29 Robertsonian translocation and its effect on reducing fertility by increased embryonic mortality in both male and female heterozygotes has been reported.¹³⁶ When a portion of a chromosome breaks off and is lost **deletion** results. All of these abnormal processes affecting one or more chromosomes during division may also occur during mitosis in an early zygote leading to abnormalities in certain tissues or organs but not in others. Other accidents of fertilization may produce **point mutations**, **replications**, and **invasions**. It is of interest to note that cells in a variety of tumors including bovine lymphocytomas and canine transmissible tumors have irregular numbers and abnormal appearing chromosomes.²⁵⁸

The occurrence in an individual of two or more cell populations or tissues each with a different chromosome complement derived from a single zygote is called **mosaicism**. If a similar condition is present but the cell populations arise from different zygotes, as in twins with placental anastomoses, the condition is called **chimerism**.

If nondisjunction, translocation, or deletion of chromosomes is moderate to severe the zygote usually succumbs early in gestation during the period of the early embryo. Some survive longer as fetal monsters, parasites on the placenta of the normal twin, or defective individuals. Defects of the sex chromosomes, since they usually do not have much influence on organ and body development, are frequently found.

Most of the genetic defects of animals are related to one or several genes on a chromosome and at our present state of knowledge these can seldom be identified and studied, and are only determined by careful extensive breeding trials.

The mode of inheritance of genetic causes for a disease or abnormality varies greatly. It is usually due to a

natural mutation that is recessive in character but may be dominant. In diseases inherited as autosomal recessive defects neither the sire nor dam is usually affected but the disease comes from both. Dominant genes causing disease would cause defects in half of the offspring of a defective parent. Dominant defective characters are uncommon in animals. Dominance may also be incomplete. The effect of certain genes may be influenced by modifiers or other modifying genes or by incomplete penetrance of the character as in hypoplasia of the gonads in Swedish Highland cattle due to a recessive autosomal gene with incomplete penetrance. In this condition only 50 percent of the homozygous cattle are able to be clinically diagnosed. Individuals affected with a single gene defect may exhibit a great difference in the expressivity or degree to which it is manifested. Certain genes exhibit multiple or pleiotropic effects probably due to some abnormality of cellular physiology. If penetrance is fairly high, dominant factors are largely self-limiting. If there are no desirable pleiotropic effects in heterozygotes, the frequency of simple recessive factors can be kept low if a constant survey of the population is implemented.^{105,163,164,213}

The female (X) sex chromosome carries genes other than those that determine sex. While the male (Y) sex chromosome carries few genes other than those that determine sex. So genes on the X chromosome produce characteristics that are **sex-linked** such as canine hemophilia A. Recessive sex-linked defects are uncommon in animals. Characteristics found only in one sex such as cryptorchidism, milk or egg production, and "white heifer" disease are **sex-limited** in character. Certain quantitative characters such as body size, milk and butterfat production and fertility are caused by many genes, **polygenes**, or multiple factors. There is a close relationship between environmental factors and certain genetic factors as they influence the expression of disease. For example, skin lesions in hematuria in a cow with white skin will not be observed if the cow is kept from direct sunlight. Mutant defective or lethal genes are carried by nearly every animal but the heterozygosity of the animal populations usually prevent their expression except under unusual circumstances of inbreeding, selection, or accident.

The Inherited or Genetic Anomalies, Malformations or Altered States in Domestic Animals

These have been reported upon and reviewed by many authors.^{100,105,126,163,164,167,172,210,213,251,279,318,360} Some have been accurately and correctly defined as inherited con-

ditions by careful research while others have been so classified by circumstantial or limited evidence. It is unfortunate that research on inherited diseases is very costly and time-consuming. As has been noted previously, chemicals, plant poisonings, radiation, nutritive imbalances, infections and physical influences may produce identical or similar teratogenic defects as those resulting from genetic causes. In fact they may have produced the original mutations that are perpetuated in the affected chromosomes or genes.^{211b,386}

Bovine Teratology

Congenital defects affect from 0.25 to 3.0 percent of calves. About one-half of the abnormal fetuses are expelled dead or die shortly after birth.^{211a,b} In nearly all cases the defects are visible on examination. Most of the anomalies or defects involve skeletal, muscular and central nervous systems.²¹⁰ In a study of about 5000 calves sired artificially, it was reported that a high figure of 6.26 percent were abnormal at birth but of these nearly half were expelled dead at term but appeared normal. The remaining calves had a variety of abnormalities. Of 1276 calves sired by 9 bulls 7.7 percent were abnormal with a range of 3.8 to 15.7 percent.² Of 8627 calves sired by 532 bulls the incidence of congenital abnormalities was 5.49 percent with 1.77 percent being small, weak newborn, 1.05 percent having defects of bone, joints or cartilage, 2.66 percent "stillbirths," 0.16 percent nerve and eye defects, and 0.19 percent epithelial and genital abnormalities. The two greatest periods of death losses were during the first trimester of pregnancy and at the time of parturition.¹²⁶ Losses due to inherited lethals might be as high as 5 to 6 percent and in certain herds might be higher.²

Selected, common, possibly inherited, lethal and semilethal characters in cattle are:

Achondroplasia, or dwarf, "comprest" or "bulldog" calves. These are seen in all breeds but most commonly in the Hereford, Ayrshire, Angus, Charolais, Simmental and Dexter breeds. The most common type is the brachycephalic "snorter" dwarf in Herefords with a short, broad head, bulging forehead, malocclusion of the jaw, prognathism of the mandible, pot-belly, low viability and great susceptibility to bloat and dystocia. This type was generally considered to be due to a simple autosomal recessive defect with some modifiers.^{40,163,231} (See Figure 23.) The use of the profilometer in evaluation of the head shape or radiography have not proven to be highly satisfactory in the detection of carrier ani-

mals.^{83,133,183} Extensive studies on brachycephalic, dolichocephalic or long-headed, intermediate, Dexter-type, and compressed dwarfs indicated that achondroplasia was inherited in a complex manner both in a dominant and recessive form, mainly the latter, and with modifiers. The "compressed" Hereford is the result of incomplete dominance. In recent years the Hereford breed has made significant progress in reducing the incidence of this abnormality. A proportionate dwarfism in Jersey cattle,²⁴⁴ not recognizable until one year of age, has been reported. "Midget" Brahmans and "stumpy" Shorthorns caused by recessive genes as well as small guinea cattle in crossbreeds native to Florida^{199,200} have been described in which the causative gene may be dominant or incompletely dominant.¹⁰⁵ In Ayrshire, Dexter and other cattle, extreme "bulldog" calves are usually aborted about the fifth to eighth month of gestation. (See Figure 31.) Hydramnios occurs in pregnant Dexter cattle carrying a "bulldog" calf. Normal Dexter cattle are heterozygotes.

Epitheliogenesis imperfecta is a condition where skin fails to form. It occurs most commonly on the legs below the knees and hocks and on the muzzle, ears, tongue and mucous membranes. It has been described in Holsteins, Ayrshires, Jerseys, Brown Swiss, Angus and Shorthorns. It is probably a single autosomal recessive defect.^{171a,b}

Hypotrichosis congenita or alopecia is a simple autosomal recessive defect characterized by degrees of hairlessness in Holsteins,^{40,152,171b} Herefords,²²³ Durhams, Swedish Friesian cattle²⁵⁷ and Jerseys having other defects such as a short lower jaw, short ears and anophthalmia.³⁸⁹ Streaked hairlessness was reported as a sex-linked lethal in Holsteins.⁹⁶ Six types of hypotrichosis in cattle, including Guernseys, have been reviewed.^{162,165,171b} (See Figure 32.)

Ehlers-Danlos Syndrome (skin fragility), several breeds, probably hereditary.^{171b}

Ichthyosis congenita is characterized by a lack of hair and a thick scaly, horny epidermis with raw fissured skin around the body orifices. It is due to single autosomal recessive genes in Brown Swiss and Red Polled cattle.^{223,171b}

Osteopetrosis in Angus cattle may be genetic in nature. It is characterized by inferior brachygnathism, narrow nose, small size, death occurring during or shortly after a premature parturition associated with moderate hydrops amnii. The long bones, which are solid without a marrow cavity, break easily.^{130,305,257} A similar condition has been reported in Hereford calves with cystic frontal bones resembling hydrocephalus and in Simmental calves.²⁴⁹

Osteogenesis imperfecta with bone fragility, marked

joint laxity, and thin dentin (pink tooth), in Holstein-Friesian cattle in Australia (and probably Texas), due to an autosomal dominant gene.^{76b}

Acroteriasis congenita or amelia and hemimelia is seen in Holsteins, Brown Swiss and other breeds.^{105,347}

This condition is characterized by missing, shortened, deformed, or "amputated" limbs.

Ankylosis, hydrops, death and mummification of the fetus in the last month of gestation was reported in Red Danish cattle due to a pair of single autosomal recessive genes.^{347,355}

Progressive ataxia, weaver condition—in young Charolais and Brown Swiss^{211b} cattle, probably hereditary.^{284b}

Cerebellar hypoplasia and degeneration is seen in Herefords, Guernseys, Limousins and Holsteins and may be autosomal recessive in nature.^{40,167,347}

Cerebellar abiotrophy in Holstein calves, which were normal at birth, but develop ataxia, opisthotonus, head tremor, nystagmus and inability to rise due to cerebellar degeneration or atrophy at 3 to 9 months of age may possibly have an hereditary basis.³⁷⁸

Ataxia with leucodysplasia seen in Angus, Shorthorns, Jerseys, Herefords, Charolais and possibly in Holsteins and Haryana cattle at 2 or more weeks of age may be due to a number of recessive conditions.^{167,397}

Mannosidosis is lysosomal storage disease of Angus and Murray Grey calves due to a single autosomal recessive trait. It is characterized by death of a few affected calves soon after birth but more commonly the development of a progressive incoordination, ataxia, head tremor, aggressiveness and death the first year of life. Heterozygotes can be detected by the level of a-mannosidase enzyme in the blood.²²⁶

Paralyzed hind quarters have been reported in Red Danish calves at birth due to a pair of autosomal recessive genes.¹⁶⁷ A similar condition has been seen in Norwegian Red Poll cattle that also developed a keratitis.³⁴⁷

Limber legs is apparently inherited as a simple recessive trait in Jersey cattle in which the newborn, both female and male, often die at or soon after birth and if viable are unable to stand due to atonic muscles and joints that can readily be rotated, flexed or extended in any direction.^{206,207}

Curved limbs with both rear and forelimbs curved cranially, have been observed in Guernseys as an autosomal recessive trait. Calves were usually stillborn or died promptly.¹¹²

Muscle contractures and ankyloses, or arthrogryposis has been reported as a recessive defect in Dole cattle in Norway;²⁵³ and an autosomal recessive with incomplete penetrance in Charolais, associated with a cleft

palate, in England.¹⁷⁶ It has also been described in Shorthorns in Canada,⁷⁰ in Holsteins,⁴⁰ in Herefords³³⁸ and in other cattle.¹⁰⁵ Arthrogryptic defects can be due to ingestion of certain chemicals and plants and due to viral infections such as blue tongue and akabane viruses affecting the embryo or young fetus.^{131,210,211b}

Hydrocephalus in Herefords, Ayrshires, Holsteins, Shorthorns and other breeds have been reported.^{18,144,200,211b,351} It is characterized by the birth of "dummy" or "bawler" calves that are unable to nurse properly and die in several days. The heads may be enlarged or normal in size but section of the head and brain reveals distended ventricles. The disease may be associated occasionally with hydramnios, dwarfism, ocular anomalies and high copper levels in the liver.²⁶⁰ This may be due to a simple autosomal recessive gene. In Shorthorns it may be dominant with incomplete penetrance.¹²⁹

Congenital dropsy due an autosomal recessive gene has occurred in Ayrshires and Swedish Lowland cattle.^{87,147} It may be characterized by the abortion of a "bulldog" anasarctous fetus often with cysts on the tip of the ears or the birth of calves with severe persistent edema of the limbs or head. (See Figures 27 and 28.)

Rectal vaginal constriction (RVC) (anovestibular stenosis) is inherited as a simple autosomal recessive defect affecting the rectal sphincter of males and the rectal and vulvar sphincter of female Jersey cattle. This results in a firm, fibrous, unyielding stricture so that normal manual rectal examination is impossible in both sexes. In females severe dystocia, requiring an extensive episiotomy or caesarean operation, occurs at calving due to the very small vestibule.^{155,225a,b,238b}

Tibial hemimelia in Galloway calves is a single autosomal recessive defect with variable expressivity, usually bilateral agenesis, with pleiotrophic effects on the

Figure 23. Yearling brachycephalic ("snorter") Hereford dwarfs.

Figure 24. Spastic syndrome, "stretches," in a grade 9-year-old Holstein cow.

central nervous, reproductive and skeletal-muscular systems.²⁶²

Arnold-Chiari malformation is a rare congenital defect in cattle, often associated with hydrocephalus and spina bifida, that is characterized by caudal herniation of cerebellar tissue through the foramen magnum into the anterodorsal spinal canal.⁵²

Brachygnathism or underdevelopment of the mandible has been reported in nearly all breeds of cattle including Shorthorns, Jerseys and Herefords. Inheritance is more than just a simple recessive but it is not complex.^{128,341}

Microphthalmia in Guernsey, Hereford and White Shorthorn cattle along with other defects have been reported.²⁹⁸

Cleft lip and palate have been reported in Jerseys,

Figure 25. Syndactyly of the forelimbs of a Holstein calf.

Figure 26. Spastic paresis in a Holstein calf, note the rigidly extended left hind leg.

Shorthorns and other breeds as a possible genetic defect.^{338,377}

Atresia of the anus, colon and ileum were reported as possible genetic defects in Swedish Highland cattle, Holsteins, and other breeds.^{126,256,269} However atresia ani might be related to palpation of the amniotic vesicles between 30 and 40 days of gestation.^{211b,379}

Anencephaly, cerebral hernia or "catlin mark" is an opening in the frontal and parietal bones associated with severe central nervous system defects in beef calves.⁵³ Prolonged gestation, a large fetus and dystocia in Holsteins may occur due to a fetal pituitary deficiency. (See Figures 29 and 30.)

Cardiac defects of patent ductus arteriosus, persistent foramen ovale and septal defects have been described in Herefords and Jerseys and are possibly due to genetic causes.^{213,353}

Chediak-Higashi Syndrome is an autosomal recessive

Figure 27. Congenital dropsy and anasarca in an aborted Ayrshire fetus. (Courtesy K. McEntee)

Figure 28. Congenital dropsy or edema in an Ayrshire calf. (Courtesy M. G. Fincher)

sive defect characterized in Hereford and other breeds of cattle and cats by oculocutaneous albinism (white animals or those with a ghost pattern in normally pigmented areas and hypopigmentation of the iris with photophobia), increased susceptibility to infections, tendency for prolonged bleeding, and reduced viability.^{55,211b,272,285a}

Partial alopecia, failure of horn growth, slobbering and stiffness ("Baldy calves") developing at about two months of age in calves and terminating in death by 6 to 12 months has been described in Holsteins. The evidence indicated that it was probably an hereditary condition.⁴⁰

Other inherited but generally nonlethal defects of cattle include:^{105,126,163,197,210,213,393,397}

Polydactylism in Holsteins and Herefords,^{210,303} is possibly an autosomal dominant character with incomplete penetrance.

Figure 29. Cerebral hernia with a pituitary defect in an overtime Holstein fetus.

Syndactylism or "mule-foot" affecting one or both front feet or all four feet has been reported in Jersey, Holstein, Angus, Hereford, Crossbred Chianina, Hariana and other cattle, and has a single autosomal recessive mode of inheritance.^{212,264} Progeny testing using syndactylous donors, superovulation, suspect bulls, embryo transfer and fetal examination shortened the time for detection of heterozygotes.¹⁷⁴ Affected Holsteins were unable to withstand stress due to high ambient temperatures and became hyperthermic.²¹⁹ The front feet of the Holstein calves were much more frequently affected with syndactyly than the rear feet. (See Figure 25.)

Muscular hypertrophy, or "double" muscling is characterized by reduced fat deposits, light bone, thin

Figure 30. Skulls of a normal calf (left) and a calf with a cerebral hernia (right).

skin, and large muscles as well as severe calving difficulties, high calf mortality, and infertility. It is seen in many breeds of cattle including Hereford, Holstein, Angus, Charolais and Piedmont. It may be inherited by an autosomal monohybrid mechanism resulting in three genotypes, homozygous, heterozygous and homozygous nondouble muscled. The former can be recognized phenotypically at birth but heterozygous cattle are difficult to identify.^{233,259,265}

Umbilical hernia was described as being a probable dominant character with incomplete penetrance in Holsteins. Umbilical hernia in Holsteins may also be caused by one or more pairs of autosomal recessive genes of low frequency or by environmental factors.^{8,124,372}

Osteoarthritis and hip dysplasia in Holsteins, Angus, Galloway, Charolais, Jerseys and Herefords have been described.^{48,374} In dairy breeds the lesions were noted in the stifle joint at 5 to 13 years of age and were possibly due to a single autosomal recessive gene. In Herefords and other beef breeds the lesions were in the hip joint and it was possibly due to an incompletely penetrant dominant or recessive character.

Spastic paresis has been described in Angus, Holstein, Charolais, Shorthorn, Ayrshire, Simmental, Brown Swiss, Hereford and rarely Jersey calves usually 2 to 8 months of age with straight rear legs and a contracted gastrocnemius muscle causing the rear leg to be held off the ground and swung rigidly. It is probably due to an autosomal recessive condition with low or incomplete penetrance or even multiple recessive genes.^{76,80,191,213,304} (See Figure 26.)

Spastic syndrome, Krampfigkeit, "Stretches" may be a latent recessive condition developing at 2 to 7 years of age and characterized by spastic contractions of the

Figure 32. Hypotrichosis congenita or hairlessness in a Guernsey calf.

rear limb or limbs and back that occur intermittently in the standing animal. The condition affects Holsteins, Guernseys, Charolais, Ayrshires, and occasionally other breeds.³⁰⁴ (See Figure 24.)

Epilepsy has been reported in Swedish Red cattle, Limousin, and Brown Swiss cattle characterized by a sudden loss of consciousness preceded by a convulsion. It may be due to a recessive or dominant factor.¹⁶⁷

Lack of lid pigmentation and ocular carcinoma is seen mainly in Herefords but also Holsteins and Ayrshires exposed for long periods to sunlight. Pigmentation of the eyelid is strongly heritable so selection for pigmented eyelids can reduce the incidence of carcinomas.⁶

Ocular coloboma in Charolais cattle affecting the optic disc is common and inherited as a dominant trait but with partial penetrance in females and complete penetrance in males.¹⁰⁴

Heterochromia irides and albinism in Herefords, Charolais, Angus and Holsteins was described due to a

Figure 31. "Bulldog" achondroplastic full-term Ayrshire fetus.

Figure 33. Guernsey fetus with adenyhypophyseal hypoplasia causing a prolonged, 338 day gestation. (Courtesy of K. McEntee)

Figure 34. Epitheliogenesis imperfecta in a Yorkshire pig.

dominant mode of inheritance. These cases were more like color dilution rather than true albinism. Some affected cattle had blood dyscrasias.^{4,211b,213,217}

Congenital cataract and blindness in Jerseys and Holsteins^{50,126} may be heritable.

Strabismus and exophthalmos "cross-eyed" or "pop-eyed" in Shorthorn, Guernsey and Jersey breeds are inherited as recessive characters.^{40,126,299}

Red factor is a simple recessive defect in Holstein and Angus cattle where red substitutes for the normal black color of the hair.

Congenital porphyria, or pink tooth has been observed in Holsteins, Shorthorns and Jamaican Red cattle as a simple autosomal recessive condition resulting in photosensitivity and dermatitis of white or even pigmented skin, pink to brown teeth and bones that fluoresce with ultraviolet light. The urine may vary in color from normal to reddish-brown.^{181,255,328,373}

Protoporphyrria, due to an autosomal recessive trait is similar to porphyria and is caused by a mitochondrial enzyme deficiency of ferrochelatase. Although typical photosensitivity and dermatitis are present, the teeth, bones and urine are a normal color in the affected Limousin and crossbred cattle.^{211b,315}

Polycythemia in one- to two-month-old Jersey calves characterized by congested mucous membranes, lethargy, dyspnea and reduced growth rate was due to a single autosomal recessive gene.³⁵¹

Blood coagulation defect, Factor XI deficiency is an autosomal recessive trait of Holstein cattle causing hemorrhage after trauma with prolonged bleeding after dehorning and venipuncture.¹²²

Curly coat has been described in Ayrshires and Swedish cattle.¹⁶³

Deformed limbs or flexed pasterns has been described in Jersey cattle.^{163,210}

Wry tail is common in many breeds.^{113,150}

Wry muzzle is a common defect in Jersey cattle.^{126,163}

Screw tail (Holsteins, Jerseys, Shorthorns, Red Polled).^{126,163,213}

Vestigial tail (Holsteins, Angus, Shorthorns).^{126,213}

Taillessness (Holsteins and other breeds), possibly inherited.^{40,105}

Multiple lipomatosis (Holsteins), possibly a dominant trait with incomplete penetrance.³

Fused teats (Guernseys, Herefords).²¹⁰

Supernumerary teats (all breeds), increased incidence with inbreeding.^{27b}

Notched or short ears (Ayrshires, Jerseys).²¹⁰

"Spread" toes or splayed toes (Breed differences, due to several genes).^{236a}

Missing phalanges or "Creeper" calves (Swedish cattle).⁴⁰

"Corkscrew," "scissor" or beak claw (each due to a different recessive gene).^{236a}

Impacted premolars and "parrot-mouth" (Shorthorns).²¹³

Short spine (Norwegian cattle).^{163,213}

Ljutikow lethal.³⁴⁷

Agnathia or absence of a lower jaw (Jerseys and other breeds).²¹³

Opacity of the cornea is possibly a recessive character in Holsteins.^{40,71}

Lumpy jaw or actinomycosis and actinobacillosis is characterized by a lack of genetic resistance in Guernseys to this disease.²⁷

Ankylosis of the jaw (Norwegian cattle).^{163,213}

Dermoid cysts on cornea, (Herefords and Guernseys).¹⁴⁶

Smooth tongue (Holsteins and Brown Swiss).¹⁵⁸

Genetic diseases or conditions related to cattle reproduction and the reproductive organs such as; prolonged gestation in Holsteins and Guernseys, segmental aplasia of the mesonephric and paramesonephric ducts, imperforate hymen or white heifer disease, gonadal hypoplasia, cystic ovaries, hermaphroditism, cryptorchidism, seminal defects, failure of the median wall of the paramesonephric ducts to fuse, impotentia coeundi, penile defects, inguinal hernia, and others will be described and discussed later.^{172,173}

Equine Teratology

It has been estimated that 3 to 4 percent of foals at birth have developmental defects. Very few of the re-

ported teratologic defects in horses have been proven by adequate studies to be due to either genetic or environmental causes. This is understandable because only in recent years has considerable research been supported in horses and the cost of the animals, slow onset of sexual maturity and the long gestation period are disadvantages in undertaking genetic or long-term studies on equine malformations.^{312,360}

Some of these defects of which little is known concerning the etiology or pathogenesis include: cleft palate, angulation of limbs, microphthalmia, cardiac anomalies including ventricular septal defects and others, atresia ani, pharyngeal anomalies, hydrocephalus, persistent or pervious urachus, unilateral kidney agenesis, dentigerous cysts with fistulae, papillomatosis of the skin at birth, cataracts, "contracted," arthrogryptic foals, contracted flexor tendons, ectopic ureter and urethra, cyclopia, polydactyly, teratomas, optic nerve hypoplasia, esophageal ectasia, and others.^{159,312,349}

The inherited lethal or semilethal characters in horses are:

Atresia coli and early postnatal death in Percherons is often associated with brain defects.^{159,347}

Hemophilia or coagulation disorder is an x-linked or sex-linked recessive defect resulting in frequent bleeding episodes in Thoroughbreds and Standardbreds caused by a factor VIII (Hemophilia A) deficiency. Affected male foals have not survived to adulthood. Carrier mares have a reduced factor VIII activity.^{89,159}

Fredericksborg lethal was related to sterility in inbred white horses due to the embryonic death of about 25 percent of the embryos in early gestation.^{159,171b,347} **Iliocolonic aganglionosis** is probably a recessive, in pink-skinned, white male or female, foals of Overo spotted breeding that die soon after birth, 1 to 5 days, due to obstructive anomalies of the colon or rectum.^{156b,293,326,359}

Epitheliogenesis imperfecta affects the lower limbs and tongue and is probably an autosomal recessive defect.^{67,159,360,171b}

Hyperelastosis cutis or subcutaneous hypoplasia has been described as an inherited disease, probably recessive, in Quarter Horses. The skin is fragile and minor injury causes gaping slow-healing wounds and scarring similar to Ehlers-Danlos syndrome in humans, cattle, dogs and other animals.²²⁸

Hereditary ataxia, Oldenberg breed.^{159,347}

Wobbles or incoordination is seen in Thoroughbreds, Standardbreds, American Saddle and other breeds and grade horses. It is most common in males by a 3 to 1 ratio. It is possibly due to a recessive defect of the articulations of the cervical vertebrae causing compression of the spinal cord, usually observed in young rap-

idly growing horses. Ataxia in Shetland ponies has been reported to resemble wobbles but the condition was associated with degeneration of the spinal nerve roots. The condition might be genetic in nature.¹⁶⁷ The equine wobbler or ataxic syndrome has been described to be due to three distinct types of pathological lesions and seven other disease entities were listed that may resemble wobbles in horses.²³⁴

Cerebellar hypoplasia and ataxia is possibly a recessive genetic defect in Arabians, Gotland ponies and others.^{29,159,275}

Absence of a retina is a recessive character.⁴⁰

Combined immunodeficiency (CID) in Arabians is inherited as a simple autosomal recessive trait affecting an estimated 2.3 percent of Arabian foals with 25.7 percent of all Arabian horses considered to be carriers. Progeny testing is presently the only means of detecting carriers since no laboratory test is available. Affected foals have a lymphopenia, deficiency in T and B lymphocytes and immunoglobulin deficiencies causing them to be highly susceptible to respiratory, especially adenoviral and enteric or systemic infections that are refractory to treatment. Death usually occurs within a few weeks or months after birth.^{159,286,360}

Other immune system failures in horses include selective immunoglobulin M deficiency associated with infections and lymphoma and agammaglobulinemia. The hereditary status of these latter deficiencies is not known.^{285a,b} Deaths usually occur within 6 months to two years in these horses.

Other Possible Inherited, Generally Nonlethal Defects of Horses are:

Persistent or pervious urachus, many breeds, unknown.¹⁵⁹

Aniridia with cataracts was a dominant autosomal character in Belgians.^{101,197}

Umbilical and inguinal hernia.^{109,197}

Entropion and microphthalmia in Thoroughbreds.²¹

Brachygnathism of the mandible.^{109,197}

Subluxation of patella, ponies and others.¹⁹⁷

Ulnar and tibial malformation in Shetland ponies was caused by an autosomal recessive gene that interfered with their locomotion.¹⁴⁵

Congenital night blindness or nyctalopia has been described in Appaloosa horses. Day vision is normal but at night or at dusk affected horses bump into objects and injure themselves or are unwilling to move. A possible recessive or congenital mode of inheritance is suspected.³⁹⁰

Strabismus or hypertropia is also suspected to be an hereditary defect in Appaloosa horses. Corrective surgery may be indicated.¹¹⁹

Angular limb deformities, carpal bone hypoplasia, osteochondrosis dissecans and congenital goiter have been associated and may have an hereditary component.^{241,242}

Multiple exostosis is due to a single dominant autosomal gene in Quarter Horses^{159,247} and Thoroughbreds that affects endochondral bones during skeletal development, usually prenatally, may impair future performance.³⁴⁰

Heaves, pulmonary emphysema or chronic obstructive pulmonary disease is produced by a hypersensitivity to environmental allergens. As in humans there is a family predisposition that is probably genetic.^{197,360}

Roaring, laryngeal hemiplegia. Recent studies have confirmed the familial and hereditary status of this disease.^{57a,65,109,197,294}

Dysplasia of the hip (Dole horses).⁴⁰

Some of the above conditions and others sometimes referred to as genetic diseases such as: splints, ringbone, spavin, scrotal hernia, and others may or may not be genetic in horses as few actual breeding trials have been conducted. Severely defective animals are usually immediately destroyed.

Porcine Teratology

Inherited congenital defects are fairly common in swine with an incidence of 1.25 percent.³³⁴ Since newborn piglets are relatively immature and their economic value low many defective pigs if they cannot nurse vigorously die within several days of birth. Thus fairly minor defects may have a lethal effect. In recent years many congenital defects previously considered to be probably genetic have been shown to be due to environmental factors such as: poisonous plants, chemicals, viral infections and nutritional deficiencies affecting the porcine embryos or fetuses during the gestation period. Selected, fairly common malformations of swine due to genetic causes are listed.

The inherited lethal or semilethal characters in swine are:

Cerebral hernia, "Catlin" mark, cranioschisis, is probably an autosomal trait in Poland China pigs.^{160,347}

Hydrocephalus is reported in Duroc Jerseys due to recessive genes.^{163,347}

Paralysis of the hind limbs due to spinal cord lesions. This is a recessive, semilethal character.^{160,167,358}

Atresia ani.^{160,251,358,397}

Thickened forelimbs is a recessive often lethal defect.^{40,251,347}

Acroteriasis congenita, "amputated," is caused by a single autosomal recessive gene.^{163,347}

Cleft palate, or palatoschisis, is seen occasionally with harelip in the Large White and Poland China breeds and transmitted as a single autosomal recessive.^{160,251,254,347}

Arthrogryposis or flexed or extended rigid limbs may be caused by a single autosomal recessive gene but is also commonly caused by plants or chemicals ingested during gestation.^{97,160}

Other Inherited Generally Nonlethal Defects of Swine are:

Porcine stress syndrome (PSS) malignant hyperthermia is a genetic disease in susceptible pigs brought on by stress such as fighting, restraint, transport, hot weather, mating, forced exercise and halothane anesthesia. At slaughter carcasses of affected swine have pale, soft exudative muscles and small adrenal glands weighing less than two-thirds normal gland weight.^{194b} During stress susceptible pigs develop tachycardia, tachypnea, erythema, cyanosis, rigid muscles, increased body temperature often followed by death. It is reported most often in Poland China, Yorkshire, Landrace and Pietrain breeds.^{19,160,346,382} Selection for the heavily muscled meat type pig¹⁶³ has favored the selection of pigs susceptible to the porcine stress syndrome. It has been suggested that this syndrome is inherited by a modified single dominant gene or two dominant genes acting together. A practical test to determine susceptible or carrier pigs is not available but selective breeding has proven effective in reducing the incidence of this common condition in many herds. Dogs, horses and heavily muscled cattle have been reported to suffer a similar syndrome under stress or halothane anesthesia.

Hemophilia, porcine von Willebrand's disease is an autosomal or incompletely dominant defect with variable penetrance affecting Poland China swine. It is clinically characterized by mild to severe hematoma formation, lameness, and prolonged or fatal bleeding after surgical procedures or farrowing. Affected pigs have a deficiency of blood Factor VIII.^{85,271}

Renal cysts in Landrace pigs were reported as an autosomal dominant gene while the number of cysts was polygenic. No clinical signs were noted.³⁸¹

Epitheliogenesis imperfecta in Berkshires and Yorkshires. (See Figure 34) is a recessive lethal or sublethal defect.^{317,171b}

Wattles, or tassels.^{163,171b,347}

Screw or kinky tail is due to either a single recessive factor with modifiers or a dominant factor with low penetrance.^{86,160,347}

Umbilical hernia^{160,163}

Inguinal or scrotal hernia, sex-limited inheritance with a double recessive genotype. About 1.5 percent of males are affected.^{160,163,251}

Hypotrichosis congenita.^{160,163,171b}

Congenital bent legs.^{251,347}

Split ears, deformed rear quarters and occasionally cleft palates in Tamworths and Poland Chinas.^{160,347}

Congenital porphyria is a dominant character. No photosensitivity is evident.^{180,347}

Cryptorchidism^{40,160,347}

Syndactyly and polydactyly are probably caused by simple autosomal dominant genes.^{160,251,347}

Hermaphroditism^{160,197,288}

Inverted teats is probably a simple recessive trait.^{160,197,397}

Hypertrophy of muscle, Pietrain pig in Belgium¹⁶³

Dermatosis vegetans, is a semilethal autosomal recessive condition.^{89a,171b}

Chromosomal abnormalities causing embryonic mortality were present in up to 30 percent of porcine blastocysts.²³⁷

Microphthalmia, anophthalmia is possibly due to a dominant gene with low penetrance. It may also be due to a vitamin A deficiency.^{160,251,347}

Barker, or neonatal respiratory distress, syndrome of the Large White breed is probably an autosomal recessive defect involving lung tissues, hypothyroidism, hairlessness, retarded ossification and reduced adrenocortical activity. Affected piglets developed respiratory distress and hypothermia soon after birth and died. Gestation length of sows with affected litters was slightly longer than normal even though affected pigs had evidence of prematurity.³⁹⁴

Myoclonia congenita, congenital tremors or "shaker" pigs has been reported as caused by a monogenic sex-linked factor in Landrace pigs and an autosomal recessive gene in Saddleback pigs. It has also been reported in pigs due to hog cholera virus, pseudorabies virus and a third unidentified virus infecting swine fetuses in utero. Tremors in newborn piglets have also been reported from sows wormed with trichlorfon between 45 and 63 days of gestation. Mortality in severely affected pigs is high due to the inability to nurse and the resulting starvation.^{88,135,196,284}

Splayleg or spraddle-legs, myofibrillar hypoplasia is probably not due to genetic causes unless associated with congenital tremors. It has been reported to be caused by slippery floors, chemicals or nutritional deficiencies. This condition may be a common expression of congenital tremors.^{88,135,160,251}

Hereditary lymphosarcoma in piglets has been re-

ported as an apparently autosomal recessive trait that can be diagnosed only after one month of age. No homozygous recessive pigs have survived to maturity.²⁴³

Cerebrospinal lipodystrophy, GM2 Gangliosidosis is a storage disease characterized by poor growth rate, "goose stepping" of rear legs, and recumbency at 4 to 6 months of age. It is an autosomal recessive trait in Yorkshires.²⁸⁷

Ovine and Caprine Teratology

In sheep the incidence of congenital defects ranges from 0.2 to 2.0 percent of all lambs born. One report on over 54,000 lambs over a 15 year period revealed bilateral cryptorchidism occurred in .0005 percent, wry neck in .0007 percent and crooked legs, unilateral cryptorchidism and "undershot" or "overshot" jaws in .001 percent of the lambs. "Stillbirths" occurred in 4.4 percent of the parturitions. Inbred groups of ewes had the highest number of defects. The musculoskeletal, cardiovascular and urogenital systems are most commonly affected.^{77,79,99} Many nongenetic environmental agents as well as genetic influences are responsible for teratogenic defects in sheep. As in the other species of domestic animals nongenetic defects can mimic very closely genetic defects. Most genetic defects are recessive in character in sheep. The following are selected, fairly common genetic defects reported in sheep.

The inherited lethal or semilethal characters in sheep and goats are:

Muscle contracture, ankylosis, arthrogryposis or flexed limbs and wry neck. These are expelled dead and are due to simple recessive genes or nongenetic causes.^{296,347}

Paralysis of hind limbs is seen in Corriedales as a simple recessive.^{296,347}

Perosomus elumbis is also common in sheep and due to an unknown cause.³¹⁹

Rigid fetlocks is characterized by a deformed body, short wool and hernias and is probably caused by a recessive gene.^{296,347}

Acroteriasis congenita or amputated limbs.^{77,79,296,319,347}

Lethal gray is seen in gray Karakul lambs as an incomplete dominant character with obstruction of the gut and possibly nerve damage.^{167,296,347}

Collagen dysplasia is due to a simple autosomal recessive lethal gene and causes the skin to be very friable and easily torn.^{77,79,319}

Lethal myodystrophia,^{319,347} inheritance is questionable and may also be due to vitamin E or selenium deficiency.

Dwarfism or achondroplasia is seen in Ancon sheep due to a simple autosomal recessive gene.^{77,163,296,347}

Agnathia is observed in a variety of forms and is due to a recessive gene as well as an environmental agent.^{77,296,319,347}

Cerebellar hypoplasia, ataxia, or "daft" lambs, is a simple autosomal recessive character in Corriedales.^{77,163,147}

Caprine oligosaccharide (lysosomal) storage disease or B-mannosidosis is due to an inborn, apparently genetic, lethal defect in Nubian goats due to a deficiency in lysosomal B-D mannosidase. Heterozygotes showed a partial enzyme deficiency. Affected kids of both sexes exhibited severe neurological deficits with axonal pathology and extensive demyelination after birth.^{506,178,179}

Other Hereditary Generally Nonlethal Defects in Sheep and Goats

Malocclusion, brachygnathism or prognathism¹⁶³

Hypotrichosis congenita^{163,171b,319}

Epitheliogenesis imperfecta is uncommon but usually affects the lower limbs, tongue and palate of lambs and it is possibly of genetic origin.^{40,171b,306}

Hermaphroditism is common in polled goats, especially Saanen.³⁰⁰

Cryptorchidism is an autosomal recessive character in goats and sheep or an autosomal dominant with incomplete penetrance in sheep.^{77,79,296,319}

Yellow fat is a simple recessive character.^{77,79,163,296}

Anury ("no tail"), brachyury or polyury are commonly associated with other defects of sheep.^{77,79,163,319}

Myotonia congenita is an inherited disease of goats characterized by a sudden development of muscle rigidity and in some prostration when they are startled.^{40,42,163,167}

Entropion has probably a complex polygenic inheritance either autosomal dominant or homozygous recessive. Rams that are affected or have produced affected lambs should be eliminated.^{40,64,229,296,319}

Hyperbilirubinemia of Southdown and Corriedale sheep is a sublethal single recessive gene with full penetrance and characterized by jaundice, photosensitization, renal fibrosis and pulmonary edema at 1 to 2 months of age.^{20,239,319}

Wattles in sheep and goats are due to a single dominant gene.^{197,296}

Hydrocephalus¹⁹⁷

Atresia ani is possibly hereditary and commonly associated with other developmental defects. Three-quarters of affected lambs were male.^{78,197}

Sperm granuloma is seen secondary to anomalies of the mesonephric or efferent ducts in male goats.¹⁹⁷

Canine Teratology

With the control of most of the infectious diseases in humans, a recent great interest has developed in environmental concerns, particularly with chemical agents, radiation, and nutritional deficiencies and their effects on the embryo and fetus. Many studies are now underway that are greatly expanding our knowledge of environmental teratogens as well as the genetic teratogenic diseases. Veterinary medical genetics particularly in polytocous laboratory and small domestic animals is a rapidly and expanding discipline along with the field of environmental teratogens which can produce disease conditions closely resembling genetic defects. These latter animals, because of early maturity, short gestation periods, large numbers of embryos and fetuses, and ease of handling and low economic cost and maintenance are being extensively used as models of human diseases. Such research is also providing great and rapid advances in veterinary medicine.^{177,240,386,392}

Because of the very great number of congenital defects in which most are possible, probable or proven to be genetic in dogs and their wide dispersion in the various breeds, the author in selecting and listing the more common genetic abnormalities will rely heavily on the reviews of Hutt,¹⁶⁴ Erickson et al.¹⁰⁰ and Patterson²⁷⁹ and Barnett.^{22,23}

The inherited lethal, semilethal and nonlethal defects in dogs are:

Eye abnormalities

Cataract in many breeds, dominant or recessive.^{100,121}

Distichiasis, a double row of eyelashes, in Pekinese, Pug, Poodles and Cocker, possibly hereditary.¹⁰⁰

Collie-eye anomaly, chorioretinal dysplasia, in Collies, Shetland Sheepdogs and others mainly recessive.^{23,100,117,164}

Entropion, in many breeds, mode of inheritance unknown.^{100,279}

Ectropion, in several breeds, as Beagles, Spaniels, Saint Bernards and others, mode unknown.^{100,164}

Primary glaucomas, in Beagles, Cocker, Miniature Poodles and Bassett Hounds, recessive in Beagles.^{23,100,117b,164}

Hemeralopia in Alaskan Malamutes, recessive.^{23,100,164}

Lens luxation and secondary glaucoma, Terrier breeds,³⁸⁴ probably an autosomal recessive.

Microphthalmia, in homozygous merle dogs in merle breeds.^{100,117}

Microphthalmia with multiple colobomas in Australian Shepherds,^{119b,120} recessive with incomplete pen-

etrance, and more severe in predominantly white pups.

Central progressive retinal atrophy, Retrievers, Springer Spaniels and Border Collies, probably dominant with incomplete penetrance.^{23,100,117}

Generalized progressive retinal atrophy or rod-cone dysplasia, in many breeds, recessive.^{23,100,391}

Retinal dysplasia, Terriers, Sealyham, Labrador Retriever and English Springer Spaniels, recessive.³²⁴

Persistent pupillary membrane, Basenji, Corgi and Cocker Spaniels, probably dominant.^{116,117}

Ear abnormalities

Deafness, associated with white and merle coat colors, Dalmations, Sealyhams, English Setters, Bull Terriers, Foxhounds, Fox Terriers and breeds carrying the merle gene,^{143c} recessive in Bull Terriers, others unknown.^{100,279}

Central Nervous System Abnormalities

Scotty cramp, recurrent tetany, in Scottish Terriers,^{100,279} recessive.

Amaurotic idiocy, C.N.S. Storage Disease, GM2 gangliosidosis, German Short-Haired Pointer, probably recessive.^{100,279}

Thoracic Hemivertebra, in German Shorthair Pointer, autosomal recessive.^{203b}

Juvenile amaurotic idiocy, neuronal ceroidlipofuscinosis, in English Setters and Chihuahuas, recessive.^{100,295}

Ataxia, degeneration of spinal cord, in Fox and Jack Russell Terriers, probably recessive.^{100,279}

Cerebellar hypoplasia, and ataxia, in Airedales, Smooth-Haired Fox Terriers and Chow Chows, possibly hereditary.^{39,195}

Cerebellar degeneration and abiotrophy in Gordon Setters, Collies, Kerry Blue Terriers, autosomal recessive.^{73,74,140}

Epilepsy, convulsive seizures, in Keeshounds, German Shepherds, Beagles, Collies, and Poodles, possibly recessive.^{100,279}

Globoid leukodystrophy or Krabbe's Disease in West Highland White and Cairn Terriers, Dalmations, Blue Tick Hounds and Miniature Poodles. Recessive in the Terriers, possibly recessive in others.^{100,279}

Hydrocephalus, internal in the Cocker Spaniel, English Bulldog, Beagle, Chihuahua and other small breeds, probably recessive.^{100,279,333}

Neurotropic osteopathy, neuropathic necrosis, gnawing of digits in Pointers, probably recessive.^{100,279}

Neuromuscular disorders, myotonia, and muscular atrophy, in Labrador Retrievers, Golden Retrievers, Brittany Spaniels, Chow Chows, Swedish Lapland dogs,

Irish Terriers and others, recessive, possibly sex-linked and polygenic in some breeds.^{100,203,279}

Neuronal abiotrophy in Swedish Lapland Dogs, recessive.^{100,279,316}

Quadruplegia with amblyopia, "swimmers" in Irish Setters,^{100,279} recessive.

Neurospinal dysraphism or syringomyelia in Weimaraners and others, due to a codominant gene with reduced penetrance and variable expressivity.^{98b,100,279}

Progressive degenerative neurologic disease or myelopathy, in German Shepherds, probably genetic.⁴¹

Behavioral abnormalities including aggressiveness, and abnormal maternal behavior in several breeds especially Poodles, Cocker Spaniels and German Shepherds, probably polygenic.^{100,279}

Urinary System Abnormalities

Cystinuria, cystine stones in a number of breeds including Dachshunds and Terriers, sex-linked recessive.^{100,279}

Bilateral renal cortical hypoplasia leading to uremia and secondary hypoparathyroidism in Cocker Spaniels, Norwegian Elkhounds and others,^{100,279} probably recessive.

Excess uric acid secretion and stones in Dalmations, recessive.^{100,279}

Ureteral ectopia with urinary incontinence especially in females, in Siberian Huskies, West Highland White Terriers, Fox Terriers and Miniature and Toy Poodles.²

Blood and Lymphatic Abnormalities

Anasarca, generalized edema in English Bulldog^{100,279} and Beagle, possibly a lethal genetic defect.

Lymphedema involving the hind legs and occasionally the body in Labrador-Poodle crosses and German Shorthair Pointers.^{100,279} Severe cases are lethal and moderate cases may recover in several months after birth, dominant.

Anemia associated with chondrodysplasia in Alaskan Malamutes, associated pleomorphically with recessive dwarf gene.^{100,279}

Pyruvate kinase deficiency, hemolytic anemia, in Basenji, probably genetic.^{100,279,350}

Factor VII deficiency, prolonged bleeding, in Alaskan Malamutes and Beagles, recessive.^{100,279}

Factor VIII deficiency, hemophilia A, prolonged bleeding, in many breeds, sex-linked, recessive.^{100,279}

Factor IX deficiency, hemophilia B, prolonged bleeding in Cairn Terriers, Coonhounds, and St. Bernards, sex-linked recessive.^{100,279}

Factor X deficiency, prolonged bleeding in newborn

and young adults, in Cocker Spaniels, incomplete dominant.^{100,279}

Factor XI deficiency, prolonged bleeding in Springer Spaniels, incomplete dominant or possibly incomplete recessive.^{100,279}

Platelet disorders or defects, prolonged bleeding in Otter, Bassett and Fox Hounds, and Scottish Terriers, incomplete dominant.^{100,279}

von Willebrand's disease, low factor VIII with prolonged bleeding time in German Shepherd, Miniature Schnauzer, Scottish Terrier and others, incomplete dominant.^{85,100,279}

Blood group incompatibility (mainly A system) in all breeds, dominant.²⁷⁹

Cyclic neutropenia, gray collie syndrome, in silver gray Collies, with cycles of neutropenia and local or systemic infections, lethal autosomal recessive.^{100,279,285a}

Granulocytopathy syndrome in Irish Setters, autosomal recessive.^{285a}

Cardiac anomalies including atrial and septal defects, valvular stenosis (pulmonary), tetralogy of Fallot, dextroposition of the aorta, mitral valve defects, patent ductus arteriosus and persistent right aortic arch in many breeds, either polygenic or unknown.^{81,100,279}

Respiratory System Abnormalities

Laryngeal hypoplasia in Skye Terriers, recessive.¹⁰⁰

Collapsed trachea in Chihuahua, toy and miniature breeds, possibly genetic or unknown.¹⁰⁰

Tracheal hypoplasia in English Bulldogs,¹⁰⁰ possibly genetic and lethal.

Stenotic nares and elongated soft palate, in brachycephalic breeds, possibly genetic.¹⁰⁰

Alimentary System Abnormalities

Esophageal dilatation or achalasia with persistent vomiting and often aspiration pneumonia, in many breeds, possibly recessive or polygenic.^{63,100,279}

Glossopharyngeal, "bird-tongue" defect, lethal recessive.^{100,164,279}

Hepatitis with secondary cirrhosis and slow loss of condition, copper toxicosis in Bedlington Terriers^{175,279,364} autosomal, recessive.

Hepatic encephalopathy associated with anomalous portosystemic anastomoses (patent ductus venosus) and hepatic insufficiency, in a number of breeds, congenital and unknown.^{24,59,363}

Pancreatic degenerative atrophy, with a deficiency of pancreatic hydrolases in German Shepherds, probably an autosomal recessive or autosomal dominant with incomplete penetrance.³⁷⁶

Skin Abnormalities

Dermoid sinus, in Rhodesian Ridgebacks, possibly incomplete dominant or recessive.^{100,171b}

Hairlessness in Ceylon, Mexican, Turkish and Chinese breeds,^{100,279} dominant; homozygous dominant is lethal.

Fragility, hyperextensibility of skin or Ehlers-Danlos syndrome, in Springer Spaniels, Greyhounds, Beagles and English Setters,^{100,171b,279} dominant.

Hypotrichosis or follicular dysplasia in Miniature Poodles, Whippets and mongrels,^{56,100,171b,247a,279} unknown, possibly autosomal dominant and sex-linked or sex-limited.

Symmetrical alopecia or ectodermal dysplasia in Whippets and Miniature Poodles, unknown, possibly genetic.^{100,171b,279}

Atopic, hypersensitive dermatitis in Beagles, Poodles, Dalmatians, Highland White, Scotch and Wire-haired Fox Terriers,^{100,279} possibly genetic, unknown.

Generalized demodectic mange, in a number of breeds,¹⁰⁰ possibly an hereditary T-cell-mediated deficiency, unknown.

Nasal solar dermatitis, in Collies and Shetland Sheepdogs¹⁰⁰ with lack of skin pigment on nose, unknown.

Ichthyosis, in mongrel and Doberman Pinschers,^{171b,248} unknown.

Skin-fold pyoderma, often requires surgery to correct, in lip-folds in Cocker Spaniels and St. Bernards, folds on bridge of nose in brachycephalic breeds, and tail-folds in screw-tail dogs such as Boston Terrier, English Bulldogs, Schipperke and Pugs, probably an inherited predisposition.²⁰²

Skeletal System Abnormalities

Cranioschisis, skull fissure(s), in Cocker Spaniels,^{100,279} probably lethal recessive.

Achondroplasia of limbs in Dachshund and Basset Hounds,²⁷⁹ incomplete dominant.

Achondroplasia and pseudoachondroplastic dysplasia,^{100,302} in Miniature Poodles and Scottish Terriers, probably a recessive.

Dwarfism (achondroplasia with anemia) in Alaskan Malamutes,^{100,279} recessive.

Carpal subluxation in Irish Setter and Labrador Retrievers,^{100,279} sex-linked recessive.

Anury, tail-less or brachyury, short, kinked tail in Cocker Spaniel (both) and Beagle and English Bulldog (latter),^{100,279} probably recessive.

Cervical vertebral deformity, spondylolisthesis, in Basset Hounds, Great Danes, and Doberman Pinschers,^{100,279,361} unknown.

Cranio-mandibular osteopathy, "lion jaw" in Cairn, Scottish and West Highland White Terriers and Labrador Retrievers,^{100,279} possibly hereditary.

Predisposition to intervertebral disc disease in chondrodystrophic breeds as Beagles, Cocker Spaniel, Dachshund and Pekinese, unknown.

Multiple epiphyseal dysplasia in Beagles and Miniature Poodles,^{100,279} recessive.

Hip dysplasia in many breeds, especially German Shepherds, Great Danes, Newfoundlands, St. Bernards, Golden Retrievers, Siberian Huskies, also Cocker Spaniels and Old English Sheepdogs, polygenic. This is the most common canine congenital defect.^{100,232,279}

Polydactyly or dew claws in many breeds, especially in rear limbs, recessive in Collies, dominant in other breeds.^{100,279}

Elbow dysplasia, ununited anconeal process, in many breeds^{100,279} especially the large and giant breeds, and Cocker Spaniels,¹⁰⁰ mode of inheritance is unknown.

Premature closure of distal ulnar physis and subluxation of elbow, in Skye Terriers, recessive.²⁰⁹

Ulnar dysostosis and elbow joint abnormalities, in Basset Hounds, possibly genetic.²⁹⁷

Patellar luxation, either medial or lateral, usually the former, in many small breeds as Pomeranians, Yorkshire and Boston Terriers, Miniature and Toy Poodles and Chihuahuas,^{100,279} possibly recessive, polygenic or unknown.

Otocephaly, partial agnathia and hydrocephaly, in Beagles,^{100,279} possibly polygenic.

Odontoid process hypoplasia or dysplasia in Miniature Poodles, Pomeranians, Yorkshire Terriers, and other small breeds,^{100,279} unknown.

Osteogenesis imperfecta in Bedlington Terriers, Elkhounds and Poodles,²⁷⁹ unknown, possibly nutritional in dogs on only meat diets.

Over- and undershot jaw in Cocker Spaniels and long-haired Dachshunds,^{100,279} unknown.

Polyostotic fibrous dysplasia, cyst formation in distal metaphyses of ulna and radius in Doberman Pinschers,^{100,279} possibly genetic.

Osteochondrosis or osteochondritis dissecans, in many breeds,^{100,266} possibly genetic and environmental causes.

Multiple cartilagenous exostoses in the dog,^{100,114} a number of breeds, unknown.

Dislocation of the shoulder in small breeds, miniature Pinschers and Poodles, Chihuahuas, Pomeranians, Griffens, and Wire-haired Fox Terriers,¹⁰⁰ unknown.

Short spine in Greyhounds and Shiba-Inu (Japan),^{100,279} unknown.

Spina bifida occulta, and spinal dysraphism, in

English Bulldogs,^{100,279,387} unknown, with urinary and fecal incontinence.

Perthes disease of hip in Fox and Cairn Terriers and Alsations,²⁷⁹ unknown.

Elbow joint malformation in Afghan Hounds,¹⁰⁰ unknown.

Miscellaneous Malformations in Dogs

Cryptorchidism in most breeds,²⁷⁹ sex-limited, recessive or unknown.

Inguinal hernia in Basset Hound, Basenji, Cairn Terrier, Pekinese, West Highland White Terrier and Lhasa Apso,^{100,279} genetic basis is unknown.

Umbilical hernia in Cocker Spaniels and Bull Terriers is recessive; in Collies, Basenji, Pekingese, Pointers, Weimaraners and Airedales,^{100,279} unknown.

Neoplasia-hereditary predisposition in certain breeds such as Cocker Spaniels and Boxers.^{100,279}

Osteogenic sarcoma in giant breeds.

Mastocytoma in Boston Terriers and Boxers.

Pituitary Tumor in Boston Terriers.

Melanoma in Scottish Terriers.

Oligodendroglioma in English Bulldogs, Boston Terriers and Boxers.

Proneness to vaginal prolapse, Boxers and Bulldogs, possibly genetic.

Proneness to disease of the ear canal, excessive hair in ear canal or heavy "floppy" ears in Poodles, Bedlington, Sealyhams, Wirehaired Fox Terriers, Cocker and Springer Spaniels and others, unknown.

Feline Teratology

Cats have the lowest incidence of congenital defects of the domestic animals. The most common abnormalities are those affecting the central nervous system, especially cerebellar hypoplasia due to the feline panleukopenia virus, eyes and eyelids, feet, tails and palates. Genetic defects are uncommon and environmental causes of defects are not well known. Reviews of feline abnormalities have been reported by Saperstein et al.,³¹⁸ Foley et al.¹⁰⁹ and Colby and Stein.⁵⁴

Inherited lethal, semilethal or nonlethal defects in cats are:

Abnormalities of the central nervous system

Feline tremors,^{109,318} probably an autosomal recessive trait.

Hydrocephalus, in Siamese,^{109,318} lethal and possibly recessive, may be associated with cleft palate and hairlip.

Craniofacial malformation in Burmese kittens, characterized by an enlarged cranial cavity with skull defect, small eyes or anophthalmia, absence of nostrils and duplication of upper jaw, palate, and "whisker pads," possibly an autosomal recessive.^{74b}

Spina bifida in Manx cats, rare in other breeds,^{109,318} is a dominant with incomplete penetrance often associated with taillessness and syringomyelia.

Neuroaxonal dystrophy with progressive ataxia,^{109,318} an autosomal recessive, developing about 1 to 2 months of age, rare.

Exencephaly, meningocele and related to anencephaly,^{109,318} unknown cause, may be associated with spinal column anomalies and cleft palate.

GM, Gangliosidosis, a lysosomal storage disease, Niemann-Pick disease in Siamese cats,^{109,318,375} an autosomal recessive lethal trait with C.N.S. signs and neuronal degeneration from 2 to 4 months of age.

Globoid leukodystrophy,¹⁰⁹ progressive neuronal deterioration with death at 2 to 6 weeks of age, possibly an autosomal recessive or unknown.

Mucopolysaccharidosis, Hurler's Syndrome, lysosomal storage disease, in white domestic short-haired and Siamese cats,¹⁴³ an autosomal recessive trait, characterized by presence or absence of dwarfism, facial dysmorphism with frontal bossing, depressed nasal bridge, small ears and cloudy cornea, hip subluxation, fusion of cervical vertebrae and pectus excavatum. The urine can be tested for excess mucopolysaccharides.

Abnormalities of the Eyes

Chediak-Higashi Syndrome, in blue-smoke Persians,^{32,55,285a,291} The iris is pale yellow-green and ocular fundi are hypopigmented. Cataracts and nystagmus were present in cats with this syndrome as well as photophobia, prolonged bleeding time and increased susceptibility to infection, a simple autosomal recessive defect.

Central retinal degeneration,¹⁰⁹ most common in Siamese, possibly hereditary.

Diffuse outer segment retinal degeneration in Persians and others,^{109,376b} probably autosomal recessive.

Strabismus, common in Siamese,³¹⁸ possibly hereditary.

Microphthalmia or hypoplastic eyeball,³¹⁸ often with other eye defects, cause unknown.

Infantile glaucoma—rare condition,³¹⁸ ectopic lens may be associated with glaucoma.

Eyelid agenesis—agenesis of outer half of eyelids, in domestic shorthaired cats and Persians,³¹⁸ unknown cause.

Dermoid near limbus or on cornea,³¹⁸ seen occasionally.

Cataracts, nuclear,³¹⁸ most common type, cause unknown, possibly hereditary.

Abnormal visual pathways, in Siamese,¹⁰⁹ often related to albinism or light coat color.

Abnormalities of the Ears

Deafness, Waardenberg Syndrome,^{61,109,318} associated with white coat color and one or two blue eyes (iris), autosomal dominant gene with complete penetrance for white coat, with incomplete penetrance for deafness and blue eyes. May be associated with lowered fertility and reduced disease resistance. Atrophy and dysgenesis of the organ of Corti is the cause for deafness.

Folded ears,¹⁰⁹ associated with short tail and hobbling gait, inheritance undetermined.

Four ears,^{109,318} with extra pinna on each side of head, rare, simple autosomal recessive trait.

Abnormalities of the Musculoskeletal System

Achondroplasia or dwarfism^{109,318} is an autosomal recessive trait.

Ectrodactyly or agenesis of all or part of the digit of the forepaws^{109,318} hereditary heterozygous condition with variable expressivity.

Arrested development of the long bones of the forelimb, "kangaroo" cat,^{109,318} possibly a sex-linked inheritance.

Hip dysplasia, rare, in Siamese and Persian and other cats,^{109,318} possibly genetic.

Polydactyly,³¹⁸ extra digits, usually on forepaws, common due to autosomal dominant gene with variable expressivity.

Tail absent or no coccygeal vertebrae ("rumpy"),^{54,72,109,318} several coccygeal vertebrae ("rumpy-riser") or several coccygeal vertebrae with severe kink ("stumpy"). Typical in Manx cats, dominant trait with incomplete penetrance for locomotor abnormalities of hind limbs. It is semi-lethal when associated with spina bifida, deformed hind limbs and pelvis, microperforate anus, incontinence and syringomyelia, enlarged bladder and megacolon.

Tail kinked,³¹⁸ usually near end of tail, recessive trait.

Congenital Abnormalities of the Urinary System

Polycystic kidneys,^{66,318} usually bilateral, due to collecting tubules failing to unite with convoluted tubules, fairly common, may develop loss of weight and uremia, probably genetic, lethal gene.

Renal agenesis,³¹⁸ usually unilateral, not uncommon, males affected more often than females, cause unknown.

Renal amyloidosis, in Abyssinian cats, possibly hereditary.^{51b}

Congenital Abnormalities of the Circulatory System

A wide variety of cardiac anomalies have been de-

scribed in the cat, as in the dog, but they are uncommon, 0.11 percent, and the cause is not determined. Some of the abnormalities described include:^{109,230,318,367b}

Aortic stenosis with enlarged left ventricle, systolic bruit.

Patent ductus arteriosus, enlarged heart, continuous bruit, possibly hereditary.

Endocardial fibroelastosis, in Siamese and others, possibly hereditary, cardiac hypertrophy, kittens grow slowly.

Persistent right aortic arch causing stenosis of the esophagus and regurgitation, corrected by incising ligamentum arteriosum.

Ventricular septal defect, probably common, enlarged right heart and thrill on palpation of sternum.

Tetralogy of Fallot, uncommon.

Congenital Abnormalities of the Digestive System

Cleft palate, often seen with other skeletal defects, in Siamese and others,³¹⁸ occasionally with hare lip, probably hereditary.

Esophageal achalasia, dilation of esophagus with regurgitation after eating, probably hereditary in Siamese cats.^{44,318} It should be differentiated from megasophagus secondary to vascular ring anomalies.

Megacolon³¹⁸ with possible absence of myenteric plexus (see Manx syndrome), unknown often lethal defect.

Portacaval anomalies with neurologic signs (hepatic encephalopathy) reported in Persian and Himalayan cats³⁶⁹ and domestic shorthair cats,^{228b} heredity unknown.

Congenital Abnormalities of the Blood

Factor VIII Deficiency, Hemophilia A in male domestic short-haired cats⁶⁰ with prolonged bleeding after surgery responding to blood transfusions, probably sex-linked autosomal recessive.

Factor XII Deficiency, Hageman Trait,¹⁹³ an autosomal recessive trait, affected animals are normal with bleeding propensities.

Congenital Abnormalities of the Skin

Skin fragility, defective collagen fibrillogenesis, cutaneous asthenia, Ehlers Danlos Syndrome,^{171b,281} is probably an autosomal dominant trait, characterized by easily stretched skin that is readily traumatized.

Epitheliogenesis imperfecta, probably rare, in Siamese,^{109,171b} possibly genetic, Lesions were on the tongue.

Rex mutant,^{171b,318} adult hair is curly, short and guard hairs and vibrissae absent or abnormal, single autosomal recessive trait.

Hairlessness, hypotrichosis, "Sphinx cat,"^{171b,318} probably a recessive hereditary defect.

Miscellaneous Congenital Abnormalities

Porphyria,³¹⁸ brownish to reddish-colored teeth, bones and urine due to overproduction of porphyrins, caused by a simple autosomal dominant trait, uncommon.

Umbilical hernia, fairly common, genetic predisposition.

Diaphragmatic hernia,^{109,318} **agenesis of part or all of diaphragm**, labored breathing, muffled heart sounds, fairly common (1 in 500 to 1,500 births), simple autosomal recessive.

Most domestic animals probably carry harmful genes in a recessive manner. For example breeding tests showed six dairy bulls selected at random carried two lethal genes, four semilethal defects and two characters causing female sterility.²⁴⁵ Probably few lethals ever reach frequencies higher than 0.10 in the general population and in most cases are at a level of 0.05 or less.³⁴⁷ In certain herds or kennels the incidence can become much higher. When a heterozygous recessive male is bred to his daughters a 7:1 ratio of normals to abnormals should be found.¹⁶⁴

The actual frequency of lethals or the genetic "load" is not known for genetic defects. To get this information would require careful postmortem and diagnostic examination of all dead or defective newborn animals and those developing possible genetic diseases later in life. When a recessive defective gene frequency of 0.50 is reached, as in achondroplastic Dexter cattle, all or 100 percent of the animals are heterozygous for the lethal gene and 25 percent of their progeny, a 3 to 1 ratio, are affected, or a ratio of 2 carriers to 1 lethal. A careful recording system for defects found in the purebred cattle breeds is highly desirable to detect carrier bulls used in artificial insemination, as well as donor cows, to prevent deleterious genes from becoming widely disseminated. This is particularly necessary when bulls used in artificial insemination are not progeny tested.

Most lethal and semilethal characters in animals cannot be detected in the heterozygous or carrier state. One of the best, but costly, way to test for carriers is test mating or progeny tests. The minimum number of progeny needed to prove with 95 percent assurance that a male is not a heterozygous carrier of a lethal trait is:^{164,347}

5 normal progeny if the sire is mated to homozygous carrier females.

11 normal progeny if the sire is mated to heterozygous carrier females.

23 normal progeny if the sire is mated to his daughters.

23 normal progeny if the sire is mated to his sibs with one parent heterozygous.

17 normal progeny if the sire is mated to his sibs with two parents heterozygous.

23 normal progeny if the sire is mated to his half sibs. Since carriers are often difficult to locate, limited progeny testing may be carried out by inbreeding a sire to his daughters or by utilizing superovulation and embryo transfer.¹⁷⁴ With a defective gene frequency of .10 in a breed or herd, random mating would produce an incidence of 1 percent defective animals. But if a carrier or heterozygous sire was used at random in these latter two populations the incidence of defective animals would rise to 0.5 and 5.0 percent, respectively. This is why it is highly desirable to mate a prospective AI stud to 200 to 600 random cows during his testing period. Adequate, prompt and complete reporting of defective calves from these matings is essential.³⁶⁷

Certain harmful traits may be spread widely if they are associated with desirable traits. This is called **pleiotropism**.³⁹⁷ For example, the simple autosomal recessive defect with incomplete penetrance of gonadal hypoplasia in Swedish Highland cattle was greatly increased by selection for the white color. In 1936 it was present in 17.3 percent of the cattle of the breed. By careful inspection and pedigree controls the condition was reduced to 9.4 percent in 1948 and 4.2 percent in 1964.²⁰ It will take many decades of careful control measures to reduce the incidence to below 1 percent of the cattle. Thus early detection and control of defective traits is imperative. To eliminate a lethal or semilethal trait in a herd it is much easier to outcross with unrelated animals. For example to reduce hermaphroditism in polled goats rapidly, a horned buck should be used. This eliminates the undesirable phenotypic character in the heterozygotes produced.

Environmental conditions may play an important role in the expression of many lethal or semilethal defects. Some animals have a recessive character but won't exhibit it unless the environment is proper. For example porphyria in cattle requires a white skin and sunlight to produce the characteristic dermal lesion. It is not unusual for a defect of one gene to produce a chain reaction in the early embryo resulting in a variety or syndrome of signs and lesions in the newborn. In reviewing the extensive lists of lethal or semilethal characters it is obvious that similar defects or homologies appear in a number of species including man.¹⁷⁷ A study of these defects in animals may thus be of benefit to the understanding of human medicine and genetics. There is no doubt but that genetics or inheritance plays an important role in the resistance or susceptibility of certain animals to bacterial, viral, parasitic diseases, tumors, metabolic and endocrine diseases. The inheritance of these characters is probably polygenic. If management, drugs, nutrition or surgery are not adequate to control the disease,

selection for disease resistance has proven of definite value and probably should be used more in animals than it is at present. Excellent discussions of the control of defective characters have been published.^{163,164,397}

Neither destroying nor ignoring defective animals is effective in eliminating a genetic problem appearing in a herd or kennel. The veterinarian should provide genetic counseling for his clients after he has mastered an understanding of genetic principles and is knowledgeable concerning the known hereditary animal diseases. According to the American Veterinary Medical Association,⁶² the performance of surgical procedures to conceal or correct genetic defects in animals to be shown, bred or sold is unethical.

"One principle is clear; it is as much the duty of the veterinarian to the community and to the state to use whatever influence and power he possesses to prevent the production of defective animals as it is to prevent the spread of infectious diseases. Each leads eventually to the same port."¹⁰⁷

Nongenetic or Congenital Defects or Anomalies in Domestic Animals

Modern teratology has largely developed within the past 40 years with the impetus of early experiments by Warkany who showed that dietary deficiencies could produce malformations; the demonstration that viral infections of the fetus (rubella) could result in defects of the newborn; and the widespread reports on thalidomide, a sedative drug, that produced many defective infants. Since then hundreds of such factors have been shown to produce anomalies in animals.³⁸⁶

Six principles of teratology have evolved that increase our understanding of teratogenic mechanisms.³⁸⁵

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and its manner of interaction with adverse environmental influences.
2. Susceptibility to teratogenesis varies with the stage of development of the zygote at the time of exposure to the adverse factor. (The embryo is most susceptible during the period of organogenesis, the latter two-thirds of the embryonic period. The zygote is not as susceptible to teratogens during the period of the ovum or blastula or during the period of the fetus, especially the last trimester of gestation.)
3. Teratogenic agents or factors act by specific mechanisms on developing cells and tissues to set in motion abnormal developments. (pathogenesis.)
4. The access of adverse influences to developing tissues depends on the nature of the agent or influence, whether physical or chemical.

5. The four manifestations of abnormal development are death with resorption or abortion, malformation, growth retardation and functional deficit.
6. Degrees and frequency of deviant development increase as dosage increases, from no effect to a lethal one.

The non-genetic anomalies, or monsters, may be of innumerable types and degrees. If the malformation involves only an organ or part of the body it is called an **anomaly**; if the deformity is extensive the animal is spoken of as a **monster**. If a similar defect appears quite frequently in related individuals or those tracing back to a common ancestor, a genetic cause should be suspected. But some of these defects appearing in families or related animals in a herd may be due to environmental causes that would be impossible of differentiation without a carefully controlled genetic experiment. Many nongenetic anomalies closely resemble genetic anomalies and are called **phenocopies**. The nongenetic anomalies or monsters are caused by a variety of environmental factors or agents called **teratogens**. In recent years much basic research has been done on identifying the many factors that can effect genes or their function and produce anomalies.^{33,88,186,208,385,386,388}

The agents or factors that have been shown to be teratogenic in one or more species include the following:

Nutritional deficiencies in the dam including: vitamin A and E, riboflavin, folic acid, pantothenic acid, niacin and other vitamin deficiencies; mineral deficiencies such as copper, iodine and manganese, and amino acids such as tryptophan may cause congenital defects. Hypervitaminoses A and D will also cause anomalies in animals.^{33,186,273,385,386} For example disorders of myelination with C.N.S. signs due to a copper deficiency may cause congenital swayback of lambs and spinal ataxia of pigs.^{88,149} Vitamin A deficiency produces compression lesions of the optic nerve with blindness, and more serious anomalies in fetal pigs.^{88,273} Manganese deficiency in pregnant cows can produce skeletal deformities in the newborn calves.¹⁴⁹ Osteogenesis imperfecta in dogs has been reported to be a genetic defect but it has been shown in many instances to be a nutritional disease caused by all meat diets low in calcium.^{204,301}

Endocrine disturbances of the dam as in: diabetes, thyroid malfunction, and large exogenous doses of glucocorticoids, ACTH, insulin, androgens, progestagens, estrogens, thyroxine and thiouracil will cause defects of the embryo. Large doses of glucocorticoids in pregnant animals at the proper stage of gestation may cause cheilopalatoschisis.¹⁰² Progestogens and androgens given

during early pregnancy can cause masculinization of the genitalia of female fetuses.^{3b,69} Numerous masculinization changes were produced in female canine fetuses when the dam was given mibolerone, an androgenic steroid used to suppress estrus, during the gestation period.^{342a}

Physical factors such as: reduced atmospheric pressures, hypothermia, hyperthermia and anoxia cause anomalies. For example, hyperthermia of 2 to 3° C. for part of the day during pregnancy in sheep caused microencephaly and growth retardation. Other animals were similarly affected.^{33,88}

Radiation by X-ray or radioactive substances induces congenital defects.^{236,386}

Drugs or chemicals as: thalidomide, quinine, sulfonamides, tetracycline, streptomycin, salvarsan, lead, mercury, nicotine, malathion, carbon tetrachloride, apholate, selenium, fluorine, cytotoxic agents including aminopterin in sheep,¹⁷⁰ nitrogen mustard, actinomycin D, 6 mercaptopurine, and other new anticancer drugs, azoserine, azo dye, trypan blue and other dyes, salicylates, histamines, ergot, "Diamox," reserpine, phenylmercuric acid, galactose, E.D.T.A. and certain plant compounds as in *Veratrum californicum* and locoweeds, possibly containing lathyrogens, have all produced fetal anomalies in animals under certain conditions.^{187,190} Many new chemicals and drugs that may be teratogenic are rapidly being developed and introduced into the environment.

Further examples of drug or chemical-induced teratogenesis in animals include:

Griseofulvin therapy for ringworms in pregnant cats³³⁰ caused multiple congenital malformations of hydrocephalus, exencephaly and spina bifida in their fetuses.

Methallibure, an effective estrous cycle control agent in swine, fed to pregnant sows caused embryonic deaths when given from days 13 to 23 of gestation and after 24 days fetal pigs developed skull anomalies, alopecia and splayed legs.³²³

Trichlorfon, a parasite treatment, when fed to pregnant sows caused ataxia and tremors in piglets, resembling congenital tremors caused by viral or genetic causes.¹⁹⁶

Parabendazole, an anthelmintic, when given days 21 to 24 of gestation, produced skeletal anomalies of the vertebral column, long bones, digits and joints of fetal lambs.³²¹ This drug was not teratogenic for swine, cattle, rabbits or hamsters but was for rats.

Cambendazole (CBZ) has been reported to be teratogenic, causing limb deformities in lambs and possibly foals, when administered early in gestation when embryonic organogenesis is occurring.^{89b} Many plants, especially certain pasture plants, are teratogenic such as:

Tobacco (*Nicotina glauca*), especially its alkaloid anabasine, produced arthrogryposis and curvature of the spine in offspring of cows and sows fed tobacco 45 to 75 days and 18 to 68 days of gestation, respectively.^{33,88,187,190}

Lupine (*Lupinus sericeus*) crooked calf disease and (*Conium maculatum*) **poison hemlock** containing the alkaloid coniine, when ingested by pregnant cattle produced similar congenital arthrogryptic defects in their fetuses.^{88,93,169,188,189} The latter toxic agent ingested by sows produced congenital tremor, ataxia and arthrogryposis in their newborn piglets. Sheep were resistant to coniine and lupine teratogenicity.

Locoweed, (*Astragalus lentiginosus* and *Oxytropis*) when ingested by pregnant ewes caused wide spread neurovisceral cytoplasmic vacuolation in their fetuses,¹⁴¹ with limb and facial deformities and abortion and occasionally small weak lambs.¹⁶⁹ These plants also produced abortion and congenital limb deformities in cattle and probably horses.^{239b}

Veratrum californicum or false hellebore if ingested about 14 days of gestation by pregnant ewes causes severe skull and facial deformities including cyclopia ("monkey-faced" lambs), lack of a pituitary gland and prolonged gestation and fetal giantism. If the toxic plant is ingested from 28 to 30 days of gestation, defects in bones of the forelimb and spine of the fetus occur.^{36-38,169}

Jimsonweed, *Datura stramonium* and **wild black cherry** (*Prunus serotina*) ingested by pregnant sows was the apparent cause in two outbreaks of severe arthrogryposis in newborn piglets.²²⁴

Other plants have been incriminated or suspected of causing congenital defects.^{33,211,213} In range or pasture areas where such plants are present and causing losses, preventive measures of destroying the plants, fencing off areas where plants are present, and other pasture management practices are indicated. Also changing the time of breeding so poisonous plants are not available for ingestion at the critical stages of gestation may be helpful.

There have been several reports of extensive outbreaks of congenital abnormalities in a herd or limited area. Although conclusive proof of the etiologic agent was not obtained, plant toxins were strongly suspected.^{216,222}

Infectious agents causing fetal abnormalities are principally the viruses and *Toxoplasma gondii* that have an affinity for the central nervous system and eye.^{33,88,139} Some of the viruses that invade the embryo and fetus and produce teratologic defects are:

Togaviridae, pestivirus

Hog cholera (swine plague) virus,^{88,98,284,366} causes growth retardation, C.N.S. demyelination, tremors and ataxia in piglets.

Bovine virus diarrhea (BVD-MD) causes growth retardation, defects of the C.N.S., cerebellar degeneration, eye defects, cataracts and others in cattle, sheep and goats.^{17,185,331,371}

Border disease—growth retardation, defects of integument and C.N.S. (demyelination) in cattle, sheep and goats, in England and possibly the U.S.A.^{88,270,352} Border disease and virus diarrhea are probably due to the same agent (BVD virus) (See Abortion, Cattle, Sheep).

Rubella (measles)—multiple defects in humans.^{88,249}

Bunyaviridae, Akabane virus—multiple C.N.S. defects and arthrogryposis in cattle, sheep and goats, in Japan, Australia and Israel.^{142,166,380}

Reoviridae, orbivirus, Blue Tongue virus—multiple C.N.S. defects and hydranencephaly in sheep and cattle in Southern U.S.A. and most tropical and semitropical countries.^{88,325}

Parvoviridae, feline panleukopenia virus—growth retardation, C.N.S. defects and cerebellar hypoplasia and ataxia in cats.^{68,194}

Many of these viruses produce malformations in fetuses closely resembling those described under genetic defects for example arthrogryposis in Charolais cattle and congenital tremors in piglets.^{88,284} In the future further studies such as the latter may assist veterinarians in determining the pathogenesis of an abnormality.

Ageing of ova by delaying ovulation 24 to 48 hours was characterized by a three-fold increase in chromosomal anomalies with a higher incidence of embryonic death in rats.⁴⁵ Similarly ageing of rabbit spermatozoa before permitting them to fertilize eggs resulted in normal fertilization but greater embryonic death losses.³⁵⁴ Pregnancy in older women resulted in greater numbers of mongoloid newborn, while achondroplasia was much higher in children from older fathers.²²⁷ Thus age affects the genes and chromosomes as does other agents.²⁹⁰

Other agents not mentioned have also been shown to be teratogens. These above agents behave very similar to genes by acting at certain critical stages of development on specific tissues. Some teratogens, as x-rays, have an acute or sudden effect on the early embryo and others exert a chronic effect such as in vitamin deficiencies. Environmental factors that effect teratogenesis include the age of the embryo at time of the insult, genetic predisposition of the species, the drug or agent present, the dose, the mode of administration, rate of excretion and the presence or absence of protective factors. In humans 30 percent of congenital anomalies were genetic, 10 percent due to viral infections of early pregnancy and 60 percent due to other environmental factors.¹⁶

The noninherited teratologic defects of development may be divided into two general classes^{290,314b}

1. Those malformations due to alterations in tissue

differentiation that have arisen from a single area in the embryonic disc. Most of these are due to the local arrest in the normal process of tissue development and produce:

Defects due to excessive division—for example, polydactylia, polythelia, polydontia.

Defects due to failure of structures to fuse normally—for example, palatoschisis, cheiloschisis, cranioschisis, spina bifida, and schistosomus.

Defects due to arrest in division—for example, cyclopia; ren arcuatus or horseshoe kidney; and syndactyly.

Defects due to complete local failure of tissue growth; for example amelia or lack of limbs; ectrodactyly or absence of phalanges; vertebral or costal abnormalities; epitheliogenesis imperfecta; acrania; agnathia; and anophthalmia.

Defects due to arrest in assumption of final form or position—for example, ectopia cordis, hypognathia, and dextro-position of the aorta.

Defects in the persistence and disappearance of contiguous structures that normally follow a certain pattern—for example, the aortic arches, foramen ovale, urachus, ductus arteriosus and persistence of the median wall of the paramesonephric duct.

Defects due to overdevelopment of local tissues—for example, double-muscling, tumors such as sarcomas, hemangiomas and teratomas.

Defects due to displacement of tissue such as teratomas and dermoid cysts.

Defects due to fusion of sexual characters—such as, true hermaphrodites, false hermaphrodites, and freemartins.

Defects due to miscellaneous causes—for example, ichthyosis, chondrodystrophies, osteogenesis imperfecta, and porphyria.

2. Anomalies or teratologic defects may be grouped for naming by the organs or tissues involved.^{290,314b}

Anomalies of the heart and blood vessels are relatively common in animals. Of 159 cases of cardiac anomalies in animals, 91 cases were in cattle, 28 in horses, 17 in dogs, 8 in pigs, and 5 in cats.^{228b} Fifteen other cases in animals, most of which were in cattle were described.^{266a} The author has recorded 37 cases of cardiac anomalies in cattle in which about one-third were associated with other teratologic defects. In many animals with cardiac defects death occurred soon after birth. A few animals survived a long period due to compensatory factors. For example subaortic septal defects in some cyanotic calves cause early death, while other calves similarly affected may live for years. In cervical ectopia cor-

dis most calves die soon after birth while others survive; the author knew of one such cow that lived for 13 years.

In cattle a subaortic septal defect was found by the author in 18 of 37 cattle with cardiac aberrations. This defect was commonly associated with anophthalmos or microphthalmos and a twisted shortened tail and was seen mainly in Guernseys. Clinically the affected animals showed shortness of breath on exercise, rapid pulse rate, increased cardiac area, cyanosis, and a marked systolic bruit especially over the right side of the thorax where a thrill was often palpable. Another very common defect, observed in 12 out of 37 cases in cattle, was the transposition of the aorta into the dextroposition or Eisenmenger complex, where it arose from the right ventricle or over the right ventricle and interventricular septum. In these cases and others the left ventricle was usually very small or nonfunctional and a persistence of a foramen ovale or a subortic septal defect or both were necessary so that blood from the left atrium could get into the right ventricle. Not infrequently the ductus arteriosus was persistent. In these cases, especially with the latter defect, similar symptoms were shown but the systolic bruit was more pronounced on the left side of the thorax and a thrill was not palpable.

Other cardiac anomalies include atresia of the aorta with persistence of the ductus arteriosus; cor triloculare biatrium; tetralogy of Fallot; ectopia cordis, either cervical, pectoral or abdominal;²⁰⁵ (See Figure 52) persistence of the right aortic arch with absence of the left causing stenosis of the esophagus; and various types of acardiac monsters.

In dogs congenital heart anomalies are quite common with an incidence of about 1 percent. Since many neonatal pups die without a postmortem examination some deaths could be due to cardiac defects. Some of these defects are genetic. The most common congenital heart defects in dogs are: pulmonic stenosis, aortic stenosis, patent ductus arteriosus, interventricular septal defect, tetralogy of Fallot, persistent right aortic arch with a left ductus arteriosus resulting in compression of the esophagus and pericardial defects.^{276,395}

Cardiovascular anomalies in the **cat and sheep** are uncommon and have been reviewed.⁷⁹ Of 4,417 lambs necropsied, 401 had congenital defects and 51 or 12.7 percent had cardiac defects, most commonly septal defects. **In horses** congenital valvular defects are most common.^{228b} One foal with a persistent right aortic arch with a left ductus arteriosus has been described.^{25a} Various human cardiac anomalies have been reviewed.^{1,208} Five cases of multiple congenital heart anomalies in Arabian or half-Arabian foals were reported.^{25b}

Anomalies of the thorax and lungs are not common in domestic animals. Occasionally congenital diaphrag-

matic hernias have been described in the dog and cat¹¹³ and in cattle.³⁶² **Anomalies of the lungs** are rare in animals. Two calves with accessory lungs and one with bronchial hypoplasia and other anomalies of the lung have been described.³⁵⁶

Anomalies of the digestive or alimentary tract. The brachycephalic breeds of dogs quite commonly are affected with cleft palate and harelip or cheiloschisis. The condition results in difficulty in nursing or drinking and milk may return through the nostrils. This condition is occasionally seen in cattle and horses. A ranula or retention cyst of the sublingual or submaxillary salivary gland is observed occasionally in dogs and other animals and is usually due to injury to the salivary ducts. True branchial cysts are less frequently seen but are lined with epithelium, not granulation tissue as are salivary cysts.^{186b} These cysts are probably due to an anomaly in the development or regression of branchial duct II, pharyngo-branchial duct II and the cervical vesicle. Severe anomalies of the face, head and thorax, obstruction of the esophagus or high intestinal obstructions in monster fetuses are often associated with hydramnios. No meconium is normally evacuated during intrauterine life except when the oxygen supply is reduced. With anoxia the fetus becomes distressed and the anal sphincter relaxes.²⁹⁰ Atresia ani is seen in all domestic animals but most commonly in swine. It may be a genetic defect. In females the anus is imperforate but often a union with the urinary and genital structures has occurred, resulting in a common cloaca.

Abdominal hernias such as umbilical hernias are due to failure of the normal closure of the abdominal ring and may also be genetic in nature. The liver is seldom affected by anomalies except for cysts often seen in cases of bovine *Schistosomus reflexus*. Congenital diaphragmatic and peritoneopericardial diaphragmatic hernias have been reported.¹⁰⁶

Anomalies of the urinary system are not uncommon. Polycystic kidneys are seen in almost all domestic animals, especially swine and cats and may be genetic. Fusion of the caudal poles of the kidneys, ren arcuatus, to form a single horseshoe-shaped kidney is occasionally observed especially in monster fetuses. Occasionally marked hypoplasia of one or both kidneys may occur, or in rare cases one or both kidneys may be absent, unilateral or bilateral agenesis.²⁵⁰ Stenosis due to local muscle hypertrophy of the ureter at the bladder, atresia of the ureters or ectopic ureters will cause cystic dilation, hydroureter and hydronephrosis. Dogs with ectopic ureters opening into the vagina or vestibule result in constant dribbling of urine from the vulva.² A similar condition has been observed by the author and others^{316a} in

a mare and a yearling filly. An ectopic ureter in a heifer that opened into the urethra caused incontinence.⁴⁹ A rare ectopic ureter in a male dog that terminated in the urethra²⁶⁸ has been reported. Other congenital anomalies of the urinary system in the dog and cat have been reviewed. In occasional instances the urachus fails to close at birth, resulting in a persistent dribbling of urine from the navel. This is seen most commonly in foals, but also in cats and other animals.

Anomalies of the genital organs and gonads will be discussed in future chapters on infertility in female and male animals.

Mammary gland anomalies include fused teats and supernumerary glands and teats. Some of the supernumerary teats, polythelia, may be fused to the normal teat. The mammary glands in virgin animals may enlarge and secrete a small amount of milk during gestation due to the effect of hormones from the placenta, from the ovary, from granulosa cell tumors or by ingestion of estrogenic mycotoxins. Congenital atresia, or stenosis of one or more teats or glands, may occur but this is difficult to differentiate from pathological processes that may have occurred prior to or after parturition. A rare case of total mammary gland aplasia was reported in a fertile cow.¹¹⁵

Hermaphroditism or intersexuality occurs most commonly in goats and pigs, and less commonly in horses and dogs. It is occasionally present in sheep and cattle and is rare in the cat. **Intersexes** are individuals in which the diagnosis of the sex is confused because of congenital anatomical variations and abnormalities of the genital organs. Conditions in intersexes include hermaphroditism, abnormalities of the accessory genital organs, gonadal dysgenesis, and freemartinism.^{35,238} These latter two conditions will be discussed later.

Pseudohermaphrodites occurred in 11.1 percent of Saanen and 6 percent of Toggenburg goats.⁹⁵ This figure may reach 14.9 percent in certain herds, with a sex ratio of 55.1 percent males, 30 percent females and 14.9 percent pseudohermaphrodites.¹² Thus these caprine pseudohermaphrodites, even though they have testes, are female according to the sex ratio, sex chromatin studies and chromosome analyses. In goats this condition is a simple sex-limited recessive character associated with hornlessness or the polled condition. Horned hermaphrodites are extremely rare. A similar recessive type of hermaphroditism in swine was described and in an inbred swine herd where 106 pigs in 11 litters were sired by a single boar there were 68 males, 22 females and 16 intersexes.^{123,288} Some hermaphrodites may be nongenetic.

A study of 48 naturally occurring and 52 drug-induced canine hermaphrodites showed 33 percent of the former were Cocker Spaniels. Evidence indicated that some of

these might be caused by a single autosomal recessive gene. Of the natural hermaphrodites 25 were male pseudohermaphrodites and 13 were true hermaphrodites. All dogs in this study had either an enlarged clitoris or an underdeveloped penis.^{139b} A specific type of male pseudohermaphroditism has been described in Miniature Schnauzers characterized by persistence of the Mullerian ducts (uterus), cryptorchidism and subsequent signs of Sertoli cell tumors and endometritis.^{203b}

Intersexes may be separated into males or females based on (1) their genetic sex, either chromosomal or nuclear sex, (2) their gonadal sex or presence of ovaries or testes, (3) their phenotypic sex or the morphology of their accessory genital organs, and (4) possibly their hormonal or behavioral sex.¹³⁷ Hermaphrodites are usually classified on the basis of gonadal sex with **true hermaphrodites** having both testes and ovaries or ovotestes and **pseudohermaphrodites** having gonads of only one sex. **Male pseudohermaphrodites** phenotypically resemble females but have testes and **female pseudohermaphrodites** resemble males but have ovaries. Some workers prefer to consider the terms true hermaphroditism and pseudohermaphroditism as misnomers indicating they should be regarded as degrees of intersexuality.

The true hermaphrodite is rare and has internal genitalia resembling both sexes and external genitalia of an intermediate type that may tend either toward the male or female. True hermaphrodites are reported most frequently in swine and occasionally in dogs.^{350a} In most cases the genetic sex is female (XX) but it is likely that on further study many of these cases may prove to be mosaics or chimeras produced by nondisjunction and/or other mitotic errors during mitosis early in embryogenesis or dispermic fertilization of an ovum by an X-bearing sperm and a nonextruded polar body by a Y-bearing sperm resulting in tissues with variable sex chromosome complements such as: XX/XY, XXY, XXYY or XXXY and etc. Two such cases of true hermaphrodites in cattle were described as occurring in single born animals; one had XX/XY and the other XX/XXY cell types especially noted in the kidneys and gonads. Both cattle appeared to be males with a penis but no testes in the scrotum. On internal examination one had an ovary and an ovotestis; the other had a normal ovary and a very undeveloped gonad consisting of primitive medullary tissue. Both had a fairly well developed uterus.^{89c}

The female pseudohermaphrodite is also rare in animals. Intersexes with female gonads and external genitalia resembling the male may be produced by exposure to androgens during embryonic life. This might be caused by a lesion of the adrenal gland or a biochemical lesion of steroidogenesis. Female or true hermaphrodites with

fairly normal external and internal female structures may rarely be fertile since ovulation may occur.¹⁵⁶

The male pseudohermaphrodite is most common with testes in the abdominal cavity or beneath the skin in the scrotal region. (See Figures 35, 36, 37.) The scrotum seldom develops in these animals, due to the anomalous growth of the external genital organs which usually resemble the female. Often a greatly enlarged clitoris is present, which with the vulvar configuration is called "fishhook" vulva in swine. This often causes these animals when urinating to direct the stream in a greater dorsal arc than does the normal female. The location of the urethral opening may be anywhere from that of the normal female to one in a penis-like structure with hypospadias in the scrotal or abdominal region. If animals possessing these abnormal characters resemble the female sufficiently to deceive the owners, they may be detected by their failure to show signs of estrus, and by

Figure 35. False masculine porcine hermaphrodite—note testes, uterus, and "fish hook" vulva.

their body appearance of a male castrate. Hermaphrodites commonly resemble cryptorchid males in their male actions and attitudes. In the male pseudohermaphrodite the internal genitalia resemble both sexes and a uterus-like structure is nearly always present. Hermaphrodites are invariably sterile, especially males with intraabdominal or subcutaneously located testes. Almost all male and female pseudohermaphrodites are genetic or chromosomal females (XX) and are positive on nuclear sexing as indicated by the presence of the sex chromatin mass or Barr body in the nucleus.

The technic of nuclear sexing consisting of examining certain somatic cells of animals for the presence of the inactive X chromosome in the nucleus has been described.^{14,246b,342} Cells from various tissues that are most satisfactory to examine will differ from species to species but buccal epithelium, nerve cells and polymorphonuclear neutrophils are most commonly utilized. The Feulgen staining method is highly satisfactory after the

Figure 36. False masculine bovine hermaphrodite—The testes were beneath the skin in the inguinal region.

Figure 37. False masculine equine hermaphrodite—This horse behaved like a stallion.

cells are fixed. The cells are examined for a dark-staining, small, about 0.8 by 1.2 micron, planoconvex mass or body against the inside of the nuclear membrane. In neutrophils this body is observed as a similar-sized small projecting mass, a sessile body or "drumstick," attached by a small stalk to the nucleus. These sex chromatin masses or Barr bodies, named after the person who first described them, are observed in most female cells examined and are absent in the cells of males. Thus females are sex chromatin positive and males are sex chromatin negative. In female or male cells with abnormal numbers of sex chromosomes, XXX, XXXY, and etc., the number of Barr bodies observed is always one less than the number of X chromosomes. Although nuclear sexing is a very helpful and simple technique, examination of the chromosomes by karyotyping is more accurate and informative especially for the determination of the true chromosomal complement of intersexes.

Figure 38. Diphallus or double penis in a bull.

When gonadal tissue in the embryo remains undifferentiated, undeveloped, is absent, or is surgically removed early in embryonic life, the internal and external genitalia become female in character. The Y chromosome is apparently necessary to initiate the development of the testis and then the testicular androgen secretions, and cause the development of the external genital organs characteristic of the male animal. An individual with XXY or XXXY chromosome make-up will have a male phenotype but he is sterile. In humans and animals extensive cytogenetic studies have been conducted on these XXY individuals with Klinefelter's syndrome. The testes are very undeveloped and hypoplastic and few or no spermatozoa are produced. This syndrome has been described in human males, in tortoise-shell male cats and in boars, rams, dogs and bulls.⁹¹ In another common chromosomal deficiency in humans and animals called Turner's syndrome the Y chromosome is missing. The human or animal which has an XO chromosomal complement is a short, small female with undifferentiated rudimentary gonads or gonadal dysgenesis.^{10,64b,154,342} In male pseudohermaphroditic swine, and the same is true in goats where this condition is also genetic, cells have only an XX chromosome complement.¹²³ Pseudohermaphroditism in swine, goats and dogs may be inherited as an autosomal or sex-linked recessive gene or a dominant gene with incomplete penetrance.^{281,300} Hypoplastic testicular development with modification of the external genital tract occurs in the absence of the Y chromosome. Autosomal modifiers in this sex-linked recessive condition might cause the development of the testes.¹²³ Injections of male sex hormones into the dam during gestation will cause modification of the external genitals of a female fetus in the male direction.⁶⁹

Recent studies^{89d,161,201,335,370} have indicated that a cell

surface component recognized serologically as H-Y antigen governs the development of the initially indifferent gonad, early in embryonic life, toward the male or testicular mode in species in which the male is the heterogametic sex. Although the H-Y gene is probably on the Y-chromosome, there are studies to show this gene may be on the X-chromosome or on an autosome. It possibly requires a male hormonal environment for its expression. It has been proposed the H-Y gene and two other genes, one that activates the H-Y structural locus and the second that codes for specific H-Y antigen receptors, may be required for testicular differentiation. After the initial differentiation of the gonad into a testis, the latter produces androgens which cause virilization of the accessory glands, ducts and external genitalia. The fetal testes also secrete a paramesonephric (Mullerian) duct inhibiting factor or antimullerian hormone, possibly from Sertoli cells, suppressing the development of the uterine tubes, uterus and cephalic portion of the vagina.

These and other studies have helped to elucidate the complex factors in the development and manifestation of characters associated with true hermaphrodites, pseudohermaphrodites, freemartins, and feminizing or masculinizing syndromes. In freemartins it is presently postulated that H-Y antigen produced by the male twin is carried to the female twin by the blood stream through placental anastomoses. This causes virilization of the gonad with the subsequent alterations of the genital structures to produce, in the genetic female bovine fetus, the freemartin condition.

Amniocentesis to collect amniotic fluid and cells for diagnostic analysis has been commonly performed in humans early in gestation to detect suspected fetal aberrations, or for sex determination. However in animals amniocentesis has only been performed in a limited manner and further studies and improvements are necessary to avoid fetal deaths and make the procedure more practical.⁹⁴

Hybrids are an extreme outcross, such as a cross of the ass on the mare to produce the mule or the sheep on the goat, the dog on the coyote, and the bison on the cow.

The ass-mare or stallion-ass breedings produce mules or hinnies, respectively.³³⁷ These hybrids are the only commercially-produced man-made animals and they are always sterile. Workers in the field of cytogenetics have been making interesting studies on these hybrids.³⁰ The ass with a diploid chromosome number of 62 when mated with the horse with a diploid chromosome number of 64 produces a mule with the chromosome number of 63. The female mule has a normal ovarian hormonal function producing normal follicles and corpora lutea, ex-

inhibiting estrus and occasionally showing mammary development with the production of milk. However, because of the very limited number of oocytes in the ovaries, estrous cycles may be of a normal length (22 days) or with long periods of anestrus between estrous periods. The female and male mules are sterile, probably due to a failure of gametogenesis caused by asynapsis during the first meiotic division. A number of alleged fertile female mules examined were found to be donkeys rather than mules when chromosome studies of their body cells were made.³¹ In the male mule a few spermatozoa may be found but they are smaller in size than those from a normal stallion or ass, possibly being quasi-haploid. Other interesting facts concerning this hybrid are that in female mules or hinnies the donkey x chromosome, of the two x chromosomes present in each cell, is inactivated. The production of PMSG from the endometrial cups in pregnant mares with horse fetuses and donkeys with donkey fetuses is high as it is in donkeys carrying hinnies. But in mares carrying mules very little PMSG is produced.³³⁷ Recent unpublished investigations at Cambridge and elsewhere into the immune phenomena occurring during early pregnancy, occasioned by the intimate association of a foreign fetal placenta with the maternal endometrium, are being studied by newer immunological and biological techniques involving hybrids of donkeys and horses and sheep and goats. For example donkey embryos transferred into mare recipients are rejected and aborted after developing to about 90 days of age; while horse embryos transferred into donkey recipients are carried to term.^{8b}

Forty-five percent of does bred to rams and ewes bred to bucks conceived, however nearly all aborted before 145 days.^{34,43} The diploid chromosome number of sheep is 54, goats 60¹⁵ and their embryonic hybrids was 57.

Figure 39. Hydrocephalus in a feline fetus.

Figure 40. Anasarca or edema of a canine fetus.

Production of hybrids from sheep and goats was reported and reviewed.⁴³ Both the dog and coyote have similar karyotypes with 78 chromosomes each and although many believe these hybrids may produce fertile offspring further experimentation is needed. Dystocia occurring at the birth of the hybrid fetus produced by mating a bison bull with possibly 60 chromosomes with a domestic cow having 60 chromosomes was due to the severe amnioallantoic dropsy regularly present.³⁸³ Beefalo bulls with more than three-eighths bison "blood" when bred to domestic cows often produce pregnancies with dropsy or abortion.⁴⁷ Further study is also needed with this hybrid to determine the mechanisms involved in the abnormality.

Anomalies of the head and central nervous system may include:

Microcephalus is characterized by a small cranial cavity and brain.

Cyclopia or cebocephalus is characterized by a single orbit in which global tissue is absent or rudimentary or in which the eyeballs vary from a single apparently normal eye through all degrees of doubling to one consisting of two complete but small adjacent globes (See Figures 41 and 42). Eyelids are rudimentary or absent and the nose is usually absent or in the form of a tubular appendage placed above the centrally located eye. This rudimentary nose does not communicate with the pharynx. The skull is usually small and the lower jaw, being longer than the defective upper jaw, is curved dorsally at its cranial end. Cyclopia is seen most commonly in the pig and sheep as a congenital but nongenetic defect but may be present in all species.

A congenital malformation of sheep affected 1 to 8 percent of the newborn lambs in flocks in southwestern Idaho. It was characterized by cyclopia or a "monkey-faced" condition, harelip, cleft palate, hydrocephalus,

Figure 41. Cyclopia or cebocephalus in a Holstein calf.

short upper jaw, prolonged gestation of 200 days or more with fetal weights up to 20 lbs., associated with involution of the mammary gland, a small dark vulva, and occasionally rupture of the prepubic tendon due to the large size of the fetus or fetuses.^{36,37,38} This condition was not due to a genetic character. Head defects were severe in the overtime fetuses. The pituitary gland or hypophysis was absent or grossly defective. Subsequent work showed the cause of this condition to be the ingestion of *Veratrum californicum* between 8 and 17 days and later the critical day was found to be the 14th day of gestation. If the feeding of this plant was continued after the 15th day, embryonic death apparently occurred in a high percentage of ewes. If flocks were on range containing this plant, the incidence of "dry" or barren ewes at lambing could be 10 to 15 percent rather than the normal 1 percent. The teratogenesis of this condition has been described.¹⁰²

Hydrocephalus is due to an abnormal accumulation

of fluid in the cranial cavity. Internal hydrocephalus is due to excessive fluid in the ventricular system. External hydrocephalus is rare and due to excessive fluid between the brain and dura mater. Internal and external hydrocephalus may be combined. About 99 percent of human cases are caused by an obstruction to the passage of the cerebral spinal fluid into the arachnoid spaces usually due to an associated spina bifida in the fetus.²⁹⁰ In severe cases the dorsal portion of the brain is encompassed only by the skin, the subcutaneous tissues, and the brain coverings. (See Figure 39.)

Cranioschisis or crania bifida are defects of the skull that may result in meningocele or meningoencephalocele. In the later instance the skull defect is large, so that parts of the brain and the meninges are extruded.

Anomalies of the head—Facial fissures include palatoschisis, cheiloschisis, macrostomia, and schistoprosopus or divided face. Lack of cranial or facial structures include acephalia, or absence of a head; acrania; hemicrania; astomia; microstomia, arhinencephalia or absence of a nose, agnathia, hypognathia, anophthalmos, microphthalmia, aprosopia or partial or complete absence of a face, anotia or absence of ears, polyotia and polydontia or anodontia. Congenital defects of the head and ears of ovine fetuses are common. (See Figure 53.)

Anomalies of the skeleton—No genetic cause was suspected for the commonly observed condition of "contracted" newborn foals.³¹¹ Mild cases might be associated with intrauterine crowding. In most cases the characteristic anatomical changes were hypoplasia of the intervertebral articulations, hypoplasia and twisting of the long metacarpal and metatarsal bones and asymmetry of the cranial skeleton. The cause is unknown. An iodine deficiency might be associated with goiter and angular limb-deformities.^{241,242} Four mares

Figure 42. Skulls of normal and cebocephalic calves.

grazing Sudan pasture early in gestation, about 20 to 50 or more days, delivered dead foals with ankylosed extremities at term. Evidence of a toxic reaction to Sudan pasture with cystitis and ataxia have been reported in adult horses.²⁹²

These anomalies of the central nervous system are often characterized externally by ankylosed joints, deformed fetlocks or "club feet" and other defects including hydramnios in some severely affected bovine fetuses. As with other markedly defective fetuses their size is usually smaller than normal due to growth retardation.

Achondroplasia, chondrodystrophy or dwarfism—There are apparently several types and degrees of the defect and most, or all, are hereditary. In achondroplastic fetuses the long bones are abnormally short. The trunk is of normal length and the abdomen is large. The head is moderately enlarged and flattened. "Bulldog" head and brachygnathism of the maxilla, "undershot," and prognathism of the mandible, "overshot," are common. In Herefords, the recessive gene for dwarfism is commonly found in the heterozygous "comprest" animal. Most dwarfs are the result of a complex mode of inheritance. (See genetic bovine defects.)

Spina bifida, rachischisis or spinal dysraphism is the absence of dorsal portions of the vertebrae or vertebral arches often in the lumbar or sacral region with defective rear limbs and tail and paralysis of the rear parts. It may be occult or a skin defect may be present. It is seen in Angus, Holsteins, Bull Terriers and other animals. The anomaly may resemble the *Perosomus elumbis* monster.

Absence of the tail, anury or *Perosomus acaudatus* is seen as a common defect in dairy and beef cattle and Manx cats characterized by a lack of coccygeal vertebrae and deformed sacral vertebrae with a sunken perineal region and in some cases a characteristic hopping gait. The condition could not be proven to be genetic in nature in cattle.^{126,161}

Hemivertebrae have been seen most commonly in English Bulldogs and Boston Terriers resulting in failure of the centers of ossification to unite. **Scoliosis**, kinked tails and a shortened spine are present if many vertebrae are involved.⁹

Anomalies of the trunk—*Schistosomus reflexus* is seen most commonly in cattle but may be observed rarely in sheep, goats,^{28,77,79} and swine. It is characterized by a marked ventral curvature of the spine so the occiput of the head lies near the sacrum. The body and chest walls are bent laterally and dorsally and the thoracic and abdominal viscera are exposed. The pelvis is deformed. The liver is abnormal in shape and cystic. The rumen is

occasionally distended with fluid. The limbs are usually ankylosed and rigid. In rare cases the limbs and head may be enclosed in a complete sack of skin. (See Figure 43.) ***Campylorrhachis scoliosa*** is a fetal monster occurring rarely in cattle and swine, characterized by a lateral curvature of the spine. The limbs are usually deformed and ankylosed. ***Perosomus elumbis*** is seen occasionally in cattle, swine, sheep, and dogs and is characterized by a lack of vertebrae and spinal cord caudal to the thoracic region. The monster has a small, flattened, deformed pelvis with strongly ankylosed and flexed hindlimbs and atrophy of the muscles of the real quarters (See Figure 44) ***Perosomus horridus*** is a bovine fetal monster with generalized, severe ankylosis and muscle contractures. It is characterized on external examination by a short spine. This is due to a marked double S-shaped lateral twisting of the vertebrae. (See Figure 45.) Fetal monsters may be present with a normal, probably dizygotic twin.

Figure 43. A bovine *Schistosomus reflexus* monster. This is an unusual type in which a sac of skin encloses the entire fetus. Note accessory limb attached to skin.

Figure 44. **Perosomus elumbis**, note lack of development of the caudal part of body and ankylosed rear limbs.

Anomalies of the limbs include amelia, missing or “amputated” extremities; (See Figure 54) micromelia; hemimelia or absence of the distal half of the limb; sire-nomelus, or fusion of the hind limbs with varying amounts of hypoplasia and deformity of the pelvis and pelvic organs; hypoplasia of the extremities; polydactyly, syndactyly; and ectrodactyly or absence of phalanges. Amelia or hemimelia were characteristic congenital defects in thalidomide toxicity in humans. Ectopia of the patella has been reported in cattle, dogs and horses.¹⁰⁸

Miscellaneous anomalies due to displacement of tissues include **teratomas**, **dermoids**, and **dentigerous cysts**. The last condition, characterized by a displaced dental follicle containing fluid and teeth, is seen most commonly in the horse. These dentigerous cysts may be located beneath the ear and are called an “ear tooth.” Dermoids are seen occasionally on the cornea, third eyelid or on the neck in cattle and other species. In horses dermoid tumors may rarely involve the ovary or testis, especially the retained testis. Teratomas are occasionally seen in all species.

Embryonic duplications are malformations due to abnormal duplication of the germinal area giving rise to fetuses whose body structures are partially but not completely duplicated. Embryonic duplications, although rare, occur most commonly in cattle and can result in severe dystocia. Whether they are caused by environmental or genetic factors or both is not known. Embryonic duplications include:²⁹⁰

- A. Free monozygotic or dizygotic twins or triplets
 1. Symmetrical twins are either monozygotic or identical, or dizygotic or fraternal.
 2. Asymmetrical twins consist of a normal and an acardiac or monster individual. These may include three types:

Hemicardius is a very imperfect individual but

Figure 45. **Perosomus horridus**. The spine has many lateral bends and all joints are functionally ankylosed.

parts are recognizable and a rudimentary heart is present.

Holocardius acephalus—The cranial portion of a very imperfect individual is lacking. No heart is present. (See Figure 50.)

Holocardius amorphus or **Amorphus globosus**—The general body form is unrecognizable. It may occasionally be seen, most

Figure 46. Porcine double monster, monocephalus tetrapus tetra-brachius.

Figure 47. **Amorphus globosus** attached to the bovine fetal membranes.

commonly in the cow, but also in the mare, ewe and goat, attached to the placenta of the normal monozygotic or dizygotic twin. These very imperfect zygotes are parasitic upon the placenta of the normal twin and are never observed in single births. The bovine **Amorphus globosus** usually appears as a round or oval, edematous structure weighing 1/2 to 7 lbs. covered with skin and hair and con-

Figure 48. An ossified remnant of the yolk sac in a mare's placenta. A thin cartilaginous shell surrounds a gelatinous mass.

Figure 49. A bovine **Amorphus globosus** attached by a stalk containing blood vessels to the placenta of a normal fetus.

taining connective tissue, fat and other soft tissue and occasionally cartilage and bone. In the mare a rare structure consisting of a round, thin, fenestrated ball of cartilage 3 to 5 inches in diameter is covered with mucous membrane. This is not an amorphus globosus but is an ossified remnant of the yolk sac. (See Figures 47, 48, 49.) The interior of this cyst-like structure is jelly-like tissue.

In humans an amorphus structure is observed in the chorion in about 1 in every 100 single births.^{184a} Based on karyotypic studies of chromosomes, human acardiac monsters were found to be the same sex as their normal twin supporting the theory of their monozygotic origin.

Figure 50. A holocardius bovine monster without a heart. Note the imperfect face, muzzle, teeth and a tail.

Figure 51. A parasitic limb, notomelus, attached to a calf.

However, three acardius twin-bovine monsters were the opposite sex from their normal cotwin.⁹⁰ This supported Williams³⁸³ theory that the **Amorphus globosus** was an imperfect zygote of dizygotic twins. It was demonstrated that the leucocytes of the normal male calf only contained the XY or male chromosome complement and no blood cell chimerism occurred. Chromosomal analysis of an ovine acephalic acardiac monster expelled with two normal male lambs revealed a chromosome aberration, increased hypodiploidy.⁹² The monster composed mainly of stomach and intestinal tissues was enclosed in its own amnion. Another case²⁵² where two acardiac monsters were attached to the placenta of a normal bovine calf was described. The author has observed a placenta of a normal calf containing six teratomatous growths.

B. **Conjoined twins** in which the components or component parts are symmetrical are called **Diplopagus** monsters or "Siamese" twins. **Triplopagus** monsters are extremely rare. Conjoined twins arise from a single ovum

Figure 52. **Ectopia cordis** in a calf, with the heart beneath the skin ventral to the neck and cranial to the thoracic inlet.

and are monozygotic.^{11,138} They occur about once in 100,000 bovine births. They are most common in cattle but are seen rarely in sheep, pigs, dogs and cats and are rare in horses.^{15,215}

1. Those conjoined twins in which each component is complete, or nearly so, include:

Thoracopagus, sternopagus, or ziphopagus twins are joined at or near the sternal region. The internal organs are usually duplicated. The components are face to face.

Pygopagus monsters are connected at the sacrum and the components are back to back.

Craniopagus twins are united at the heads. Components may be facing in the same or in the opposite direction.

Ishiopagus fetuses are joined at the lower pelvic region and the bodies extend in a straight line and the heads in opposite directions.

2. In this group the two components equal one another but each is less than an entire individual. This is usually associated with lateral fusion. These may vary from single normal individuals to those of two normal but superficially joined individuals. Duplication may lead to doubling of the cranial end of body while the caudal end remains single; or the caudal part may be doubled and the cranial part single. Duplication can occur at both cranial and caudal ends with the middle area of the monster remaining single. Duplication of the cranial part of the fetus is more common than that of the caudal portion.

- a. Duplication in the cranial region. (See Figure 46.)

(1) **Monocephalus** includes those monsters with partial duplication of the frontal region, nose and mouth called **Diprosopus** or double face.

Figure 53. An ovine monster twin to a normal lamb—A cystic esophagus, agnathia, cyclopia and microcephalia were present.

Figure 54. Amelia in a Jersey calf—A portion of the humerus and the distal portion of the left forelimb was missing at birth.

Either face may be complete or one eye of each may be fused into a common medial orbit. **Di-, tri- or tetraophthalmos** and **di-, tri- or tetraotus** may be present.

- (2) **Dicephalus** or two heads, with **distomus** or **monostomus** occasionally is seen. **Tricephalus** is very rare. A **Dicephalus dipus dibrachius** monster has two forelimbs and two hind limbs with partial duplication of the spine and one or two tails, **dicaudatus**. **Dicephalus dipus tribrachius** has 3 forelimbs; **Dicephalus dipus tetrabrachius** has 4 forelimbs.
- b. Duplication in the caudal region is designated as **Dipygus**. **Tripygus** is very rare.
 - (1) **Monocephalus tripus dibrachius** has 3 rear limbs.
 - (2) **Monocephalus tetrapus dibrachius** has 4 rear limbs.
 - (3) **Cephalothoracopagus** has a single neck and more or less complete fusion of the heads to form an almost single face. **Syncephalus** has one face, four ears, and a single or partially doubled cerebrum. **Janiceps** is a monster with two faces on opposite sides of the head.
- c. Duplication of both cranial and caudal regions is **Dicephalus dipygus**.
 - (1) **Dicephalus tripus tribrachius**, **Dicephalus tetrapus tetrabrachius**, **Dicephalus tripus tetrabrachius**, or **Dicephalus tetrapus tribrachius** have been described.

C. **Unequal and asymmetrical conjoined twins** are composed of one very imperfect and incomplete twin, called the **parasite**, dependent on the other twin, the **au-**

tosite. This is called a **heteropagus monster**. The autosite is nearly normal and the parasite is attached to it as a dependent growth. (See Figure 51.)

1. The parasite may be attached to the visible surface of the autosite. Common junction sites are the back (notomelus) thorax, sacrum or pelvis, and in rare cases the abdomen, head, or buccal cavity. The latter is called **epignathus**. Five cases of notomelus in heifer calves were reported.²¹⁵ Some of the smaller, more imperfect parasites may be called **teratomas**.

A parasite can rarely develop within the autosite usually in the abdominal, thoracic, pelvic or cranial cavity, or in the spinal canal or scrotum. **Teratomas** in the abdominal cavity and between the mandibles were described in two calves.^{148b}

Chapter IV

PHYSIOLOGY OF THE GESTATION PERIOD

In this chapter the estrous cycle, estrum, ovulation, and fertilization are purposely omitted inasmuch as they will be discussed later in Chapter XII on Physiology of Reproduction.

Shape and Location of the Pregnant Uterus

In all domestic animals as pregnancy progresses the uterus with its contents moves forward and downward in the abdominal cavity. In the cow and mare the uterus rests on the abdominal floor beneath the intestines after the fourth or fifth month of gestation. In the ruminant the uterus is usually located on the right side of the abdomen because the left side contains the rumen. In advanced pregnancy in the cow and mare the length of the fetus may exceed the distance from the diaphragm to the pelvis. In the mare this often results in the uterus and fetus assuming a diagonal position in the abdominal cavity. In the cow, in the last month of gestation, the nose and the forefeet of the fetus, together with the enveloping uterine wall and fetal membranes, may enter the pelvic cavity and extend caudally over the cervix.

The mesometrium, or broad ligament, attaching the lesser curvature of the uterus of the cow to the caudal lateral flank and pelvic regions, is stretched and pulled forward by the weight of the gravid uterus. However the ovary is never further than 20 to 25 cm. from the pelvic brim. The uterus of the cow is cornuate in shape and conical, with its greatest diameter from the cervix through the middle of the horn containing the fetus. The distal third of the horn narrows rapidly toward the apex. The opposite nongravid horn in both the cow and mare remains relatively small even though fetal membranes extend into it. These characteristics of the uterus in the cow facilitate torsion of the uterus.

In the mare the mesometrium is attached to the dorso-lateral aspect of the uterus and dorsally to the sublumbar and dorsal pelvic regions. As the uterine weight increases the ovary is pulled ventrally, but seldom more than 25 cm. from the lumbar vertebrae; the ovary can frequently be felt per rectum for much of the gestation period. The apices of the horns are directed dorsally by

the attachments of the mesometrium. The body and the horn containing the fetus are tubular and about the same diameter from the cervix to near the apex of the horn.

In the ewe the shape and location of the pregnant uterus is similar to that of the cow. The frequent incidence of bicornual twin pregnancy and the relatively smaller abdominal cavity in the ewe may be a factor in preventing uterine torsion.

In multiparous animals, as the bitch, queen and sow, the gravid horn is tubular and about the same diameter its entire length. The fetuses are usually nearly equally distributed between each horn. The horns become very long in the sow. Each pregnant horn may be 1.8 meters in length. They rest on the floor of the abdominal cavity in a folded manner, similar to intestines.

In the cow twinning usually results in bicornual twins, one fetus developing in each horn. In about 10 percent of twin pregnancies, both twins develop the same horn, unicornual twins. In these cases the horn containing both fetuses is very long and is bent at an 180° angle at the diaphragm, with one fetus lying parallel to the other. The fetus in the apex of the horn may be delayed in its expulsion at parturition or be overlooked.

Rectal examination of the cow during gestation often reveals a rotation of the uterus of from 20 to 90 degrees. This amount of rotation is apparently corrected spontaneously before or at the time of parturition. It seems possible that some of the 180° torsions of the uterus causing dystocia at the time of parturition may have their onset at some earlier period of gestation. If circulatory embarrassment of the uterus does not develop, no symptoms of torsion will be observed until the onset of parturition when the fetus cannot be expelled due to the narrow, twisted birth canal.

In 1 in 1,000 equine pregnancies, a single fetus may develop in both horns, bicornual pregnancy, instead of the body and one horn.⁶ With this unusual type of development, the uterus and fetus must lie diagonally in the abdominal cavity, since the length of the fetus is longer than the transverse diameter of the cavity. Bicornual pregnancy in other species of domestic animals rarely occurs because of the acute angle at which the horns leave the "body" of the uterus. In the mare a bicornual

pregnancy may in rare cases become rotated ventrally so that the two horns and the fetus come to rest under the body of the uterus. At the time of parturition this condition produces a long birth passage and severe, often fatal, dystocia.

Position of the Fetus in the Uterus

In domestic animals the tubular uterus that lies more or less parallel to the long axis of the dam requires the developing fetus the last third of gestation to assume a longitudinal position in relation to the long axis of the dam. During the first half of gestation the small fetus may lie in any direction. The length of the bovine and equine fetus after 5 months of gestation is greater than the diameter of the gravid horn. The umbilicus of the fetus, in the cow and ewe opposes the lesser curvature of the uterus with the dorsum of the fetus lying against the greater curvature or dorsal surface of the uterus. This relationship of the dorsum of the fetus to the unattached portion of the horn occurs in the cow and ewe but not the mare, sow, bitch and queen. Most authors^{1,3} agree that in advanced pregnancy in the mare, sow, bitch, and queen, the fetus rests with its dorsum or dorso-lateral side against the abdominal wall and ventral portion of the uterine horn in a dorso-pubic or dorso-iliac position. This is said to account for the rolling tactics of the mare at the time of parturition. At birth the fetus of the mare, sow, queen, and bitch normally passes through the birth canal with its dorsum against the sacrum of the dam. This is brought about by a rotation of the fetus. In the mare the lack of space for fetal development in bicornual pregnancy often results in flexion of the fetal head and neck alongside the body, and because movement is thereby limited wry neck often results.

In the cow over 95 percent of the fetuses were in anterior presentation, with the cranial extremities toward the pelvis, by the seventh month of gestation.^{1,4,6} At 7 months of gestation in the mare only about 60 percent of the fetuses were in anterior presentation but by the ninth month over 99 percent were in anterior presentation. Less than 1 in 500 fetuses in foaling mares are in posterior presentation.^{3b} Late rotations of the equine fetus probably are made possible by a rotation of the amnion and fetus within the allantoic cavity.¹ In late gestation in the cow over 95 percent of the fetuses are in anterior presentation with their cephalic poles facing the cervix.^{1,10,11} During the early months of gestation, 2 through 6 and 2 through 4, in the cow and ewe, respectively, the incidence of anterior and posterior presentations is about equal. In the ewe, over 95 percent of sin-

gle fetuses are in anterior presentation after 120 days of gestation and at parturition.³ The incidence of posterior presentations in twin ovine fetuses and possibly twin bovine fetuses is significantly greater late in gestation than in single fetuses.^{4,5} Anterior presentation occurred in 55 to 75 percent of porcine and canine fetuses at parturition.^{1,1,2,3} A high incidence of posterior presentations over a 2-year period in an inbred line of Hereford cattle bred to one bull suggested an hereditary factor might condition such mal-presentations.⁷ The reason for the very high incidence of anterior presentations late in gestation and at birth in the cow and mare is not known.

Since in the cow and mare the percentage of anterior presentations is so much higher than that of posterior presentations and the incidence of dystocia or difficult birth is so much higher in posterior presentations, the latter presentation in these two species may be pathological.¹¹ Further evidence indicates that posterior presentation is abnormal.^{1,12} In posterior presentation, compression of the fetal abdomen as it enters the pelvis expands the ribs and costal arch; while in anterior presentation the fetus is wedge-shaped thus tending to dilate the birth canal during parturition and compressing the rib cage. The passage of the fetus in posterior presentation is against the direction of its hair creating more friction and resistance. Lastly, more space is required in the posterior presentation in uniparous animals to extend flexed hind limbs.

Number of Fetuses in the Uterus

Domestic animals may be divided into two groups with respect to the number of ova normally released at the time of ovulation and therefore the number of fetuses in the uterus.

Unipara, or monotocous animals such as the cow and mare, normally have one ovum released at ovulation and one fetus develop in the uterus. Occasionally twins or in exceptional instances triplets or greater numbers of fetuses may be present. This uniparous group of animals is characterized by the presence of a well-developed cervix. The placenta of the single fetus fills both horns and the body of the uterus. The weight of the fetus at the time of parturition is about 10 percent the weight of the postpartum dam.¹ In unipara the large size of the fetus and their long extremities, make dystocia due to wedging of twins in the pelvis quite common. Sheep are usually classified as unipara but the incidence of twins and triplets is so common that the term "bipara" has been suggested for this species.

Multipara or polytocous animals such as the bitch,

queen and sow, normally have 3 to 15 or more ova released at each ovulatory period and although an embryonic mortality of 20 to 40 percent commonly may occur during early gestation in these species, usually more than two fetuses are present in the uterus. In unusual cases multipara may have only one viable fetus. In general multipara have a poorly developed cervix. The placenta of each fetus is limited to a portion of the horn. The fetuses are nearly equally distributed between the horns. The fetal membranes of one fetus rarely extend through the body and into the opposite horn. The weight of each fetus at the time of parturition is only 1 to 3 percent of the postpartum weight of the dam. The small size of the fetus and its short extremities make it more bullet-shaped. Dystocia due to wedging of the fetuses in the pelvis at parturition is rare. The average numbers of fetuses usually present in the uterus of multipara are as follows: sow 6 to 12; bitch, variable between breeds, large 6 to 10, medium-sized 4 to 7, and small bitch 2 to 4; and queen 3 to 5.

Females that have never conceived or carried young are called **nullipara**. Those that have conceived and have had only one gestation period are called **primipara**. Females that have conceived two or more times and had two or more gestation periods are called **pluripara**.

Twinning and Multiple Births in Unipara

When an uniparous animal aborts or gives birth to two or more fetuses or young they are called twins, triplets, quadruplets, quintuplets, or sextuplets.

In the mare the incidence of twin births is about 0.5 to 1.5 percent.^{1,4} Double ovulation, based on slaughter specimens, occurred in 4 to 40 percent of the estrous periods of mares.^{1,6,45} Triple ovulations were very rare. Many double ovulations occurred on the same day but the time between ovulations varied from 2 to 5 days. There was a tendency for certain mares to have double ovulations. Possibly increased nutritive intake or "flushing" as in ewes may promote multiple ovulation in the mare. Double ovulation in ponies was uncommon. Although nearly all twin equine pregnancies are of the fraternal or dizygotic type rarely an identical or monozygotic twin pregnancy is observed with a single allantois chorion, two separate amnions and with both fetuses of the same sex and markings.¹³ The incidence of triplets in mares is reported as about 1 to 300,000 single births.

In 95 percent of mares with twin ovulations one or both embryos were apparently resorbed or aborted during the embryonic period.^{23b,28} The few surviving twin embryos were usually bicornual. Between 7 and 9 months

of gestation in twin pregnancies abortion is common. A report on Thoroughbreds revealed that 64.5 percent of known twin pregnancies resulted in abortion. Only 25 percent of 124 twin fetuses were viable at birth and only about one-half of these survived to two weeks of age.³³ Of 403 parturitions in 102 draft mares 13 twin pregnancies were recorded.⁵ Nine of these twin pregnancies resulted in abortion or death of the fetuses. In two twin births both twins survived and in the other two only one twin survived. In another study 14 of 17 (82 percent) of observed twin abortions occurred between 6 and 11 months of gestation.^{23b} But 7 of 24 (29 percent) of twin pregnancies resulted in the birth of live foals.

The high in-utero death rate of twins in mares is reported to be due to a competition between the twin fetuses for placental area.^{19,33} Although the chorions may fuse, anastomosis of the blood vessels does not occur. One chorion invaginates into the other. In time the smaller severely growth-retarded fetus dies due to a lack of nutrients and may rarely mummify and remain in the uterus with the normal twin until parturition. Usually when the smaller fetus dies both twins are aborted. In late gestation the expulsion of a dead twin may be accompanied by the premature birth of the larger twin. Rarely are both twins of equal size and viable at birth. (See Abortion in Mares.)

In ewes and does the incidence of twinning is greatly influenced by the nutritional status of the animal at the time of ovulation as well as the hereditary background of twins in the breed. Of nearly 60,000 sheep in Sweden of different breeds 45 percent of ewes had twins; 2.3 percent, or 1 in 50 had triplets, 0.1 percent, or 1 in 1,000 had quadruplets and 0.009 percent, or 1 in about 10,000, had quintuplets.³⁴ Under favorable conditions 60 to 70 percent of adult sheep may have twins, 25 to 30 percent triplets and 2 percent quadruplets.^{1,2} As low as 2 percent twins are reported as occurring in certain breeds and under less favorable environmental conditions. Primiparous ewes bear twins and triplets much less often than do pluriparous ewes. Finnish Landrace sheep normally produce 2 to 4 lambs per pregnancy and larger numbers are not uncommon. These have been imported into the U.S. for crossbreeding purposes.

In goats about 63.3 percent of births are of twins.¹¹ In a report from the New York State Conservation Department (1949), the northern mountainous wooded Adirondack region of the State had a deer herd producing 4 young per 100 female fawns and 93 young per 100 does. In the southern part of the State, where much more feed was available, the deer herd produced 38 young per 100 fawns and 161 young per 100 does. This clearly illustrated the effect of nutritional and environmental

conditions on the rate of reproduction of deer in the same State. Monozygotic twins in sheep are uncommon.^{2,50}

Monozygotic or identical twinning probably occurs in cats but positive evidence is lacking even when two littermates are found in the same placental sac, synchorial embryos or fetuses. Queens are commonly polyovular having 2 or more ova in a single ovisac or follicle.^{10b}

In cattle multiple births have been the subject of much study.^{5,8,9,7,27,40,48} Records on over two million births in dairy and beef cattle showed the incidence of twinning was 1.04 percent or 1:96 single births in dairy cattle, 1:87 in humans, and about 0.5 percent or 1:227 single births in beef cattle. A recent summary of many studies on twinning in cattle confirmed these earlier reports and indicated a breed difference in the incidence of twinning.⁴⁸ The frequency of multiple births in dairy cattle may be estimated as follows.⁵

Twins	1 to 96 single births
Triplets	1 to about 7,500 single births
Quadruplets	1 to about 700,000 single births
Quintuplets	1 to about 60 million single births

Thus in the U.S. about 200,000 twin calves, 2,000 triplets and 30 sets of quadruplets are born each year. From data on nearly 750,000 beef cattle the ratio of triplets was 1:106,979 and quadruplets 1:748,855 births.

Twinning is to some extent a breed characteristic.^{8,9} The incidence of twinning in about 33,000 dairy cows in the U.S. in 1957 was 2.58 percent with 8.85 percent for Brown Swiss, 3.08 percent for Holsteins, 2.8 percent for Ayrshires and 1.95 percent for Guernseys. In 1978 in over 21,000 cows the incidence (percent) of multiple births in the dairy breeds was 4.08 for Brown Swiss, 4.75 for Holsteins, 2.33 for Guernseys, 2.62 for Ayrshires and 1.83 for Jerseys.^{7,40} Thus the larger breeds have a higher incidence of twinning. Also twinning increased from 1.05 percent for Holstein heifers to 6.18 percent in cows in third and greater parities. The better fed older cows are more likely to double ovulate and maintain a twin pregnancy. The twinning rate for Holstein heifers in another study was 1.3 percent, at the second calving it was 4.4 percent and it rose thereafter to 7 percent at 10 years of age.¹⁷

A high incidence of infertility has been associated with double ovulation in cows, as in mares.⁶ In a total of over 600 bovine ovulations 13.1 percent had double ovulations but the incidence of twinning was only 1.92 percent.³⁵ Many multiple conceptions terminate early in the gestation period in embryonic death and absorption, and later in abortion or premature birth. A study reported that 90 percent of bovine twin pregnancies were bicornual and 10 percent were unicornual.¹⁸ This is probably a reflection of a higher embryonic death rate in unicornual

pregnancy after double ovulation on the same ovary since 66 percent of double ovulations should by chance occur from one ovary.

The incidence of monozygotic or identical bovine twins and dizygotic or fraternal twins to all twins was 4 to 6 percent and 93 to 95 percent, respectively.^{5,9,6,27} The incidence of monozygotic bovine twins to all like-sexed twins was 8 to 12 percent or about 10 percent. The incidence of monozygous twins to all cattle births was 0.05 to 0.3 percent. The incidence of monozygotic twins to all twins varied from 0.7 to 18 percent. Monozygotic twins arise from one fertilized ovum that divides into two zygotes in the oviduct or soon after entry into the uterus.^{42b} Dizygotic twins usually arise from the ovulation of two follicles, often one in each ovary, or rarely the rupture of a single follicle containing two ova.¹ Monozygotic twins may occur as members of triplet or greater multiple births. The higher the order of multiple births, the more likely the occurrence of monozygotic pairs.⁵ Monozygotic twins are of value in many types of nutritional, physiological and behavioral experiments in which animals with the same genetic makeup are desired for the evaluation of different environmental factors. Monozygotic twins have similar characters in respect to color, color pattern, number of teats, topline, tail, hair whorls, muzzle pattern, etc. They are always of the same sex and have the same blood type. Skin or organ grafts survive for an indefinite period when exchanges are performed between monozygotic twins.

Dizygotic or fraternal twins bear no greater resemblance to each other than do full siblings. Dizygotic twins have different blood types that frequently show blood chimerism due to early anastomosis of the placental vessels of the two twins and the exchange of primitive erythrocytic cells that become established in both embryos.^{52,53} From information based on a study of freemartinism approximately 90 to 92 percent of all bovine twins develop placental anastomoses.⁵⁷ In 21 cases studied all 9 unicornual twins developed placental anastomoses. Hemoglobin and transferrin characters in blood also showed chimerism. Thus the study of immunogenetics is of value in the diagnosis of freemartins.

Immunogenetics is the branch of genetics concerned with the inheritance of antigenic and other characters, especially blood factors, relating to the immune response. Rapid advances in this science have been made in recent years. In domestic animals the most study and progress has been made in cattle where blood typing using 80 different reagents,^{7c} about 50 routinely, has contributed significantly to the artificial insemination industry. Blood typing can usually solve problems of questionable parentage in nearly 100 percent of cattle

and 95 percent of horses by eliminating animals that are not the sire or dam of a particular individual. On the basis of 1347 parentage tests 20 percent of cows bred artificially to two different sires at 1 to 11 day intervals became pregnant on the first service while 6 percent of cows conceived on the first service when bred twice at 15 day intervals.⁴ Thus blood typing for determining parentage should be performed when a cow is bred to two different sires at an interval of 16 days or less or when the gestation length is 8 to 10 days shorter than expected on the basis of the date of the last service or when the identity of the sire is in doubt. If the sire has been blood-typed, samples from the offspring and dam when typed will invariably reveal whether the sire is, or is not, a parent of the offspring.

Immunogenetics has proven useful in the study and identification of monozygous twins and nonchimeric or chimeric dizygotic twins and freemartins by means of blood factors. It has even aided in the discovery of chimeric animals born as a single fetus where the other "twin" was lost, aborted, or mummified. In recent years electrophoretic studies of serum proteins and transferrin types in blood and the use of tissue transplants or grafts have expanded the scope of this field.^{5,6,7,8,9,10} Studies have been made to see if certain blood characters are related to other desirable or undesirable traits in cattle to aid in early selection or elimination of animals. At present there appears to be little evidence of progress in this area.

All dairy bulls used artificially and purebred stallions of a number of breeds (Thoroughbred, Morgan and others) in the United States must presently be blood-typed to facilitate the accurate determination of parentage. Blood typing in horses is practical and with the present number of reagents parentage determination was satisfactory in practically all cases.^{1a,b,c,2b,7b,c,10} The current status of blood-typing in horses, with special emphasis on the Thoroughbred horse, has been recently reviewed.^{1a,b,c,2a,b} Presently there are 16 different blood antigens and serum proteins that are available for the determination of parentage or identification. In recent years an equine lymphocyte antigen (ELA) system with 10 initial specificities has been developed similar to the HLA system in man that may be incorporated with the former tests in the future to increase the accuracy of blood-typing of horses. A number of breed registries are presently blood-typing stallions and are considering blood-typing mares and all foals. An excellent review of blood groups in the larger domestic animals was compiled in cattle, horses, sheep and pigs.^{7b,c,8}

The study of canine blood groups has indicated that most cases of hemolytic disease in newborn pups is associated with type A positive pups and A negative dams

immunized against type A blood.¹¹ With further work and the development of more reagents greater accuracy in parentage determination will be possible. More immunogenetic studies in these and other species of animals will undoubtedly be made in the future.

A developing area of immunogenetics that shows promise of being highly informative is the study of transplantation or histocompatibility antigens that are co-dominant and inherited in a Mendelian fashion.^{1a,b,c,2a,b} One group of genes that codes the strongest for these antigens is located at one point on one of the chromosomes. It is called the major histocompatibility complex or lymphocyte antigen system. Because of the extreme polymorphism of the major histocompatibility complex (MHC), it will doubtless be of use as an adjunct to current methods of parentage determination, such as red blood cell typing. It may eventually replace those systems by virtue of its greater discriminatory ability. Furthermore because MHC has been shown to control immune response genes in laboratory animals and man, there are implications for selection of resistant genes in the MHC in domestic animals in the future in areas of disease resistance, avoidance of allergic conditions and possibly in certain infertility problems.

A **freemartin** is an infertile female with a modified genital tract born cotwin, or in greater multiples, with a male with which it has exchanged whole blood.³ In a summary of reports on 348 unlike-sexed twins, 91.4 percent of the female twins were sterile and the other 8.6 percent were fertile.⁵ Thus out of 10 to 12 females cotwin to bulls only one is fertile.⁵ This infertility is of importance and interest from both the economic as well as the scientific viewpoint. The freemartin is one of two dizygotic individuals that are of different sexes and do not resemble each other. Two corpora lutea are invariably present in the ovaries. Judging from statistics on sex ratios the freemartin should be a female. There is rarely any sex intergrading between the freemartin and the male. Freemartins have been proven to be genetic females as they are positive for sex chromatin (Barr) bodies and their tissue cells have a female, XX, karyotype.^{29,42}

The development of the freemartin condition occurs when the blastodermic vesicles from each developing zygote meet and fuse in the uterus about day 18 to 20 of gestation.^{3,5} By the time the embryo is 28 days old the allantois chorion and blood vessels of the two placentas have united. This occurs well before sexual differentiation, which takes place about the 30-mm. stage or about 40 to 50 days of gestation.

Lillie (1916) originally proposed that the interstitial cells of the testes of the male developed earlier than the

female ovaries and secreted an androgen that reached the female embryo by way of the anastomosing blood vessels in the placenta and this inhibited the development of the female gonads and genital tract.³⁸ This theory has been modified by recent research to show that the H-Y antigen of the male fetus governs the development of initially indifferent gonads of the female twin toward the male mode and subsequent androgen and antimüllerian hormone produced by the gonads of the male twin and possibly the freemartin, suppress the development of the uterine tubes, uterus and cephalic portion of the vagina and promote the development of mesonephric duct remnants such as the vesicular glands^{14a, 16, 30, 43a, b, 44a, 57b} (See Chapter III on Intersexuality) (See Figures 55 and 56).

In the "pseudohermaphroditic" freemartin the "ovaries" usually fail to develop and remain small, about the size of a flattened barley grain, and undifferentiated. In rare cases some differentiation toward the female or male gonad may occur. There was no relationship between the degree of abnormality of the genital tract of the freemartin and the number of XY lymphocytes in the blood. In both the freemartin and the bull cotwin the numbers of these cells in the blood varied from less than 5 percent to more than 95 percent.^{16, 39} The vulva is fairly normal except for the occasional presence of a prominent clitoris and a large tuft of vulvar hair. In the yearling animal,

Figure 55. Freemartin genital tract. Note rudimentary uterine horns, grain-sized gonads, lack of cervix and remnants of vesicular glands (mesonephric duct structures).

Figure 56. Clinical diagnosis of a freemartin. Note a normal vagina is lacking. (Courtesy M. G. Fincher.)

no estrous cycles occur; the udder and teats remain very small and the animal's external characteristics resemble a steer.

For a definitive diagnosis of the freemartin condition Fincher²¹ advised that a 3/8- to 1/2-inch test tube or glass speculum be inserted with lubrication into the vulva of the "heifer" in question (See Figure 56). If the animal is a freemartin the tube will insert no farther than the caudal portion of the vagina or about 7.5 to 10 cm. in a young calf, as there is no normal vagina. If the female is normal some resistance may be encountered when the test tube passes through the vulvovaginal region. But it then will pass 5 to 7 inches into a freely dilatable vagina and the use of a light will reveal a normal small cervix. In the freemartin the usual vaginal opening cannot be found anterior to the urethral opening on the floor of the vulva. A possible chance for error in this technique is in rare heifers with an imperforate hymen. After the freemartin becomes 8 to 14 months of age, a rectal examination is possible. This reveals the marked arrest in the development of the vagina, cervix, uterus, and gonads. Usually these structures cannot be found on rectal examination or they are extremely small. Pseudohermaphrodites may be mistaken for the freemartin condition. In these cases further careful in-depth diagnostic, cytologic, histocompatibility and other tests might be indicated.

In rare instances a typical freemartin may be born as a single calf. This individual was probably cotwin to a male fetus that died *in utero*, mummified and was ex-

Figure 57. XX and XY white blood cells from a chimeric bull, cotwin to a freemartin. The chromosomes are in metaphase. (Courtesy of H. O. Dunn.)

pelled unobserved in the fetal membranes. Fertile, chimeric, heterosexual twin bovine females have been reported.^{43b} In these cases choriovascular anastomosis probably occurred after the differentiation of the ovaries and genital tract.

Most bovine twins are blood cell chimeras because of early placental vessel anastomosis. Of 74 pairs of heterosexual twins 89.2 percent had erythrocyte chimerism including 12 freemartins and their bull cotwins. None of the 8 females born cotwin with bulls and not having erythrocyte chimerism were freemartins.⁵¹ The percentage of heterozygous twins that would tolerate reciprocal skin grafts was the same as the incidence of freemartins indicating that the early transfer of blood elements between the fetuses caused the development of tolerance.⁴ About 90 percent of unlike-sexed twins have XX/XY white blood cell chimerism (See Figure 57).^{15,16,20}

Male chimeric cotwins to freemartins are usually considered to be fertile. However recent studies of chimeric bulls in artificial insemination studs showed that the number of XX lymphocytes in blood of these bulls varied from 5 to 95 percent. Seven of 12 chimeric bulls

(58%) were culled because of poor quality or no semen compared to less than 6 percent of 128 single-born bulls. The reasons for the poor reproductive performance in many of the chimeric bulls was speculative.^{14,15,16,49} In early cytogenetic studies a few authors reported finding XX cells in the testes of young calves.⁴⁴ Since then no such findings have been reported in male calves or mature bulls cotwin to freemartins.¹⁶ Further studies are indicated.

Freemartinism is rare in other domestic species of animals but probable cases have been reported in sheep, pigs and goats.^{1,5b,23,31,39} The chorions of twins or greater multiples in these species often fuse but anastomosis of blood vessels is apparently rare.

The Undesirable Nature of Twinning in Mares and Cows

Multiple births or twinning in the mare and cow is generally considered undesirable since it often results in an economic loss. The abortion rate of twin fetuses in

horses is exceedingly high, over 90 percent. After viable twin births in mares usually less than a quarter of the foals survive and these frequently require careful nursing care.

In cows the abortion rate for twins after 3 months of gestation is much greater than for single fetuses. It is estimated that 30 to 40 percent of such twin pregnancies terminate in abortion.^{5,17} In normal single pregnancies only 3 to 5 percent end in observable abortions. Another study revealed a 13.1 percent incidence of double ovulations in a herd but only a 1.92 percent incidence of twin births. This was potentially an 85 percent loss of twin zygotes.³⁵ A 35 to 41 percent death loss of embryos in ewes with double ovulation on one ovary and only a 22 to 26 percent loss with a single ovulation⁸ underscore the high embryonic losses associated with multiple ovulations in uniparous animals, especially in double ovulations from the same ovary even in sheep where genetic selection has favored twin and multiple ovulations and pregnancies.⁴⁸

Many twin pregnancies in unipara terminate prematurely. The duration of gestation for bovine twins is an average of 5 days shorter than for single calves.^{5,7,48} Male twins were carried 1 to 2 days longer than twins of both sexes, and 3 to 5 days longer than female twins. The incidence of abortion and premature birth is even higher in triplets and greater multiples. Fewer fertile female progeny are associated with twinning in cattle than with single births because male and freemartin calves comprise about 65 percent of twin offspring.¹⁷

Viable twins are of smaller size and vigor than single young. Single bovine males weigh 25 to 45 percent more than twin males, and single females weigh 30 to 50 percent more than twin females.^{5,7} This reduced weight of the individual twin is possibly due to a reduced amount of available nutrients for each fetus, and to the shortened gestation period. The combined weight of both twins is usually 35 to 40 percent greater than that of a single calf. A much higher percentage of dead fetuses are expelled at term in twin births than in single pregnancies. About 5 percent of twins are expelled dead at term, compared with 0.9 percent for single calves. In addition about four times as many twins die at a young age than do calves born singly.^{5,8,9,7}

Following twin births or abortions, delayed uterine involution, retained placenta, septic metritis, and temporary or permanent sterility are common. Retained placenta occurs in about 50 percent or more of twin calvings, 5 to 10 times more frequently than in single births. The placental retention is probably due in most cases to the abbreviated gestation period, to a prolonged parturition, and to a delayed involution of the uterus.¹⁷

Many authors cited evidence to show that the calving interval especially in dairy cattle, following twinning was definitely prolonged over those preceding the twin pregnancy⁹ due to greater infertility associated with retained placenta, postpartum metritis and other factors. In beef cows nursing two calves, a delayed return to postpartum estrous cycling usually occurs. The mortality in dams following twin births is higher than in single births.

The incidence of dystocia at the termination of twin pregnancy is also much greater than in single births even though the fetuses are smaller.⁷ This is due to various causes including: the atonicity of the distended uterus; the frequent presence of a dead, flaccid fetus; the wedging of the extremities of bicornual twins in the pelvis; and the frequent occurrence of posterior presentation in one of the twin fetuses.

In dairy cows decreased milk production and an increased number of days open after the calving probably associated with the postpartum metritis and other disease factors, may follow twin pregnancy.^{7,9} If twin births are not associated with disease factors, increased milk production often results.

Twins are uneconomical for herd replacements since half the pairs consist of male and female and 91 percent of these females are sterile. The male calf may be normal or have reduced fertility, but in most dairy herds these male calves are sold for veal. In beef herds this latter factor is not important. The advantages and techniques for increasing the numbers of twins have been studied in beef herds with the goal of producing more beef per cow unit.³⁷ Neither selection, hormonal induction nor embryo transplantation (inovation) have proven practical. Furthermore the behavioral response of beef cows having twins under range conditions requires further study.^{2,48}

Induction of twinning in beef cattle was accomplished by embryo transfer bilaterally, an embryo placed in each horn, and unilaterally by transfer of an embryo five days after natural service into the horn contralateral from the ovary containing the corpus luteum.^{2b} The twin pregnancy rate at 45 days of gestation was 71 and 66.6 percent and the twin calving rate was 50 and 41 percent in 35 cows and 39 heifers, respectively. The incidence of dystocia was the same, 20 percent, for the beef dams producing twins or single calves but the incidence of retained placenta was higher 14 percent and 0 percent, respectively. Calf loss was slightly higher in twin births. Thus twinning in beef cattle may have less contraindications than in dairy cattle.

For the above reasons it does not appear that selection, hormonal treatment programs, or embryo transfer procedures to promote twinning in the dairy or beef cow or

mare is presently either economically feasible or desirable.^{7,9} However, dairy cows having twins had a higher production of milk, except possibly the lactation following pathologic twin calvings, thus favoring their genetic selection by dairymen. This should result in a rise in the incidence of twinning as indicated by a rise from 2 to 3 percent to 4 to 6 percent in twinning in a short period of time in New York State.^{6b,21b}

Causes of Twinning

The causes of multiple births should be noted so that possible means to prevent this generally undesirable occurrence may be considered. The causes of twinning in uniparous animals may be divided between those which are environmental and those which are hereditary.

Environmental causes of twinning that have been reported include: **Age of the dam**—It is well known that in sheep, cattle and humans the incidence of twinning in the young is low and increases with age until senile changes commence, at which time the incidence again is lowered.^{17b} A twinning frequency of 1.3 percent for first calvings, 4.4 percent for second calvings and then a gradual rise to 7.1 percent for the tenth calvings was reported.¹⁷ Other workers^{5,7,36,48} similarly reported that in cattle there is a consistent rise in multiple births up to 5 or 6 years of age. This rise levels off and then drops after 8 to 12 years of age.

Significantly increasing the plane of nutrition; "flushing" in ewes, does and sows for several weeks prior to breeding has been shown to increase the number of ova ovulated in mature females previously kept on a maintenance or marginal level of feed intake. Such a practice in cows has not been practiced to produce an increase in twinning. However a high plane of nutrition in dairy cows has been associated with an increase in the incidence of cystic ovaries and subsequent twinning. **Sires**—The immediate influence of sires on the production of twins is limited to monozygotic twins, a small percent of the total number of twins. **Injections of gonadotrophic hormones**—Increased ovulation rates or superovulation by the injection of one or two doses of pregnant mare serum gonadotrophin (PMSG) or daily injections of purified pituitary gonadotropin (FSH and LH) starting about 10 or 12 days post estrus and removing the corpus luteum manually or preferably by the injection of prostaglandin 2 to 3 days after the first administration of a gonadotropic hormone usually results in estrus and superovulation by 15 to 17 days post estrus (See Chapter on Embryo Transfer). However because of variations in the individual cow's response to gonado-

tropins, the number of ovulations cannot be controlled.³⁷ Conception rates at 60 days where 2, 3, 4 and 5 to 6 ova were released were 55.3, 48.7, 29.2 and 25.0 percent, respectively. Low conception rates were frequently observed when superovulation was confined to a single ovary. Superovulation and conception results were unpredictable and in general not highly satisfactory. Usually only about 25 to 30 percent of treated cattle had twin or triplet births.^{24,25,26,32,37,41,54}

Although the numbers of fertilized zygotes in an animal may be greatly increased by hormonal means (superovulation) or by embryo transfer, such an increase does not result in greatly increasing the number of offspring at birth either in uniparous or multiparous animals. The uterus apparently has a mechanism whereby it can and does limit the number of embryos or fetuses that will survive beyond the first few months of gestation. Although uterine capacity varies between species and breeds, it obviously plays a role in controlling the number of offspring at birth. But since most of the limiting action occurs early in gestation while the uterus is still relatively small other limiting physiologic mechanisms apparently exist. At present these latter mechanisms are not known.^{55,56}

The hereditary basis for twinning has been reviewed,^{5,17} and has been established by records of breed differences, differences between herds, sires, and families within a breed, the repetition of multiple births in the same cow, and the effect of inbreeding on the incidence of twinning.^{5,17} **Breed differences**—The incidence of twinning in beef cattle is low which may be an indication that twinning in dairy cattle is related to the high production of milk, high nutrient intakes, and to the pituitary deficiencies associated with abnormalities of ovulation, such as cystic ovaries. In the dairy breeds the incidence of twinning is highest in Holsteins and Brown Swiss, with Guernseys intermediate, and with Ayrshires and Jerseys the lowest.^{5,8} **Differences between dams, sires and families**—A herd incidence of twinning may reach 10 to 20 percent as against the overall average of 2 to 8 percent.⁵ Dizygotic twinning is affected more by inheritance than is monozygotic twinning. In one study 2.65 percent of a bull's 377 offspring were twins; but in his daughters that produced 360 calves sired by other bulls, twins occurred 9.17 percent of the time. Thus the hereditary tendency for twinning was passed by the sire to his daughters.⁵ In a large herd of Holsteins 313 multiple births, 4.2 percent of 7387 calvings, were reported. Fourteen percent of 1905 cows produced twins at one or more calvings.¹⁷ Daughters of twinning cows had twins significantly more frequently than daughters of nontwinning cows, 17.4 percent and

13.0 percent, respectively. It was also demonstrated that the sire contributed to the twinning tendency of his daughters.¹⁷ The frequency of twinning in certain cow families has been observed by many veterinarians, farmers, and research workers. In another herd, 10 of 21 families comprising 90 percent of the dairy had no twins. The other 11 families had an incidence of twinning ranging from 2.6 to 18 percent.⁵ **The repetition of multiple births in the same cow** is principally a tendency for multiple ovulation. After the first multiple birth the frequency of succeeding multiple births was 8 to 12 percent. **Cystic ovaries**—This pathological condition, occurring usually in high-producing cows during their peak of lactation, has been associated by many workers with twinning. Although cystic ovaries are associated with high production and heavy feeding in cattle, no reports or studies have been made on the effect of a high versus a low plane of nutrition on the incidence of double ovulation in cattle. Conceptions occurring soon after recovery from cystic ovaries resulted in a high percentage of twins.^{10,12} At that time recovery was spontaneously aided by repeated removal of the cysts by manual pressure. It has been observed by the author that cows treated with luteinizing hormones and bred the following heat period did not have the high incidence of twinning noted in the former study although an increased incidence of twinning should be expected in individuals with a tendency toward ovarian cysts. Another report noted an incidence of 12.9 percent multiple ovulations in cystic parities as compared to 4.2 percent in noncystic parities.³⁶ A further study¹⁷ showed that 15 percent of cows that conceived within 75 days after treatment for cystic ovaries had twins compared to 4.9 percent of the cows conceiving 75 or more days after therapy for cystic ovaries. The condition of cystic ovaries is hereditary and bulls may transmit this tendency to their daughters.^{22,46}

In herds where selection for twinning was followed, the incidence rose to 10 to 20 percent. These facts show that twinning is definitely influenced by heredity. It might even be possible to postulate that twinning was caused by a simple recessive character with modifying genes

and environmental factors that could influence its expression.¹⁷ With the increase of artificial insemination in dairy cattle and the rise in production of milk per cow, that has been shown to be closely associated with an increased incidence of cystic ovaries, the problems arising from twinning will probably become greater. This is further complicated by the generally successful treatment of cystic ovaries with gonadotropic hormones that allow cows with this inherited tendency to produce many daughters who may also be affected. There is need for further research to see to what extent the hereditary tendency toward cystic ovaries is related to the hereditary tendency toward twinning. If twinning is a serious problem in a herd, involving 10 percent or more of the cows, an older sire with a low percentage of his daughters producing twins or a son from this bull from a family free of twins should be selected as a herd sire.

There is no evidence on the heritability of twinning in horses, although twin-prone mares are often recorded. The heritability of multiple birth in sheep was reported to be rather low,⁴⁷ except in certain breeds and their crosses such as the Finn sheep. The repeatability of twinning in ewes in another study was high and amenable to selection for improving reproductive efficiency.⁴⁸

Sex Parity

Sex parity or the sex ratio is usually expressed as the percent of male births; in older references the complete ratio of males to females was given. From a theoretical genetic basis the union of a haploid, X, ovum with either an X or Y haploid sperm cell should produce 50 percent males. Records of large numbers of animals approximate this theoretical percentage. The primary sex ratio is determined at conception. The secondary sex ratio in domestic animals expressed as percentage of males at birth is shown in Table 6.^{1,8,11} Another study provided essentially the same figures.¹⁴

On a basis of 197,936 births cited by different workers on cattle, the sex ratio of calves averaged 51.12 percent

Table 6. Secondary Sex Ratios in Domestic Animals
(percent males at birth).

Horse	49.9	Ass	48.6
Cow (<i>Bos taurus</i>)	48.6–51.5	Goat	50.1–51.3
(<i>Bos indicus</i>)	50.5–51.1	Man	50.5–51.3
Guernseys	44.4	Dog	50.4–55.9
Sheep (All)	48.3–51.0	Hybrids—Jack X Mare	44.4
Merino	46.8		
Pigs	48.5–51.9		

males with variations from 42.6 to 53.7 percent because of the low numbers of cattle in some reports.⁵ In about 200,000 bovine births in the Netherlands there were 50.6 percent male calves. Fifty-six percent of abortions were male calves and at parturition 7.9 percent of males and 4.8 percent of females were stillborn.³ A healthy beef herd of high fertility at branding time had 94,436 calves, with a sex ratio of 51.1 percent males.¹² The variations from approximately 50 percent are highly interesting but not explainable at present. The age of the dam or the sire and the season of the year had no effect on this ratio. Most workers agreed that there is a much higher percentage of males at conception in domestic animals and man than at birth.¹¹ On the basis of sex chromatin studies of human fetuses obtained at lawful abortions, sex ratios at 6, 10 and 14 weeks of gestation were 89, 68 and 58 percent males, respectively.⁹ The sex ratio of fetal calves, of 5 to 10 cm., 11 to 20 cm. and 81 to 90 cm. crown-rump length were 66, 56 and 50 percent males, respectively.⁵ In another study significantly more, ($P < .01$), male bovine fetuses were present prior to 100 days of gestation.⁷ A higher percentage of males than females are conceived, absorbed, aborted, expelled dead at term, or present in dystocia.¹¹ Of 11,527 calvings in range cattle 397 fetuses were expelled dead, 59.5 percent of these were males.⁶ This is further illustrated by sex ratios in multiple births, in which there apparently is an increased intrauterine mortality of males. The sex ratio in cattle for single births is 51.1 percent males, for twins 49.1 percent, for triplets 47.6 percent and for quadruplets and quintuplets about 45 percent. The sex ratio for premature twin births in cattle was 52.7 to 53.7 percent males.⁵

Occasionally claims are made that certain specific and intentional procedures will influence the sex ratio. One of these early claims which received wide publicity was the altering of the pH of the vagina before service. These claims are usually premature and false. With the widespread use of artificial insemination many further experiments have been conducted in efforts to separate the Y-bearing spermatozoa from the X-bearing spermatozoa by electrophoresis, centrifugation, sedimentation and other techniques.^{4,10} It is known that the amount of DNA in the Y-bearing sperm cell is less than that in the X-bearing cell. These experiments have not been successful. There is no basis that beliefs such as prolonged storage of semen, breeding at certain times during estrum, using young or old males, age of cow or season of breeding, and others have any effect on the sex ratio.^{2,8} Since physical and chemical techniques were unsuccessful in manipulating the sex ratio possible genetic variations in sex ratios was reviewed.¹⁰ Evidence for a hereditary basis for alterations in the sex ratio of domestic animals

was not found. A study of XX/XY chimeric bulls cotwin to freemartins did not reveal any bulls that sired a significant excess of female calves, although a few bulls cotwin to a freemartin produced an excess of female calves in a limited number of breedings (See Dunn et al. (1979) under Freemartins). The number of animals used in an experiment to alter the sex ratio should be considered; this number should be very large for the substantiation of any such claim.

The Bacterial Flora of the Pregnant Uterus

Although the literature reveals an apparent controversy on this subject, practically all workers agreed that from 20 to 80 percent of pregnant bovine uteri have some bacteria between portions of the maternal and fetal placentas, in the uterine cavity or in the organs of the fetus.^{12,12} Many pregnant uteri are bacteriologically negative. Although this may be ideal, it apparently is not essential for a healthy normal gestation and parturition. A careful examination of almost all placentas will show a few areas where some pathology or disease process, either acute and active or chronic and inactive, is present. The organisms most commonly found are streptococci, staphylococci, and coliform bacilli. Many other bacteria, molds, and viruses have been reported. These organisms gain access to the uterine cavity and placenta by way of the cervix and the caudal portions of the genital tract at the time of estrum and service, are still present from the time of a previous parturition, or they may come from the blood stream of the dam and localize in the uterus. During most of the gestation period in domestic animals, the uterus and uterine endometrium is under the influence of progesterone from the corpus luteum or placenta. During the estrual cycle the uterus of the cow is resistant to infections at the time of estrum when under the influence of estrogens, and more susceptible to infection during the rest of the cycle when the uterus and endometrium are under the influence of progesterone.^{2,13} It is possible that the favorable environment produced by progesterone, necessary to maintain pregnancy in domestic animals, may favor the establishment of infections in the gravid uterus.

The above findings may indicate to some that the presence of bacteria is of itself dangerous or harmful to the pregnancy. This is not necessarily true. One might liken the condition to an internal parasitism where a few parasites, particularly nonpathogenic parasites have no effect on the individual. It is only when the individual's resistance is overcome or an excessive number of virulent "parasites" are present that the condition reaches

disease proportions with definite symptoms and extensive pathology. It is difficult to delineate between health and disease. Slight to definite infection and evidence of disease of the placenta may be present in an apparently physiological birth. In the more severe infections greater damage to the placenta and endometrium may produce fetal deaths, maceration of the fetus, abortions, premature births, dystocia, retained placentas, septic metritis, and subsequent sterility. These latter diseases may be associated with the lowering or lack of resistance of the dam or the fetus; previously undiagnosed damage to the endometrium; and the type, pathogenicity, virulence and numbers of organisms present during the various stages of gestation.

Although healthy, gravid uteri frequently have some bacteria present, the healthy, nongravid uteri does not have a bacterial flora. Most workers, find healthy non-gravid bovine uteri free of bacteria.¹² Judging from extensive work based on cervical and uterine cultures made during estrus, this is true in the normal healthy mare. A number of other workers have reported that infertile cows, or cows that have an obvious genital disease and have failed to conceive often may have infection and endometritis of a sufficient degree to prevent conception.^{4,12}

DURATION OF GESTATION

Many factors influence the duration of gestation. The length of the gestation period differs between the animal species, breeds and hybrids (See Table 7). In cows and mares male fetuses are carried one to three days longer than female fetuses.^{23,30} Male fetuses in cattle also weigh 2 to 10 lbs. more than female fetuses. Young cows in their first and second gestation periods carry fetuses one to two days less than older cows. It appears that calves born during the winter or spring have slightly longer gestation periods. Foals born from January through April have gestation periods about 5 to 10 days longer than foals born from May through September. When mares were exposed to 16 hours of daylight through the last half (December through April) of their gestation period, the length of gestation was reduced 10 days over control mares, 338 vs 348 days. This prolonged exposure to extended light had no effect on the fetus, foal size, hormonal levels or the postpartum period to ovulation.^{30b} Differences in gestation length between years may be as great as 6 to 7 days.^{30a} In rare instances, mares will have gestation periods up to 375 days in length, and even up to 400 days with a live foal being produced.^{30,33,41,50} Most studies indicated that the breed of the sire and dam has

an influence on gestation length in cattle, sheep, horses, hybrids and pigs (See Table 7).^{4,5,6,14,30,31,46,49} The length of gestation is primarily a characteristic of the fetus and that by selection of male and female calves having a short gestation period the mean length of gestation could probably be decreased 10 days within three generations.¹⁴ Thus each individual fetus determines its own length of gestation.

In 290 normal pregnancies in Beagle bitches the mean gestation length was 65.3 days, range 57 to 72 days.^{12b} In 54 of 62 cycles in which the LH peak was accurately determined by radioimmunoassay and pregnancy occurred, the apparent gestation lengths ranged from 58 to 71 days with an average of 64.7 days. The interval from LH peak to parturition was less variable, 64 to 66 days, average 65.1 days. The first acceptance of the male for mating by the bitch usually occurs two or three days after the LH peak so this further confirms the 62 to 63 day mean normally given as the duration of gestation in the bitch.

Short gestation periods are often associated with abortions and premature births. The gestation period of twin fetuses in cattle is an average of 3 to 6 days shorter than gestation periods of single fetuses.³¹ In beef cows with multiple pregnancies following the administration of PMSG, the duration of pregnancy for single fetuses, twins, triplets, quadruplets and quintuplets was 280.8, 277.4, 269.2, 262.5 and 258.0 days, respectively.⁵⁸ A similar, but more moderate, reduction in the length of gestation has been observed in ewes and does carrying two or more fetuses.⁴⁶ Adverse disease factors influencing the health of the endometrium and placenta or infecting the fetus may cause abortion or short gestation periods. Besides infections these adverse influences may also include malnutrition, chronic debilitating diseases, deficiency diseases, starvation, severe stress or other conditions favoring or causing abortion or premature birth. Premature births in cows are those between 250 and 270 days of gestation, in the mare between 310 to 330 days, in sows between 105 and 110 days, in ewes between 130 and 140 days, and in bitches and queens between 52 to 58 days. Special care and supportive therapy is often necessary for these premature neonates if they are to survive and even then early deaths are common. A genetic involution of the corpus luteum of pregnancy associated with hyperplastic adrenal cortices resulted in abortion in inbred Angora goats.⁶⁰

Prolonged gestation periods are observed in a variety of conditions in animals³⁴ including:

- (1) Iodine deficiency in sows, or the administration of thiouracil to produce hypothyroidism, caused gestation periods 4 to 10 days longer than normal

Table 7. Duration of Pregnancy in Domestic Animals.*

Days			
Cow—273 to 296			
Aberdeen Angus	273 to 282		
Ayrshire	277 to 279		
Jersey	277 to 280		
Holstein	278 to 282

*The above data from various sources, including^{2,4,7,2,4,12b,18a,21,23,30,31,35b,41,46,48a,b}

with poorly viable, goiterous, hairless pigs.

- (2) Delayed parturition in sows, bitches, ewes and cows has been produced with large continued injections of progesterone or progestins. Most fetuses died in the month following a normal length of gestation and became macerated or mummified.^{8,36}
- (3) Ewes consuming *Veratrum californicum* about the 14th day of gestation, causing severe deformities of the face and head with hypoplasia or aplasia of the hypophysis, had greatly prolonged gestation periods of up to 230 days with fetal giantism and rupture of the prepubic tendon. Prolonged bovine gestation periods were associated with the ingestion of *Veratrum album* in Japan. The defective bovine fetuses were shortlimbed, semi-hairless and had an aplasia of the hypophysis.^{34b} Prolonged gestation in Karakul sheep in South Africa associated with giant fetuses has been described but the cause, possibly genetic in nature, is unknown.¹⁵
- (4) An inbred line of sows carried their fetuses 3 to 4 weeks overtime.¹⁰
- (5) Decapitation of fetuses during pregnancy resulted in overtime small, weak edematous fetuses with adrenals one-fourth to one-fifth normal size.^{11,38,57}
- (6) Destruction of the pituitary glands of fetuses by electrocautery at 90 to 142 days of gestation produced prolonged gestations.³⁹
- (7) In a number of cattle breeds three types of prolonged gestations have been observed:
 - (a) Prolonged gestation was seen associated with postmature, long-haired fetal giants in Holsteins and Ayrshires,⁶⁴ and in other breeds in which a homozygous recessive autosomal gene was involved. These postmature fetuses had long hooves; their incisor teeth were erupted and dehydration was evident. These calves had hypoplastic adrenals.^{17,31} In this condition the gestation was prolonged for 20 to 90 or more days and the fetuses weighed from 130 to 200 lbs. Vaginal delivery was impossible and severe dystocia resulted unless a cesarean operation was performed early. Affected calves had hypoglycemia and died shortly after delivery with an Addisonian-like syndrome characterized by marked adrenal insufficiency and possible anterior pituitary gland abnormalities. Following birth by caesarean section a continuous regimen of corticosteroids was necessary to maintain the life of the calf.
 - (b) Prolonged gestation is also seen associated with cretin-like, immature fetuses with cranial and

central nervous system anomalies, including hydrocephalus, anencephaly, or cyclopia and short, deformed loose-jointed legs with an aplasia of the anterior pituitary gland and a degree of hairlessness. The adrenal glands may be very hypoplastic or absent. These defective fetuses may be carried 20 to over 230 days overtime, average 120 days, and they are relatively small in size. Hydramnios is frequently present. If parturition commences dystocia may occur but is not a serious problem. It is seen most frequently in Guernseys, Swedish Red and White cattle and possibly Ayrshires. This anomaly is due to an autosomal recessive mode of inheritance.³⁵ (See Figure 33.)

- (c) The author has observed 4 Holstein calves with cerebral hernia, "catlin mark," a sloping forehead, a greatly reduced cranial cavity and abnormal brain, long hooves and hair, dystocia due to its excessive size after a prolonged gestation, 20 to 60 days overtime, and death before or soon after birth. (See Figure 29.) In one of these calves that was autopsied the adrenals were markedly hypoplastic. In a similar case⁹ the cerebellum was absent, the cerebrum was small and the pituitary gland was absent on gross examination, the calf weighed 130 pounds and was delivered by caesarean section on the 329th day of gestation.

In these last three conditions no prepartum or partum changes were observed at the time of expected parturition and the udder was undeveloped until after the fetus had been removed. Parturition does not occur unless the fetus dies *in utero*. As pointed out, no bonafide greatly prolonged gestation in a cow has ever produced a morphological or metabolically normal calf.³¹ Prolonged bovine gestations including endocrine levels in the dam and fetus were reviewed recently.^{16b}

In a recent study bilateral adrenalectomies on ovine fetuses were performed at 110 to 120 days of gestation. This resulted in prolonged gestations of 157 to 180 days. When only one of a pair of twin fetuses was operated on the normal intact fetus died *in utero* while the adrenalectomized fetus survived the prolonged gestation period but died at or soon after birth. Thus there is a good correlation between prolonged gestation in cows and ewes and abnormal anterior pituitary glands and adrenal cortices. Aplastic, hypoplastic or damaged pituitary glands of the fetus result in prolonged gestation. Hyperplasia of the adrenal gland with excess glucocorticoid production results in abbreviated gestation in goats.⁶⁰

Aplasia or severe hypoplasia of the adrenal gland, secondary to a pituitary deficiency, results in prolonged gestation in cattle. The control the fetus exerts through its pituitary-adrenal axis over the duration of gestation is obvious. This control is probably triggered by the release of ACTH from the fetal pituitary gland.³⁹

Premature birth of viable young can occur in the cow from about 240 to 270 days and in the mare from 310 to 320 days. Delayed births in cows are usually considered as gestation periods over 295 days, except for Brown Swiss and Brahman cattle, and in mares over 350 days. These figures are relative but are given because viable, apparently normal young may be produced, the parturitions be uneventful and the dams survive, over a wide range of gestation lengths.

The birth weight of newborn animals is closely associated with gestation length and other factors acting during the gestation period. In this area studies in cattle have predominated. The average birth weight of calves for the various breeds are as follows: Sindhi, 45 lbs; Jersey, 55 lbs; Aberdeen Angus, 60 lbs; Guernsey, 68 lbs; Africander, 71 lbs; Hereford, 72 lbs; Shorthorn, 72 lbs; Ayrshire, 73 lbs; Holstein, 92 lbs; South Devon, 100 lbs; Brown Swiss, 101 lbs. and Charolais, 105 lbs.⁴ Calves born to mature cows are heavier than calves from heifers. There is a positive correlation between the weight of the dam and sire and the calf. Season of the year at birth had little influence on the weight. Bull calves were generally 2 to 9 lbs. heavier than female calves. Most authors indicated the sire had a significant effect on the calf's birthweight. In general the longer a fetus was carried the greater the birth weight. Birth weight and gestation length are influenced by heredity and influenced more by the calf than the dam that carries the calf except possibly where breeds of great disparity in size are interbred. Single lambs at birth weigh about 7.5 percent of the combined weight of the dam and sire divided by 2. Individual twin lambs weighed 16 percent less than single lambs but their combined weight was 67 percent more than singles. The sire had little effect on the birthweight of lambs.⁵⁵ Boar pigs weighed 5 percent more than gilts at birth. This greater weight of male fetuses in domestic animals is probably a cause of dystocia in small primiparus females.

Hormonal Control of Gestation

The placenta connecting the fetus and mother provides best for the needs of viviparity.³ Because it is able to provide this protection, the mammal relies less on large numbers of eggs released and more on the survival of a

few young in order to perpetuate the species. During evolution the placenta has developed endocrine functions that allow a longer gestation period with the birth of young which are more mature and thus better able to cope with the external environment. In marsupials the gestation period is equal to the length of the estrous cycle, and removal of the ovary any time during pregnancy terminates the pregnancy. In the higher mammals such as the horse and primates the placenta tends to assume some of the endocrine control of pregnancy. Nervous control of the uterus is not essential during gestation in man and other animals. Conception, gestation, and possibly normal parturition can occur with complete paralysis and lack of nerves in the lower portion of the body. Gestation and the onset of parturition are entirely under hormonal control.

In the mare the fertilized ova pass into the uterus about six days after ovulation while unfertilized ova are retained and degenerate in the oviduct. This probably constitutes the earliest maternal recognition of pregnancy in domestic animals.

At approximately 12 days in the ewe, 13 days in gilts, 14 to 16 days in mares and 15 to 17 days in cows after estrum and fertile coitus, the trophoblast or blastocyst has grown very rapidly and brings about the maternal recognition of pregnancy. This is accomplished by the luteotropic secretions of the blastocyst that cause a persistence of the corpus luteum, a suppression of the uterine luteolysin or prostaglandin, and a cessation of the estrous cycle. The luteotropic substance produced by the blastocyst in the cow is composed of one or more heat labile molecules. In the pig estradiol, and in the mare estradiol and androgen, appear to be the major luteotropins produced by the blastocyst. However estradiol therapy will not stimulate progesterone production in bovine luteal cells.^{7,22,29}

In bitches and queens this early provision for promoting the attachment of the developing embryos is pseudopregnancy. In bitches which ovulate spontaneously, the corpora lutea that develop after every estrous period persist for about 60 days or the duration of gestation. In the queen, which requires mating or a similar stimulus to produce ovulation, the cause of pseudopregnancy is also ovulation and corpora lutea formation. The length of pseudopregnancy in the queen is about 40 to 50 days.⁶¹ The levels of progesterone in the feline blood plasma rise rapidly within 10 days of ovulation due to the formation of corpora lutea stimulated by the release of luteinizing hormone (LH) after coitus resulting in ovulation.

During pregnancy the progesterone from the corpus luteum or the fetal placenta is essential for endometrial

gland growth and secretion of uterine milk, for endometrial growth and attachment of the placenta for the later nourishment of the fetus, and for inhibiting uterine motility to aid in placental attachment. A certain amount of ovarian or placental estrogen appears necessary to enhance the effect of progesterone and in later pregnancy to produce udder development, relaxation of the pelvic ligaments, initial uterine tonus, cervical relaxation and to sensitize the uterus to oxytocin and prostaglandins. Other hormones essential in maintaining pregnancy are the gonadotropic or luteotropic hormones from the anterior pituitary gland necessary for the persistence of the corpus luteum and its active secretion of progesterone. In the mare gonadotropins (PMSG or ECG) are produced by the endometrial cups and in woman by the chorion (HCG) of the fetal placenta during the first trimester of pregnancy. Further studies are needed to fully explain the role of PMSG in the maintenance of pregnancy. It is also obvious, as noted in the previous section on prolonged gestation, that the endocrine glands of the fetus, thyroid, adrenals, gonads, anterior pituitary gland and possibly others besides the fetal placenta, play important roles in maintaining and terminating pregnancy. Further study is necessary to determine the exact interplay between maternal and fetal hormones in maintaining pregnancy in the various species of animals.

In the cow, doe, sow and bitch the corpus luteum of pregnancy is required throughout gestation to maintain a normal gestation period and permit a normal parturition. Removal of the corpora lutea or ovariectomy before term in these animals results in abortion or premature birth.^{4,18,20,27,54} The weight of single bovine corpora lutea throughout pregnancy was 6.4 gms (5.5 to 8.5 gms) and each of twin corpora lutea was 3.9 gms.⁶³ The ovaries or corpora lutea may be removed in the queen after 50 days, the mare after 70 to 150 days and the ewe after 55 days of gestation and pregnancy will continue normally and without interruption.^{4,6,32} In the latter animals the placenta and fetus produce the necessary steroid hormones, progestins and estrogens to maintain pregnancy. Pregnancy may be maintained in most cows ovariectomized during pregnancy by the injection of 100 mg of progesterone daily, 500 to 1000 mg. of Repositol progesterone every 7 to 10 days, or feeding 4 mgm MGA (melengestrol acetate) daily.^{10,63} In sheep the placenta or fetal cotyledons were the major source of progesterone the last 100 days of gestation since removal of ovaries from ewes after 50 days of gestation did not cause abortion or a drop in the blood serum level of progesterin.^{37,44}

Cole and Cupps and others^{4,6,62} have summarized in graph form the blood levels of progesterone and estrogen

in the larger domestic animals during the gestation period:

The cow has progesterone levels of 6 to 10 ng/ml from the development of the mature corpus luteum to within a day of calving. The estrogen levels are low the first 4 months of pregnancy, reach a level of about 100 pg/ml between 140 and 245 days and then rise precipitously to a peak of 1500 to 10,000 pg/ml two to five days before parturition. Both corticosteroids and prolactin levels rise rapidly from base levels the last 24 to 48 hours of gestation.

The ewe has progesterone levels of 2 to 3 ng/ml at 50 days, a rise to 12 to 20, or more, ng/ml at 125–130 days, then a steep fall to less than 1 ng/ml at lambing. Estrogens during gestation are low, 50 pg/ml and rise to 100 to 400 pg/ml a day before parturition. Both corticosteroid and prolactin levels rise rapidly the last few days of gestation.

The sow has progesterone levels that rise rapidly to a peak of 35 ng/ml on day 12 decline to about 17 ng/ml at 24 days and then remain nearly stable until a fall to less than 1 ng/ml at parturition. Estrogens are about 20 pg/ml for 24 days and then rise to 100 pg/ml by 90 days and rise precipitously to 300 pg/ml the last 10 days of gestation.

The doe has progesterone levels that rise from 5 ng/ml to 33 ng/ml by 90 days and then decline to 7 ng/ml at 140 days and to very low levels by parturition. Estrogen levels are low, 5 pg/ml until 30 days, rise steadily to 15 pg/ml at 50 days, 272 pg/ml at 85 days, 450 pg/ml at 125 days and 622 pg/ml at parturition. Prolactin levels rise rapidly the last few days of gestation.

The mare has progesterone levels that rise to 7.5 ng/ml at 8 days, and plateau at 10 to 15 ng/ml from 50 to 120 days and decline to 5–7 ng/ml at 150 days and 2 ng/ml at 180 days and remain low the remainder of gestation. However certain progestogens including the 5 α -pregnanes, increase to 8 to 16 ng/ml from 180 days to the end of gestation.^{24,40,43,48b} These latter progestogens apparently are produced by the placenta. Progestogen blood level in mares is quite high at parturition but drops rapidly within 24 hours after parturition. This pattern differs from other domestic animals but not the woman. Estrogen levels in the mare are 10 to 20 pg/ml until day 80 when they rise gradually to a peak of 825 pg/ml at 210 days then fall gradually to 370 pg/ml on day 300 and 150 pg/ml near parturition after which estrogen levels fell rapidly. It is interesting to note that the greatest size (7 × 4 cm.)

of the fetal gonads nearly coincides with the peak blood levels of estrogens at 180 to 240 days of gestation. Equine fetal gonads have massive numbers and size of interstitial cells. Fetal gonadectomy at 210 days resulted in a marked reduction of conjugated and unconjugated estrogen levels in the maternal blood. Progesterone levels remained unchanged.⁴⁵

Equine gonadotropin, PMSG or ECG produced by the endometrial cups rises rapidly from 0 IU/ml at 36 days to a peak of 67 IU/ml at day 57 then declines to less than 1 IU/ml by day 150. Ponies have higher levels up to peak values of 400 IU/ml, while mule pregnancies have very low levels of PMSG. Since the endometrial cups are of fetal cell origin, their degeneration and involution at 120 to 150 days of gestation is possibly similar to the rejection of a heterologous tissue graft.^{1b} The high levels of PMSG in mares have little effect on the ovaries. However, ovulation and the formation of secondary or accessory corpora lutea commonly occur between 40 and 90 days of pregnancy in mares and regress by 150 days of gestation coinciding with the production of PMSG by the endometrial cups.⁴ The mare's ovaries are apparently refractory to exogenous and endogenous PMSG because the latter binds very poorly, less than 10 percent, to LH receptors and not at all to FSH receptors in the ovaries. Therefore ovulation and the formation of secondary corpora lutea occurring during early pregnancy are probably due to seasonal release of maternal pituitary FSH. PMSG may be the stimulatory factor causing the great growth of the fetal gonads between the third and sixth month of pregnancy.⁵⁶ HCG injections induced pregnancy loss when given before gestation day 38 but injections after that day did not induce luteolysis and pregnancy loss possibly because of the presence of PMSG.^{1c} Evidence has been presented that human chorionic gonadotropin, HCG, is probably a trophoblastic surface antigen that blocks the action of maternal lymphocytes and prevents the rejection of trophoblastic placental tissue during nidation of the embryo.^{1a} A similar action for PMSG in the mare seems logical since the highest levels of PMSG coincide with the period of the implantation of the equine blastocyst. The role of PMSG in the production of accessory or secondary corpora lutea for the maintenance of pregnancy is in doubt.

If an equine pregnancy fails spontaneously or is induced after the endometrial cups have formed, the cups will continue to produce PMSG until about 120 days after conception. During this period mares usually will not cycle normally or conceive due to a period of anestrus characterized by small, hard inactive ovaries, especially

in Thoroughbreds, or irregular cycles with follicular activity but failure of ovulation and infertility, especially in ponies.^{1c,d}

Corticosteroid levels in the blood of mares rose at the end of gestation as in the other animals.^{12c} Prolactin levels during gestation were variable without a definite pattern.⁴⁰

The bitch has progesterone levels that rise from 0.5 pg/ml in proestrus to 25 to 30 ng/ml at 10 days and to a peak of 40 to 50 ng/ml at 20 to 25 days of gestation. In unmated or sterile bitches, progesterone levels declined after 20 to 30 days from levels of 25 to 30 ng to less than 0.5 ng/ml after 80 days. In pregnant bitches progesterone levels declined gradually from the peak at 25 days to near parturition. Progesterone levels declined rapidly from 6 to less than 2 ng/ml the last 24 to 48 hours before whelping. Progesterone synthesis by the canine placenta is minimal. Estrogen blood levels rose gradually from about 10 pg/ml early in pregnancy to a peak of about 15 pg/ml at 50 days and then declined to 8 pg/ml at parturition. Plasma corticoid levels increased to 15 to 35 ng/ml the last few days of gestation. Prolactin increased during pregnancy with a sharp rise just prior to whelping.^{4,12,51} Twice daily rectal temperatures taken during the last week of gestation revealed a characteristic drop of 0.8 to 1.0° C (1 to 1.8° F) during the last 24 hours before whelping.¹² An interesting observation that hematocrit values in pregnant bitches fell gradually during gestation from 50 to 30 with a significant decline after days 22 to 24. This low hematocrit value at term was over 30 percent lower than that in "pseudopregnant" or nonpregnant bitches 60 days after ovulation.¹²

The queen has progesterone blood levels that rise gradually to a peak of 35 ng/ml by day 21, decline gradually to 10 ng/ml at day 60, to 5 ng/ml just before parturition and to 1 ng/ml just after parturition. In pseudopregnant or sterile queens, progesterone blood levels rise to a peak of 24 ng/ml at day 21 postovulation and decline gradually to 4 ng/ml by day 40, to 2 ng/ml by day 50 and to 1 ng/ml by days 63 to 65. The feline placenta produces significant amounts of progesterone late in pregnancy. Estrogen and progesterone profiles and levels in pregnant queens are nearly the same as in bitches. Estrogen blood levels in pregnant queens are from 6 to 12 pg/ml and rise moderately near term and drop precipitously at parturition.^{51,61}

The hormonal and other factors initiating the onset of

parturition at the prescribed time for the various species of animals involves a fairly rapid series of hormonal changes in progesterone, estrogen, oxytocin, cortisol and prostaglandin levels which will be described subsequently.

Duration of Reproductive Ability

The duration of reproductive ability in domestic animals depends basically on two factors. **First**, the breeding or reproductive life of an animal ceases when at any age physical decrepitude occurs. This may be caused by disease or by defective nutrition secondary to a loss of teeth resulting in senility and emaciation. **Second**, reproduction ceases when the reproductive organs are injured severely or their function destroyed by disease factors. In the female those diseases limiting reproduction affect mainly the endometrium and epithelium lining the tubular genital organs and less often the ovaries. In the male, pathological changes in the seminiferous tubules of the testes caused by diseases, trauma, or senile changes, are the most common causes for loss of reproductive ability. Occasionally sires may develop arthritic joints or spinal lesions that make copulation impossible and thus their natural reproductive life is terminated.

The average duration of reproductive life in the dairy cow is about 8 to 10 years of age, with the production of about four to six viable calves. In beef cattle this average duration of reproductive life may be slightly longer, 10 to 12 years. Exceptions to these averages are numerous. Cows have been recorded^{11, 15} that had calves regularly to 16 to 18 years of age and in rare cases to 25 or more years of age. Bulls usually can breed until 10 to 14 years of age and in exceptional cases up to 18 years of age.

The average duration of reproductive life in the mare is approximately 18 to 22 years. The number of mares that become pregnant and carry a foal after 24 years of age is low although a few mares were reported to have had foals from 25 to 33 years of age. In ewes and does the average duration of reproductive life is about 6 to 10 years of age but ewes and does have been known to reproduce until 16 to 20 years of age.¹² The sow is capable of reproducing until 6 to 8 years of age and occasionally to 10 or even 15 years of age. In sows the size of the litter tends to decrease after 4 to 5 years of age. Beyond this time, although the female may be capable of reproduction, the litters produced are so small that it is uneconomical to continue breeding the sow. In bitches and queens the average duration of reproductive life is about 8 to 12 years of age. However, they have been known

to produce young at 14 to 17 years of age.

Animals prevented from breeding after puberty have increased difficulty to conceive the longer the nonpregnant state is maintained. Mares that do not have foals before 10 to 12 years of age experience difficulty in conceiving after that time even though their physical condition may be excellent. Cattle not bred until 4 to 5 years of age are also difficult to impregnate and frequently develop cystic ovaries and endometrial abnormalities.⁵ Bitches that are not bred by 4 to 6 years of age frequently develop cystic endometrial hyperplasia associated with infertility and often endometritis and pyometra. Probably in other domestic species delaying conception for a long period after puberty probably has a depressing effect on reproductive ability by the adverse effects on the endometrium.

In women changes resulting in the menopause take place at an average age of 49 years.⁶ In animals, with the possible exception of the mule, this condition characterized by a nearly complete loss of oocytes from the ovaries and cessation of the estrous cycle, has not been observed. Domestic animals usually die or are disposed of for other reasons before this stage of life. Observations in animals tend to indicate that cessation of reproduction in females with little or no genital disease is a more gradual process than it is in humans. It is rather closely linked with the lack of nutrition caused by the wearing out of the teeth and the resulting senile changes produced. It has been proven in practice that if genital and mammary disease could be controlled many cows could have 2 or 3 or more additional years of reproductive life. This would be of great economic value to the farmer.

Rate of Reproduction in Animals

The rate of reproduction depends basically on three factors: the length or duration of reproductive life, the number of young produced at each parturition, and the frequency of parturition.

The first factor has been discussed. The second factor is largely a characteristic of the species of animals concerned, whether unipara or multipara. However, the number of young produced at each parturition in any species may be increased or decreased to a limited extent by hereditary factors and selective breeding. Environmental factors apparently play a minor role in most animals, but in ewes, does, deer and possibly sows a high level of nutrition during the breeding season favors a greatly increased incidence of twins, triplets and greater litter size. In multiparous animals such as the sow the size of the litter tends to increase slightly up to maturity

and then decrease in size with advancing age. A high level of nutrition prior to breeding and a lower level thereafter increases the number of porcine ova ovulated and reduces the embryonic death rate in swine, respectively.

The third factor in the rate of reproduction, namely the frequency of parturition, is of great concern to the farmer as well as to the veterinarian, since any delay in getting farm animals to conceive is of economic importance. Once conception has occurred the duration of gestation is definitely established for each species. In an ideal breeding program most cattle or horse breeders strive for a calf or foal every 12 months. Although this can be attained with certain individual animals, it is a difficult goal to reach on a herd basis.

Because of the photoperiodic breeding season in ewes and the variation between breeds, it is possible by intensive management for ewes to have three lambings in two years. Sows are regularly managed to have two to three litters of pigs per year. Many adverse management, hereditary, and disease factors are present to prevent the achievement of these goals. It requires the close cooperation and active interest of both the farmer and the veterinarian, especially in dairy cattle and horses, if these adverse factors are to be kept at a minimum. The greatest departure from the ideal breeding performance is seen in those breeds most artificially maintained, that is, the dairy cow, the race horse, and the breeds of pet dogs.¹² The adverse management, hereditary, and disease factors that tend to produce infertility, cause abortion, or result in dystocia and postpartum disease, are being studied intensively by veterinarians and animal husbandrymen in an effort to curb or control the economic waste they produce.

Abnormalities of Fertilization and the Gestation Period

Wandering of the embryo—In uniparous animals such as the cow the corpus luteum of pregnancy is rarely found in one ovary and the embryo or fetus located in the opposite or contralateral horn. The incidence of this occurrence in the cow is less than 1 percent.^{2,13} However, transuterine migration of the zygote very early in gestation is common in the mare, ewe, sow, bitch and queen. Transperitoneal migration of the ovum has not been described in the domestic animals. In sows when fertile ova were surgically implanted in the apices of both horns, 34 percent of the zygotes migrated to the opposite horn between the 10th to 13th day of gestation.⁷ Intrauterine migration and spacing of embryos in sows is necessary

to fully utilize uterine space and to maintain pregnancy. If only one horn or one-half of each horn is occupied at 12 to 14 days postovulation the sow will return to estrus.^{4,7} At least four live embryos were necessary in sows for pregnancy to be maintained to 40 days.^{4,7} In sheep 7 to 10 percent of zygotes migrated to the contralateral horn when double ovulation occurred on one ovary.³ Embryonic death loss was much greater where both ovine zygotes remained in the same horn after double ovulation from that ovary. This is apparently also true in cows because twin fetuses in one horn are seen in only 10 percent while bicornual twin fetuses are seen in 90 percent of bovine twin pregnancies. The mechanism of the intrauterine migration and spacing of zygotes in multipara is not well understood but probably involves the muscular activity of the uterine wall and the attainment of a certain size of blastodermic vesicle.

Superfecundation is the result of a female ovulating two or more ova during one estrum and copulating with two or more males during that estrum with ova being fertilized by spermatozoa from each male. This condition may be suspected by the breeding history. After parturition it may be obvious because of offspring resembling each sire. Superfecundation is observed more commonly in multipara, especially bitches and queens, because multipara regularly ovulate two or more ova, have long heat periods, and opportunities for services by different males are greater than in unipara. Superfecundation in unipara has occasionally been reported, for example, the birth of twin horse and mule foals and twin calves sired by bulls of different breeds.

Telephony is a superstitious belief prevalent especially among dog breeders that offspring from one sire may derive characteristics from a sire to which the same dam has previously borne offspring. This belief is most commonly recalled when by accident a purebred female is bred by a mongrel and has offspring from this mating. It is then falsely believed that the dam is "tainted" and that even though she may be bred later to a purebred sire the offspring from this purebred mating will have certain mongrel characteristics. There is no basis for this erroneous belief.

Superfetation may occur when a pregnant female, carrying one or more live fetuses comes in estrum, is bred again, and a second conception occurs in a uterus already containing at least one live fetus. This condition is seemingly authentically reported more often in multipara and only rarely in unipara. It appears unlikely that in uniparous animals, even if ovulation occurred, the spermatozoa could pass through a cervix closed by an adhesive cervical seal and through the pregnant uterus to the oviduct. If the ovum was fertilized and reached

the uterus, the endometrial area of both horns would in most instances already be utilized by the first embryo or fetus. If by chance the second zygote should develop in the horn opposite to the one containing the embryo, when the earlier fetus was expelled the later fetus would probably be expelled at the same time. These viscissitudes cause many authors to doubt the occurrence of superfetation in uniparous animals.

Although the literature includes many reports of alleged cases of superfetation, most are unauthentic and lack essential details. Twin foals usually differ in size, one large and one small. The expulsion of unequal sized twins, even though the mare has been bred twice, does not constitute a claim for superfetation. In cases in which one cow in a herd gave birth to twins on pasture with one of the twins being adopted and suckled by a second cow in advanced pregnancy, superfetation is often claimed when this second cow, especially if it had been bred twice at the proper intervals, gives birth later to her own calf. A third condition may possibly occur wherein a cow or mare carrying bicornual twins in separate membranes gives birth to one twin a number of weeks or months before the second.⁸ The first twin is always smaller at birth than the twin born several weeks or more later. Several ewes aborted one of twin fetuses at 105 days of gestation. These ewes then delivered normal lambs at term over a month later.² This phenomena, although rare, has been reported in cows, sows, ewes and women as **double parturition**. It seems a more logical explanation for the birth of young at different periods following conception than does superfetation.¹²

In multiparous animals with a poorly defined cervix and cervical seal, superfetation is more likely to occur.^{10,11} Two normal feline term fetuses were removed from one uterine horn by cesarean section. A small 5 week-old fetus, 33 mm CR length, was found in the opposite horn of the uterus.⁹ They cited references to indicate that pregnant cats might develop mature follicles and ovulate as late as 6 weeks after conception. All the fetuses of one service could develop in one horn and then subsequently an estrum occur with ova fertilized from the second service developing in the opposite horn. Parturitions could occur at different times from each horn. This is unlikely as in double parturition in swine, fetuses are expelled from both horns at each farrowing period.¹⁴ This possibility might occur in cows with a true uterus didelphys or double uterus with a separate cervix for each horn. In the apparently authentic bovine case reported to the author, a double uterus was not present.⁴

Although superfetation may occur very uncommonly in multipara and rarely in unipara, it would appear highly improbable in most reported instances. Many reports on

superfetation are obviously incorrectly diagnosed without proper information and sufficient detail on which to base a claim. A few rare reports, however, appear sufficiently authentic to make one unwilling to state positively that superfetation does not occur in domestic animals, especially sows and cows.

Pseudopregnancy in the bitch and queen—False pregnancy or pseudocyesis is common in the bitch because the metestrus, luteal, or postestrus phase of the cycle is about 8 to 9 weeks long, or approximately the same duration as pregnancy.² During this metestrus period in the bitch the endometrium resembles that in pregnant bitches. The corpora lutea are large and active during postestrus but gradually reduce in size and become inactive at 8 to 9 weeks after estrum or sterile coitus. At this time many bitches exhibit mammary development and may lactate if nursed. The mammary development is not as great as in pregnant females. Toward the end of pseudopregnancy, false pregnancy or pseudocyesis certain bitches, especially the smaller breeds, may be nervous, aggressive, excitable, restless or withdrawn and may even exhibit "phantom whelping" by preparing a "nest" and mothering and protecting some inanimate object. Often bitches in pseudopregnancy will put on weight and their abdomen will increase in size. Most bitches do not exhibit these signs. If the symptoms at the termination of this period are objectionable to the owner, small doses of estrogen or testosterone may possibly aid in hastening the return to normalcy. The use of tranquilizers in the affected bitch may reduce the objectional behavior patterns during this transient period. In most affected bitches these symptoms tend to recur following each estrum so ovariectomy may be considered unless the bitch is to be bred. In the queen pseudopregnancy or metestrus lasts about 30 to 40 days but without noticeable signs.

Miscellaneous Fetal Patterns and Lactation

Although the rate of growth and body characteristics of the fetuses of domestic animals have been described in this and preceding chapters, other fetal developmental patterns and activity occur that should be noted.^{16b} Since the weight of male bovine fetuses and the uterus were heavier, and cotyledon, placenta and fetal fluid weights were not influenced by the sex of the fetus, it was concluded the uterus increases in size to accommodate the size of the fetus and that the size of the uterus has no influence on fetal size.²²

Blood flow to the bovine uterus, as measured in the uterine artery to the gravid horn, increases from 120 ml/

min. at 40 days, to 205 ml/min. at 90 days, to 1960 ml/min. at 145 days, to 3200 ml/min. at 188 days, to 3900 ml/min. at 215 days of gestation. Utero-ovarian vein blood flow in ewes at 120 days of gestation was about 1350 ml/min. with twin pregnancy and about 1750 ml/min. with triplet pregnancy. Thus in both of these studies uterine blood flow and nutrient uptake were closely related to the amount of uterine, placental and fetal tissue.^{3,11}

Fetal movements or kinesis occurs throughout the greater part of pregnancy and has been studied by ultrasonography. Simple movements were detected from 90 days of gestation in the equine fetus and averaged 9 movements per 10 minutes. Later in gestation movements became more complex and lasted longer, especially during the prepartum period. This activity is necessary for the normal development of muscles and joints and to assume the correct posture for birth.¹⁵ Ovine fetuses of 109 to 143 days of age swallowed 100 to 500 ml. of amniotic fluid daily during two to seven random episodes. Since from about 115 days the ovine fetus produces thick mucoid oral and tracheal secretions and its mouth and pharynx are always filled, the factors initiating these swallowing movements is not known.²

In the bovine fetus, as other species, lymphocytes develop first in the thymus by 50 days then by 175 days in all the peripheral sites. Associated with this lymphoid development was the ability to mount an antibody or immune response or become immunologically competent depending upon the nature of the antigen. This varied from 100 to 250 days of gestation with many bovine bacteria and viruses.^{16b,25}

Although the mammary gland is a highly modified and specialized sebaceous cutaneous gland, it is normally considered to be an accessory gland of the reproductive system because of its intimate association with reproductive functions and hormones. In domestic animals the mammary secretion provides early passive immunity to the newborn as well as supplying its nutritive needs. In the cow most of the immune globulins transferred from the blood to the udder secretion or colostrum takes place a short time before, during and after parturition whether the cow has been premilked or not. If the cow or mare has been premilked or the colostrum has leaked from the udder the level of globulins present per unit of lacteal secretion is reduced.^{20,24} In the mare, cow, ewe, and doe, the mammary gland is located in the inguinal region. In the mare, ewe, and doe the gland is divided into two halves with a single lactiferous sinus in each half opening into the two teats. In the cow the udder is divided into four quarters, each with its own lactiferous sinus and teat. Supernumerary teats and glands are common

in the cow. There is no communication between the halves or quarters of the mammary gland. In the sow, bitch, and queen the paired mammary glands are located on the ventral surface of the body in the pectoral, abdominal and inguinal regions. There are from 4 to 9 pairs of glands. The lactiferous ducts or streak canals at the ends of the teats are closed by a sphincter muscle. There is a single streak canal in the teats of cows and ewes but two streak canals in mares and sows. Bitches have 7 to 16 duct openings in the teat. The blood supply of the inguinal mammae is the external pudic arteries, of the pectoral mammae the branches of the internal thoracic arteries, and of the abdominal mammae from both sources. In the cow the main veins of the udder are the external pudic and the subcutaneous abdominal or "milk" vein. The latter empties into the internal thoracic veins. A well-developed lymphatic system is also present in mammary tissue.²⁸ The nerve supply to the mammary gland is the inguinal nerve from the ventral branches of the second through fourth lumbar nerves. The mammary branch of the internal pudendal nerve supplies the caudal part of the bovine udder. The motor nerve supply to the udder is entirely autonomic or sympathetic; the cell bodies of these nerves are located in the lateral horns of the spinal cord. Superficial innervation and blood supply of the skin of the udder comes from the subcutaneous vessels and nerves in the skin regions surrounding the udder.

Relatively little mammary development occurs before puberty. In the newborn, slight mammary and teat development is noted along with a slight amount of serous secretion. This is probably due to the placental transmission of some of the circulating maternal steroidal hormones. In rare cases this may be marked in dairy calves. There have been a few instances of dairy heifers 5 to 12 months of age or older that developed marked mammary development with milk secretion. The cause is usually not known. Granulosa cell tumors of the ovary or the consumption of estrogenic mycotoxins may rarely be the cause. Suckling by other heifers causes udder growth and an increase in the amount of milk secretion. After isolation, the mammary development of the heifer will recede spontaneously within four to six weeks. With the onset of estrual periods after puberty there is a slight mammary development. In animals exhibiting pseudo-pregnancy such as the bitch, mammary development may be quite marked and be nearly equal to the development in the pregnant bitch, and milk secretion will occur.

During the first half of gestation in the cow cellular proliferation of the mammary ducts and alveoli occurs under the influence of the steroid hormones, progesterone and estrogen, from the ovaries and the placenta. By the fifth month growth of the secretory tissue is nearly

complete. During the latter half of gestation cellular hypertrophy and limited secretion is noted. Abortion after the middle of gestation followed by regular milking of a cow or heifer results in lactation. The nearer to the calving date the abortion occurs the greater the production of milk. The failure of animals to reach high levels of production after an abortion is due to insufficient hormonal stimulation for milk secretion rather than to incomplete development of the mammary gland.²³ In the normal high-producing heifer or young cow excessive edema or engorgement of the mammary gland and the adjacent skin and tissues dorsal to the udder and forward on the abdominal floor to the xiphoid region may occur. This is apparently a circulatory phenomena caused by a greater blood supply to the gland than the venous system can accommodate. Excessive edema of the abdominal floor is sometimes confused with rupture of the prepubic tendon, umbilical hernia, a hematoma, or an abscess. Occasionally the greatly enlarged and edematous mammary gland may cause pain and discomfort, necrosis of the skin, failure to let down milk and stretching or even rupture of its supporting ligaments. Massage, the use of mild counterirritants, premilking, udder supports, cold and hot applications, and controlled exercise may be used to prevent or treat excessive udder edema. (See Figure 58.)

In recent years the oral or intramuscular administration of diuretics, specifically the carbonic anhydrase inhibitors with or without corticosteroids, for udder edema after parturition has been particularly helpful especially in young cows with a physiologic edema. These treatments are usually given for one to 3 days.²¹ Large doses or prolonged intake of lower doses of the glucocorticoids late in gestation may cause premature parturition often associated with retention of the placenta in cattle. The level of grain feeding, before parturition, whether high or low, had no influence on the degree of udder edema that developed.^{17,26} However, high prepartum grain feeding increased slightly the udder edema in heifers but not in cows.⁸

Mammary growth and lactation is mainly under the control of hormones.^{4,9} Nerves in the teats and skin of the udder may play an indirect part in milk secretion by stimulating the pituitary gland to release prolactin and possibly other hormones necessary to initiate and maintain lactation and oxytocin necessary for milk-ejection or "let-down." This latter term by signifying the ability of the animal to control her milk flow at will is incorrect.^{13,14} Vasomotor nerves probably play an indirect role in milk secretion by regulating the blood supply to the gland. Inguinal nerves have been cut without producing any change in milk production. Estrogens and proges-

Figure 58. Udder and subcutaneous edema in a parturient heifer. (Courtesy D. Morrow.)

terone produced in the ovaries and in the placenta work together in animals to cause mammary development. The estrogen causes the initial budding and the growth of the duct system. Progesterone causes further duct growth and alveolar development. In certain species, such as does, estrogen alone induces complete udder growth and lactation but some of the female's other endocrine secretions probably play a role.

The onset of lactation at the time parturition coincides with the drop in progesterone and estrogen levels in the blood that have provided for mammary growth, and with a marked rise in the levels of prolactin or lactogenic and growth hormone from the pituitary gland necessary for the initiation of milk secretion and maintenance of lactation. High prolactin levels are favored by the mammary stimulation of suckling and removal of colostrum and milk from the alveoli of the mammary gland except in sheep and goats.⁷ Prolactin secretion is usually initiated toward the end of gestation and rises rapidly just before and after parturition. Growth or somatotrophic hormone is also very important in the initiation and stimulation of lactation in cows. Oxytocin released by suckling might be closely associated with or cause the release of prolactin and growth hormone, STH, from the anterior pituitary gland. In most domestic animals suckling of young prevents or delays the onset of postpartum estrus compared to females whose young were weaned soon after parturition. This is especially noted in beef cows that suckle their young, especially twins, compared to dairy cows who don't. This delayed onset of postpartum estrus in suckled females is not due to lactation per se but is possibly due to the stimulus of repeated daily suckling that causes a reflex secretion of cortisol and prolactin that exert an antigonadal action by

suppression of the gonadotropic hormone, LH. Further study is necessary to elucidate the exact effects of frequent periods of suckling on the endocrine and reproductive systems.^{4,7,7b,17b} Low levels of administered estrogens aid in the release of prolactin and stimulate milk production.³¹ This may account for the drop in milk production in high-producing cows following treatment for cystic ovaries.

Normal lactation requires mammary development during pregnancy by hormonal stimuli. These stimuli comprise a complex of mammogenic hormones including progesterone, estrogen, relaxin, growth hormone, prolactin, corticosteroids and placental lactogens.^{7,9} Placental lactogens have potencies similar to prolactin and growth hormone and were found in bovine, caprine and ovine plasma. In the former, levels were low until 160 days of gestation and then increased to 200 days and plateaued until parturition. In the doe evidence was presented to indicate that does carrying twins or triplets had a higher milk yield due to the increased production of placental lactogen than occurred in single births.^{8b} The actual initiation of lactation requires low progesterone and estrogen levels and a high prolactin level such as occurs immediately postpartum. Maintenance of a high level of milk production requires oxytocin, prolactin, growth (STH) hormone, adrenal corticoids and parathyroid hormones.^{20b}

An enormous amount of work is performed by the lactating udder in the high-producing cow, 450 volumes of blood are required to produce one volume of milk. Dairy cows require an optimal length of 40 or more days dry period. Dry periods shorter than 40 days in length resulted in over a 1000 lbs less milk the following lactation.^{4b}

Thyroid stimulating hormone, TSH, has a galactopoietic effect. Thyroxine or other similar substances such as iodinated casein (**Protamone**) also have a galactopoietic effect on lactation. The daily feeding of iodinated casein or thyroprotein with a 3 percent throxine potency at a level of about 1 gram per 100 lbs. of body weight to lactating cows has caused increases in milk production and butter fat of 5 to 25 percent depending upon the cow's genetic constitution and the level of feed intake.¹⁶ Increased intake of T.D.N. or energy is essential in most treated cows. Since not all cows respond equally, individual supervision of cows is necessary. Milk records of cows on thyroprotein are not officially recognized by the Dairy Herd Improvement Assoc. If thyroprotein is removed suddenly from the ration a marked drop in milk flow usually occurs. Although a few well managed dairy herds have had good results by the properly supervised use of this product, many herds have experienced poor

results. In properly-conducted experimental long-term trials the use of thyroprotein has not appeared promising. Some dairymen are using this product selectively to boost production in cows the latter half of lactation when the cow's production declines below 40 pounds per day to prevent a prolonged dry period.

The artificial or hormonal induction of lactation in cattle and to a lesser degree in ewes, does, and laboratory animals has been the subject of much experimental work over the past 30 years.^{9,15b,17c,20b} Nulliparous cattle have given a much more uniform and satisfactory response than have sterile pluriparous cattle. The general technique consists of administering by injection or implants estrogen, estrogen and testosterone, or preferably estrogen and progesterone into animals to maintain fairly high daily levels for a period of one to three weeks to promote mammary duct and alveolar growth. After proper mammary growth has been achieved the injections are stopped or the implants are removed and regular frequent milking is started. The quantity of milk secreted is extremely variable between animals and ranged from 250 to 500 ml. daily to amounts normal for cattle after a gestation period. Failure to induce satisfactory lactation appeared to be due to low prolactin production.¹⁸ The response of nulliparous animals is more consistent than multiparous animals but in general this procedure is not satisfactory enough for practical use.

Two complications may be observed in this procedure: The cattle may develop cystic ovaries with symptoms of nymphomania. Fractures of the pelvis and limbs have been reported due to excessive mounting and a marked relaxation of the pelvic ligaments. If cystic ovaries do not occur the ovaries become small and inactive. The suppression of the gonadotropic hormones and ovarian activity is released when the estrogens are withdrawn. If lactating cows are injected with large doses of estrogens lactation promptly declines. If cows are pregnant they often abort due to the long-continued estrogen levels. Fluoroprednisolone acetate (**Predef**) given daily at doses of 10 to 15 mg. for 15 days caused the induction of lactation during gestation in heifers.³⁰

The diverse effect of estrogens on lactation requires further explanation. In therapy for humans, estrogens are widely used in low doses to relieve swollen, engorged breasts or in larger doses to suppress and stop lactation. This effect is evident when estrogen is used toward the end of pseudopregnancy in bitches with mammary enlargement. Most veterinarians are fearful of causing a decline in milk production with estrogen therapy to reduce milk flow and relieve udder congestion in domestic animals after parturition. Almost all such cases generally respond to less heroic therapy. In the preceding para-

graph the use of an estrogen was described to promote mammary growth and lactation. In the nonlactating cow estrogen at low, prolonged levels promotes mammary growth and development. While this is occurring, secretion is slight. The high blood levels of estrogen must drop so that the full secretion of milk may begin, since maximal growth and secretion cannot occur simultaneously. Prolonged high estrogen levels may suppress or hold in check the pituitary secretion of prolactin and growth or somatotrophic hormone or more likely effect the mammary tissue so it can't respond to the stimulus of the anterior pituitary hormones necessary for lactation. When this estrogenic check is removed the pituitary hormones are released and lactation results. At the time of estrum a slight drop in milk production often results due to the increased restlessness and nervousness of the cow at this period as well as to the decreased feed intake and the increased estrogen production from the follicle. In most pregnant dairy cows the gradual increase in estrogens produced by the placenta from the fifth month to term together with the increased nutritive needs of the fetus, tend to result in a regular decline in milk production. Sterile high-producing cows may lactate at a high level for two or more years. There is no evidence or proof that ovariectomy of lactating cows has any influence on prolonging lactation or increasing production.² Some cows and mares may be difficult to "dry off" because of the high production of milk 10 or 12 months and 5 or 6 months, respectively, after parturition. Marked temporary reductions in nutritive intake and water together with gradually prolonged periods between milkings will involute the mammary glands of domestic animals.

The ejection or "let-down" of milk which is closely associated with the reproductive organs and their hormones, is caused by stimuli, such as suckling, milking or massage of the udder and teats and conditioned stimuli developed by routine premilking barn procedures that effect a release of oxytocin and vasopressin from the posterior pituitary gland by means of neural stimuli acting on the hypothalamus. These hormones are carried to the udder by the blood stream and cause contraction of the myoepithelial cells around the alveoli and ducts. Vasopressin exhibits about 20 percent of the milk-ejection activity of oxytocin.^{13,14} This results in an increase in intracistern pressures from 15 to 20 mm. up to 30 to 45 mm. of mercury with distention of the teat and gland cisterns with milk.⁴ Oxytocin was released transiently and at low levels, about one-twentieth to one-tenth of a unit, to cause milk let-down in a cow within about 40 to 50 seconds. The elevated intramammary pressure was maintained for about one hour unless the cow was milked.

The half-life of oxytocin in animals is quite short, only one to two minutes. The posterior pituitary glands of does and cows contain about 10 to 15 and 30 to 50 units of oxytocin, respectively.¹⁹ The effectiveness of the expulsion reflex is transitory and prompt removal of the milk is desirable for effective proper milking. This neurohormonal reflex mechanism is suppressed by excitement, noise and fright which cause the secretion of adrenalin or epinephrine. This failure of milk let-down was probably due to a central block of the release of oxytocin from the hypothalamus and pituitary gland rather than to an inhibitory effect exerted by adrenal stimulation.⁶ Adrenalin caused vasoconstriction and reduced the blood supply and the amount of oxytocin to the myoepithelial cells in the udder.² The release of oxytocin does not occur at milking time in goats and is not essential for the complete milking of the goat udder.^{13,14} The understanding of this mechanism is helpful in cows in developing a proper, relaxed, quiet, regular procedure of milking that results in good milk ejection and rapid and prompt evacuation of the mammary gland. Prolonged milking caused by improper milking procedures results in loss of time, loss of milk, greater rate of involution of the mammary gland, and decline of milk production, besides favoring mastitis in chronically-infected glands. In certain heifers with greatly engorged and painful udders after calving, ejection does not occur, due to the pain and irritation of the swollen edematous udder. These cases benefit greatly from the intravenous or intramuscular injection of 5 to 15 units of pituitrin or oxytocin, and the prompt removal of the milk as the injected hormone rapidly induces milk let-down. These recommended low doses of oxytocin are in reality massive when compared to the physiologic amounts released by posterior pituitary gland. In cows given an intravenous dose, this let-down occurs within one to two minutes; in intramuscular doses it occurs within four to six minutes. The ejection of milk can frequently be stimulated by massage of the uterus, vagina or intrapelvic structures per rectum. It may be noted at the time of removal of a retained placenta, or in performing an infertility or pregnancy examination. It is also observed on vaginal or vulvar examination in cows and mares. Mares may exhibit milk ejection and leaking of milk just prior to, during or after coitus with a stallion.

Milk is produced by a true secretory process. The initial portion of bovine milk at a milking has a low fat content of about one percent while the "strippings" have a ten percent fat content. Most of the milk given at a single milking is present in the udder at the time of milking. In high-producing cows this causes a stretching of the udder tissues, and an intramammary pressure devel-

Table 8. Composition of Milk in Percent in the Domestic Animals*^{1b, 10, 28}

	Water	Fat	Protein	Lactose	Ash
Cow	86.2	4.4	3.8	4.9	.7
Ewe	82.9	6.2	5.4	4.3	.9
Goat	87.1	4.1	3.7	4.2	.8
Sow	83.0	7.0	6.0	4.0	.9
Cat	82.0	5.0	7.0	5.0	.6
Dog	79.0	8.5	7.5	3.7	1.2
Horse	89.0	1.6	2.7	6.1	.5
Man	87.4	3.8	1.6	7.0	.2

ops which suppresses further secretion. Thus in high-producing cows more frequent milking yields greater amounts of milk per day. Cessation of milk secretion or "drying off" is accomplished by allowing the intramammary pressure of milk to increase and remain high for four to five days. A six to eight week dry period between lactation periods is essential in cows for maximum milk yield. In most cows a shorter dry period is accompanied by a 20 to 30 percent decline in milk production the following lactation period.^{25, 29}

The average composition of milk in domestic animals is given in Table 8.

The amount of milk produced by domestic and wild animals varies greatly between species, breeds, individual animals, the level of energy intake, the quality and amount of protein and the amount of minerals, salt and water intake.^{1b} Environmental, management and disease factors play an important role in determining the amounts of milk produced. In general, cows produce 25 to over 100 pounds daily, mares 20 to 50 pounds, goats 3 to 15 pounds, ewes 2 to 10 pounds and sows 5 to 20 pounds daily.

Chapter V

DISEASES AND ACCIDENTS OF THE GESTATION PERIOD

Abortion

Abortion is defined as the expulsion of a dead conceptus or a living one incapable of independent life at any period of gestation. Pregnancy wastage or losses occurring during the period of the early embryonic period, or even during the late embryonic or early fetal period are usually unobserved and unrecognized and economically are not as serious as abortions late in gestation. These early large losses are usually considered to be infertility since conception appears to have failed to occur. These losses will be discussed under infertility in subsequent chapters. Preterm births of immature viable fetuses are called **premature births**. With proper care and nursing, some immature newborn can be raised. By common usage dead fetuses expelled at term are called **stillbirths** (See Chart I). The phrase "born dead" is improper.

Economically and emotionally mid term or late abortions are of great concern to the owner whether the animal is on a commercial or hobby farm because the fetus(es) are lost, the unproductive female must be maintained for a long period or sold at a loss, a prolonged period of uterine disease and infertility or sterility may follow, and if the cause of the abortion is infectious, the disease threatens the rest of the herd.

The many agents causing abortion may be categorized into groups that include: physical causes (hyperthermia, trauma, hypoxia); genetic causes; environmental causes (nutritional deficiencies, toxic plants, agents, chemicals or drugs); hormonal causes (excess estrogens, prostaglandins and cortisol, and progesterone deficiency); and infectious causes (viral, bacterial, fungal, protozoal, and others). Prior descriptions of teratogenic agents producing disease of the embryo or fetus of the domestic species of animals should be noted (See Chapter III). The ingestion or exposure to large amounts of these agents often caused the death of the embryo or fetus and abortion. Lethal or semilethal defects were often observed at birth or in the postnatal period whether due to these toxic agents, nutritional or genetic causes. (See Chart I and teratogenic anomalies and infertility.) These multiplicity

of agents may act singly or in various combinations to result in abortion.

Death of the conceptus usually results in abortion. But in the embryonic or early fetal period maceration and resorption may also occur (See Figures 59 & 60). During the early fetal or second trimester of gestation fetal death may be followed by mummification in all domestic animals, especially the multipara. Maceration of a dead or mummified fetus may rarely occur during the first or second trimester with an accompanying pyometra. Fetal emphysema may occur during an abortion in the late second or third trimester, or dystocia in premature or term birth.

In most abortions during the second and third trimester the fetus is autolyzed because fetal death usually occurs 2 to 5 days before expulsion. This postmortem fetal decomposition is characterized by grey or cloudy corneas observed about 12 hours after death. At 24 hours the kidneys become soft and pulpy and the abomasal contents are cloudy, mucoid and often flocculent. At 36 to 96 hours after fetal death the subcutis is gelatinous and reddish or blood-tinged, the liver is soft and friable and the abomasal contents are reddish.⁸ Diseases of the fetus and placenta do not always result in fetal death. Neonates may be born prematurely or at term and be weak and diseased and die shortly after birth or survive.

Further studies are needed to explain the various mechanisms of bovine abortion or fetal mummification after fetal death. Prostaglandin blood levels increase 5 to 10 fold in cows just before abortions, accompanied by a sudden decline in blood levels of progesterone probably due to the involution of the corpus luteum,^{2a,2b} similar to that occurring just before a normal parturition. Further studies on uterine contraction and cervical dilation and blood levels of estrogen and cortisol are indicated.

It is apparent that many of the causes of abortion in domestic animals are not yet known and the pathogenesis of many known causes is not understood even though in the past 20 years many studies have discovered new causes of abortion and new knowledge concerning the known causes. During this period much research on the

viral causes of fetal disease has occurred. The affinity of rapidly growing fetal and placental tissues for viral multiplication is evident. The cellular and humoral aspects of the immune response develop sequentially in the fetus. Infection prior to immune competence may result in abortion, fetal malformation, and occasionally viral persistence and immune tolerance. Immune responses, if they occur, cause an elevation of immunoglobulin and antibody in the fetus. The latter may be of diagnostic value.^{23b}

Even with these many studies, the actual incidence of abortion in the various domestic animal species is not known. Nor has the relative importance or incidence of the various etiologic agents of abortion in each species been established. Even when a freshly aborted fetus and placenta and maternal blood sample are promptly and properly collected, stored, refrigerated or frozen and delivered with a complete and carefully documented history and clinical report to a highly competent diagnostic laboratory with trained microbiologists, pathologists, toxicologists, immunologists and electron microscopists less than 50 percent confirmed diagnoses are made. One important reason for the difficulty in making a laboratory diagnosis of abortion is the autolysis that occurs in most aborted fetuses prior to expulsion.

A variety or battery of diagnostic serologic tests have been developed to screen or test blood samples from the dam and fetuses after expulsion for bacterial and viral diseases associated with abortion. It may be desirable in some instances to take a second blood sample from the dam two to three weeks later to see if a rise in titer occurs, that might explain a recent bacterial or viral infection. However, testing of paired serum samples seldom provided helpful or valid results.⁶ Furthermore up to three or more positive serological tests for different viral antibodies were noted in the plasma or fetal fluids of most aborted fetuses. Undoubtedly the dams' plasma would reveal similar antibodies.^{9,10,21a,b,22} A positive serologic test of the aborted fetus or dam for antibodies against an abortifacient, infectious agent does not indicate when the infection occurred or if that agent was responsible for that abortion. In fact in IBR abortion late in gestation the fetus usually dies rapidly before antibodies can be produced.^{16a,b} Also nearly all bovine infectious organisms can infect the fetus *in utero* causing the production of antibodies whether or not abortion occurs.

Thus viral, bacterial or other serological determinations have serious diagnostic limitations and require interpretation with history, clinical signs, necropsy and isolation of infectious agents. A serological diagnosis is a retrospective aid and seldom provides answers of immediate use in outbreaks. Antibodies may result from

prior infection, vaccination, colostral antibodies, or cross-immunity reactions. The presence of antibodies in the serum of aborted fetuses indicates prenatal infection but does not indicate that infectious agent produced the abortion. Conversely failure to detect antibodies in a fetus does not eliminate that agent as a cause for the abortion.^{15b}

Bacterial, viral, fungal and protozoal cultures of the organs of the aborted fetuses, the placenta, the amniotic fluid, the uterus and the dam's vagina and urine may be taken. Gross and microscopic examinations of fetal and placental tissues that are not autolyzed can be made for bacteria, viruses or fungi and pathological lesions including intranuclear inclusion bodies. Specific fluorescent antibody tests are also helpful in diagnosing certain viral and bacterial diseases in partially autolyzed tissues of the fetus or placenta.¹⁷ A careful histopathological examination of fetal organs and tissues and the placenta, if autolysis is not advanced, is one of the most useful and informative procedures in diagnosing the cause of abortion. Abortion is primarily a disease of the fetus not the dam, and the placenta as an organ of the fetus should also be carefully examined.^{16a} A complete reproductive and health history of the affected animals and the herd is necessary and helpful in making a diagnosis. This should include records of the type, brand and date of vaccinations of the dam and any medications given the dam. A history of the ration, grain, forage and minerals fed the cows and herd including any possible access to drugs, poisonous plants and toxic chemicals. Certain endocrinological and toxicological tests may be indicated. Infections may not be the cause of the largest group of abortions but it is most frequently diagnosed.

Such careful competent tests of each aborted conceptus submitted costs about \$150 per specimen. With only a 25 to 50 percent rate of probable diagnoses, the total cost for each positive diagnosis would be \$300 to \$600. When one considers that a careful interpretation of tests is necessary to be certain a positive serological result actually was related to the abortion and a positive culture does not necessarily mean the recovered agent caused the abortion, the justification of such costly testing might certainly be questioned for many cases of abortion.¹⁶ This underlines the great need for adequate research to accompany diagnostic efforts in this important area.

Sporadic causes of abortion are more difficult to diagnose than epizootic abortions since present knowledge and laboratory procedures are of little assistance in diagnosing non-infectious abortions due to toxins, genetic defects, nutritional deficiencies and hormonal deficiencies or excesses.^{17,18} If an epidemic of abortions is occurring in a herd, the cause is more readily diagnosed. It is common practice to accept an incidence of 3 to 4 percent of

abortion in a herd. Therefore, if several abortions have occurred before a diagnosis is attempted, the disease, if epizootic, may have spread through the herd unless diagnosed promptly with the first abortion.

The incidence of pregnancy wastage or losses, based on limited data is in the range of 30 to 40 percent in cattle, with a 7 to 12 percent of incidence of abortion in cattle after they were diagnosed pregnant by rectal examination at 30 to 50 days.^{5,21,22}

Although direct trauma per rectum to the embryo or young fetus and manual removal of the bovine corpus luteum may cause its death and resorption or abortion, external trauma to either man or animal seldom results in abortion.¹⁴ It is a common misconception by laymen that external injuries or trauma can readily cause abortion in animals.

Abortion in Cattle

Because of the multiplicity of agents causing abortion in cattle, an incidence of 2 to 5 percent sporadic abortions in a herd are common and expected in an area free, or with a very low incidence, of bovine brucellosis. When the incidence exceeds 5 percent most owners become se-

incidence of abortions, stillbirths and postnatal deaths were 2.1, 5.9 and 3.2 percent, respectively. Lesions related to anoxia were found in 73 percent of all stillborn fetuses. Stillbirths were higher in primipara than multipara, 9.3 vs 3.7 percent, and in unattended births than in those that were monitored, 9.4 vs 2.7 percent, respectively.^{11b}

Brucellosis (Contagious or Infectious Abortion, Bang's Disease) is caused by a small gram-negative coccobacillus, **Brucella abortus**, that grows intracellularly. It

Table 9. Summary List of Causes of Abortion in Cattle

Infectious Causes

Bacterial—Brucellosis (**Br. abortus**), Leptospirosis (**L. pomona**, **L. hardjo** and others), Listriosis (**L. monocytogenes**), Salmonellosis (**S. typhimurium**, **dublin** and others), Campylobacteriosis (**C. fetus venerealis**), Tuberculosis (*Mycobacterium bovis*) miscellaneous bacteria, and other organisms, streptococci, diplococci, staphylococci, *E. coli*, *C. pyogenes*, *Erysipelothrix rhusiopathiae*, *C. fetus intestinalis*, *Alcaligenes fecalis*, *Pseudomonas aeruginosa*, *Mycobacterium avium*, *Pasteurella multocida*, *Nocardia asteroides*, *Mycoplasma bovis* and *agalactiae* var *bovis*, *B. cereus*, *Hemophilus somnus*, *Yersinia pseudotuberculosis*, *Serratia marcescens*, *Spherophorus necrophorus*, *Rickettsia* (*Ehrlichia phagocytophilia* Tick-borne fever), *Coxiella burnetii* and *Chlamydia* spp.

Viral—Infectious Bovine Rhinotracheitis (IBR-IPV), Bovine Virus Diarrhea—Mucosal Disease (BVD-MD), Miscellaneous viruses—Myxovirus parainfluenza 3, bovine enteroviruses, bovine parvovirus, Bluetongue virus (BT), and Pseudorabies, Malignant Catarrhal Fever, Akabane, Foot and Mouth Disease, Rinderpest, Rift Valley Fever and Bovine Infectious Petechial Fever Viruses.

Mycotic or Fungal—Aspergillosis (*Aspergillus* spp.), *Mucorales* spp., *Allescheria boydii*, *Torulopsis glabrata*, *Mortierella wolfii*, *Absidia ramosa*, *Cephalosporium*, and the yeast *Candida tropicalis*.

Parasitic protozoal—Trichomoniasis (*T. fetus*), anaplasmosis (*anaplasma marginale*), Toxoplasmosis (*T. gondii*), Besnoitiosis (*B. besnoiti*) and Babesiasis.

Noninfectious Causes

Chemical, drug and poisonous plants—nitrates, chlorinated naphthalenes, arsenic, locoweed (*Astragalus* and *Oxytropis*), perennial broom weed, pine needles, sweet clover hay, mycotoxicosis, polybrominated biphenyls (PBBs).

Hormonal—estrogens, glucocorticoids, prostaglandins, progesterone deficiency.

Nutritional—starvation and multiple deficiencies including vitamin A, iodine and selenium deficiencies.

Physical—infusion or insemination of the pregnant uterus, rupture of the amniotic vesicle, crushing embryo or fetus, decapitating fetus, removal of corpus luteum, torsion of uterus or umbilical cord, stress due to work or fatigue, disease, transport or major surgery.

Genetic or Congenital—defects of embryo or fetus, chromosomal or genetic abnormalities.

Miscellaneous—twinning, allergies, tumors, adhesions of uterus, endometrial deficiencies.

was first described in Denmark by Bang in 1897. It is the most important worldwide cause of abortion in cattle except in countries such as the U.S. where the widespread use of strain 19 vaccination has been incorporated into a control program to greatly reduce the incidence of the disease. Brucellosis has been well-described.^{4,11,15}

Br. abortus causes abortion in cattle during the last trimester of pregnancy and a subsequent period of infertility is usually experienced. The disease is also important because **Br. abortus** causes undulant fever or brucellosis in man from drinking raw or improperly pasteurized infective milk or more commonly from exposure to infective discharges or tissues. Farmers, packing house workers and veterinarians are high risk groups. The medical procedures to follow after the accidental injection of **Br. abortus** strain 19 into humans have been reported.¹⁸

Br. abortus is mainly infective for cattle but occasionally other species of animals such as sheep, swine, dogs, donkeys, horses and humans may become infected and abort.^{11,20} In horses **Br. abortus** and *Actinomyces bovis* are commonly present in poll evil and fistulous withers. A high incidence of brucellosis has been reported in herds of bison and elk but the incidence in white-tailed deer and other wild ruminants is low. **Br.**

abortus has been reported in many free-living or wild animals.^{11,20}

The organism is rapidly destroyed by disinfectants, sunlight, drying, putrefaction, and pasteurization but may survive for several months in a moist, cold environment. The **Br. abortus** organism is found in the chorion of the placenta where it produces severe pathologic changes including necrosis and edema and causes severe pneumonic lesions in the fetal lungs. It is often recovered from the stomach contents of the fetus. It also is found as a persistent infection in the udder and the supramammary lymph nodes of adult cows and in the testes, epididymides, vasa deferentia and the vesicular glands of bulls. After abortion the organism does not persist in the uterus and disappears in about 4 weeks as apparently it grows well only in the fetal placenta.¹⁶ The sugar alcohol, erythritol, present in the placenta and male genital tract is a strong growth stimulant of **Br. abortus** accounting for its localization in these tissues.¹¹ Persistently infected udders, which are common in infected cows, appear clinically normal. Occasionally *Brucella* organisms persist in joints or bursae. Infections and blood titers in calves or immature cattle seldom persist as they do in sexually mature cattle. However it has recently been demonstrated that 2 to 3 percent of calves born to in-

infected dams can persistently harbor infection acquired *in utero* or from ingesting infective milk. These calves may be serologically negative until their first pregnancy when they may abort or calve and develop a blood titer and be a source of the spread of *Brucella* organisms to other cattle.⁴⁰

Infection is usually introduced into susceptible herds by the purchase of an infected cow. The incubation period, whether from the time of exposure until a positive serologic reaction occurs or until abortion or parturition when organisms are discharged, varies widely depending upon the age of the animal, the stage of gestation, the exposure dose, the vaccinal status and other factors.^{33b} With massive exposure, positive serologic reactions usually occur in 21 to 42 days. With other degrees of exposure, abortion or parturition with an infected conceptus, may have an incubation period of 53 to 251 days.³⁷ Further evidence of the unreliability of serologic tests as an indication of *Brucella* infection was the report that 13.3 percent of cows aborting culture-positive fetuses were serologically negative at the time of abortion.³² Thus, the variable incubation period and difficulties of diagnosing infection until after probable transmission to susceptible herdmates create serious technical problems in the understanding of the epidemiology and the development of control measures for brucellosis.²⁶

Infection with *Br. abortus* occurs most frequently by the ingestion of genital discharges of aborting cattle that contaminate the feed and water. Transmission may also occur through the mucous membranes of the eye and by intrauterine artificial insemination of infective semen. One infected bull whose semen was used for artificial insemination infected 71 percent of the cows and brucellosis appeared in 41 previously brucella-free herds.³ There is little evidence to show that brucellosis is spread from an infected bull to susceptible cattle by natural service.¹⁷ Calves nursing infected cows may spread the disease by fecal contamination of food ingested by susceptible animals. Occasionally *Br. abortus* may be spread by discharges from fistulous lesions of horses or possibly by quarter to quarter spread of organisms as occurs in mastitis.^{11,15} Once infection occurs in sexually mature cattle about 85 percent remain infected for their lifetime.

Abortions due to *Br. abortus* usually occur from the 6th through 9th month of gestation and premonitory signs of udder enlargement and vulvar edema often are present. The incidence of abortion will vary from 5 to 90 percent in a herd depending upon the number of susceptible pregnant cattle, the rate of transmission, the virulence of the organism and other factors.

The fetal membranes are edematous, hemorrhagic, leathery and necrotic and often there is a brownish-yel-

low pasty exudate in the uterochorionic space. Retained placenta and metritis with a subsequent period of genital discharge and infertility are common sequelae. After one abortion most cows have normal pregnancies but a few cows may abort two or three times. Infected fetuses may be born alive but many are weak and premature and die within a few hours. The dead fetus may exhibit some autolytic changes of edema and hemorrhages of the tissues and body cavities and the hair and skin may be stained with meconium. The most outstanding fetal lesion is bronchopneumonia. If a severe fetal pneumonia is present brucellosis should be suspected.¹⁹

A diagnosis of brucellosis requires laboratory tests that include:

(1) Isolation of the organism from the fetal lungs, stomach or placenta. In adult cattle organisms may be recovered from the milk or semen, or from lymph nodes after slaughter. Fluorescent-antibody staining is of diagnostic value for examining contaminated fetal or placental tissues or discharges from the uterus.¹¹

(2) A number of serologic tests have been developed to detect agglutinating antibodies in the blood of cattle. These tests have recently been reviewed^{33a} and include:

- (a) The tube agglutination test.
- (b) The rapid plate agglutination test.
- (c) The card test, a sensitive screening test that utilizes a low pH stable buffered antigen (in other countries this is called the Rose Bengal test).

These above three tests are considered official tests in the U.S. Other supplemental tests that are useful in distinguishing between naturally-infected cows and cows with vaccination titers include:^{11,30,33}

- (d) The mercaptoethanol (ME) test.
- (e) The rivanol plate agglutination test.
- (f) The complement fixation (CF) test. This test is highly specific for detection of infection.²¹
- (g) Four new tests that have been developed to detect infected cows earlier and are undergoing further evaluation are the ELISA or enzyme-linked immunosorbent assay test, the indirect hemolytic test and the radial immunodiffusion test.^{5,33a} Cell-mediated immune responses to *Br. abortus* and Strain 19 are under study using an *in vitro* lymphocyte stimulation test (LST).^{13,26}

The card test is a sensitive, rapid test for field screening of herds, particularly in range areas. It is superior to the tube test in detecting infected animals.^{26,28} Interpretations of results of official and supplemental tests require proper and knowledgeable evaluations.²⁶ In the official tests noted above a 1:50 reaction in a nonvaccinated cow

is usually considered to be a suspicious reaction and 1:100 a positive reaction. In an officially calf-hood vaccinated cow 1:100 is usually considered to be suspicious and 1:200 is positive. But these standards in an inconstant biological system are not always correct.

Cattle with suspicious reactions to diagnostic tests should be isolated and retested in two to four weeks. There is no practical method at present to distinguish between a serological titer for brucellosis due to vaccination with Strain 19 and infection with a field strain of the organism. The other supplemental specialized serological laboratory tests for brucellosis diagnosis described above are very helpful in problem herds in locating infected cattle that fail to show a reaction to the tube or rapid plate agglutination tests.^{1,28}

Although blood samples in cattle may easily be drawn from the jugular or external abdominal veins, especially in dairy cattle, bleeding from the tail is also simple and rapid and is favored by many in collecting blood samples from beef cattle, bulls and even dairy cattle.⁶ In blood testing cattle one should use proper hygienic precautions so that if anaplasmosis or other disease is present in the herd, the spread of the disease is not favored. The use of market-testing with back tags for identification of beef cattle going to slaughter where blood samples are taken, has proved very valuable in detecting infected beef herds not subject to milk ring test surveillance testing. Cross-reactions in the various diagnostic tests are uncommon. Cross-reactions between brucella, pasteurella and leptospira antibodies were not observed.^{9,29} Serum antibodies provoked by intramammary inoculation of *Yersinia enterocolitica* reacted strongly to the standard test for *Br. abortus*.²²

(3) Agglutination tests on milk include the milk ring test (M.R.T.), or the Brucellosis Ring Test (B.R.T.) for herds and the whey agglutination test for individual cows. In infected cattle in problem dairy herds the efficacy of these tests for the detection of reactor cattle was 92 and 73 percent.²⁸ As a herd screening procedure on bulk milk the M.R.T. is highly successful in indicating dairy herds containing one or more brucella-infected cows. Such detection is followed by blood testing of the individual animals in the herd. The testing of all dairy herds in an area two or more times a year with the M.R.T. has proven highly effective in the diagnosis and elimination of reactor cows.¹¹ After testing over 36,000 cows in 645 dairy herds, periodic blood tests on cattle negative to the milk ring test (M.R.T.) were found to be unnecessary.²⁸ The simple, easily performed ELISA test described above for serum showed promise of being satisfactory for detecting antibodies to *Br. abortus* in milk.¹⁰ This procedure is not applicable to beef herds.

(4) Agglutination tests are highly effective in detecting an increased local antibody level for *Br. abortus* in seminal plasma from bulls³ and in vaginal mucus from cows when an infection is present in the uterus.¹⁴

The herd history is often useful in the diagnosis of the cause for abortion. A differential diagnosis among the causes of abortion may be very difficult and often impossible without good laboratory assistance. The placental lesions in brucellosis, vibriosis and mold or fungal infections in cattle appear clinically similar.

Treatments for brucellosis, including a variety of antiseptics and antibiotics, have been attempted in cattle but with no success because of the intracellular location of the organism. Hygienic measures are essential to a control program within a herd. Infected animals should be sold for slaughter or should be kept carefully isolated at the time of parturition or impending abortion and for a month or more thereafter when the greatest spread of *Brucella* organisms may occur.^{38,39} Aborted fetuses and placentas should be buried or burned and contaminated areas should be disinfected with a 4 percent compound solution of cresol or a similar disinfectant. All cattle coming onto the farm should be tested and isolated for 3 to 4 months and retested before placing with the herd unless they came from a known brucella-free herd. These hygienic procedures are necessary even in vaccinated herds where the field strain of the organism may infect the cow and spread to the udder and lymphoid tissues.

In properly vaccinated cattle, abortions due to brucellosis are uncommon. Vaccination of calves from 2 to 6 or 4 to 8 or 10 months, depending on the various states' regulations based on the incidence of infection, with 2 ml. of freeze-dried, dated, refrigerated, low virulent, reduce-dose Strain 19 *Brucella* vaccine subcutaneously immediately after reconstitution produces a rapid rise in serum antibody titer that recedes in over 90 percent of young prepubertal cattle within 6 to 12 months after vaccination.^{17,26,34} It is imperative that this vaccine be refrigerated and handled properly to assure potency and viability. The immunity in cattle vaccinated with the former larger dose of Strain 19 vaccine at 2 to 6 months of age is equal to that in calves vaccinated at 4 to 10 months of age and lasts in most cattle through their fifth gestation.¹⁷ At the time of vaccination, calves should be carefully restrained and care should be used as Strain 19 can produce brucellosis or undulant fever in man if inoculated subcutaneously or conjunctivally. Vaccination of sexually-mature cattle causes more persistent blood titers and in pregnant cows may rarely cause abortion. In infected herds only 50 percent of calves from infected dams responded to Strain 19 vaccine if vaccinated prior to 95 days of age because of the presence of colostral

antibodies. Calves from infected dams should be vaccinated after 5 months of age.⁷ In a severely infected herd or area, veterinarians may recommend the vaccination of adult cows to prevent severe economic losses by the farmer. This should not be done in an area where eradication or control procedures are being carried out without the approval of state officials. Strain 19 vaccine is the only approved vaccine in the United States. Other vaccines to prevent *Br. abortus* infection such as 45/20 and H38 have been studied but they have not proven to be as satisfactory as Strain 19.²⁶

Occasionally calves or cows show generalized reactions for up to 7 days after vaccination with Strain 19 including, elevated temperatures, rapid respiration, dullness and anorexia. In rare instances, deaths of calves due to anaphylaxis or *Brucella* septicemia may occur within a few hours or several days.³⁵ Bull calves or adult bulls should not be vaccinated as Strain 19 may rarely localize in their genital tract and a persistent serum titer may develop. No useful purpose, other than providing a degree of immunity, is achieved by the vaccination of male cattle. Veterinarians should use great care that contaminated syringes used for vaccinating calves with Strain 19 are not used for other injections as brucella-infection and serum titers can be produced in other cattle in this manner.³

Recent studies have shown that a reduced dose of Strain 19 vaccine containing about 1 to 3×10^9 *Br. abortus* organisms, instead of the former recommended dose of about 25 to 125×10^9 organisms, given subcutaneously to calves, yearlings or adults resulted in fewer, less severe reactions to the vaccine. But high levels of immunity, up to 80 to 90 percent on a herd basis, were produced. Abortifacient effects of Strain 19 vaccination with the former large or reduced doses are minimal and uncommon in cows vaccinated during gestation. The reduced-dose of Strain 19 vaccine also greatly decreased the number of persistent udder infections when compared to the former massive dose.^{2,27} Even cattle vaccinated with very small doses subcutaneously or conjunctivally became immune.^{8,23,24,20,27,30,31} Furthermore the reduced subcutaneous doses of vaccine, $1/25$ th the former dose, have resulted in no decrease in protection when compared to the former standard dose and significantly decreased the length of time post-vaccinal titers persisted. However, in adult vaccinated herds supplemental serologic tests, especially complement fixation and rivanol tests, are necessary to reduce or minimize false positive serologic reactions with sensitive procedures such as the standard agglutination tube or card tests when done within 2 to 4 months of vaccination.^{2,24,26} Owners of herds in the acute infection phase of brucel-

losis at the time of adult vaccination should expect occasional abortions to continue, usually with a marked reduction after 60 days. In chronically infected herds adult vaccination will produce little immediate change in clinical signs of the disease. With proper management of infected herds most adult vaccinated herds can be free of brucellosis within 2 or 3 years.^{2,26} Non-vaccinated heifers or cows should not be introduced into these acutely or chronically infected herds or areas as they are highly susceptible to *Br. abortus* infection and may cause an increased incidence of infection and prolong the eventual control or eradication of the disease.^{38,39}

After vaccination of large numbers of calves in an area has continued for 4 to 8 years, various test and eradication programs can be instituted until the area is free of brucellosis resulting in minimal losses to the farmers.

The milk ring test (MRT) is an efficient method for the surveillance of possible brucellosis in dairy herds. The market cattle test or "back tag" method is used for beef herds but is less efficient and effective than the MRT. Blood samples are collected on cattle at auction sales and abattoirs and, if positive, the herd of origin is tested. The use of supplemental serologic tests combined with bacteriologic findings have given excellent results in eliminating infection in problem herds.^{26,28} In some herds the MRT is positive but there are no reactors to tube or plate agglutination tests. Supplemental procedures are also useful in these herds.

Over the past 45 years the incidence of brucellosis in cattle in the United States has been reduced from about 10 to 15 percent to about 0.5 to 1.0 percent with a marked reduction in human cases of brucellosis. This has been accomplished by official federal and state brucellosis control and eradication programs with the cooperation and support of cattle owners and veterinarians at a cost of over 2 billion dollars. However eradication of brucellosis is still a distant goal.

Presently there are 10 states, mostly in the southern part of United States, each with 300 to 3,000 known infected herds, that comprise 90 percent of the infected herds. In spite of greatly increased control activities and expenditures, the percentage and numbers of blood test reactors have not decreased in the past 20 years. There are a number of obvious and significant factors that mitigate against a prompt conclusion to a brucellosis eradication program:

(1) The intrinsic nature of the disease has been further elucidated by the coordination of older and more recent studies. Brucellosis is an insidious disease with both latent and acute manifestations, with a variable and often prolonged incubation period. In the absence of practical diagnostic cultural methods to detect carrier animals, a

somewhat confusing, inconsistent and often apparently arbitrary serologic tests and their interpretation have been relied upon.

(2) The changing aspects of the cattle industry in recent years has been toward much larger dairy herds of 200 to 2,000 head of cattle with confinement housing. Beef herds, especially in the southern part of the United States where stock is pastured the year around, have also greatly increased in size. Along with this increased size of cattle herds, the mobility of cattle and the need for many replacement cattle provided by truck transport from other cattle-raising areas has greatly increased. Thus, the opportunity for within herd spread of disease that is very difficult or impossible to control in large units is made more certain by the introduction of infected animals from other herds or areas. In 1978 about 2,000 herds in the United States were "depopulated" at a great cost because brucellosis could not be controlled in them by routine procedures.¹²

(3) Miscellaneous obstacles to an eradication program are the facts that brucellosis may occasionally be carried by many other domestic animals and some wild animals.²⁰ The costs of an eradication program are escalating to the point of diminishing returns. Although in recent years the Federal and State brucellosis control and eradication program has become somewhat more flexible, it is still a fairly rigid, restrictive program that is not highly acceptable to many individual cattle owners and veterinarians. Furthermore because of the complexities and severity of the disease, especially in large purebred herds, the vagaries of serologic testing and the rigidity of the state and federal regulations which are often political and don't always conform to the actual nature of the disease, brucellosis testing has a high malpractice potential for the veterinarian and the owner selling cattle.³⁶ A continuous long term country-wide vaccination program of calves and, if necessary, adult cattle is essential along with other proven control measures.

"Future efforts should be directed toward a broad-based control program which emphasizes prevention and is founded on solid scientific economic and logistic standards."²⁵ If this is accomplished the goal of eventual eradication of brucellosis in the United States might be a possibility.

Leptospirosis is due to small filamentous spirochetes with about 150 serotypes in 18 serogroups.¹¹ The six serotypes most commonly infectious for cattle are *Leptospira pomona*, *L. hardjo*, *L. grippityphosa*, *L. canicola*, *L. icterohemorrhagiae* and *L. szwajizak*. In the U.S. *L. pomona* and *L. hardjo* are the most common and serious of the six as a cause of disease and abortion in cattle.^{11,10,21} *L. sejroe* was also isolated from

the kidneys of aborting cows and serologic evidence of the infection was confirmatory in an outbreak of leptospirosis in cattle characterized by abortion, stillbirth and weak calves.¹³ The incidence of leptospiral antibodies in serum of cattle in the United States varies from 5 to 20 percent in random herds to 50 percent or more in herds and animals suspected of having leptospirosis.^{5,10,11} Leptospirosis is not amenable to eradication because of the widespread occurrence of the serotypes in many species of wild and domestic animals and because of the difficulties in detecting carrier animals. *Leptospira* are found in all species of domestic animals including dogs and cats but are most widespread in swine and cattle. Swine may shed organisms in the urine for six months to a year or more. Some of the wild animals found to shed leptospira in the urine include: skunks, raccoons, opossums, foxes, wild cats, beavers, nutria, rabbits, woodchucks, moles, shrews, mice, rats, deer and others.¹¹ The first three animals have the highest incidence of infection and the skunk, like the pig, can shed organisms for a year or longer. However with *L. hardjo* evidence indicates that the bovine animal is the major, or possibly the only, maintenance host^{5b} and can shed the organism for more than one year.^{10b} Man can become infected with various leptospira but more than half of the human cases in the U.S. due to *L. pomona* has been caused by swimming in contaminated surface water or has occurred in abattoir or dairy workers, especially the latter working in milking parlors with sunken walkways resulting in a exposure to bovine urine.^{3,9} These organisms are readily destroyed by heat, sunlight, drying, acid, and chemical disinfectants. They can survive for days or weeks in a moist environment at moderate temperatures as in stagnant ponds, streams or wet soil.

Leptospirosis was first described in cattle in the U.S. in 1944 and 1948.^{1,12} Subsequent work has shown the disease to be widespread in cattle in the U.S. as it is in most other countries of the world. Outbreaks of the disease in cattle herds may be rather sporadic. The incidence of herd epizootics varies from year to year and may be more common in certain geographical areas. *Leptospira* enter the cow by penetration of the abraded skin of the feet and legs when wading and by passage through the mucous membranes of the mouth and pharynx, nose and eyes by contact with contaminated water and feed or urine. Bulls infected with *L. pomona* shed the organisms in their semen and urine for months or more and could infect susceptible cows by natural service.¹⁷ *L. pomona* can survive for 7 days at 5° C in standard bovine semen extender containing 500 units of penicillin and 500 micrograms of streptomycin per ml. It was later shown that the addition of penicillin (1000

units) and streptomycin (1000 micrograms) per ml. of extended semen prevented the transmission of *L. pomona* in extended frozen semen because of the combined effects of dilution, antibiotic action and chilling on the organism.² However, in artificial insemination studs only bulls free from leptospirosis should be used.^{3,16}

The incubation period in cattle is 4 to 10 days when an elevation of body temperature to 103 to 107° F occurs together with a leptospiremia that lasts for 2 to 6 days. The signs of the acute disease may vary from mild or inapparent signs in about 70 percent or more of affected cows, to moderate signs with anorexia, a drop in milk flow with a slack udder containing slightly thick, "gargety" colostrum-like milk in about 25 to 30 percent of the cases in dairy cattle, to severe signs in a few cattle with a marked drop in milk with a thick secretion containing blood clots, a flaccid udder, severe loss of appetite and loss of condition, anemia, hemoglobinuria, dyspnea, icterus and rarely death within one to three days. The severe cases are seen more frequently in young cattle up to 8 months of age. In rare cases neurologic manifestations due to leptospiral meningitis in young cattle have been reported.^{4,10} Following recovery from the acute period of illness the leptospira tend to localize in the tubules of the bovine kidney and organisms are shed in the urine in variable numbers for 2 to 3 months and occasionally up to 1 year or more.^{5a,5b,23a} Leptospira may also be shed in the milk during the acute stage of illness. A serologic response can usually be elicited within one week after exposure to leptospira and the serum titer usually reaches a peak in about 2 to 6 weeks and then declines to more moderate levels but persists in many cattle for 5 or more years.^{5,6,15} After intravenous inoculations of heifers with *L. pomona* organisms between 150 and 180 days of gestation, abortions occurred 18 to 19 days later. In 5 heifers dead fetuses were present in heifers 17 days after inoculation. No *L. pomona* organisms were present in the blood after the 6th day and antibody titers of 1/100 to 1/1,000 were present on the tenth day. No organisms were recovered from the fetuses apparently due to autolytic changes.¹⁴

In all forms of the disease abortions, especially in cows in the last half of gestation, may occur from 1 to 4 weeks after the acute febrile or leptospiremic stage in *L. pomona* infections^{5,6,10,19} and from 6 to 12 weeks in *L. hardjo* infections. Thus serologic titers should be high at the time of abortion in the former infection and falling or low in the latter.^{5c} The incidence of abortion may vary from 5 to 40 percent of the herd depending upon the number of susceptible cattle in the last third of gestation, the numbers and virulence of the infective organisms and the opportunity for the spread of the infection. Not all

susceptible infected cows in advanced pregnancy will abort. Occasionally an infected cow will give birth to a live, weak, infected calf that dies within a few days. Retained placenta and its sequelae of metritis and infertility are common. Recovered animals are immune to the leptospiral serotype causing the illness and abortion but are still susceptible to infection with other serotypes.^{10,21}

Abortion outbreaks are seen most often in susceptible cattle during the pasture season. The disease can be introduced into a herd by purchasing an infected cow, from cows infected at fairs or shows, from swine running with cattle or from contact with infected wildlife. In range herds serious outbreaks have followed the concentration of stock for winter feeding, blood testing, vaccination, dipping, worming or pregnancy examinations, or other situations where the spread of the urinary infection is favored.^{4,10}

Fetal death and abortion has been shown to be the usual consequence of an acute or subacute fetal infection.^{7,8} The time of 2 to 5 weeks from the initial infection of the cow with *L. pomona* and abortion is the time required for the two consecutive infections in the dam and fetus to complete their courses. Organisms can be demonstrated on silver-impregnated stained sections of fetal livers and kidneys. Organisms are seldom isolated from aborted fetuses because they fail to survive the 12 to 48 hours between the death of the fetus and abortion and the autolysis that occurs in the decomposing fetal tissues. Autolytic lesions characteristic of abortions due to a variety of causes in the cow may be observed in the fetus and fetal membranes but gross diagnostic lesions are not present.

The diagnosis of abortions due to leptospira in cattle is more difficult than those due to brucellosis. The history and clinical symptoms as described above, together with necropsy findings of widespread petechia indicative of a severe septicemia are helpful. Culture of the fetus, especially the kidney, for leptospira in laboratory animals or in special media is difficult and requires time, skill and experience.^{5c} Silver staining of liver and kidney sections may be helpful if autolysis is not severe. Dark-field examination of material from fresh aborted fetuses or urine may reveal the leptospiral organisms with their typical "spinning" motion.¹⁰ The use of the fluorescent antibody technique with a carefully prepared conjugate from an organism from a fetus on tissue homogenates of lung, liver or kidney of aborted fetuses have proven quite accurate even when autolysis was severe.^{5c,18} The fluorescent antibody technique may also be used to stain leptospire in infected urine from aborting cows; culturing of urine at this time may also be diagnostic.

Serologic tests for the diagnosis of leptospiral abortion

have a number of shortcomings. By the time the cow is infected and has a leptospiremia that affects the fetus resulting in its death and abortion, the cow is serologically positive. Because this serologic reaction can persist for years the time of exposure cannot be determined. However a high titer may be indicative of a fairly recent infection. Generally there is little relationship between antibody levels and abortion.^{4,5,6,10,23a} Blood samples taken at the time of abortion and then several weeks later often are not diagnostic.^{10,21} Taking at least 10 blood samples at random from the herd in which leptospiral abortion is suspected including some from cows that have aborted, as well as from nonaborting cows is more diagnostic.²¹ If recently aborting cows have a high titer and nonaborting cows generally have negative titers a diagnosis may be warranted; but if some of the cows that recently aborted are positive only in a low titer a definite diagnosis of leptospirosis is not justified.

Ellis has reported on *L. hardjo* infection of cattle in Northern Ireland where 4 to 6 percent of aborted fetuses and 68.7 percent of aborted fetuses from herds with abortion problems were positive based on culture, immunofluorescence and fetal serology. Only 4.6 percent of abattoir collected fetuses were positive for *L. hardjo* based on culture and fluorescent tests and these fetuses were negative on serologic tests. Using the microscopic agglutination (MA) test, which was superior to the CF and plate test, with a fairly sensitive antigen since serologic titers with *L. hardjo* are definitely lower than those of *L. pomona*, 81.2 percent of aborting cows with a titer of 1:1000 or more had *L. hardjo*-infected fetuses but these comprised only 46.3 percent of aborting cows with *L. hardjo*-infected fetuses. Of aborting cows with *L. hardjo*-infected fetuses 22.8 percent had no detectable antibodies. Paired serum samples have little or no diagnostic value since serologic titers are declining at the time of abortion due to *L. hardjo*.^{5c,d,e} In *L. pomona* abortions, because they occur more acutely, paired samples may be of some value.

Two serologic tests have been adopted and used by various diagnostic laboratories. They are the macroscopic plate agglutination test using many serogroup formalin-killed leptospiral antigens, and the microscopic agglutination test with live antigens. Agglutination in the 1:40 dilution or greater is considered positive with the macroscopic plate test. Some workers consider agglutination at a 1:10 dilution significant with *L. hardjo*. Agglutination in the 1:100 dilution or greater is considered positive with the microscopic agglutination (MA) test.¹⁰ Other special serologic tests have been used but have not been generally adopted. Vaccinated cattle will have a serologic titer for many months.

Since eradication of leptospirosis is not possible, control and treatment of bovine leptospirosis may be accomplished by hygiene and sanitation, vaccination and antibiotic therapy. Water supplies should be protected from contamination, wet areas should be drained or fenced off, ingestion of contaminated feed should be prevented and exposure to infected urine and semen should be avoided. Newly purchased animals might be serologically tested, isolated and retested in two or three weeks. If these animals are positive, parenteral antibiotic therapy would be indicated before introducing them into the herd. If negative, vaccination would be desirable. Since cattle recovering from leptospirosis are immune from reinfection with that serotype, various vaccines have been developed and evaluated. Multivalent bacterins containing 3 or more serotypes are widely used and provide an excellent immunity for a period of 6 to 12 months. For this reason some cattle subject to frequent possible exposure to leptospirosis are vaccinated twice yearly. If breeding is limited to a short period or infection occurs only during certain seasons of the year, once a year vaccination is usually satisfactory. Vaccination will provide protection against the clinical forms of the disease but it does not provide complete protection against infection and the urinary shedder state.

In the face of a herd outbreak of abortion due to leptospirosis, all cattle, especially pregnant cows should be promptly vaccinated. It may be advisable to give aborting, exposed cows or all the cows 25 mg of dihydrostreptomycin per kg. of body weight intramuscularly to eliminate the carrier or shedder state and reduce the spread of the infection in the herd.^{4,10,19,20,23} Others have administered therapeutic doses of dihydrostreptomycin or tetracyclines for several days. Antibiotic treatment at the same time as vaccine injection does not interfere with the development of immunity.^{10,20} Abortions may continue for several weeks until an immunity from the bacterin is produced. Vaccination of cows in advanced pregnancy provides a degree of colostral immunity for calves that lasts until they are 3 to 4 months of age when vaccination is indicated in areas or on farms with a high incidence of the disease. With the advent of more highly concentrated purified bacterins the incidence of cases of anaphylaxis at vaccination has declined markedly.

The treatment of the acute stages of leptospirosis includes the parenteral administration of large doses of antibiotics including dihydrostreptomycin 5 gms, twice daily, or the tetracyclines, 2.5 to 5 gms, daily, per 1,000 lb. animal for 5 days. This treatment also eliminates the renal carrier state. Early treatment is essential^{10,20} to possibly prevent death or abortion. Guidelines for the prevention and control of leptospirosis in bull studs has been out-

lined including serologic, vaccination and treatment procedures.²² In cases with hemoglobinuria and anemia, blood transfusions and supportive therapy may also be indicated but the prognosis in severe cases is poor.^{4,9}

Campylobacteriosis (Vibriosis) due to **Campylobacter fetus venerealis** is an occasional cause for a 2 to 10 percent incidence of abortion in susceptible herds. Vibriosis is a venereal disease that can be transmitted at coitus. Older bulls may be chronically infected. The organism may be present and infective in improperly treated semen. With widespread artificial insemination using antibiotic-treated semen, abortions due to **C. fetus** are presently uncommon in dairy areas. Occasional sporadic abortions due to **C. fetus intestinalis** occur the third trimester of gestation in cattle. Because vibriosis in cattle is more closely associated with infertility and early embryonic deaths than abortion this disease will be discussed in Chapter XIII on Infertility in Cattle.

Listeriosis is caused by **Listeria monocytogenes** which is a gram-positive slightly motile rod or coccoid organism with a wide host range among mammals and birds throughout the world. Although infection with *Listeria* is frequent, the occurrence of clinical disease is uncommon. Numerous antigenic serotypes are recognized. **L. monocytogenes** is widespread in nature and is resistant to adverse environmental factors as it can be found in moist or dry soil, bedding, fecal material and secretions and tissues of normal and diseased animals. It has been found in silage and actually propagates in poor quality silage with a high pH.^{4,11,2,3,5} The organisms can penetrate the intact mucous membrane of the respiratory or alimentary tracts producing a transient rise in body temperature due to a bacteremia. A latent infection in various organs may then be established although clinical signs are uncommon and these carrier animals may spread the organism for a long period in their nasal secretions and feces. Sudden changes in management or feeding practices inducing stress and lowered resistance are often associated with outbreaks of clinical cases of listeriosis. A close relationship between silage feeding and the incidence of this disease is frequently observed. Listeriosis is observed more often in the late winter and spring months. The incidence varies greatly between years.

Three clinical forms of listeriosis are observed: **the septicemic form** affecting young perinatal animals and humans and characterized by the early death of the newborn with hepatic lesions, gastroenteritis and meningitis,⁶ **the encephalitic form** affecting relatively mature animals, especially ruminants with meningoencephalitis; and **the reproductive form**, seen in ruminants and humans, characterized by abortion the last trimester of gestation without clinical illness. *Listeria* organisms are car-

ried hematogenously to the placenta and into the amniotic fluid and fetus.^{4,3} The above forms may be observed together in the same outbreak. In cattle aborting from the 7th to 9th month of gestation the fetus may be well-preserved with few if any lesions in the fetal organs. Retained placenta, metritis and dystocia were commonly observed. If fetal death occurred before the 7th month the fetus was often retained **in utero** for up to 5 days before expulsion, autolysis of the fetus was advanced and retained placenta and metritis were not uncommon.^{11,12} In women infection due to *Listeria* apparently persists and may result in habitual abortion.^{1,3,10} Recurrent bovine listeric abortions may recur each year on some farms and even in the same animal.^{3,9}

Sporadic bovine abortions due to *Listeria* are seen most frequently but occasionally herd outbreaks may occur with a 5 to 15 percent, and rarely higher, incidence.^{9,11,12} Fetuses are usually expelled dead but a few calves may be weak at birth and die shortly thereafter. A history of the introduction of carrier animals from affected herds, or a recent change to silage feeding, or some severe stress may be associated with an outbreak. *Listeria* were isolated from the feces in 25 percent and from the milk in 16 percent of cows aborting due to listeriosis.^{3b} The healthy carrier animal may be a latent and important reservoir of infection. *Listeria* infection may pass between different species. There are no suggestive or pathognomonic lesions of listeriosis in aborted fetuses and membranes other than occasional small focal, necrotic areas in the liver. The diagnosis is based on the isolation and identification of the organism which may be difficult.

Fetuses should be collected, chilled and cultured promptly. Taking a large volume of tissue from the fetus, preferably the liver and thoroughly macerating and emulsifying it in a nutrient broth is advised. After inoculating bacteriologic media, the emulsion should be stored at 4° C. and recultured repeatedly especially if listeriosis is suspected.^{9,11} This latter procedure is important for the recovery of ***Listeria monocytogenes***. In most cases the organism was recovered on reculture within 20 days of storage but sometimes recovery occurred only after 6 months of storage. A rapid method for the isolation of *Listeria* by inoculating 20 day old mice intracerebrally with suspect material was described.⁷ This cold enrichment method is not as necessary for culturing fetal body tissues as it is for brain tissue.¹⁷ *Listeria* were usually recovered from the exudate in the genital tract taken shortly after abortion, the placentomes, the spleen, the brain, the stomach and the kidneys of aborted fetuses.^{8,9} In fetuses that have undergone little autolysis small pinpoint yellow foci of necrosis may be observed in the liver and spleen.^{15,8,9} In experimental aborting cattle, *Listeria*

were recovered from the genital tract for about 10 days after abortion, and from body tissues at slaughter 25 to 36 days after abortion.⁸ The immunofluorescent methods for the detection of *Listeria* in fetal tissues are of diagnostic value in cattle.^{11,3b}

A rise in the agglutinin titer in affected animals based on the somatic agglutination tests conducted on blood samples taken at the time of abortion and 60 to 90 days later, and on the basis of the antigen-fixation test was reported.^{8,9} They showed this infection to be widespread in animals in affected herds. In the experimental cattle the antibody titers reached a peak at the time of abortion and dropped rapidly within the next 30 days. Further work is necessary to develop serologic tests to the stage where they are precise enough for routine diagnostic application.

Therapy or treatment of herds with abortions due to *Listeria* would include the cessation of silage feeding if this was occurring and controlling other factors that might lower the resistance of the cattle. Hygiene and sanitation practices consisting of segregation of aborting cattle and destruction of aborted fetuses and membranes should be followed. Antibiotic therapy with large doses of the tetracyclines or penicillin and streptomycin for four to five days might be attempted in valuable animals. In herds where the disease tends to recur the use of an autogenous bacterin might prove of value.⁴ No commercial bacterin is available.

Salmonellosis in cattle is principally caused by *S. typhimurium* and *S. dublin* with occasional outbreaks caused by other serotypes.^{4,11,5,6,7} *S. typhimurium* is widespread in the world in many species of animals and feed. *S. dublin* is host adapted to cattle and occurs in Europe, Great Britain and western United States. In recent years evidence has indicated the latter serotype is spreading eastward and in the future will probably be of concern to veterinarians throughout the United States.¹ *S. dublin* is highly contagious for humans. Carrier cattle commonly occur in *S. dublin*-infected animals as the organism often colonizes in the gall bladder and is spread in the feces for years or a lifetime. Whereas cattle infected with *S. typhimurium* usually only remain carriers and shedders for several months.^{11,5,6} Herds can be freed of *S. dublin* infection by culturing fecal samples of all cattle in the herd and eliminating all infected cattle.

Abortion is only sporadic in pregnant cows with clinical signs of *S. typhimurium* infection. Abortion is usually caused by infection of the fetus and its membranes with fetal death or possibly it may be secondary to the hyperthermia and stress of the acute severe enteritis and septicemia in the pregnant cow. Abortions occur in the

second half of the gestation period and usually within 10 to 20 days of the onset of the clinical disease in the pregnant cow. *S. typhimurium* can usually be recovered from the feces of the cow and the autolysed fetus.^{4,11,4,6}

Abortion due to *S. dublin* however frequently produces abortion after midgestation without clinical signs of enteritis and septicemia in the cow. *Salmonella dublin* abortion was clinically seen as only abortion in 77 percent of the cases. It was associated with enteritis in 14 percent of the cases and in most of these abortion followed the dysentery. In most *S. dublin* abortions, not accompanied by diarrhea, the infection present in the feces, vaginal mucus and milk ceased 3 to 5 weeks after the abortion. Adult cattle recovering from *S. dublin* dysentery invariably became consistent fecal excretors of the organism and this was associated with congenital infection of some of the calves at subsequent calvings.³ *S. dublin* can be readily recovered by culture from the aborted fetus and fetal membranes and from genital discharges for 3 to 5 weeks after the abortion. The mortality in cows infected with *S. typhimurium* is higher than in cows with *S. dublin*.^{11,6,7}

In both types of salmonella infections stress produced by a change in feed, shipping, surgical operations or acute illness may result in releasing latent or quiescent infections that can cause an epizootic outbreak in susceptible cattle.^{2,4,5} Following salmonella abortion retained placentas and metritis are common but most cows recover and subsequently conceive. Veterinarians handling abortions and their sequelae should take precautions to protect themselves from infection. Treatment with antibiotics usually does not prevent the carrier state so affected animals particularly those carrying *S. dublin* should be isolated and after recovery consideration should be given for their slaughter in an effort to eliminate infection in the herd. Vaccines, both live and dead, for both above serotypes, are available in Great Britain but their value is difficult to assess.^{4,5a,7} In other countries an autogenous bacterin might be considered under certain circumstances especially to protect newborn calves by immunization of the dam prior to birth so colostral antibodies are high. Vaccines, however, cannot substitute for good management and hygiene in the control of salmonellosis.^{5a,7}

Miscellaneous Bacteria and Organisms, Not Including Fungi, Viruses or Protozoa.

Tuberculosis caused by *Mycobacterium bovis* is present worldwide in cattle and is of major importance in dairy cattle that are closely housed or pastured in limited areas. In the past 30 years tuberculosis in cattle has been reduced to a very low level in the U.S. and out-

breaks of tuberculosis, particularly advanced cases in which the genital organs may be involved are extremely rare. In other countries where tuberculosis is still common it may occasionally cause metritis, salpingitis, infertility and recurring abortion. Abortion in cattle due to *M. avium* has been described.^{6,29} Tuberculosis due to *M. bovis* may also occur in man, goats, pigs, deer and occasionally other wild animals. The infected animal may spread the disease organisms in excreted air, sputum, feces, milk, urine, semen and genital tract discharges. Susceptible animals either ingest or inhale the infective organisms. Moisture favors the survival of the organism for long periods outside the body.^{4,11} Occasionally cows may become infected at coitus with a bull with lesions of the prepuce and penis, accessory glands or testes,⁴¹ or by intrauterine insemination of infective semen.^{3,31} The bull may on occasions be only a carrier or contact spreader between an infected cow with a tubercular genital discharge and a susceptible cow. Uterine tuberculosis however is uncommon but may result from, coitus with an infected bull, intrauterine insemination with infective semen, by continuity from peritoneal tuberculosis, or probably most often by hematogenous spread. In tuberculous metritis infertility is frequent and recurrent abortion or the birth of a tubercular calf that dies a short while later may occur. Retained placenta and lesions in the placenta similar to those of brucellosis may occur and a chronic "curdled milk" type of uterine exudate that persists is often observed in this form of tuberculosis.^{4,11} The bilateral granulomatous uterine lesions, salpingitis and adhesions may be palpated per rectum in the non-pregnant cow or cow in early pregnancy.

Infected animals should be eliminated and the disease eradicated in the herd and geographical area if possible. The intradermal tuberculin test applied regularly with the removal and slaughter of reactors has been used quite successfully in the U.S. to greatly reduce the incidence of the disease. False positive reactions to this test may occur due to other mycobacteria. In cases of uterine tuberculosis the disease may be so advanced that no reaction will be elicited on the intradermal tuberculin test.⁴¹ In isolated cases of uterine infections, culture of the fetus, the fetal membranes and the genital discharges usually reveal the organism. If cases of this type are present in a herd usually other cases of generalized pulmonary or intestinal types are present also. Further information on bovine tuberculosis, diagnostic tests, control measures and vaccination are reviewed elsewhere.^{4,11}

Miscellaneous bacterial infections associated with sporadic bovine abortions include the so-called "wound" infection organisms that are probably carried to the pregnant uterus by the blood stream or possibly by extension

from the caudal portions of the genital tract.³⁰ These organisms probably originate in infectious processes such as: traumatic gastritis, liver abscesses, ulcers of the stomach or intestine, abscesses in the lung, foot rot, acute mastitis, and pneumonia. These organisms include: *Bacillus* spp.; streptococci; diplococci;⁴⁰ staphylococci; *E. coli*, *Alcaligenes fecalis*; *Pseudomonas aeruginosa*; *Corynebacterium pyogenes*, *Erysipelothrix insidiosa*; *Bacillus cereus*, which causes a necrotizing placentitis;⁴⁴ *Yersinia pseudotuberculosis*;²⁰ *Serratia marcescens*;^{18,43} *Hemophilus somnus*;¹¹ and *Spherophorus necrophorus*.⁴⁰ *Vibrio fetus intestinalis*, a common cause of abortion in sheep, only occasionally causes sporadic abortion in cattle.¹⁵ *Mycobacterium avium* has been reported as a cause of sporadic abortions in cattle that are housed with infected chickens. In this latter disease small granulomatous lesions develop in the endometrium and placenta and recurrent abortions may occur as with *M. bovis*.^{6,29}

Sporadic abortions are infrequently associated with febrile septicemic bovine diseases such as pasteurellosis due to *Pasteurella multocida*,^{18,40} actinomycetes (*Northcardia asteroides*) and anthrax. *Mycoplasma bovis* and *M. agalactiae* var. *bovis*,^{3,10b,16c,20b,32} have been recovered from aborted bovine fetuses.^{20,1,2,3,8,32} *Mycoplasma* and *ureaplasma* have been found in the fetal membranes and fetuses of spontaneous abortions in women.^{13,19} *Ureaplasma* have been isolated from aborted bovine fetuses.^{10c,20b} To illustrate the ability of a variety of organisms to cause abortion in cattle by the hematogenous route, the author observed a pregnant cow given *Streptococcus agalactiae*, an organism not considered pathogenic outside the bovine udder, intravenously. Ten days later the cow aborted and a pure culture of the organism was recovered from the fetal organs. If mixed cultures of organisms are obtained from the aborted fetus the possibility of contamination of the fetus following death, or during expulsion, should be considered.

Endotoxin produced by gram-negative organisms can cause abortions in cows, ewes, sows and does.^{5,10} It was proposed that endotoxins and the associated severe stress reactions were the cause of some abortions in animals rather than the elevated body temperatures that frequently accompany septicemic and toxic infections with gram-negative organisms.^{7,10}

***Hemophilus somnus* (agni)** the wide spread causative agent of the sporadic diseases of bovine thromboembolic meningoencephalitis and pneumonia, especially in feeder cattle has been reported as a cause of abortion and possibly infertility.^{18,20b,39}

Rickettsial infections of *Coxiella burnetii* caused Q fever worldwide and *Ehrlichia* (*Rickettsia*) *phagocy-*

tophilia causing tick-borne fever in Great Britain and Europe have been reported as causing bovine abortion.^{4,12,42} **Coxiella burnetii** occurs mainly in dairy cattle in areas of the United States and world-wide. Cattle are one of the major hosts shedding large numbers of organisms, that are infectious for man, at successive parturitions in the placenta, its fluids and milk. Between calving periods the infection may remain latent.⁴ Abortions due to **Coxiella burnetii** have been produced in cattle experimentally but in naturally infected cows abortions are rare.^{4,11,12} In tick-borne fever in cattle abortions, which occur the last two months of gestation, follow a period of pyrexia. It is not known whether abortions are due to the fever and stress or to the rickettsial organism.^{4,11}

Epizootic Bovine Abortion (E.B.A.) or foothill abortion is apparently caused by an agent of the psittacosis lymphogranuloma, **Chlamydia psittaci**, group of organisms, an obligate intracellular pathogen.^{4,11,20,23,25,34,36} In 1956 this disease that had been observed in California since 1923 was called epizootic bovine abortion (E.B.A.).¹⁴ Because of breeding practices in beef herds it occurred mostly in first calf heifers or newly introduced cattle during the months of July through October in the foothills adjacent to the Sacramento and San Joaquin valleys. Fetuses were expelled during the 6th to 8th months of gestation. The incidence of abortion would reach 30 to 40 percent in some herds with occasionally up to 75 percent or more of susceptible females aborting. In a susceptible herd animals of all ages would abort but thereafter abortion was largely limited to heifers. Recent studies on the nature of EBA or foothill abortion have indicated a tick, **Ornithodoros coriaceus** is the probable vector of the causative agent. These ticks harbor **Chlamydia** and two different viruses. The latter were found not to cause

Figure 60. Bovine fetal resorption 60 days post-conception.

abortion.²⁶ However this tick has been shown to harbor the IBR virus. (See viral abortions.) **Chlamydia** abortions have been reported in the Intermountain region in both the epizootic and sporadic forms and to occur in February and March in beef herds and throughout the year in dairy herds. McEntee and coworkers in New York State have tentatively diagnosed rare sporadic cases of this type of abortion in dairy cattle from its characteristic lesions although the causative agent has not been isolated.^{20,22,20b} The disease has been described in central and southern Europe.³⁶ Since typical lesions of chlamydial abortion have been described in areas where neither ticks nor a typical pattern of EBA abortion occurs and since two capable researchers in California question whether EBA or foothill abortion is caused only by **Chlamydia**^{15,15,16,17} this author reserves judgement until further study resolves the etiologic factors involved. There is definite evidence from experimental and clinical studies that **Chlamydia** can cause abortion when injected into susceptible pregnant cows. Further studies are needed in cattle to demonstrate whether intestinal chlamydial infections can be transmitted by the oral route as occurs in sheep and other species. Great similarities exist between EBA and enzootic abortion of ewes (EAE) which is due to the same, or very similar chlamydial agent.^{23,36} This agent has also been isolated from bulls affected with a seminal vesiculitis syndrome.³⁵ Mycoplasma infection of the male bovine genital tract can simulate this syndrome. Thus the present name of the disease may be a misnomer because it is not limited to epizootic outbreaks and it may cause abortion and possibly other disease syndromes in both cattle and sheep.

Outbreaks of E.B.A. occur suddenly without premonitory signs of illness or impending abortion. The disease primarily affects the fetus as there is no clinical evidence

Figure 59. Embryonic death of one of twin 35-day bovine zygotes.

of infection in the cow. Intravenous inoculation of the agent causes abortion 3 to 6 weeks later, intramuscular inoculation 3 months later and subcutaneous inoculation 4 to 4-1/2 months later. Abortions occur from the fourth month of gestation to term but most commonly the 7th, 8th, and 9th months. Some fetuses were expelled dead at term or calves were born alive and weak and succumbed later. About 50 percent of aborting cows had retained placentae and the subsequent fertility of the cows was impaired at least for a number of months.^{23,34} Once a cow aborted an immunity was apparently produced and only occasionally did cows abort a second time due to this agent. Aborted fetuses were clean, fresh and pale or anemic and death had apparently occurred during delivery or shortly thereafter.^{15,15,17} Since fresh fetuses with no autolysis are seen in relatively few forms of abortion in animals for example E.B.A. in cattle and equine herpesvirus 1 in horses, the author would speculate that the adrenals of these fetuses might be hyperplastic thus causing the onset of parturition or abortion prior to the death of the fetus. (See section on hormonal causes of abortion.)

Aborted fetuses exhibited characteristic lesions of anemia and extensive petechial hemorrhages of the conjunctival and oral mucosa and skin. The subcutaneous tissues were edematous especially those of the head. Straw-colored fluid was usually present in the body cavities. The most striking lesion seen in 50 to 60 percent of E.B.A. abortions is the swollen coarsely nodular yellow-colored liver that develops secondary to chronic vascular lesions and chronic passive congestion. (See Figure 62.) Nearly all the lymph glands were enlarged and edematous. The basic histological change of this disease was a granulomatous inflammatory process or a diffuse or focal reticulo-endothelial hyperplasia that irregularly involved all organs. Fetuses aborted before the 7th month are more autolyzed and usually do not have the above typical lesions. The fetal membranes in cases of E.B.A. abortion are usually edematous but are not of diagnostic value.

The recovery of the chlamydial agent from aborted bovine fetuses is more difficult than from aborted ovine fetuses probably because of fewer organisms present due to the chronic disease process in the bovine fetus together with the generalized reaction present indicative of an active defense response. Cultures into the yolk sacs of chicken embryos and in recent years, tissue cultures^{20b} should be made from any or all organs and the placenta and even then many fetuses yield negative results. If the fetus is positive the organism is usually recovered from only one or two organs. The E.B.A. and E.A.E. agents have similar biological and pathogenic properties and share

common specific antigens. Pregnant cows aborted after being inoculated with E.A.E. agent and pregnant sheep aborted after inoculation with the E.B.A. agent.³⁴

The modes of transmission, the reservoirs of the agents or other epidemiological aspects of E.B.A., and E.A.E., have not been clarified. The two diseases occur independently and an interchange of infection between cattle and sheep is probably of minor importance. Veneral transmission may possibly play a role in cattle since workers have recovered *Chlamydia* from the semen and epididymis of young bulls with a seminal vesiculitis syndrome.³⁵ However, it has not been proven that the disease can be transmitted by coitus.^{23,25}

At present there is little that can be done to control the disease. Abortion produces an immunity to future natural infection in most animals. However, various vaccines have been tried without success.²⁴ Preventive management procedures to control EBA have been recommended⁷ that either expose sexually mature heifers to a heavy infestation of infected ticks 3 months before breeding or possibly altering the breeding season so exposure occurs late in gestation.

It is evident that further studies on chlamydial abortions and EBA are necessary to develop a logical comprehensive understanding of the etiologic factors, the pathogenesis and the control of this disease complex. More study is needed on the epidemiologic factors involved in the transmission of this disease.

Viral Causes of Abortion in Cattle

Infectious bovine rhinotracheitis ("red nose") and infectious pustular vulvovaginitis (I.B.R.-I.P.V.) vi-

Figure 61. Pustular vulvovaginitis in a heifer due to IBR-IPV virus.

Figure 62. Nodular chronic lesions of the fetal liver in epizootic bovine abortion.

IBR is a common cause of abortion in cattle in the U.S. and in other countries.^{4,13,12} This is a Herpesvirus and has many features similar to rhinopneumonitis virus or equine Herpesvirus 1 in horses, and Herpes simplex in humans. This disease of cattle has received much study over the past 20 years. Other domestic animals are not susceptible to this virus but it has been reported in mule deer.⁴ I.B.R.-I.P.V. virus is widely distributed over the world and in the U.S. The clinical morbidity may vary from 10 to 100 percent in a herd. The mortality is generally under 10 percent with only occasional deaths in adult animals in uncomplicated outbreaks. Deaths in prenatal fetuses and neonatal calves may be high. The diagnosed infectious causes of abortion comprised 23.3 percent of 3812 aborted fetuses examined from 1960 to 1970^{13b} and 34.0 percent of 2500 aborted fetuses examined from 1973 to 1976.¹⁸ Of the diagnosed infectious causes of bovine abortions, IBR comprised 12.6 and 8.8 percent, respectively. Over 90 percent of the diagnosed viral abortions were due to IBR viruses.^{13b,18} Although a generalized viremia develops in nearly all I.B.R.-I.P.V. infections, localized manifestations of the disease occur that confuse the diagnosis.^{4,13,12}

The varied clinical forms of this disease include: (1) The **upper respiratory form** or "red nose" which occurs in cattle feed lots and dairy herds in the Fall and Winter months, and is the most common form seen in the United States and Canada. It is characterized by fever of 104°–107° F., anorexia, depression, reddened nasal mucous membranes and nasal discharge, pustules and ulcers in the mucosa of the nose, pharynx and trachea, infrequent coughing, and a drop in milk production lasting 2 to 7 days except in severe cases in which secondary

tracheitis and pneumonia may occur. (2) The **conjunctival form** which exhibits marked lacrimation changing to a mucopurulent profuse discharge from the eye along with the septicemic signs exhibited in (1). The conjunctiva is reddened and swollen and contains necrotic pustules and ulcers.^{1,27} (3) The **neonatal digestive form** in young calves from birth to 2 to 3 weeks of age is associated with a high mortality and is characterized by severe signs of septicemia resembling that associated with *E. coli* but exhibiting necrotic lesions in the mouth, pharynx, larynx, esophagus and forestomachs with diarrhea and death within 1 to 3 days.³⁴ (4) The **meningoencephalitic form** is seen occasionally in young cattle 4 to 10 months of age and is characterized by dullness, incoordination, tremors, amaurosis, opisthotonus, coma and death within 3 to 4 days.⁷ (5) The **vulvovaginal form**, the most common form of the disease in Europe and Australia,¹⁶ is characterized as in the others by signs of a generalized septicemia but also pustules and ulcers of the vaginal and vulvar mucosa especially in the region of the lymphoid follicles with swelling and a purulent discharge.^{4,16,17} (See Figure 61). This form of the disease was previously called coital vesicular exanthema or Blaschenausschlag. The respiratory form of the disease is rarely observed in outbreaks of this genital form.¹⁵ (6) The **preputial form** in bulls is characterized by pustules and ulceration of the penis and prepuce.³³ IBR in bulls usually causes severe degenerative changes of the seminiferous epithelium and a period of infertility or sterility lasting up to 3 to 4 months. (7) The **prenatal or abortive form** of the disease is characterized by infection and intrauterine death of the fetus and abortion 2 to 5 or more days later.^{16,19} Abortions may occur in all three trimesters of gestation^{16,24} but are most common from midgestation to term. The incidence of abortion in a herd will vary from 5 to over 60 percent with an average of 5 to 20 percent depending on the virulence of the organism and the numbers of susceptible cows in advanced pregnancy.²⁶ Abortions are most common following the respiratory and conjunctival forms²⁷ and rarely occur in cases of infectious pustular vulvovaginitis. Retention of the placenta occurs in about 50 percent of the abortions. (8) The **intrauterine form** of the disease caused a necrotizing endometritis when I.B.R.-I.P.V. virus was present in semen at the time of artificial insemination. This resulted in a tonic, edematous uterus and a short estrous cycle of 9 to 15 days in length. Conception did not occur in 11 of 12 heifers inseminated with semen containing virus but did occur at the next estrus when noninfected semen was used.¹⁸ A herd outbreak of I.B.R.-I.P.V. was reported where strong evidence indicated the infection was introduced by frozen semen shipped from another

state.¹¹ I.B.R.-I.P.V. virus has been recovered from three ampules of frozen semen from a single collection of one bull.³² Frozen semen ampules from 39 other bulls from 3 AI centers were negative for this virus. The author has received a number of reports from veterinarians that a period of infertility lasting about 3 to 4 weeks followed the vaccination of heifers with a live attenuated I.B.R. vaccine.

As noted above all forms are characterized by a viremic and septicemic phase with an elevated temperature, depression, and anorexia lasting from 2 to 10 days but in many animals these signs may be subclinical. In all forms of the disease immunity develops as evidenced by the appearance of virus neutralizing antibodies in the plasma by 14 days after exposure.^{9,12,16} In general if one form appears on a farm the other forms are seldom observed but conjunctivitis is seen occasionally, and meningoencephalitis on rare occasions terminally, with the upper respiratory form. The author has observed a few outbreaks of the upper respiratory form with concurrent vulvovaginal lesions.

Abortions may occur in pregnant animals from 2 weeks to 2 to 3 months^{6,12,16} after any form of the disease, especially the respiratory and conjunctival forms, but is only rarely observed in the vulvovaginal form.

Since abortion is not associated with the genital form of the disease in cattle and since in humans the oral and genital forms of Herpesviruses are serologically distinct, some have speculated that the genital and respiratory forms might also be different in cattle. However, no serological or other differences between viruses recovered from the two sites in cattle could be found.^{2,16} Inoculation of venereal strains of IBR-BVD into the nose and eyes of cattle indicated that these strains were less virulent than the respiratory strains of the virus.^{1b} Recent studies using restriction endonuclease analysis have shown that I.B.R. virus and I.P.V. virus from their respective sites in the body are different even though some similarities were present.^{6b} Further studies are indicated with this IBR-IPV herpesvirus as well as the respiratory and abortive forms of equine herpesvirus 1.

The virus is carried in the blood in the leucocytes and abortions occurred 18 to 64 days after inoculation of the virus.^{10a,23} I.B.R.-I.P.V. virus may cause infection following intranasal, conjunctival, intravaginal, preputial, oral, intrauterine, and intramammary as well as subcutaneous, intramuscular or intravenous inoculation. Besides direct and indirect contact transmission of IBR virus, it may probably be transmitted by arthropod vectors such as *Ornithodoros coriaceus*.^{33b} The site of inoculation determines the clinical form of the disease produced especially in the first four modes of administra-

tion. The incubation period for viremia and the acute manifestations of the disease is 1 to 5 days experimentally and may range from 3 to 10 or 20 days naturally.^{6,19} The I.B.R.-I.P.V. virus in the dam's blood stream during viremia, 2 to 10 days postinoculation, entered the cotyledon but produced no local inflammatory reaction or spread of virus. The viremia terminated in the dam with the development of antibodies detectable in the blood. At the time of abortion the cow has already developed virus neutralizing antibodies in the plasma, therefore paired serum samples taken at the time of abortion and several weeks later are of no diagnostic value. After a week to 2 months the virus, protected from the maternal antibody by its location in the cotyledon, infects the fetus and causes its death within about 24 hours.^{6,16,19} About 50 percent of susceptible animals pregnant 165 days or more, may abort after an IBR viremia whether caused by natural field exposure or by immunization with a modified live virus.¹⁶ In recent years intranasal MLV vaccines have been developed that do not cause abortion in pregnant cows.^{9,12}

Signs of impending abortion are usually not observed. Aborted fetuses are invariably expelled dead with a degree of autolysis. Calves normal at birth may become infected and die in 24 to 48 hours with I.B.R.-I.P.V. viral infection. The lesions described in aborted fetuses may be of diagnostic value. There is no evidence of uterine disease. The placenta shows autolytic nondistinctive lesions characterized by edema and the presence of a yellow, brown amniotic fluid. Autolysis of the fetus is always present to a varying degree with reddish-brown subcutaneous edema and dark red watery fluid in the body cavities. Hemorrhages and petechiae are often widespread in the fetus.

Microscopically characteristic lesions of focal necrosis in the liver, lymph glands, kidneys, other organs and placenta are usually observed.¹⁵ The most striking gross changes occur in the kidneys which are usually surrounded by a marked hemorrhagic edema. A severe hemorrhagic necrosis is confined largely to the cortex and is often so severe that the medulla and part of the cortex are floating in dark red fluid. Pin-point, 1 to 2 mm, necrotic, white foci may be observed in the adrenal glands. Intranuclear inclusion bodies are seen infrequently in these autolysed fetuses,^{16,19,20} but if present are most numerous in the lungs, cotyledons and adrenal glands. During the acute state of illness virus may be recovered from the nasal cavity, the vagina, the conjunctiva and the prepuce in the upper respiratory, the vulvovaginal, the conjunctival and the preputial forms, respectively. Usually within 10 to 26 days after the acute illness the virus disappears.

Culture of the fetal organs and fluids and especially the fetal cotyledon may recover the I.B.R.-I.P.V. virus.^{6,16,24,31} In many cases the virus cannot be recovered because of the advanced autolysis of tissues in the fetus. However, the fetal cotyledon may contain a high level of virus and because of its close proximity to the maternal circulation, autolysis of the fetal placenta and chorion are delayed. I.B.R.-I.P.V. virus has been recovered from a cotyledon following the birth of a normal calf. In bulls the disease may be subclinical and require a number of passages for recovery of the virus and the infection may persist in a latent form for over 360 days. The I.B.R.-I.P.V. virus has been cultured intermittently from the vagina and from the nasal cavity of infected heifers for 578 and 510 days, respectively.^{28,29,31} This prolonged intermittent appearance of the virus even though antibody titers were present in the blood of the animal is characteristic of herpesvirus infections and may explain the frequent reoccurrence of the clinical disease in the field. Many latent herpesviruses will recrudescence when the carrier animal is stressed or when a series of cortisone injections are administered. As with other herpesviruses the site of the latent infection is the trigeminal ganglion cells.⁸

Serological testing using the serum-neutralization test is best conducted on double serum samples taken at the time of the acute illness, when most samples are negative, and again 2 to 6 weeks later. In cases of abortion the serum titers are elevated in the dam at the time of the abortion. In a herd outbreak of I.B.R.-I.P.V., samples might be taken of representative cattle that are normal, recovered, aborting or acutely ill. Samples should be taken in as near sterile a manner as possible in sterile vacuum vials so the serum neutralization test, utilizing tissue cultures will be satisfactory. Antibody response following the various forms of the disease, experimental intravenous or intramuscular inoculations and vaccination is variable.^{9,12,16,23,31} It appears the greatest and most rapid antibody response occurs after abortion and the intravenous and intramuscular administration of virulent I.B.R.-I.P.V. virus. The antibody response is the slowest and poorest after the vulvovaginal and the preputial forms of the disease when the rise in titer may be slow and extend in the latter over 8 months. After vaccination with a number of commercial vaccines some titers did not develop until 4 to 30 months after vaccination. There was evidence that once serum titers developed that fluctuations occurred due to anamnestic responses following recrudescence of virus multiplication but titers remained for at least 3 to 4 years or more or for a lifetime due to the latent infection with the virus. Thus it was evident from serologic studies that I.B.R.-I.P.V. virus acts like

Herpes simplex in humans and rhinopneumonitis virus in horses where clinical lesions with multiplication of the virus may develop even when low levels of antibodies are present in the blood stream. Factors of stress, especially in the winter months, that lower resistance appear favorable for the reappearance of the I.B.R.-I.P.V. virus in body secretions. Massive exposure of mucous membranes to the virus may produce clinical lesions even though antibodies in the plasma may be present. Thus occasional abortions due to IBR may occur in immunized dams.^{12,16} Obviously more work and study is necessary to further clarify the pathogenesis of this disease.

The I.B.R.-I.P.V. virus tends to localize in lymphoid tissue.^{10a,25} Vulvar scrapings from cattle affected with the vulvovaginal form of I.B.R.-I.P.V. can be examined by means of the fluorescent antibody technique for the presence of virus. This virus could be demonstrated with the fluorescent antibody technique^{16,19,20} in the placenta of infected cows 3 days after the death of the fetus. This technique could also be used to diagnose the presence of virus in other infected tissues of the adult or fetal animal.

Control and treatment of I.B.R.-I.P.V., as with other infectious viral diseases, can be assisted by blood testing and isolation of new arrivals into the herd with a second sample taken one to two months later. Any animal with a positive titer should be considered as a potential carrier of the virus. In an outbreak, contact between animals should be kept at a minimum depending upon the facilities available on the farm. In cases involving the vulvovaginal or preputial form of the disease, breeding should be stopped for 3 to 4 weeks to prevent further spread. Local oily antibiotic preparations might be applied to the ulcerated mucous membranes of the genital tract in severe cases in dairy cows. In valuable cattle suffering from the respiratory form of the disease, antibiotics are often administered to prevent pneumonia or secondary bacterial respiratory complications. Supportive treatment and good nursing is imperative. In abortions due to I.B.R.-I.P.V. the fetus and its membranes should be destroyed and the cow isolated from other pregnant susceptible cattle for 3 to 4 weeks. If calves on a farm are infected and ill, pregnant cows should be kept from contact with them. If virus-free semen is desired, then I.B.R.-I.P.V. infection of donor bulls must be prevented.^{12,13,32} However because of widespread and latent I.B.R. infections, maintaining an artificial insemination stud free of IBR virus is impossible. Regular vaccination programs and frequent examinations of semen for the presence of IBR virus are now practiced.¹²

I.B.R.-I.P.V. modified live virus (MLV) vaccines are available either alone or in combination with B.V.D.-M.D. (Bovine virus diarrhea-mucosal disease) virus or

parainfluenza virus. Vaccines given intramuscularly may combine IBR and BVD viruses while those given intranasally often combine IBR and Parainfluenza (P13). Killed or inactivated IBR vaccines have been produced. These vaccines should be handled carefully and kept refrigerated so as to maintain their potency. Vaccine instructions should be read and followed carefully as certain vaccines should not be given to pregnant cows or to calves they are nursing. Severe signs of disease with diarrhea often was associated with natural concurrent I.B.R.-I.P.V. and B.V.D.-M.D. viral infections.^{10b,12} It is possible that severe clinical reactions in adult cattle following vaccination have occurred with the combined vaccines and where other diseases such as salmonellosis or B.V.D. are present and active at the time I.B.R.-I.P.V. vaccine is administered. These severe reactions may be associated with BVD virus which has an immunosuppressive potential in cattle. To provide protection against I.B.R.-I.P.V. virus, vaccination is best carried out in heifers at 6 to 8 months of age when a good immunity will develop that will last 3 or more years.¹² Vaccination if done earlier may be ineffectual because of maternal colostral antibodies often present in calves getting colostrum from immune dams. In recent years the M.L.V. vaccines, especially the intranasally administered ones that combine IBR and P13 viruses can be given to cows at any stage of gestation and even in the face of an outbreak. These are used routinely in an annual preventive vaccination and revaccination or "booster" program in many dairy and beef herds. Both intramuscularly and intranasally administered vaccines produce systemic antibodies within 7 to 14 days. The latter also produces a local antibody reaction and IgA which on challenge results in the rapid production of interferon titers.^{9,12,13}

Another bovine herpesvirus, Movar 33/63 type, was isolated along with BVD virus from an aborted 6 month old fetus.^{27b}

Bovine virus diarrhea-mucosal disease (B.V.D.-M.D.) virus was originally reported as a cause of abortion in over 20 percent of the cows from 2 to 9 months of gestation in 5 herds with severely affected cattle.^{11,19} Since 1946 few outbreaks have been recorded in N.Y. State and the clinical disease has been largely limited to a few young heifers, 6 to 24 months of age, in which the outcome is uniformly fatal.^{5,13,17} Serological surveys using serum neutralization tests to determine the incidence of antibody titers for the B.V.D.-M.D. agent in the cattle population have revealed an incidence of 50 to 70 percent B.V.D.-M.D. reactors in the U.S. and 20 to 50 percent in Europe.^{5,11,13,18} Thus cattle are the main reservoir of infection and most infections are inapparent as the clinical form of the disease is seldom observed.

Two herds experiencing an epizootic disease characterized by fever, depression, some anorexia and diarrhea in older lactating cattle were carefully studied. In one herd good circumstantial evidence indicated the disease was due to virus diarrhea and in the other herd serologic evidence confirmed the cause to be B.V.D.-M.D. virus. In the first herd 39 pregnancies terminated with 24 normal parturitions, 11 or 28% abortions, 2 early neonatal deaths and 2 live ataxic calves with cerebellar hypoplasia. In the second herd, 5 or 20% abortions occurred in 25 pregnant cows, 1 calf was "stillborn" and 2 calves had cerebellar hypoplasia. Abortions occurred 1 to 5 months or more after the initial epizootic and in the latter half of gestation. A few fetuses showed evidence of death, mummification and delayed expulsion from the uterus. Six months after the time of infection in the first herd, 97 percent of the animals had B.V.D.-M.D. antibody in their serums.^{9,10}

Dual I.B.R.-I.P.V. and B.V.D.-M.D. infections exhibit severe signs of disease.³ B.V.D.-M.D. virus from 2 aborted bovine fetuses 7 and 8 months of age was recovered.² The experimental evidence was cited that incriminated B.V.D.-M.D. virus as a probable cause of sporadic abortions. Eleven susceptible heifers at 5 to 7 months of gestation were infected with this virus recovered from an aborted fetus. One heifer calved prematurely, 3 calves had mild ulcerative mucosal lesions at birth referable to an intrauterine infection including one calf with cerebellar hypoplasia. Thus fetal lesions may resemble lesions seen in the mouth and digestive tract in older animals with the acute form of the disease.^{15,20} All calves in the above experiment had active B.V.D.-M.D. titers in their serum at birth and before colostrum ingestion. These titers persisted for over 6 months.

Kendrick^{12,13} has reported that BVD-MD virus is a mild virus for the fetus compared to the IBR virus. In all cows in which the fetuses were inoculated at 180 to 225 days of gestation, every fetus survived and showed no evidence of disease except the isolation of low levels of virus and the presence of a specific antibody to BVD in the fetal plasma. These antibodies were the result of an active immune response. When these calves were allowed to live, no virus could be recovered and the antibodies persisted for at least a year. When fetuses were inoculated with BVD virus at 150 to 170 days of gestation and examined a week later, they showed some evidence of disease, edema and hemorrhage, due to a vasculitis, moderate levels of virus but no antibodies indicating a lack of an immune response. Four weeks later the fetuses had recovered from the acute disease, virus was still present but no antibodies had developed. Later

in gestation the fetuses developed antibodies and the virus was eliminated. None of these fetuses had virus present at birth. When fetuses were inoculated with BVD-MD virus at 80 to 120 days and examined a week later, all were alive, some vasculitis was present and large amounts of virus was isolated. But between 7 and 14 days these fetuses died and most were aborted and a few became mummified. Viral infection of the fetus with BVD virus at 90 days of gestation causes necrosis of the dermis and partial alopecia if the fetus survives to term. Similarly fetuses infected at 125 to 150 days of gestation may develop necrosis of the external granular layer of the cerebellum producing cerebellar hypoplasia in the newborn calf. Also at this stage eye lesions and cataracts may develop.

In a recent study of the BVD-MD virus by Done and coworkers,¹ 15 pregnant heifers (1 with twins) with no antibodies for BVD-MD virus, were inoculated intramuscularly with combined field strains of cytopathic virus at 100 days of gestation. The heifers exhibited no clinical signs of disease but seroconverted within 6 weeks. Five heifers, including one with twins, had fetuses that died **in utero**. Four aborted about one week after fetal death 36 to 54 days after heifer inoculation. The other heifer had a mummified fetus. All aborted fetuses showed signs of growth retardation. The remaining 10 heifers produced live calves at term that were carefully cultured, examined serologically and autopsied. All 10 calves showed growth retardation and thymic hypoplasia. Four had C.N.S. malformations, 8 had spinal dysmyelination and 3 had microencephaly, internal hydrocephalus and/or cerebellar dysgenesis or hypoplasia. Two of the calves had specific serum antibodies against BVD-MD virus and no virus was recovered from them. But the other 8 calves had not seroconverted and a noncytopathic BVD-MD virus was recovered from these calves. These latter calves had developed either immunological tolerance or immunological paralysis. This study further indicates that the BVD-MD virus can be immunosuppressive. This study noted the great similarities between BVD-MD virus, Border Disease virus and hog cholera (swine fever) virus which are all pestiviruses. It further stressed the possible importance of the BVD-MD virus in the world, by indicating that potentially 1 in every 16 bovine fetuses in Britain was at risk from this virus. Because of the widespread presence of the BVD-MD virus and its immunosuppressive potential when associated with other bovine disease it may be one of the most important causes of economic loss to the cattle industry.^{4,16} Also related to this potential is the evidence that 0.5 to 1 percent of severe postvaccinal disease problems follow the administration of MLV, BVD-MD vaccines. BVD-MD

virus in newborn calves either contracted **in utero** or postnatally may cause enteritis and death.¹⁴

It is obvious, because of the widespread presence of this virus and serologic reactions in cattle, that a rise in titer or a titer going from negative to positive as determined by paired samples is necessary for a possible or probable diagnosis of BVD-MD abortion. Of 47 paired blood samples taken from cows at the time of abortion and two to three weeks later, 15 percent showed a rise in titer of BVD-MD antibodies.¹⁵ After a natural infection a lifelong immunity developed.^{5,6,11,12,13}

Commercial MLV vaccines are available that induce a permanent lifelong immunity when administered to calves at 6 to 10 months of age. Vaccination at an earlier age may be ineffective because of a passive immunity induced by the maternal colostral antibodies. Stressed cattle should not be vaccinated or the vaccine should be used with caution.^{5,6,11,13} Vaccination during pregnancy should be avoided. Dual IBR-IPV and BVD-MD attenuated vaccines tend to produce occasional or sporadic moderate to marked postvaccination reactions especially in stressed cows or calves.^{3,4,14} Some veterinarians recommend annual "booster" vaccinations after calving and 30 to 60 days before breeding.^{4,14} Inactivated BVD-MD vaccines have recently been marketed that may prevent the occasional reactions seen after using the MLV or attenuated vaccines. Further studies on BVD-MD vaccines and vaccination procedures are indicated.

Miscellaneous Viral Infections including Parainfluenza and Bluetongue associated with bovine abortions are usually sporadic unless highly susceptible cows at the proper stage of gestation are heavily exposed to a virulent virus. Most of the following viral diseases are inapparent or nonclinical infections in the adult animal.

Bovine myxovirus parainfluenza 3 (PI3) was recovered from an aborted bovine fetus and produced abortion in a pregnant cow 9 days after intrafetal inoculation.^{11,14} Signs of fetal septicemia with petechial hemorrhages were observed. Abortions have not been produced by virus inoculated by natural means. This virus is apparently widespread in cattle as serological studies have revealed it to be present in 50 to 95 percent of the cows.^{6,14} Viruses such as BVD-MD and bovine parainfluenza 3 are present so commonly in cattle that occasional isolations from fetuses might be accidental or in association with another agent that caused the abortion. Bovine parainfluenza 3 virus is usually associated with shipping fever pneumonia.¹¹ The virus alone is only a very mild pathogen and can be recovered from healthy cattle. Since most cattle are PI-3 seropositive and resist transplacental transmission of virus, PI-3 virus is not a common cause of fetal disease and abortion. **In utero**

inoculations of bovine fetuses with PI-3 virus cause fetal disease and fetal immune competency.¹⁴ PI-3 virus may be a more important cause of abortion in dairy herds in northeastern United States because PI-3 antibody was demonstrated in 53 percent of aborted fetuses and 29 percent had PI-3 antibodies in combination with other antibodies.³ MLV vaccines for immunizing calves and cows against parainfluenza-3 alone or in combination with other viruses, such as IBR, are commercially available for intramuscular or intranasal use.^{11,6}

Bovine enteroviruses—In 100 aborted bovine fetuses, 5 to 8 months of age, examined only 27 definitive diagnoses of the causative agent could be made. However, serologic studies on these 100 fetuses revealed antibodies to PI-3 in 53 percent and enterovirus in 41 percent often combined with antibodies against other viruses.^{3,4} Enteroviruses and parvoviruses can cause fetal deaths in swine. Further studies on the role of enteroviruses in bovine abortion is indicated. Evidence for this agent as a cause for abortion has been reported from England and the United States.^{3,4}

Bovine parvovirus is common in some areas of the United States with 65 percent of cows carrying antibodies.^{1a,b,12} Fetal inoculation with parvovirus during the first trimester of gestation resulted in growth of virus in the fetus and abortion. Fetuses inoculated during the second trimester became infected with the virus. Fetuses inoculated during the third trimester developed antibody titers and no virus was recovered. A cow pregnant about 175 days was inoculated with bovine parvovirus and aborted a partially mummified fetus about 80 days later and virus was identified in the fetus and resulted in a latent uterine infection.^{1b,12} Further study on the lethal effects of bovine parvovirus on fetuses is indicated.

Bluetongue virus of sheep, goats and cattle which is widespread in tropical and semi-tropical climates and in the western and southern half of the United States has been reported as a cause of abortion^{4,11,1a,9,10a} as well as congenital defects described in Chapter III. The disease is spread naturally by insect vectors, particularly gnats, *Culicoides variipennis*. This insect vector is responsible for the geographic distribution and seasonal occurrence of the disease. Elk, white-tailed deer and other wild ruminants are susceptible to bluetongue virus and may be long-term carriers or potential reservoirs of the virus.^{6b} Bluetongue is not a problem in cold climates because the *Culicoides* vectors that spread the disease cannot survive. New Zealand and Australia are presently considered free of the disease. Most cases of bluetongue in cattle, which are considered to be the reservoir host, are subclinical but occasionally severe cases exhibit a characteristic elevated temperature, drop in milk production,

ulcers in the mouth with slobbering, ulcers on the teats and inflammation on the muzzle and coronary band with lameness. There are four serotypes of bluetongue virus in the United States,^{4,7,9,10} and 20 in other world countries.^{10b} Following infection a viremia occurs lasting several weeks during which the virus may pass to the embryo or to the fetus, especially in early or midgestation, and cause its death with abortion or mummification or cause fetal disease especially of the central nervous system with hydranencephaly, contracted, deformed extremities, or the birth of apparently normal immunological tolerant calves that are latent carriers of the virus.^{4,7,8,9,10} Bluetongue virus may be found in the semen of apparently normal bulls and be transmitted to the cow at the time of breeding.

Fourteen susceptible heifers were bred naturally to a bull shedding bluetongue virus in his semen.⁸ All heifers developed viremia but no clinical signs were observed. Twelve heifers conceived on the first service but one aborted about 60 days of gestation. Two heifers were rebred twice at irregular intervals before conceiving. Only one of the 14 heifers developed a precipitating antibody to bluetongue virus. Thirteen of the 14 heifers calved with gestation periods of 281 to 297 days. All twelve calves born were viremic and had congenital anomalies and five of these were weak and ataxic at birth. Thus natural service, and probably artificial insemination of semen infected with bluetongue virus by a carrier bull is an effective nonvector-mediated means for the spread of bluetongue virus in cattle.⁸

The complement fixation test, SN, ELISA^{10b} and agar gel immunodiffusion (AGID) tests are used to detect antibodies indicative of prior infection. Virus isolation and immunofluorescent procedures can also be used for virus identification in cows and fetuses. In the United States there is only one M.L.V. vaccine containing only one serotype approved for use against bluetongue in sheep but none for cattle. Work is in progress on an inactivated or killed bluetongue vaccine for sheep and cattle.¹³

Pseudorabies or Aujeszky's disease or malignant catarrhal fever caused by a herpesvirus may result in abortion if the pregnant affected cattle do not die within a few days of the onset of the disease. A new herpesvirus and a cytomegalovirus were reported to have been recovered from aborted bovine fetuses.^{2b} Since more recent reports on these agents have not appeared, the earlier, apparently rare findings, are of limited importance. Prenatal transmission of **bovine leukemia virus** is uncommon and abortions due to this virus have not been reported.^{4b}

Foreign bovine diseases, not presently in the United States but associated with abortion, include **foot and**

mouth disease, rinderpest, Rift Valley fever,^{4,11,16,24} and Akabane virus disease.⁵ This latter disease in its mode of spread and its effects on the late embryo and fetus closely resembles bluetongue virus disease. Abortion, stillbirths, premature births, hydranencephaly, and arthrogryposis occur depending on the stage of gestation when infection of the fetus occurred (See Chapter III). Akabane disease has been reported in Japan, Australia and Israel.

Mycotic or Fungal Causes of Abortion

Almost all mycotic bovine abortions or internal mycoses are caused principally by two groups of fungi. About 60 to 80 percent are caused by *Aspergillus* spp. and most of these are *Aspergillus fumigatus*.^{3a} The *Mucorales* order of fungi, especially *Mucor pusillus*, are responsible for most of the remainder of mycotic abortions. Other uncommon fungi include: *Allescheria boydii*, *Torulopsis glabrata*, *Mortierella wolfii*, *Absida ramosa*,^{3a} *Cephalosporium*¹⁰ and rarely the yeast *Candida tropicalis*.^{11,12,13} The incidence of bovine mycotic abortion varies from 4 to 20 percent of all diagnosed infectious bovine abortions.^{13b,18,12} The higher incidence is noted in areas where brucellosis and vibriosis have been controlled. Most mycotic abortions are sporadic but the author has observed a number of small herds having 3 to 5 mold abortions, up to 5 to 10 percent of the herd, in a winter season.

Aspergillus, *mucor* and other molds are ubiquitous in nature and are usually saprophytic. Occasionally they may localize in the body producing serious systemic diseases. The highest incidence of mycotic abortion occurs in the winter months^{13b,4,6,12} often following a wet summer season when the hay and straw was baled while damp and mold developed. One study found no correlation between total rainfall or rain days during the months that hay was baled and the incidence of the disease the next year. However, the abortion rate was highest in cows fed in cowsheds.¹² Molds apparently are taken into the body by inhalation into the lungs or by ingestion. The mold spores are then carried to the placenta in the bloodstream from lesions in the respiratory tract or ulcers, mycotic rumenitis or other lesions of the digestive tract. This results in a slowly developing fungal placentitis, interference with the nutrition of the fetus, fetal death and abortion after a number of weeks or months. Abortion occurred about 35 days after the intravenous inoculation of spores of *Aspergillus fumigatus*.⁴ Most mycotic abortions occur about the 5th through the 8th month of gestation but may occur from the second month to

term.^{3b,4,6,12} A few live normal calves have been born with a placenta having a severe mycotic placentitis. The fetuses in most mycotic abortions show evidence of growth retardation. The fetus is usually expelled dead with a degree of autolysis present but in some cases premature or full term calves are alive but weak at birth and die shortly thereafter. Mycotic infections could not be established by the intrauterine infusion of *Aspergillus fumigatus* spores at the time of insemination. The non-gravid uterus appeared quite resistant to mycotic infection.⁵

Mycotic abortion is usually characterized by marked gross changes in the fetal membranes resembling, but much more pronounced than, those due to **Br. abortus**, **C. fetus** and chlamydia.^{15,7,8} The chorion is thick, edematous, leathery, and necrotic. The primary lesions are in the placentomes. Both the maternal caruncle and fetal cotyledon are very large, swollen, edematous, and necrotic. The enlarged cotyledons may be firmly incarcerated and resist detachment for 8 to 10 days or more after abortion. The placentomes may then become completely detached due to severe necrosis involving the cotyledons, caruncles, and the caruncular stalks. In a few instances these necrotic structures remain in the uterus for several months after abortion or normal birth and retained placenta, and resemble a macerating fetus and/or pyometra. The cow must often be sold as sterile.

The necrotic cotyledons show a dull grey center surrounded by areas of hemorrhage and are firmly attached to the leathery chorion. In the uterochorionic space is usually some reddish fluid with large flakes of pus. The fungus spreads by extension through the fetal membranes to the fetal fluids. The fetus may be normal in appearance or in about 30 percent of the cases, mold may grow on the skin in patches or plaques that resemble congenital ichthyosis or ringworm.^{4,12} (See Figure 63.) Straw-colored serous fluid may be present in the fetal tissues or body cavities. In rare instances the liver is enlarged and swollen. The mold can often be recovered from the stomach contents or from the diseased chorion or cotyledons of the placenta. In a few fetuses the lungs are involved with a mycotic bronchopneumonia and the brain with a mycotic granuloma.^{3b} The endometrium is as severely involved as is the chorion but even with this severe uterine infection, generalized symptoms of septic metritis are seldom exhibited. Recovery in severe cases may be slow and prolonged or permanent sterility may follow. In one study 80 percent of the cows conceived after mycotic abortion but conception rate on first service was only 33 percent.¹²

The diagnosis is confirmed by histologic examination of the placental or fetal tissues and by culture of the mold on artificial media. In submitting specimens to the lab-

oratory for diagnosis it is imperative to include placental tissues as frequently the placenta is severely affected by mold but the fetus is not infected.^{9,12,13}

Infectious Parasitic Protozoal Causes for Bovine Abortion

Trichomoniasis due to *Trichomonas fetus* is a venereal disease characterized, as is campylobacteriosis (vibriosis), by infertility and early embryonic death. Abortions due to trichomoniasis usually occur during the first trimester or through the fourth month of pregnancy. Abortions after the fifth month of pregnancy are rare. For this reason retained placenta is uncommon in trichomonad abortion. Observed trichomonad abortions are uncommon. The disease is fully discussed in Chapter XII on Infertility in Cattle.

Abortions in cattle due to other parasitic protozoa are uncommon. These protozoa, except the anaplasma, are members of the order of Coccidia. The sporocysts are passed from the intestine of carnivores, especially cats and dogs, and when ingested by other animals invade the body tissues producing disease.^{4,2,5b,9,11} These parasitic protozoa include: *Toxoplasma gondii*, *Sarcocystis* spp. and *Besnoitia besnoiti*. The latter organism is apparently limited in occurrence to southwest Europe and Africa while the other two organisms have a worldwide distribution. Cattle, in contrast to sheep, are rather resistant to toxoplasmosis and abortion due to *Toxoplasma gondii* is rare if it does occur naturally.^{4,1,11,12}

Anaplasma marginale has been described as a cause for abortions in cattle when susceptible cattle are acutely infected the third trimester of pregnancy.^{8,14,16} Transplacental transmission of anaplasma to the fetus is uncommon. In further trials susceptible pregnant heifers inoculated with *A. marginale* the second trimester of pregnancy did not abort.^{15,16} Thus it is likely that abortion late in gestation due to acute *A. marginale* infection occurs secondarily to the acute anemia of the dam with fetal acidosis, anoxia, and death, when fetal demands for oxygen are elevated as compared to the oxygen requirements of fetuses during for second trimester of pregnancy.¹⁴ This hypothesis is further supported by evidence that severe anemia secondary to a heavy sucking louse (*Haematopinus eurysternus*) infestation also causes bovine abortion in late pregnancy.¹⁴ A further experiment repeating these studies and including hormonal studies, especially of fetal and maternal cortisol levels would be most interesting and informative. Four injections IM of a long-acting oxytetracycline (20 mg/kg) at

3-day intervals eliminated the naturally-infected anaplasmosis carrier state in 14 cattle.^{11c} Further studies are indicated.

Abortions due to *Sarcocystis cruzi*, *bovicanis* and others and *Toxoplasma gondii* have been produced experimentally in cattle by massive exposure to sporocysts and tachyzoites of these respective protozoa.^{5b,c,d,7a,b,11a,b,c,12,13} In abortions following experimental exposure to *Sarcocystis* no organisms were found in the dead fetuses but migratory merozoites were found in the uterine caruncles.^{6,9} Abortions have been described in the last trimester of pregnancy in severely affected naturally-occurring outbreaks of sarcocystosis (Dalmeny disease or rat-tail syndrome).^{7a,b,9,11a} The severity and chronicity of this clinical disease leads one to suspect hormonal changes due to stress to be a possible cause of abortion. However recent reports have described sarcocystis organisms throughout the aborted fetus, especially in the endothelium and brain.^{7a,11a} Abortions did not occur in pregnant cattle fed toxoplasma oocysts from cat feces. It was concluded that abortions in cattle due to toxoplasmosis were unlikely, but infected weak, stunted calves with congenital chorioretinitis might occur.^{1,12}

Besnoitia besnoiti causes a severe extensive dermatitis, diarrhea, debility and a low mortality rate.^{4,2} Abortions in pregnant cows and sterility in bulls is reported in bovine besnoitiosis.^{4,2} *Trypanosoma theileri* has been recovered from the stomach of an aborted bovine fetus.⁶ **Babesiosis** or piroplasmosis due to *Babesia bigemina* and *argentina* may cause abortion if an adult pregnant female cow is severely affected by fever, hemoglobinemia, jaundice, anemia and loss of condition.⁴

Abortions in Animals Infectious to Humans

With more women entering the field of veterinary medicine, attention should be called to the infectious diseases capable of causing abortion in both animals and man: brucellosis, listeriosis, campylobacteriosis (vibriosis), mycoplasmosis, ureaplasmosis, chlamydiosis, toxoplasmosis, possibly leptospirosis and salmonellosis and others.^{3,5a,5c} All of these infectious causes of abortion or teratogenicity have been reported in most of the species of large and small domestic animals. Veterinarians are frequently called upon to care for aborting animals and treat the secondary retained placenta and metritis that often follows the abortion without a knowledge of the causative agent. It behooves all veterinarians, especially pregnant ones, to take careful hygienic and other precautions

Figure 65. Chronic ergot poisoning of a Jersey cow carrying a normal 6-month fetus.

to avoid exposure to these agents infectious to man and human fetuses.

Chemicals, Drugs and Poisonous Plants as Causes for Abortions in Cattle

Nitrate poisoning ("lowland or marshland abortion") was originally described in Wisconsin as occurring in cattle pastured on unimproved weedy muckland pasture.^{27,28} Up to 80 percent abortions in a herd occurred from 3 to 9 months of gestation and no infectious agent was found. When these pastures were improved by treating with herbicides and fertilizer to promote the growth of grasses abortions no longer occurred. It was considered that nitrate concentrated in certain plants was possibly the cause of abortions. Workers in Missouri^{17,30} published extensively on the progressive stages of nitrate intoxication including the lowering of the vitamin A levels, loss of production and abortion. In the early 1960's extensive experimental studies and reports^{3,4,5,17,32} demonstrated that low to fairly high levels of nitrates in the feed produced no harmful effects on cattle or caused abortions. A few abortions in experimental cattle and in field outbreaks were produced but they were associated with very high levels of nitrate ingestion producing severe toxic reactions, marked methemoglobinemia and occasional death.^{2,4,29} Since experimental nitrate feeding produced levels of 65 to 75 percent methemoglobin without respiratory distress in pregnant heifers^{4,29} and fetal oxygen tensions are normally only 20 to 30 percent of adult values, fetal hypoxia might have been the cause of fetal death in heifers given near lethal doses of nitrate.

Chlorinated naphthalenes formerly used in lubricants produced hyperkeratosis or X disease and an acute vitamin A deficiency characterized by dry, thick, wrinkled skin, metaplasia of the epithelium of many internal structures and glands, metritis, abortion, dystocia and retained placenta.¹¹ The occurrence of this disease in recent years has been rare.

Chronic arsenic poisoning has been reported to be a cause of abortion.³¹ Although **lead** poisoning has been associated with abortions in humans it has not been reported in animals.

Sodium iodide given in large doses intravenously has occasionally been reported as causing abortion in pregnant cows.^{9b} Sodium iodide injected in large doses often causes a rise in body temperature, depression, and anorexia. The author has on numerous occasions administered sodium iodide to pregnant cows without abortion resulting. Another study also reported that sodium iodide given intravenously failed to cause abortion in cows.²¹ However a recent report indicated an organic iodide, ethylenediamine dihydroiodide, when fed dairy cows at approximately 1000 times the daily requirement for 30 days resulted in 12 abortions, or 20 percent of the herd, within 68 days. Abortions occurred in 66 percent of the cows from 1 to 90 days of gestation but in only 9 percent of the cows over 180 days of gestation. No infectious causes of abortion were detected.²³

Locoweeds (*Astragalus lentiginosus* and *Oxytropis sericea*) caused abortions in cattle when ingested at any stage of the gestation period. The rate of abortions was related to the amounts of the plant ingested and the severity of the poisoning.^{13,14,15,18} No typical lesions were observed in the aborted fetus or membranes but some evidence indicated the fetuses suffered from malnutrition possibly related to placental changes. Consuming lesser amounts of locoweed resulted in deformed fetuses with rotation and ankyloses of the limbs. Sheep were similarly affected. This plant was habituating and animals would eat it even when good grass was available. In advanced cases neuronal degeneration and emaciation developed, due to the indolizidine alkaloids.^{24b} Many nitro-containing and selenium accumulating varieties of *Astragalus* are not abortifacient.¹³

Perennial Broomweed (*Gutierrezia microcephala*) when ingested caused 10 to 60 percent of the fetuses in affected herds to be expelled prematurely either dead or weak at birth. Calves were small, 8 to 50 lbs., and retained placentas were common. A variation in the toxicity of the plant grown in different types of soil was noted. Abortions were due to a saponin in the plant.^{6,7}

Sweet Clover Hay or Silage may cause fatal fetal hemorrhage due to the action of dicoumarol. None of 14

calves born to dams fed sweet clover hay survived for more than a few hours. The cows were not affected. Elimination of sweet clover hay from the ration resulted in a cessation of losses. The toxic compound is produced by fungi growing in moldy sweet clover hay. Neither this nor any other known mycotoxin is actually abortifacient.¹⁹

Pine needle (*Pinus ponderosa*) ingestion causes abortion in cattle from 21 to 142 days after the ingestion of the pine needles in the Western United States and Canada. A recent report indicated abortion may occur after only one or two days of feeding pine needles especially if the cow was stressed.¹² Abortions may occur from 6 to 9 months of gestation. Many affected calves are born prematurely, small and weak and die soon after birth. Retained placentas and metritis are common. The toxic agents which are heat labile are probably diterpene resin acids.^{20a} Vitamin A levels in aborting cattle are normal.^{1,9a,12} Pine needle abortion resembles closely perennial broomweed abortion.¹²

Ergot poisoning due to the consumption of *Claviceps purpurea*, a fungus that grows on rye, wheat, barley and many grasses, has been reported to cause outbreaks of bovine abortion. These reports in most cases were in error as abortion is not a feature of ergot poisoning in cattle.^{19,34} In cattle and humans large continued doses of ergot result in gangrene of the extremities and central nervous disturbances.^{10,19,25,34} The author has observed, as did the latter authors, cows with gangrene of the extremities still maintaining a normal pregnancy. (See Figure 65.) There are 6 or more toxic principles, mostly alkaloids, produced by ergot. Ergonovine, which is one of these produces an oxytocic effect on uterine muscle that lasts a number of hours following a single dose. Tall fescue grass, *Festuca arundinacea*, infected with a fungus containing alkaloids similar to ergot,^{2b,16,18,19} which when consumed by cattle caused a similar necrosis of the extremities. No abortions have been reported in these cattle. Recent studies indicate that a mycotoxin produced by an endophytic fungus in fescue hay or seed, not a plant alkaloid, is the agent causing fescue toxicity.^{26b} Ergotism was produced in pregnant sows by feeding barley containing 1 percent ergot. No abortions occurred in the sows but the pigs were weak and small and the sows had a lack of udder development and agalactia. Agalactia has been reported in other species of animals that have consumed ergot.^{20b,24}

Polybrominated biphenyls (PBBs) when fed at high levels to pregnant heifers and cows caused toxic clinical signs, resembling chlorinated naphthalenes or X-disease, including anorexia, lacrimation, salivation, diarrhea, emaciation, dehydration, depression and abortion with

an autolyzed fetus and a necrotic placenta. Metritis and retained placentas were common in cattle aborting from 5 months to term. All animals became moribund within 33 to 66 days.^{8,22}

Pesticides including **Diazinon**, **Sevin**, **Marlate**, **Ciodrin**, **Vapona**, dieldrin, DDT, **Epoxide** and other organic phosphates were studied and no evidence was found that they contributed to the incidence of abortion on Wisconsin dairy farms.³³

Although **dietary urea** has been suspected of having a possible effect on bovine reproduction including abortion, no studies have shown a definite effect when urea is fed at recommended levels.

Hormonal Causes of Abortion in Cattle

Estrogenic compounds if given in large doses over a period of time will cause abortion in cattle by causing regression of the corpus luteum.^{9,21} The injection of 100 mg of **Repositol** diethylstilbestrol intramuscularly to pregnant heifers up to 4 months of gestation and 25 mg more for each additional month of gestation produced abortions in 3 to 12 days after the injection in 79 percent of 761 heifers. Those that failed to abort were retreated with slightly larger doses and 50 percent of those aborted after the second treatment.⁹ Retained placentas and metritis occurred in some cows aborted in late gestation. For this reason inducing abortion between 5 to 9 months, especially with large or repeated doses of estrogens, should be undertaken with caution.⁴ Abortions were produced in 19 heifers pregnant 2 to 6 months with 80 mg. of stilbestrol in oil given twice at 3 day intervals.³ Similar results can be expected with high doses, or repeated doses, of estradiol cyclopentylate (E.C.P. or cypionate), aqueous suspensions of estrogens, pellet implants of estrogen or even high levels of orally ingested estrogens. Abortions occurred in heifers fed silage sealed with manure from hexestrol-fed steers.¹⁶ Abortions in 13 of 33 cattle from 105 to 204 days of gestation were reported after consuming poultry litter from birds being fed grain containing dienestrol.⁸ Much estrous activity was exhibited by the herd during this same period. When feeding of the poultry litter stopped, abortions and the estrous activity ceased. Estradiol valerate, at a dose level of 20 mg intramuscularly, at 60 to 120 days of gestation caused abortions in 8 of 10 heifers between 8 and 16 days after injection. A second injection of estradiol caused abortion in the two heifers not aborting after the first injection.⁶ Single moderate doses of estrogen such as 20 to 40 mg. of stilbestrol or 2 to 4 mg of estradiol have not produced abortions on experimental injection into pregnant cattle.

If large doses are administered to cattle to overcome anestrus, the uterus should be carefully palpated per rectum to make certain that pregnancy is not present. Abortion under these circumstances can be highly embarrassing for a veterinarian even though the owner did not know the animal was pregnant and reported her to be anestrus.

The **glucocorticoids** or **hydrocortisone** may cause abortion in cattle. The close relationship between the adrenal cortex and the maintenance of pregnancy has been reviewed.¹⁸ The gonads and adrenals have a common embryological origin and produce steroids that are chemically similar and closely related. The adrenal gland can readily convert progesterone and androgens into cortisone and cortisol. Prolonged gestation in Holsteins and Guernseys, as discussed previously, are caused by inherited fetal defects including hypoplastic adrenal glands and adeno-hypophyseal hypoplasia or aplasia resulting in a failure to produce cortisone essential for normal parturition (See Chapter VI). Parturition was induced in 9 cows with prolonged gestation, 290 to 349 days, with one or two injections of 10 to 20 mg. dexamethasone and 10 to 50 mg. estriol. Abnormal calves with aplastic adrenal and pituitary glands were expelled one to three days later.^{9c}

Five heifers, pregnant 193 to 222 days, were given recommended amounts of glucocorticoids for 4 to 8 days; 4 heifers were injected with 5 mg daily of flumethasone and 1 heifer received 2 boluses orally daily of dexamethasone, 5 mg per bolus. All heifers aborted between the 4th and 13th day after the start of the experiment; one fetus was undergoing beginning maceration.¹² The injection of 20 mg of dexamethasone intramuscularly into 22 cows, 235 to 280 days pregnant, resulted in 19 calving or aborting within 22 to 56 hours or an average of 45 hours.^{1,2} Three of 5 cows under 260 days of gestation failed to calve or abort. All but one of the cows produced live calves but only 2 of the 22 treated animals dropped their afterbirths normally. Within 24 hours after the injection the vulva was swollen and relaxed and the udder had filled with milk. In a subsequent study it was concluded that dexamethasone most successfully induced parturition from day 255 of gestation to term. Induction failure increases as the length of gestation decreases.^{1,2} Estrogens and especially glucocorticoids might well be indicated to produce abortion in occasional cows with a prolonged gestation. It is interesting to speculate on the role of stress and increased cortisone production on abortions or premature births in cows in late gestation that occur following severe systemic diseases, malnutrition or starvation, severe prolonged physical work or long distance transportation to shows or fairs. Administration

of cortisone the last few weeks of gestation should be avoided unless premature births are required.

Prostaglandins either prostaglandin F_{2a} ("Lutalyse") or prostaglandin analogues cloprostenol ("Estrumate") and others are excellent compounds used in cycling cows to induce luteolysis or involution of the corpus luteum for estrus synchronization and in pregnant cows to induce abortion or evacuate the uterus in cases of mummified fetuses or pyometra. A prostaglandin analogue, 250 and 500 μ g. of cloprostenol, injected into pregnant heifers was a safe and effective abortifacient up to day 120 and from day 121 to 150, respectively. Most heifers aborted 3 to 4 days after the injection.^{21,22} Fifteen heifers 29 to 52 days pregnant aborted before 72 hours after the administration of 15 or 30 mg of PGF_{2a} .¹³ Two daily doses of 12.5 and 25 mg PGF_{2a} injected into heifers at 60 to 120 days of gestation caused 10 of 10 heifers to abort an average of 3.6 days later.⁶ A dose of 27 mg PGF_{2a} would be expected to produce an abortion rate of 85 percent in pregnant heifers less than 150 days into the gestation period.¹¹ Since inducing abortion in heifers over 150 days pregnant was inconsistent and unsatisfactory, even when larger doses of prostaglandin were administered, a combination of cloprostenol (500 mg) and dexamethasone (25 mg) was given to Group I, 37 heifers, 1 to 4 months into gestation, Group II, 40 heifers, 4 to 6 months into gestation, Group III, 40 heifers, 6 to 8 months into gestation. Group IV, 30 heifers, 1 to 8 months into gestation were not given any injection. In Group I all heifers aborted; in Group II and III 37 of 40 heifers aborted with 2 heifers diagnosed with mummified fetuses and one pregnant in each of these two groups. No abortions occurred in Group IV.⁵ Mummification instead of abortion may have been due to incomplete regression of the corpus luteum. Thus prostaglandins alone in adequate dosage regularly terminate pregnancy in cattle the first five months of gestation and the last month of gestation. During 5 to 9 months of pregnancy, high doses of prostaglandins should be combined with high doses of cortisone to induce abortions or terminate pregnancies. Apparently prostaglandin acts to greatly reduce the ovarian source and dexamethasone the uterine source of progesterone to bring about abortion.^{9b} If single products are used repeatedly large doses may be necessary until desired results are obtained. Greater complications from dystocia, retained placentas and metritis should be expected when abortions are induced between 6 and 8-1/2 months of gestation. (See Induction of Parturition.)

Progesterone deficiency appears to be a cause of early abortion in cattle but confirmed cases have not been described. Enucleation of the corpus luteum will regularly cause abortion when performed the first 160 days of ges-

tation.^{4,21} Maintaining pregnancy by the supplementation of existing progesterone levels during pregnancy by the parenteral injection of 500 mg of **Repositol** progesterone every 7 to 10 days starting 20 to 30 days before the expected abortion until 180 to 230 days of gestation in habitually aborting cows provides circumstantial evidence that a lack of progesterone may be the cause of the abortion. Improved embryo survival rates were also observed in ovariectomized gilts maintained on higher daily doses of progesterone, 80 to 160 mg. vs. 40 mg.⁷ About 1000 mg of **Repositol** progesterone every 10 days was required to maintain pregnancy from 30 to about 100 days of gestation and 500 mg after 100 days when the corpora lutea were removed from cattle.^{14,20} Abortions due to progesterone deficiency occurred at 45 to 180 days, but most often, 83 percent, prior to 100 days of gestation. The same cow tended to have repeated early abortions. At these times a large follicle may develop possibly resulting in a high estrogen level and involution of the corpus luteum and abortion. These cows appear to have an unstable endocrine constitution. Possibly improved techniques now available will permit more careful monitoring of the progesterone level in the serum during pregnancy in these animals and thus aid in determining whether an actual progesterone deficiency does occur in cattle. Reduced levels of plasma progesterone were noted after fetal death and prior to abortion caused by experimental inoculation of **C. fetus** into pregnant cows the last half of gestation.¹⁵

Oxytocin given during gestation will not cause abortion in animals. In humans and mares the latter hormone has been used by the slow intravenous drip method to induce labor once certain preparturition changes have occurred including the suitable relaxation of the cervix. This technique shows promise in horses for inducing parturition after the genital tract is relaxed and the udder contains colostrum (See Chapter VI). Oxytocin given daily to a cow on days 2 through 6 after service will interfere with luteinization resulting in a short estrous cycle of 8 to 12 days. Such a treatment would probably prevent conception.²¹

Nutritional Deficiencies as a Cause of Abortions in Cattle

Nutritional deficiencies may occasionally be a cause for abortion. The response of both wild and domestic animals to their food supply is markedly reflected in their reproductive processes. If food supply is low, reproduction either is greatly reduced or ceases under these adverse conditions. Prolonged malnutrition results in a ces-

sation of the estrous cycle and failure of conception. Acute severe starvation may result in abortion in pregnant cattle. It is very difficult to assess the more specific effects of nutrition on reproduction because only a few nutrients exert a direct effect on reproduction.³ In many cases animals are suffering from multiple deficiencies and thus present a confusing picture. Much of the data is not based on carefully controlled experiments, or is based on too limited a number of animals.

Multiple deficiencies brought on by starvation during the severe drought in the Midwest in the 1930's caused many cattle to become extremely emaciated and cachectic, resulting in a high incidence of abortion and birth of dead, weak, or premature calves. Animals on a very low plane of nutrition abort as a protective mechanism to conserve their own body reserves. Hyperplasia of the adrenals and elevated cortisol levels may be present.

Vitamin A deficiency adversely affects reproduction in all species. Pregnancy usually terminates in abortion late in pregnancy, or in the birth of weak or dead young.⁴ As mentioned previously severe vitamin A deficiency may cause birth defects especially involving the eyes. The female animal requires more vitamin A than does the male, and the pregnant female apparently requires more vitamin A than does the nonpregnant female.³ Vitamin A deficiency causes keratinization of the vaginal epithelium and degeneration of the placenta leading to abortion. If pregnancy goes to term, birth may be difficult and infection and retained placenta follow. Under range conditions protein, phosphorus, and carbohydrates, as well as vitamin A, are likely to be deficient.

An iodine deficiency and the associated hypothyroidism in cattle has been reported to cause weak or dead calves at term and abortion in cattle.¹ **A possible selenium deficiency** was described in northeastern California characterized by the birth of dead, weak or premature calves, as has been described in sheep, and a high incidence of retained placenta that appeared to respond to the injection of a therapeutic dose of selenium.^{2b} In a group of 18 yearling Chianina heifers with myodegeneration due to a combined vitamin E and selenium deficiency in Pennsylvania, 2 aborted, 8 calves were still-born or died within 48 hours and 7 of the heifers with periparurient recumbancy died or were euthanized.^{2a} There is no evidence that other vitamin, mineral, protein or other nutritional deficiencies will cause abortion in cattle.

Physical Causes for Abortion in Cattle

Douching the uterus by invading the cervix and rupturing the fetal membranes,⁵ with a pipette or catheter

and introducing 50 to 100 ml. of a weak, Lugols' solution (1 to 2 ml per 100 ml of water), 200 ppm chlorine solution or a mild potassium permanganate solution or other aqueous or oily antiseptic solutions from 7 to 60 days of gestation will usually induce abortion in the cow without producing a severe metritis. If this practice is followed the third or succeeding months of gestation complications may arise including metritis or fetal maceration. Intrauterine insemination or douching should never be performed if the cow is pregnant as this act often results in abortion. All cows inseminated for the second or subsequent times should have the semen deposited in the mid-cervical region.

Manual rupture of the amniotic vesicle or rupture of the fetal heart or large vessels by manual pressure on the amniotic vesicle in early pregnancy, 30 to 60 days of pregnancy and division of the fetus after rupture of the amniotic vesicle at 60 to 70 days will terminate pregnancy.^{2,5} In some cases the fetal membranes persisted and even grew for 2 to 3 weeks before resorption or expulsion. The latter was rarely observed. Thus estrus may not occur for a month or longer after the death of the embryo. The dangers of abortion by failure to handle the amniotic vesicle gently when it is easily traumatized during pregnancy diagnosis at 35 to 45 days of gestation, requires emphasis. Palpation of the amniotic vesicle as a diagnostic aid in early pregnancy examinations should be avoided by all but skilled examiners. After 45 to 50 days of gestation it is much more difficult to damage the amniotic vesicle by routine pregnancy examinations. To prevent twinning rupturing the amniotic vesicle of one of the embryos at 33 to 45 days of gestation has been attempted.^{4,5} In two experiments about 50 to 70 percent of the pregnancies terminated with estrus recurring in 4 to 8 weeks even though only one amniotic vesicle was crushed.

Three manual methods of inducing abortion early in gestation that can be applied to the conceptus per rectum are: rupture of the amnion and crushing of the embryo or fetus from 35 to 66 days of gestation, decapitation of the fetus in cows 66 to 120 days into gestation and rupture of the amnion without crushing the fetus in cows less than 70 days of gestation.^{1,3} All cows aborted between 10 and 54 days, with a mean interval of 21 to 27 days, after treatment except 3 of 29 cows in which only the amnion was ruptured. Mummification of the fetus occasionally occurred following fetal decapitation. It was difficult to rupture the amnion after 65 days and to decapitate after 90 days of gestation.

Removal of the corpus luteum of pregnancy in the cow invariably results in abortion. Removal of the corpus luteum to bring a cow into estrus should never be

performed without a careful examination of the entire uterus to detect a possible pregnancy. Probably waiting until the fourth week after service to be sure the cow has conceived is indicated before the corpus luteum is removed by manual manipulation of the ovary through the rectal wall when abortion is desired.⁵ This technique should be employed before the fifth or sixth month of pregnancy since by this time removal is difficult or impossible because the ovary is pulled forward and downward out of reach. After the sixth month, abortion may not occur and dystocia may result, particularly in heifers. It is advisable to watch the cow for symptoms of estrus and abortion after removal of the corpus luteum, to make sure that abortion has occurred. In exceptional instances abortion may not result because all of the corpus luteum might not have been removed, or another corpus luteum may be present in the opposite ovary.

Other miscellaneous physical causes for fetal death and abortion in cattle include **severe torsion of the uterus**, more than 180° and **rare displacements of the umbilical cord** over the head and neck of the fetus or **torsion of the umbilical cord** causing fetal death by interference with the circulation of fetal blood. (See Figure 66.)

Occasionally abortions in cattle are observed following severe transportation fatigue, severe systemic diseases and major operations such as for traumatic gastritis late in gestation. Excess production of glucocorticoids from the adrenal may be implicated in these abortions. Violence and trauma are explanations often relied upon by laymen and veterinarians as an easy way to explain certain abortions when the cause cannot readily be ascertained. If abortion does occur after an injury it is fortuitous and usually not due to the trauma so other causes should be considered.

Genetic or Chromosomal Causes of Abortion

Inbreeding has resulted in increased embryonic deaths, abortions and stillbirths because of a greater concentration of lethal genes per zygote than in crossbreeding. Abortion at term or "stillbirths" were increased with inbreeding in cattle and were associated with posterior presentation, dystocia, malposture of the fetus, twinning and fetal abnormalities.¹⁰ Sixty-two percent of the "stillbirths" were males. The incidence in first-calf heifers was 6.7 percent compared to 2.4 percent of the rest of the cattle. Certain genetic defects of the bovine fetus may result in intrauterine death and abortion such as, fetal anasarca in Ayrshires, osteopetrosis in Angus, and severe achondroplasia in Dexters (See Chapter III).

An incidence of 20 and 45 percent, respectively, of chromosomal anomalies were present in over 300 spon-

taneous abortions in humans.^{1,2,9} About half of these abnormal embryos had an extra chromosome, trisomy; others were monosomic or polyploid. In another study of nearly 40 human couples in which the female partner had a history of habitual abortion, it was shown that most of these men and women did not have demonstrable genetic chromosomal abnormalities and this was not a common cause of recurring abortions.⁷ However, one female heterologous translocation carrier was discovered that was traced through three generations. Impairment of fertility occurred in 3 of the 4 female carriers of this chromosomal defect.

An abnormal diploid chromosome number was reported in the Swedish Red and White breed.⁴ In 1173 animals examined 14 percent were heterozygous with a chromosome number of 59 and 0.34 percent were homozygous with 58. This was caused by a translocation, Robertsonian, between the largest and smallest chromosome pairs. This resulted in a 2 to 3 percent lower conception rate in heterozygous bulls and cows due to an increased incidence of early embryonic deaths. Few reports of similar cases in animals of early embryonic deaths and aborted embryos and fetuses are available. It is probable that a certain percentage of abortions in cattle are due to chromosomal abnormalities. Ten to 12 percent of the blastocysts from normal sows had detectable chromosome defects and this may account for about 30 percent of the total pregnancy wastage which in sows is about 30 to 40 percent of the fertilized ova.⁵ Polyploidy was the most common chromosomal abnormality in those defective zygotes. Tetraploid cells were found in a bovine blastocyst.⁶ Polyspermy associated with delayed insemination of sows may be a factor in causing polyploid embryos. In one Holstein herd abortions and fetal mummification occurred commonly at 120 to 180 days of gestation in daughters of two popular sires when they were mated to the other sire. It was postulated these abortions and mummified fetuses were caused by an autosomal recessive gene carried by the heterozygous sires and dams. When the owner ceased to use these two bulls on each other's daughters the losses stopped.⁸ The genetic aspects of fetal and newborn calf losses has been reviewed.³

Miscellaneous causes of abortion

Twining in cattle, as discussed previously, is associated with a higher rate of premature births, abortions, dystocias and expulsions of dead or weak fetuses at term than occurs with single fetuses. Retained placenta is also common after the birth or abortion of twins. This may be associated with a lack of placental area and

nutrition for the fetuses, uterine inertia or "wedging" of the fetus from each horn into the pelvis at the time of expulsion or possibly other causes. Abortions and fetal loss is more common with unicornual than bicornual twin pregnancies in cattle.

Allergies and "anaphylactic" reactions may cause abortion in cattle. Abortions that followed within 2 to 3 days the anaphylactic reactions observed after using an early leptospiral bacterin containing rabbit serum were described previously. Four cows aborted within two or three days following an allergic reaction due to the intravenous administration of tuberculin.² Urticaria associated with milk allergies in cattle, especially Jerseys and Guernseys, occurring at the time of "drying off" have resulted in abortions and premature births.³ Attempts to produce abortions in cattle as a sequel to an incompatible blood transfusion failed.⁵ However, organisms such as *Alcaligenes fecalis*, *Pseudomonas* and others or their products present in contaminated sodium citrate solution if added to blood at the time of blood collection produced a severe anaphylactoid reaction resembling either an incompatible transfusion reaction, or most likely an endotoxin reaction in transfused cows resulting in abortion several days later. The anticoagulant sodium citrate solution should be made up fresh, just before use, with pyrogen-free sterile water to prevent these untoward transfusion reactions in cattle.

Other miscellaneous abortions have been associated with lymphocytoma in which the uterine wall was extensively involved, in *C. pyogenes* abscesses of the uterine wall, in extensive adhesions of the uterus to the body wall or other viscera limiting uterine enlargement, and in cattle where there is a congenital or acquired lack of most of the uterine caruncles and endometrial glands. Abortion in anemic cattle severely infested with the sucking louse has been reported.^{1,4}

Fetal mummification due to the intrauterine death of the fetus and failure of its expulsion or abortion is due to many of the factors described above that cause bovine abortions. These will be discussed later in this chapter.

A Review of Aids in the Diagnosis of the Cause of Abortion

In order to improve the possibility of making a diagnosis of the actual cause or causes of abortion in cattle the attending veterinarian should secure a very careful, detailed history of the herd and cows involved over the past 6 to 9 months including breeding dates, sires used, whether natural or A.I. service, previous breeding history of the cow or herd, herd health history especially noting any illness in the herd over the past few months,

new arrivals into the herd or possible contacts between the herd and other herds should be noted. The health and reproductive history of the herd of origin of purchased cattle or the contact herd is desirable. The number of abortions and the time in gestation they occurred should be recorded. The freshly expelled fetus and its membranes including the cotyledons and amniotic fluid, if available, should be taken as cleanly as possible and placed in a waterproof plastic bag or clean can and refrigerated and delivered immediately to the diagnostic laboratory. If the fetus is large, a careful necropsy should be performed and specimens of the stomach, tied off at each end, lungs, liver, spleen and kidneys should be saved for culture and gross and histologic examination. These also should be carefully refrigerated and taken immediately to the laboratory along with representative portions of the fetal placenta. Freezing of tissues while good for recovery of most organisms and viruses may interfere with the diagnosis of certain protozoal causes of abortion and with tissue sections and their examination. In an outbreak of abortion it may be necessary to examine 3 or 4 fetuses to find one that may yield clues to the cause of the outbreak. Blood samples from the aborting cows should be taken in a near sterile manner at the time of abortion and then again 2 to 3 weeks later. Samples from other cows in the herd, those acutely ill, representative cows or recently introduced cattle might also be collected for blood testing. The serum from these samples should be removed and saved, even by freezing, if necessary, for serologic determinations. Sending whole blood samples into the laboratory during the hot summer months may result in hemolyzed samples if they become overheated or in the winter if they become frozen. It should be recognized at the present time that because of the multiplicity of causes for bovine abortion, the as yet unknown causes, and the great frequency of partially autolyzed fetuses by the time they are expelled that only about one in three or four, 25 to 30 percent, of aborted bovine fetuses can be accurately diagnosed with respect to the causative agent. Laboratory procedures for the diagnosis of the major infectious causes of bovine abortions have been described.¹⁷

ABORTION IN MARES

The incidence of equine abortion is higher than that experienced by cattle and is given as about 10 to 15 percent. About 8 to 10 percent of mares diagnosed pregnant at 40 to 45 days lose their conceptuses by 90 to 100 days and 4 to 6 percent lose fetuses from 100 days to term.^{4,27} Many of these abortions are apparently not associated with infectious agents. A good diagnostic laboratory supplied with fresh, properly-handled, chilled equine fetuses and membranes can usually determine the cause of abortion in 60 to 80 percent of the cases. This is particularly true if there is an enzootic outbreak of abortion on a farm and a number of specimens are examined. Most observed abortions in mares occur after the fourth month of gestation. The diagnosis of most of the causes of early unseen embryonic or early fetal deaths in mares is speculative or unknown. As in other species of animals, equine abortions may be caused by bacterial; viral; fungal; protozoal; chemical, or hormonal; nutritional, physical, genetic or chromosomal and miscellaneous causes. Twinning is a common cause of observed abortion from 5 months to term with a reported incidence of 20 to 30 percent of these late abortions.^{14b,27,31} (See Table 10.)

Infectious Bacterial Abortions in Mares

Evidence would indicate that many of the infectious bacterial organisms causing abortion result from ascending infections through the cervix. Bacterial infections of the placenta and fetus may cause abortion at any stage of gestation.^{2,4,9,11,27,28,31,32} Early abortions from 25 to 150 days are seldom observed especially in mares on pasture. Thus these abortions early in gestation, usually detected by rectal examination, at 20 to 60 days and again at 100 to 150 days are often considered as embryonic or fetal resorptions or infertility of unknown cause. Uterine cultures of mares several months after early fetal loss are usually negative for evidence of infection. However, when some of these early autolyzed fetuses and placentas were examined a variety of pathogenic and contaminating bacteria were present including in a majority of cases a

Table 10. Summary of Causes of Abortion in Mares

Infectious causes

Bacterial-**Streptococcus zooepidemicus**, alpha hemolytic streptococcus, **Salmonella abortus equi** and leptospirosis (**Leptospira pomona** and possibly other leptospira), **Hemophilus equigenitalis** (C.E.M.).

Miscellaneous Bacterial-anaerobic, motile (Lancefield Group D) and other streptococci, **E. coli**, **Pseudomonas aeruginosa**, **Corynebacterium equi**, **Actinobacillus (Shigella) equuli**, **Streptococcus equi**, staphylococci, **Klebsiella**, **Brucella abortus**, mycoplasma, diptheroids, sarcina, **Pasteurella hemolytica**, **Listeria monocytogenes**, **Corynebacterium pseudotuberculosis**, **Acinetobacter calcoaceticus**, and **C. pyogenes**,

Viral-Rhinopneumonitis or Equine herpesvirus I, arteritis virus

Miscellaneous viral-equine infectious anemia virus

Mycotic or fungal-**Aspergillus fumigatus**, Mucorales, **Allescheria boydii**, Histoplasma, **Coccidioides immitis** and the yeasts, **Candida albicans** and cryptococcus

Protozoan-**Trypanosome equiperdum** (dourine), **Babesia equi** and **caballi** (piroplasmiasis), Bedsonia, and Sarcocystis

Noninfectious causes

Chemicals, drugs and poisonous plants (no material or substance confirmed as a cause for equine abortion)

Hormonal-estrogen, prostaglandins, oxytocin(?), progesterone deficiency, and cortisone excess (stress)

Nutritional-reduced energy intake and other stresses.

Physical-manual dilation of the cervix and douching of the uterus, trauma or injury to the very young blastodermic vesicle, torsion and strangulation of the umbilical cord and torsion of the uterus or strangulation of the uterus by a lipoma

Genetic or chromosomal-fetal anomalies, early embryonic deaths

Miscellaneous causes-twinning, early embryonic deaths, early conception after foaling(?), increasing age of mare, and effect of sire on abortion.

microaerophilic, alpha hemolytic **streptococcus spp.** with fastidious growth requirements.³² This organism has also been recovered in cultures of the endometrium and external genitalia. Another preliminary study¹⁶ has confirmed the original observation³² that nonfecal alpha hemolytic streptococci are a cause for early fetal deaths from 45 to 90 days of gestation. This organism when inoculated into the mare's uterus during the estrous period did not cause infertility or early embryonic death.¹⁶ Further studies on this organism and its role in early abortions are indicated.

A possible factor favoring infections of the caudal portions of the genital tract ascending through the cervix in early pregnancy is the high rate, 72 percent and possibly more, of secondary ovulations from 50 to 75 days of gestation with a concurrent relaxation of the cervix.^{1,32} However, it should be noted that from 30 days in gestation the cervix and vagina contain a large amount of heavy, tenacious, thick mucus that acts as a seal to prevent bacterial invasion of the uterus. This natural defense mechanism deserves further study to determine its efficacy. Furthermore, stress factor during early pregnancy in the mare may also result in abortions^{4,22,23,26} with a temporary invasion of the uterus by bacteria from the caudal portions of the tract during the period from fetal death to final expulsion. (See early embryonic deaths in horses.)

Nearly all fetuses and placentas examined and cul-

tured by diagnostic laboratories and reported upon have been 5 through 11 months in gestational age at the time of abortion. There are no venereal diseases of horses, such as campylobacteriosis and trichomoniasis in cattle, causing endometritis and early embryonic deaths except contagious equine metritis (CEM) caused by **Hemophilus equigenitalis** and possibly certain pathogenic strains of *Klebsiella* and *Pseudomonas* which will be discussed in Chapter XIV on Infertility in the Mare. Other bacteria, especially **Streptococcus zooepidemicus**, found in the caudal portions of the genital tract should not be considered as organisms causing a contagious venereal disease.

Streptococcus zooepidemicus (genitalium), a beta hemolytic streptococcus, is the most common bacteria found in genital infections in horses. This organism is a hemolytic streptococcus, Lancefield's Group C, found ubiquitously on the external genital organs of all mares and stallions. It may be cultured from the genital tract for a few days after foaling in about 90 percent or more of mares. It is usually found as a contaminant from the prepuce in the semen of stallions. It is the most common organism associated with metritis, cervicitis, and vaginitis secondary to pneumovagina or "windsucking." Streptococcal abortions are most common on poorly managed farms. By proper management procedures, routine genital examinations and cultures, antibiotic therapy, vulvasuturing, sexual rest, and regulated, supervised hygienic

breeding, almost all mares infected with this organism can be cured and the infection prevented or controlled. This results in a very low incidence of "strep-infected" mares on a well-managed farm. Mares with a lowered resistance, trauma, or disease of the genital tract, mares bred on the ninth day after foaling, mares with lesions of the genital tract and pneumovagina, and old mares with localized areas of dilation of the uterine wall and cystic degeneration of the endometrium are most prone to the establishment of this common infection in the genital tract. The healthy genital tract of normal mares is resistant to infection including *Str. zooepidemicus* commonly introduced at parturition and breeding.

Streptococcus zooepidemicus may cause 10 to 20 percent of abortions especially on poorly managed farms. It has been reported in up to 40 percent of the aborted fetuses infected with bacteria. Since this infection is limited to the genital tract and is not spread by ingestion or other means, abortions occur in chronically-infected mares in a sporadic manner. Streptococcal abortions may occur at any stage of gestation. This organism is a common cause of infertility and early abortion from 2 to 5 months of gestation and infection in newborn and postnatal foals.^{1,3,11} Following streptococcal abortions in the last third to one-half of gestation, retained placentas are frequent and infections of the uterus tend to persist after abortions. Some abortions are preceded by a mucopurulent vaginal discharge.

Aborted fetuses show autolytic changes that vary from slight changes to complete maceration of the fetus. *Streptococcus zooepidemicus* may be recovered from the fetus, the fetal membranes and the genital discharges. There is no serologic test for streptococcal antibodies.

Prevention of abortion due to *Streptococcus zooepidemicus* relies on proper management and the breeding of only normal healthy mares. Barren mares should be culled in the fall of the year and if infected should be given suitable antibiotic and surgical treatment so the infection is overcome before breeding. Proper hygiene in the breeding shed and avoiding frequent copulations may be helpful. Certain older pluriparous mares with a lowered resistance to infection may require local antibiotic therapy after service and/or artificial insemination with semen containing antibiotics. Chapter XIV on Infertility in Mares discusses in detail the diagnosis, therapy and preventive procedures for *Streptococcus zooepidemicus* infection of the mare's genital tract.

Salmonella abortus equi causing contagious equine abortion was first reported in 1893² and studied and described in Kentucky in 1911 where outbreaks were common. This cause of abortion in mares has been reported

in a number of states in the U.S., several European countries, Canada, South Africa, South America, and Japan. *Salmonella* abortion in mares has not been described in the United States since 1932 except for two isolated outbreaks in Illinois and Washington.^{5,6,24} The reason for the near disappearance of this disease is not known. *Salmonella abortus equi* may be carried in the intestinal tract of apparently normal horses. Other *Salmonella* serotypes have not been described as a cause of abortion in mares with the possible exception of *S. anatum*.¹⁵

Salmonella abortus equi is spread by ingestion of feed and water contaminated by feces or genital discharges from aborting mares, especially when horses are on pasture. The incubation period is from 10 to 28 days and just before abortion occurs the mare may exhibit a general reaction, depression, anorexia and fever. If the mare is not observed closely these signs are missed and abortion results without apparent premonitory signs. Retention of the placenta may occasionally follow abortion. Most abortions occur between the 6th and 9th month of gestation but some may occur as early as the 4th month to as late as the 11th month. Infected foals born at term are weak and usually die within several days. In a susceptible band of mares the incidence of abortion may reach 50 to 90 percent. The abortion usually has no effect on the future fertility of the mare unless lacerations or other infections cause subsequent chronic infection of the mare's genital tract.

The allantois chorion of the placenta often shows non-specific edema, necrosis, and hemorrhage. The fetus exhibits autolytic lesions of edema and the presence of reddish serous fluid in the body cavities. The organism may be cultured readily from the fetal organs and tissues, the fetal membranes, and the uterine exudate. Organisms in the uterine discharge disappear rapidly within a few days after abortion. Further diagnostic confirmation can be obtained by the agglutination test on the serum of the aborting mare.

The yearly use of bacterins has been highly successful in immunizing of mares against *Salmonella* infection contracted by ingestion. Mares were vaccinated subcutaneously at 4 months of gestation at weekly intervals with 1 ml, 2 ml, and 2 ml (double strength) bacterin. This procedure was repeated 3 to 4 months later. Isolation, quarantine, and sanitation procedures were helpful in limiting or preventing severe outbreaks of abortion. For the past 25 years vaccination of mares has not been performed in the U.S.

In an outbreak, or preferably before, the mares should be kept in small units or bands isolated from each other. Aborting mares should be isolated from the normal mares.

All fetuses and membranes should be removed and destroyed and the area disinfected. The bacterin is usually used in an outbreak but some mares may abort before immunity has developed.

Leptospirosis due to *L. pomona*, and possibly other leptospiral serotypes **hardjo**, **bratislava** and **icterohemorrhagiae**^{13b} has occasionally been reported as a cause for abortion in mares from the seventh through eleventh month of gestation.^{8,12,13b,c,14,17,29} Although serologic evidence of leptospirosis was reported in 45 percent of 1606 horses in Georgia⁷ and 5 percent of 1346 horses in northeastern United States,³⁰ no reports of abortions were recorded. Acutely infected mares may show a mild systemic reaction with a moderately elevated temperature of 102 to 103° F, slight icterus, anorexia, and depression that lasts for 3 to 4 days. One to 3 weeks later abortions may occur. The aborted fetus may be slightly icteric and show autolysis. The mare will often exhibit a high leptospiral titer of the blood using the MA test at the time of abortion. The blood testing of normal, acutely ill, aborting and recovering mares in an outbreak may aid in diagnosis. A rising titer associated with abortion is highly significant. As in cattle, recovery of the organism from autolysed, aborted equine fetuses, is difficult. Special staining of fetal organ sections and the fluorescent antibody technique is of diagnostic value in leptospiral abortion in mares. Following experimental infection, horses can shed *Leptospira pomona* in the urine for 70 to over 94 days, but less than 120 days.²⁵ Periodic ophthalmia occurred in some of these horses 12 to 14 months later. Treatment of leptospirosis in horses with antibiotics is similar to the treatment in cattle and swine. Yearly vaccination of horses at risk with a bacterin the first trimester of gestation may prevent abortion as well as periodic ophthalmia due to *L. pomona*. Since no leptospiral bacterins are available for horses the bovine bacterin is used. Occasional local reactions to the bacterin may develop. If the early mild signs of acute illness due to leptospirosis are observed including: moderately elevated body temperature, depression, inappetance and slight icterus, the affected animal should be placed on therapeutic levels of streptomycin and penicillin for 4 to 5 days. This therapy during the early stages of the disease may prevent abortion as well as periodic ophthalmia caused by *L. pomona*.

Miscellaneous bacterial infections associated with sporadic abortions in horses may cause from 5 to 10 percent of the total abortions due to bacterial agents.^{2,4,9,11,28,31} These include: anaerobic **Streptococci viridans**, motile **Streptococci** (Lancefield Group D), **Streptococcus equi**, **Staphylococcus aureus**, **Escherichia coli**, **Actinobacillus** (**Shigella**) **equuli**, **Corynebacterium equi**, **Kleb-**

siella spp, **Pseudomonas aeruginosa**, diphtheroids, **sarcina**, **Brucella abortus**,^{10,20,21} **Pasteurella hemolytica**,³³ **Acinetobacter calcoaceticus**,^{13a} **aerobacter agglomerans**,^{13b} **Listeria monocytogenes**,¹⁹ **Corynebacterium pseudotuberculosis**,¹⁸ **Corynebacterium pyogenes**, and mycoplasma.^{16c,3,28} Pure cultures of bacteria from the organs of aborted fetuses is the usual means of diagnosing these sporadic causes of abortion. Many bacterial agents causing abortion may be present in the cervix and uterus at conception and persist for a varying period. Other organisms may ascend through the cervix into the uterus during early pregnancy. While others, such as leptospira and salmonella, gain access to the uterus hematogenously during pregnancy. It is probably uncommon for organisms to enter the uterus through the normal closed and sealed cervix during late pregnancy.

Viral Causes of Abortion in Mares

Abortion in mares is known to be caused by the rhinopneumonitis or **equine herpesvirus I**. Rarely abortions are reported associated with **equine infectious anemia**, **arteritis virus** and other viral diseases.

Abortion due to the **equine herpesvirus I** (EHV1) or **rhinopneumonitis virus**.

Abortion in mares is commonly due to **equine herpesvirus I**. This virus has many similarities in common with the IBR-IPV virus in cattle.²⁹ However, the IBR viral vaccine did not produce antibodies or heterotypic immunity to equine herpesvirus in horses. Other herpesviruses have been isolated from horses.³⁶ These include equine herpesvirus 2 (or equine cytomegalovirus), and equine herpesvirus 3 (or equine coital exanthema virus). The former ubiquitous virus that persists in a horse for long periods, has been associated with some forms of respiratory disease and the latter virus causes an acute mild venereal disease characterized by pustular lesions on the vaginal and vestibular mucosa and skin of the perineal region of mares and the modified skin of the penis and prepuce. Neither of these latter two viruses, EHV2 or EHV3 cause abortion.^{2,4,22,36}

Virus abortion was prevalent in Kentucky at least as early as 1922. It was shown to be caused by a virus in 1936.¹¹ In 1941 it was reported that equine virus abortion was secondary to influenza. In 1954 Kentucky researchers^{11,17} demonstrated that the virus of equine virus abortion and equine "influenza" virus were the same. Since then two true influenza viruses, Prague, A₁ and Miami, A₂, have been isolated, so the name rhinopneumonitis and then equine herpesvirus I was given to the herpes virus causing an upper respiratory disease in horses

and abortion in mares. The incidence of herpesvirus abortions in Kentucky varied from 4 to 26 per thousand broodmares with an average of 10/1000 or 1 percent from 1957 to 1977.⁴

Rhinopneumonitis, abortion and neurologic disease or paralysis due to equine herpesvirus I have been commonly diagnosed in Europe, Japan, Canada, Australia, and the U.S.^{1,2,2,8,9,16,19,23,24,36} The respiratory form of the disease is very common; the abortigenic form is less common. The neurologic form which occasionally follows the respiratory or abortigenic forms is uncommon or rare. The disease may be introduced into a farm by infected foals or horses and by infective material carried by persons, dogs, foxes, or carrion birds. This virus is quite resistant and may survive 7 to 42 days or more in dry stable surroundings.¹⁴ Following a natural infection the horse may spread the virus for 3 to 4 weeks. This virus, as other herpesviruses, may persist or be latent in certain tissues of "carrier" animals for long periods of time. Stress probably plays a role in releasing this virus and causing an exacerbation of the disease. Equine herpesvirus I is only naturally pathogenic for horses. It can be adapted and grown in suckling hamsters and in cultures of kidney tissue cells from a number of animal species.

Recent studies^{19,24,36,37,39} on respiratory and abortigenic strains or subtypes of equine herpesvirus (EHV) I using restriction endonucleases to analyse the DNA of the virus have shown them to be dissimilar. Based on this and clinical, serological and laboratory observed differences in the strains^{24,36,37,39} it was suggested that further studies on the various subtypes and vaccine effectiveness are indicated.

The clinical signs of rhinopneumonitis are those of a mild, febrile respiratory disease usually observed in young horses 4 to 8 months of age in the fall and early winter months. The incubation period is 2 to 3 days. The body temperature is elevated to 102 to 104° F. A serous rhinitis with congestion of the nasal mucosa and conjunctiva occurs often associated with coughing, inappetence, and depression. A leucopenia usually is present. In about 7 to 10 days, the febrile period ends and a mucopurulent rhinitis, "the snots," develops which, along with a cough, lasts for several weeks or longer. The disease can occur in any age of horse at any time of the year. The virus is highly infectious and contagious and is spread mainly by inhalation or droplet infection or occasionally by ingestion. In older mares this disease may frequently be so mild as to be unrecognized.

The incubation period for abortion in natural infections due to rhinopneumonitis virus or equine herpesvirus I is 20 to 30 days with a range of 14 to 120 days.^{13,36}

Since evidence indicates that fetuses die soon after they are infected with herpesvirus I and are aborted, the long incubation period of this disease is intriguing. It has been shown that a viremia with the virus in the lymphocytes and monocytes^{2,3,4,21} may last for about 21 days. It has been hypothesized that the virus may reside in the chorion of the placenta for a time, as is possible with IBR virus in cattle, before infecting and rapidly killing the fetus.²⁶ Thus abortions in mares on breeding farms often follow the outbreak of the respiratory disease in foals by several months.¹⁶ If the mare exhibits typical respiratory signs of the disease, abortions may follow apparent recovery by several weeks or months. Fetal deaths and abortions seldom occur before 5 months of gestation and over 90 percent of the abortions occur from 8 to 11 months of gestation. Often foals infected in utero may be born alive but die within a few minutes to 4 days postpartum. Some workers consider this neonatal EHV I infection, associated with a high mortality rate from respiratory failure, a fourth form of the disease.^{5,10} Live foals infected with EHV I virus before birth often have an elevated temperature, heart rate and respiratory rate, edema and congestion of the lungs and a leucopenia. Thus breeding practices largely determine the season or time when abortions occur; in Kentucky 90 percent of the abortions occurred from December through April.

Immunity to herpesvirus (EHV) I, like other herpesviruses, is relatively short lasting only a few months to a year and requiring frequent natural exposure or vaccination to maintain protective antibody levels in the blood.^{1,2,3,4,14,30,36} The degree of immunity and the number of pregnant mares at the time of the outbreak determine the abortion rate on a farm which may vary from 1 to 90 percent of a band of mares. Keeping the pregnant mares on a farm separated into small units well-isolated from other mares, horses, and young stock does much to reduce the spread and incidence of abortion in an outbreak. In Kentucky 85 percent of the farms had 3 or fewer cases of virus abortion with an average abortion rate per farm per year of 2.5 percent, with a range of 1.6 to 6 percent. Abortions on a farm will occur over a period of 2 weeks to 3 months with 88 percent of the abortions occurring within 60 days of the first abortion. Data from Kentucky in 1963 indicated that this virus was present in 52 percent of aborted, infected fetuses and caused 26 percent of the total abortions in mares.¹⁶

The equine herpesvirus I causes the death of the fetus and no signs of impending abortion are observed. Retention of the placenta is uncommon. The mare is not traumatized unless a large fetus causes tearing of the tissues of the vulva or perineal region. Following viral abortions, mares usually conceive readily the next breed-

ing period unless secondary infections have occurred.^{1,2,8,16,33}

Examination of the aborted fetus and membranes in this disease usually reveals a "fresh" nonautolyzed fetus, an edematous amnion, yellow amniotic fluid, a slightly yellow or icteric color of the fetal body tissues, straw-colored fluid in the thoracic cavity, interlobular edema and small hemorrhages in the lung, petechial and ecchymotic hemorrhages in the epicardium, and small whitish-yellow, pinhead-sized foci of necrosis in the liver. On microscopic examination of stained liver, bile duct, lymph node, thymus, and bronchial cells, intranuclear inclusion bodies are frequently found. These latter signs in the fetus are of great diagnostic value. (See Figures 67 and 68.)

The neurologic form of herpesvirus I may follow or occur with abortion in pregnant mares or after the onset of the respiratory form of the disease when EHV I invades the central nervous system producing disseminated, necrotizing myelo- and meningo-encephalitis with vasculitis of the smaller vessels of the brain and spinal cord. The clinical signs vary from a mild ataxia to complete paralysis and death.²⁵ In recent years this form of the disease has been reported widely in a number of states in the United States, Canada, Europe and Australia. Some of these reports described cases of epizootic outbreaks of the neurologic disease.^{10,23,27} A number of cases followed about 10 days after the vaccination of horses with a MLV herpesvirus I vaccine grown in a vero-monkey tissue cell line.^{20,28} Although this commercial product had undergone extensive trials prior to approval, it was withdrawn from the market because of its propensity to rarely produce neurologic disease. Treatment of this neurologic

syndrome is entirely by supportive therapy and deaths are common.³⁵

There is no permanent immunity to viral rhinopneumonitis or abortion. Many aborting mares apparently develop a fairly long immunity of one to two years. The respiratory form of the disease does not provide as long nor as good an immunity as occurs following an abortion. Some horses may lose their immunity within 3 to 6 months after infection or vaccination but the disease is so common that most horses are frequently exposed and thus maintain a satisfactory immunity. Repeated frequent exposures to diseased horses or repeated vaccinations with a vaccine increases the level of resistance. Strict isolation of mares on breeding farms without vaccination is therefore likely to increase their susceptibility.

The complement fixation (CF) test or serum neutralization test can be used to determine antibody levels in the serum of horses following this viral respiratory disease or abortion but it is not diagnostic. Antibodies persist for only a month or two up to one year even in aborting mares.^{3,14,16} This test is also of limited value in diagnosis since both CF positive and negative mares may abort or not abort when challenged by the equine herpesvirus I. During and after a respiratory infection or exposure to virus from an abortion, there is a viremia persisting for up to 3 weeks in mares despite the coexistence of virus neutralizing antibody in the blood.³ The virus is carried within the lymphocytes and the latter cells carry the virus throughout the body and to the placenta. It was shown that several "grades" of immunity existed depending upon the amount of antibody present at the site of infection in the nasopharynx. This immunity was a reflection of the level of virus neutralizing antibody in

Figure 69. Torsion of the umbilical cord of a 7-month equine fetus resulting in abortion.

the blood.^{2,3,4,12,30} Culture of the liver or lungs of freshly aborted fetuses on tissue culture medium often results in the recovery of the virus. The fluorescent antibody test applied to fetal tissues also is of great diagnostic value.³⁴

Although many small horse farms with multiple equine activities experience a constant influx of "outside" horses and a constant exposure of broodmares to infection with EHV I virus, they seldom experience a serious epizootic outbreak of virus abortion. However, in controlling herpesvirus I infection on a large breeding farm certain management procedures should be considered. Outside horses, especially from sales, should be carefully isolated for a month or more as virus may be shed from the respiratory tract and the horse appear clinically normal. Furthermore, if the addition to the farm is a mare in the

Figure 70. *Toxoplasma gondii* abortion in a ewe. Note the white toxoplasma bodies in the maternal caruncles.

latter half of gestation, isolation should be longer since the incubation period for abortion may be up to 4 months. Pregnant mares should be handled to avoid stress. Mares should be placed in small bands and not changed around. These bands should be kept separate from each other. Foals on nursing mares should be weaned early in a manner to avoid stress on the mare and to keep foals with the commonly occurring herpesvirus respiratory disease separated from the broodmares during the late fall and early winter. Pregnant mares in the last trimester of gestation should be kept from exposure to EHV I virus during this critical period. Since vaccination does not protect all broodmares, management procedures to reduce stress and prevent the spread of the disease should be instituted.^{1,4,19}

Since 1950 various vaccination procedures have been developed and discarded as better ones have superseded them. Initially a vaccine was prepared from equine fetal tissues.¹⁸ This killed vaccine which contained some red blood cells produced isoantibodies in some mares resulting in neonatal isoerythrolysis in their foals. The next vaccine was prepared from hamster tissues containing a live virulent virus that was injected intranasally.^{12,14,15} This product was not satisfactory for use on farms with a long breeding season as this vaccine produced a "controlled" or "planned" infection that could spread to other horses and it required that all horses on a farm be vaccinated at the same time and "quarantined" for 3 to 4 weeks.

In recent years two other vaccines have been developed. One, a modified live virus (M.L.V.) vaccine that is given in two doses 4 to 8 weeks apart in pregnant mares after the second month of pregnancy and repeated every six months. Since immunity is rather short-lived repeated vaccinations are necessary to maintain high levels of antibody in the blood. This vaccine does not cause abortion or respiratory disease and does not spread to susceptible horses.¹ The other vaccine is an inactivated EHV I vaccine with an added adjuvant that is recommended for use in pregnant mares at 5, 7 and 9 months of gestation to maintain a high level of protective antibody.⁴ Both of these latter vaccines apparently provide a significant protection against abortion due to EHV I. However, a few vaccinated mares if stressed and/or exposed to a severe challenge with virulent virus may abort.^{1,4,19} Of 8638 pregnant mares vaccinated from 1977 through 1980 with the inactivated vaccine, 1.6 per thousand aborted compared to 6.8 per thousand in 20,732 nonvaccinated mares.^{4,39} Of 233 abortions in vaccinated mares during a five year period a field strain EHV I was isolated from 93 fetuses. For this reason claims for its effectiveness in protecting pregnant mares from abortion

have been largely omitted. However, serological and clinical protection on two horse farms indicated the MLV vaccines probably are of value when used every 3 to 4 months.^{4,30} If an abortion due to EHV I occurs in a band of broodmares, prompt vaccination of all unvaccinated or susceptible mares is indicated to cause a rapid rise in levels of antibody in the blood. Adverse local reactions such as abscesses may rarely occur following the use of vaccines.⁴

One study indicated it was extremely difficult to evaluate the efficacy of vaccines in preventing EHV I abortion because of the paucity of non-exposed mares, the lack of tests to measure residual protection and an incomplete understanding of the pathogenesis of the disease.²¹ Further studies on the development of vaccines against the strains of EHV I, respiratory and fetal, are indicated.^{24,36,37,38,39}

Since vaccination at present is not completely effective in the control of abortion due to EHV I, sound management procedures should be combined with vaccination to control this disease.

Equine viral arteritis (EVA) or epizootic cellulitis-pinkeye syndrome is caused by the arteritis virus, a togavirus, Bucyrus strain,² that produces signs of severe general respiratory disease including abortion. These signs are closely related to the constant and characteristic necrotic lesions in the media of the small arteries produced by the arteritis virus and causing edema, hemorrhages, and infarcts. The disease is usually brought to a farm by an infected or convalescent horse. Outbreaks are presently very infrequent in the U.S. The disease has been described in Europe.² The virus is spread by droplet or aerosol infection and contracted in inhalation. Thus close contact between horses is necessary for the spread of this disease. The horse is apparently the only natural host of the disease. Since a carrier state can exist, spread of this disease at the time of coitus may occur.¹²

Clinical signs of the disease are often severe and should not be confused with the milder "shipping fever" type diseases of influenza or rhinopneumonitis.^{1,2,6,9,10} Horses of all ages may be affected. The incubation period of the disease is 3 to 9 days. The signs of the disease often include: an elevation of the body temperature to 103 to 106° F; leucopenia with panlymphopenia; conjunctivitis, lacrimation and occasionally keratitis, photophobia and palpebral edema; severe depression; a serous nasal discharge and congested nasal mucous membranes; an increased respiratory rate of 30 to 50 per minute, and occasionally dyspnea with a "heave line"; generalized weakness and stiffness; anorexia; a rapid loss of weight; and frequently colic and diarrhea. In a few horses edema of the limbs and/or the ventral abdominal wall develops.

The course of the disease is 2 to 15 days. Deaths in natural outbreaks are not common but experimentally infected old horses, pregnant mares, and weanlings may develop a severe illness with a 30 to 50 percent mortality due to pulmonary edema, pleural effusion, and secondary cardiac disturbances. However, some natural cases of the disease may be so mild the signs of illness may pass unnoticed.

Abortions are closely associated with the febrile and early convalescent period of the disease and occur 1 to 14 days after the onset of signs of illness. The mare fails to show signs of impending abortion. Abortion may occur in up to 50 percent of the pregnant susceptible mares exposed to the virus.^{2,8,9} Some mares abort without obvious signs of clinical illness and some mares with definite signs of illness will not abort. Most abortions occur in mares from the fifth through tenth month of gestation. Retention of the placenta is uncommon in aborting mares. Some fetuses apparently die 2 to 4 days before abortion because autolytic changes are common in contrast to the freshly aborted fetuses associated with rhinopneumonitis virus (EHV-I) infection.² Postmortem fetal lesions include petechial hemorrhages on the peritoneal and pleural surfaces, epicardium and endocardium, and pleural effusions. These lesions indicated viral induced fetal death was followed by abortion. No inclusion bodies are found with this disease but the virus can be recovered from many fetal tissues including the liver and lungs.^{3,16} The virus can be grown on tissue cultures of horse and hamster kidney cells.^{3,15,16} Complement fixation and serum neutralization tests have been developed to detect antibodies.⁵

Following recovery a prolonged immunity to arteritis virus is probable. An attenuated live virus vaccine has been prepared that is an effective preventative.^{7,11,13} This has not yet become available commercially, because of the very limited occurrence of the disease. About 20 years after the severe epizootic outbreaks of viral arteritis on Standardbred farms in the Midwest, a serologic survey in 1972 revealed 55 percent of Standardbreds, 25 percent of a limited number of Saddle-breds and only 1.6 percent of Thoroughbred horses in the United States had positive titers for arteritis virus. An incidence of 2 to 5 percent positive titers were present in horses in England and Switzerland.¹² Thus an apparent subclinical infection was present that conferred a lifetime immunity that resisted challenge with a virulent virus. However, it is evident that Thoroughbred horses in the U.S., England and Japan because of a very low incidence of antibodies are at risk of a serious and widespread epizootic outbreak of viral arteritis should a virulent strain appear. Only 0.3 percent of 3772 horses tested by the National Veterinary

Services Laboratory in 1978 and 1979 were seropositive for EVA.⁶ Proper segregation, isolation, and quarantine along with other sanitary procedures and with prompt vaccination, would be indicated in preventing the spread of this infection on a farm.

Equine infectious anemia is occasionally characterized by abortion in infected pregnant mares.^{2,1,2} The pathogenesis of abortion due to equine infectious anemia virus has not been established and more study is indicated.

Mycotic or fungal agents of the species *Aspergillus fumigatus*, the order *Mucorales* and *Allescheria boydii*, may cause sporadic abortions in mares. Occasional cases of yeast abortion due to *Candida albicans*¹ or *cryptococcus*^{7b} as well as rare cases of abortions due to histoplasma² and coccidiomycosis due to *Coccidioides immitis* have been reported.⁶ Mycotic agents may cause 5 to 10 percent of all abortions in mares in central Kentucky. Mycotic abortion has also been reported in Germany and England.^{1,3,4,5,7} The cause of the abortion is apparently a severely diseased necrotic, thickened allantois chorion which interferes with fetal nutrition and causes growth retardation and fetal death. (See Figure 64.) Mold may be cultured from the placenta, and occasionally the fetal organs such as liver, stomach, lungs and the fetal skin. It is likely that the mold is carried to the placenta in the blood stream from lesions in the wall of the intestine or lungs. It may also be associated, as in cattle, with the ingestion or inhalation of mold spores from moldy hay or straw during pregnancy. Because of the excellent equine uterine defense mechanism, it seems very unlikely that mold introduced into the uterus at the time of copulation would remain viable for months and then infect the placenta. It is possible that fungi could invade the uterus and placenta through the cervix around the second month of pregnancy as described under bacterial causes of abortion. Mold abortions usually occur from the 4th to 11th month of gestation. Following abortion the mold infection does not persist in the uterus but service on the foal estrum should be avoided.

Parasitic protozoan organisms including *Trypanosome equiperdum* causing dourine,^{1,2} *Babesia equi* and *caballi* causing piroplasmosis,⁸ *Bedsonia spp.*,⁷ and *Sarcocystis*³ spp may occasionally or rarely produce abortion in mares. Dourine is transmitted almost entirely by sexual contact. It was first recognized in the U.S. in Illinois in 1885 by W. L. Williams in horses bred to a stallion shipped from France. By use of the complement-fixation test and destroying all reactors the disease has probably been eradicated from the last infected area in southwest U.S. This disease is discussed in more detail in a later chapter.

Babesiosis or piroplasmosis may result in abortion in severely affected horses.^{1,6,8,10} This disease has been reported in South Africa and is endemic in many tropical countries. At present in the U.S. it is limited mainly to Florida. Signs of the disease closely resemble those of equine infectious anemia except icterus and hemoglobinuria may also be present. The parasite is spread by bloodsucking ticks and it may be found, for diagnostic purposes, within the erythrocytes by proper staining techniques. In infected, aborted, premature or term fetuses or foals, icterus and anemia is present requiring differentiation from equine infectious anemia, rhinopneumonitis virus abortion, neonatal isoerythrolysis, and leptospirosis.^{9,10} Abortion may be due to fetal or maternal stress with cortisol production. The fluorescent antibody technique may be helpful in detecting the parasite in the red blood cells of the fetus or foal.⁵ The complement-fixation test on horse serum is highly specific for *B. caballi* infection and blood titers persist for 1 to 5 years.⁴ Therapy for mares with piroplasmosis is available and effective.^{1,9}

Noninfectious Causes for Equine Abortion

Chemicals, drugs and poisonous plants including: phenothiazine; thiabendazole; "Lentin"; purgatives, such as arecoline, aloes; sudan or sorghum pastures,^{34,37} organic phosphate insecticides and anthelmintics; ergot, locoweed (astragalus)^{22a} and others have been reported as possibly causing abortions if given to or ingested by mares in advanced pregnancy. Iodine when fed greatly in excess of normal requirements to pregnant mares for a number of months caused hyperplastic thyroid glands, weak legs and premature birth of moribund foals.¹⁰ Such causes of sporadic abortions are often proposed but the scientific basis for these reports have not been adequately substantiated. If abortion should follow the administration or ingestion of these or other possibly toxic materials the attending veterinarian should obtain a careful history and have the fetus(es) necropsied and examined carefully for the more common, known causes of abortion in horses.

Hormonal causes of abortion in horses have received limited study.

Estrogens in large doses over a long period regularly produces abortion in other species of animals. In mares evidence is lacking for an abortifacient effect of estrogens. One report indicated that estrogen implants of 50 to 150 mg caused abortion in one of 3 mares.³⁹ Further studies are indicated.

Oxytocin or pituitrin administered to pregnant mares prior to 310 days of gestation has not been proven to cause abortion. Oxytocin may induce parturition in mares after 345 days of gestation. Induction of equine parturition will be discussed in Chapter VI.

When pregnant ponies were injected with **human chorionic gonadotropin (HCG)** at a dose level of 2000 I.U. every other day for 3 doses before 39 days of gestation, abortion resulted. Whereas pregnant ponies similarly injected from 40 to 97 days of gestation did not abort.¹

Prostaglandin, PGF_{2a} or one of its analogues, if injected in a single luteolytic dose before 38 days of gestation will regularly cause abortion within 2 to 5 days.^{14,36} A single large dose of P.G.F._{2a} injected into pony mares 70 to 300 days of gestation failed to cause abortion. When repeated doses of 2.5 mg. PGF_{2a} were given at 12 to 24 hour intervals for an average of 3.7 doses all 13 mares aborted within 4 to 5 days, average 38+ hours.⁹ However PMSG remained elevated after abortion in those mares having elevated levels before treatment. Although luteolysis occurred subsequent estrus and ovulation was erratic and generally occurred only after a prolonged interval in mares over 40 days pregnant at the time of treatment. In another trial about 1 mg/45 kg. (10 mg./1000 lbs) PGF_{2a} was given daily to 25 mares pregnant 100 to 245 days. Abortion occurred in 76 percent of the mares within 3 to 6 days and in the others the second through fourth week.¹⁴ Dystocia occurred in one mare. In an experiment with **Equimate** (fluprostenol-ICI) a single 250 µg. injection produced abortions in 2 to 3 days in 7 of 8 mares pregnant 35 days.³⁶ Repeated injections of a similar dose at 12 to 24 hour intervals was necessary to produce abortion at 70 days of gestation. The interval from abortion to first estrus averaged 11 days in mares aborted at 35 days of gestation and 35 to 45 or more days in those mares aborted at 70 days of gestation. None of the former and 75 percent of the latter had an anovulatory estrus prior to an ovulatory estrus following abortion. Apparently if mares abort from 40 to 110 days of gestation when the endometrial cups are present, these structures must involute before normal reproductive cycling is reestablished. For these reasons breeding mares aborted after 40 days within the same year was very difficult.

A **deficiency of progesterone** has been suspected and diagnosed by veterinary practitioners as a cause of abortions from 1-1/2 to 8 months of gestation for the last 20 years based on clinical observations. The primary corpus luteum of pregnancy, along with secondary or accessory corpora lutea developing the first 60 to 90 days of gestation maintain pregnancy until the fourth to fifth month of pregnancy when the placenta, and probably the

fetal gonads, produce sufficient steroids and progestogens to maintain pregnancy to term. After the third to fifth month of gestation the ovaries and corpora lutea involute and have no role in pregnancy maintenance. (See Chapter IV.)

As mentioned previously, many veterinarians have reported an incidence of about 15 percent abortion rate in mares between pregnancy diagnosis at 40 days of gestation and term with two-thirds of that pregnancy loss between 40 and 150 days. Many of these early abortions occur without being seen, often in mares with a history of recurrent or "habitual" abortion. Since most of these aborted fetuses and placentas when examined are negative for evidence of infection or teratologic defects it is logical to possibly suspect a hormonal cause for this high incidence of abortion.

Whether a progesterone deficiency is actually a reason for abortion in the mare is still uncertain.¹⁵ However exogenous supplemental progesterone produces no adverse effects, and has apparently resulted in many abortion-prone mares successfully completing their pregnancy. It has been demonstrated that about 3 to 4 ng/ml or more of progesterone in plasma is necessary to maintain pregnancy.^{14,15,16,36} Daily injections of 200 mg. of progesterone in oil or weekly injections 1000 to 2000 mg. of respositol progesterone resulted in plasma progesterone levels of 2 and 2.5 to 4.5 ng/ml, respectively in ovariectomized mares.¹⁵ In another study pregnant mares were given either 250 mg. progesterone-in-oil or respositol progesterone intramuscularly on day 255 or 270 of gestation. Plasma progesterone levels peaked at 6.5 to 7.2 ng/ml in 6 hours and receded slowly to preinjection levels of 3.4 ng/ml 6 to 8 days later.⁸ These workers recommended injections of 250 mg progesterone in oil every 2 to 3 days or the same dose of respositol progesterone daily to maintain plasma levels of 1 to 2 ng/ml in progesterone-deficient mares.

Administering 22 and 44 mg. of allyl trenbolone orally daily or injecting 1000 mg of respositol progesterone every four days maintained pregnancy in nearly all mares in 3 groups of 8 mares each that were diagnosed pregnant at 30 days of gestation and ovariectomized on days 34 and 35. All eight control mares, 7 of 8 mares given 500 mg. respositol progesterone every 4 days and 3 of 8 mares given 250 mg. of progesterone in oil every two days aborted 4 to 9 days after ovariectomy when the progesterone levels in their blood plasma fell below 2 mg/ml.^{36b} It should be noted that these mares were ovariectomized before placental progestogens were produced.

Since pregnant mares would be producing their own progestogens, the supplemental doses needed to maintain pregnancy might well be somewhat lower than the

above. Possibly they need not be as high 500 mg. progesterone-in-oil given every 48 hours as recommended in a third study.¹² When injections of progesterone are given regularly there is an accumulative effect on the maintenance of high plasma progesterone levels.^{12,16} Further detailed, long-term studies on possible progesterone deficiencies in abortion-prone mares are indicated.

The author has experienced three unusual, recent clinical cases to illustrate the value of supplemental progesterone injections to prevent abortions in mares. One has been reported;^{33a} the two others^{33b} were very similar to the former. These were Thoroughbred mares 7 to 8 months pregnant. One had a history of being barren for several years and aborting twins the year previously. They were observed to suddenly be dripping milk from their udders and showing marked relaxation of their vulva and perineal region indicating impending abortion, possibly associated with twinning. The mares were confined and placed on antibiotics and supplemental progesterone injections of 200 to 500 mg. of progesterone in oil daily for several days followed in one mare by 500 mg repositol progesterone every 3 to 5 days for a month and in the other mare with 200 to 300 mg. of progesterone in oil daily for 14 days. After 10 days these mares were examined, the udder had involuted and the perineal region was no longer relaxed and edematous. In one mare the vaginal mucus was blood-tinged but the cervix was tightly closed in all mares. Rectal examination revealed a live 7 to 8 month-old fetus in each mare. These mares were given 500 mg. of repositol progesterone intramuscularly weekly until 330 days of gestation. These mares each delivered a live but small, 50–60 lb. foal together with a mummified, slightly macerated fetus enclosed in a necrotic, yellowish placenta. The mares and their foals recovered uneventfully. In the three cases impending abortion was “triggered” by the death of one fetus located in one horn based on the examination of the three placentas at birth. The normal placenta and fetus occupied the other horn and the body of the uterus. It appeared evident that the progesterone administered prevented the abortive process possibly occasioned by the release of cortisone or the release of prostaglandin by the dying fetus, the fetal membranes or endometrium. Possibly with the death of the fetus, the deficiency of placental progestagens from that “dead” placenta dropped the progestogen levels low enough to initiate expulsion of the fetuses or all three factors might have combined to initiate the near abortions. Studies of the blood levels of hormones in such cases would be most informative.

A further observation on the value of progesterone in preventing abortion in the “abortion-prone,” nervous mare

is that progesterone therapy in mares, stallions, cats and other animals apparently has a “tranquilizing” and calming effect. This is most noticeable in pregnant animals the latter half of gestation. Thus progesterone therapy may minimize stressful influences that induce cortisone production in the pregnant animal.

Excess cortisone levels induced by stress on the dams or by the exogenous injection of cortisone into pregnant mares requires further investigation. In other species of animals such as cows and ewes cortisone injections or stress particularly late in gestation readily induces abortion or premature birth. Hillman¹⁷ reviewed studies on the effect of cortisone (dexamethasone) in pregnant mares and concluded that induction of abortion early or birth late in gestation even with large daily doses of 10 to 80 mg usually failed. At 320 to 325 days of gestation massive doses of 100 mg. of dexamethasone daily for 3 to 7 days were required to induce foaling. This may reflect the much higher threshold for hormonal effects required in mares compared to other domestic animals.

Despite the above evidence of the lack of the effect of cortisone on pregnant mares, strong clinical evidence cited by Mitchell^{24,25} and Osborne²⁹ and observed by the author³² and other practitioners would indicate that transportation, physical, nutritional or “emotional” stress in certain pregnant mares is definitely related to abortion at any stage of gestation. On horse farms where pregnant mares were used to collect urine as a source of estrogen, 87.3 percent of 237 abortions occurred between 90 to 150 days of gestation and 89 percent of these abortions occurred within 28 days after removing the mares from pasture and stabling them under stressful conditions.²⁵ No infectious agents could be found in these fetuses. By instituting improved management practices the incidence of abortion could be greatly reduced. In another experiment 44 percent of 95 yearlings and two-year-old mares aborted between 30 and 160 days of gestation possibly due to immaturity, inadequate nutrition and physical stress²⁴ as the fetuses on examination and culture failed to show any infectious agents.

Besides the 5 abortions in 6 mares 4 to 5 months pregnant subjected to stress in shipment from New Mexico to New York State cited in the second edition of this book, the author has observed a number of other similar occurrences. Most notable was a stakes-quality nervous Thoroughbred mare with a history of 8 abortions from 2 to 7 months of gestation over the prior 8 years. Culture and biopsy of the uterus were negative and no reason for the recurrent abortions was found. Before breeding she was vaccinated, wormed and had her teeth checked and feet trimmed. The mare conceived readily; was placed in a paddock on the farm with another old nonpregnant

mare for company and was not handled, treated, or removed from the paddock. Ten and one-half months later she delivered a live, normal foal.

Osborne²⁹ observed a 50 percent abortion rate in pregnant mares at all stages of gestation when stressed in shipment to an abattoir where a postmortem survey on 5198 fetuses was performed. Early embryonic resorption was reported in many mares in South Africa that was apparently caused by a severe nutritional stress of the mares³⁸ 7 to 10 days after being placed on poor pasture at 18 days of gestation. Even in other species excessive stress or handling of normal pregnant females greatly decreases the chance for survival of their offspring. Free-ranging female monkeys had a 2.7 percent incidence of stillbirths, caged monkeys a 15 percent and captured wild monkeys brought to the United States a 50 percent incidence of stillbirths.¹⁰⁰ Modern practices of transportation, changes in feeding and environment, thermal and physical stresses frequently imposed on pregnant mares may have a definite influence on the increased incidence of embryonic and fetal deaths and abortions recorded in recent years, especially in racing and show mares.

Nutritional deficiencies as causes for abortion in mares have been reported.^{13,14,19} Many early embryonic deaths occurred 7 to 10 days after the mares were placed on poor pasture at 18 days of gestation.¹⁹ A high incidence of abortion resulted at 3 to 5 months of gestation in mares 1 to 14 days after confinement in barns and the feeding of a poor ration together with a reduced water intake.^{13,14} These early embryonic and fetal deaths although associated with a lowered level of nutrition may have been due to other hormonal or physiological factors previously discussed. There are no authoritative reports on abortions due to vitamin or mineral deficiencies in horses.

Physical causes for abortion in mares

The **manual dilation of the cervix** and the introduction of several hundred milliliters of physiological saline, dilute Lugol's solution or iodized oil readily produces abortion within 3 to 10 days in most mares. Occasionally a second treatment may be necessary.^{17,21} Purposely aborting mares the last 3 months of gestation is not recommended because complications may arise due to the large size of the fetus.

Natural service during early pregnancy, especially the first 3 months of gestation, is not uncommon due to increased ovarian follicular activity during this period. Abortions following natural matings during pregnancy are rare. Artificial insemination with intrauterine deposition of semen causes abortion during early pregnancy.

Trauma or injury has been reported as a cause of abortion in mares. These reports are not well-docu-

mented. Rough manipulation of the blastodermic or chorionic vesicle per rectum from 20 to 50 days of gestation should be avoided. Rectal palpation of the chorionic vesicle for pregnancy diagnosis should be performed carefully and gently to prevent injury. Frequent rectal palpation of 27 mares between 20 and 82 days of gestation caused no abortions.²¹ Only 2 of 6 mares aborted after 145 days of gestation when exposed to severe rectal and vaginal mechanical and thermal irritation. Thus a normal pregnant mare is relatively resistant to abortion produced by physical means. In twin pregnancy diagnosed prior to 30 days of gestation manual destruction of one blastodermic vesicle permitted the other to develop normally.^{7,11b,22} Severe stress produced by prolonged difficult shipping, hard, sustained work, difficult and complicated operations, vigorous struggling and trauma during casting may cause abortion in mares as discussed previously.

Placental insufficiency due to body pregnancies with little or no extension of the placenta into the uterine horns, adhesions or strictures limiting the size of the uterine lumen or access of the placenta to a portion of the uterine horns and extensive areas of chronic endometrial fibrosis may rarely cause abortion.^{20b}

Torsion or strangulation of the umbilical cord is responsible for about one-half to one percent of the equine fetal deaths and abortions from 150 to 300 days of gestation.^{1,5,20} The equine amniotic sac and fetus float free within the allantoic cavity except for the umbilical cord. The long, 55 cm. (range 30 to 95 cm.) umbilical cord in the normal foal has from 1 to 3 rotations.²⁰ In occasional fetuses the cord becomes excessively twisted, swollen and edematous (See Figure 69) or rarely becomes wrapped tightly around a fetal extremity closing the lumen of the blood vessels between the placenta and the fetus. A long umbilical cord may be associated with ischemic necrosis of the cervical pole of the chorioallantois.²⁰ This appears to be accidental. Most of the excessive twisting and vascular occlusion occurs in the amniotic portion of the cord. Strangulation of the uterus by a lipoma or torsion of the uterus may rarely cause fetal death.

Genetic or chromosomal and other causes of abortion

Fetal anomalies as a possible cause for mid to full term equine abortion have been reported in about 1.3 percent of aborted equine fetuses from 1926 to 1947 in Kentucky.⁵ In a recent report from the same station the incidence had risen to 9.7 percent. The contracted foal syndrome was the most common anomaly at 3.8 percent.¹⁸ Further studies on the causes of these anomalies and their increased incidence is needed. Chromosomal

defects of the equine zygote as in other animals (See abortion in cattle) may cause early embryonic deaths. These defects are favored by aging of the spermatozoa or ovum prior to fertilization which is highly possible in mares due to their long estrous period. A review and study of the cytogenetic basis of prenatal loss in the mare while inconclusive indicated the need for further studies.³

Miscellaneous causes of abortion

Twinning is the cause of 20 to 30 percent of all observed equine abortions.^{16,18,20b} Double ovulations are reported in 4 to over 40 percent of estrous periods, especially in a few mares prone to twinning.^{2,8a,b,9,15} Double ovulations are most common in young and middle-aged mares and toward the end of the breeding season.⁹ Twinning is rare in ponies.⁸ Twinning in mares may be due to genetic factors. However, only 0.5 to 1.5 percent of mares give birth to twins.^{9,17b} The mortality rate of equine twins greatly exceeds that in any other domestic animal. Most equine twin zygotes undergo early embryonic deaths.^{8b,9} Certain mares, as cows, apparently produce twins more frequently than other mares;^{8b} one mare observed by the author aborted twins in 4 of 9 gestation periods. About 60 to 80 percent of twin fetuses that survive through the fourth month of gestation are aborted from 5 months to term with 72.6 percent from 8 months to term. Of 124 twin fetuses 31 were born alive and only 18 or 14.5 percent survived to 2 weeks of age.⁹ A failure of the placental vessels of the allantois chorion of one twin to anastomose with the other, possibly because of the early physical distance between the two blastocysts together with a lack of sufficient placental area for adequate nutrition of one of the fetuses results in the death of that fetus and the abortion of both fetuses.^{6,9} Occasionally the larger twin may die and be aborted with the living smaller fetus. Occasionally mummification or maceration of the dead fetus will occur with its subsequent expulsion at a later date when the other fetus is aborted or born at term. This unequal size of the placental areas available for nutritional exchange probably accounts for the unequal size of most equine twin fetuses by growth retardation of the "malnourished" twin.⁹ Mares cannot increase the size of the uterus or placenta to accommodate twins. The differences in the size of the twin chorions may be due to the time of fertilization or implantation of the zygotes or the rates of growth of the placentae. This is often incorrectly diagnosed as superfetation. Since it is probable that in the latter half of gestation in the mare progesterone necessary to maintain pregnancy is produced in the allantois chorion, it may be possible that abortion is due to a sudden drop in pro-

gesterone levels or a rise in prostaglandins or both caused by the death of one fetus and its membranes (See progesterone deficiency).

Since twinning is the second most common cause of abortion^{1,9,16} various procedures have been attempted to avoid or prevent twin pregnancies, especially in the occasional twin-prone mare. These include:

1. Rectal examinations at daily or more frequent intervals are performed, especially in the twin-prone mare and,

a) Breeding is only permitted when one mature follicle is present. Care must be used here because sometimes a follicle develops rapidly late in estrus and ovulates, asynchronous ovulation.

b) If two mature follicles are present then one may be tapped by an ovarian needle per vaginum.

c) Wait until one follicle ovulates and then breed 12 to 18 hours later since the life of an unfertilized ovum is only about 10 to 12 hours.

2. In the future ultrasonography may aid in diagnosing double follicles and early twin pregnancy, 15 to 30 days of gestation. This equipment presently is very expensive. (See Pregnancy Diagnosis, Chapter II.) By ultrasonography and rectal palpation twin pregnancy should be diagnosed if possible before 35 days of gestation. This may be difficult because the embryonic vesicles are small, may lie nearly together or one may be in the body of the uterus. If pregnancy is terminated after 38 days of gestation it is very difficult to get a mare to conceive that year because of the presence of the endometrial cups and the erratic estrous cycles, anovulatory estrous periods and the long time, usually 40 to 60 days or more before a normal ovulatory cycle occurs. If twin pregnancy is diagnosed then one can:

a) Douche the uterus, cause abortion and rebreed at the next estrous period which occurs normally within 10 days if the pregnancy is terminated before 35 days.

b) Inject the usual single luteolytic dose of prostaglandin or its analogue to abort the embryos before 35 days with estrus occurring as in a).

c) Destroy one embryo as early as possible, 20 to 35 days, usually by manual means. The other embryo often survives.^{7,11b,22} The administration of progesterone and an antiprostaglandin such as butozolidin or flunixin meglumine ("Banamine") before manually crushing one embryo might be indicated to prevent the loss of the remaining embryo. Further controlled trials are indicated. Ultrasonography for the early diagnosis of pregnancy, <30 days, makes such experiments possible. With the death of one embryo, both usually succumbed if surgical intervention or aspiration is employed.^{8b}

d) Allow the pregnancy to proceed. Most twin pregnancies are lost by the death of one or both embryos or fetuses as described under progesterone deficiency in this Chapter. The mare with twins may be put on supplemental injections of progesterone and watched closely. If signs of udder development or perineal and vulvar relaxation occur immediately give large doses of progesterone for 10 to 14 days. This may prevent the twin abortion. At term a normal, usually small, single foal is born along with a mummified, dead fetus.

None of these procedures used to prevent or "treat" equine twin pregnancies is highly satisfactory in the handling of this common condition except the manual crushing of one chorionic vesicle early in gestation or the administration of progesterone late in gestation to prevent abortion. Both of these practices require further controlled investigation.

Early embryonic deaths in horses have received little experimental study. Contagious equine metritis (CEM) due to *Hemophilus equigenitalis* is the only venereal disease causing early embryonic deaths in horses. Most recognized abortions in mares occur after 4 months of pregnancy. However, many unrecognized and unseen expulsions or abortions of embryos and fetuses probably occur from 8 days to 4 months of gestation. In the first few months of gestation maceration and partial or complete absorption of the dead conceptus may occur.^{17b,19} Probably most of these macerating embryos are expelled after a variable period except in cases involving the death of only one of twin embryos with the other embryo remaining viable.^{2,8b,14b,33b}

Many cases of early embryonic death, especially from 20 to 60 days of pregnancy, are erroneously diagnosed as failure of conception, "missed" or "silent" estrous periods, "spurious" conceptions or pseudopregnancy.⁸ A mare with a "spurious" conception has been serviced by a stallion, apparently conceived, and failed to exhibit estrus thereafter, even with a good "teasing" program. She exhibits normal vaginal signs of pregnancy but is not pregnant when examined rectally 30 to 50 days after service. This same condition of pseudopregnancy also occurs commonly in the bred or unbred mare due to a persistent corpus luteum.⁸

Recent studies based on embryo recovery in embryo transfer experiments show that about 80 percent of mares are pregnant at 8 days of gestation but at 35 days only about 65 percent are pregnant, a 15 to 20 percent loss of embryos.^{17c} On well-managed farms with veterinary supervision of the mares, a 2 to 10 percent and occasionally up to 20 percent loss of embryos and fetuses is experienced between routine pregnancy diagnoses at 40

and again at 110 days of gestation.^{3,4,10} An incidence of 21 percent early embryonic death loss the second month of pregnancy in 573 foaling mares compared to only 2 percent loss in barren mares was reported.¹² The incidence was highest in the mares conceiving on the foal estrus. The possible relationship between these early embryonic deaths and lactation was considered. Embryonic deaths from 25 to 31 days of gestation associated with malnutrition was reported.¹⁹ On the basis of studies in other species, some of these losses in mares may be presumed to be due to genetic or chromosomal defects resulting in improper development of the embryo or fetus.³ One infertile stallion produced conceptions with twice the early embryonic death loss of other stallions.⁴ Increased embryonic death loss may result from an abnormal uterine environment in mares infected with *Streptococcus zooepidemicus*, klebsiella, pseudomonas or other bacteria. Bacterial infections are often associated with improper closure of the genital tract due to poor conformation, lacerations and chronic scarring of the vulva resulting in pneumovagina, severe chronic lacerations or scarring of the cervix, and cystic degeneration of the endometrium in older mares. Some mares may lack sufficient progesterone to maintain early pregnancy as discussed previously.

Platt¹⁶ reported on factors influencing the incidence of abortion and noted that abortion rates, 21 percent, were higher in foaling mares conceiving from 7 to 21 days postpartum, compared to mares conceiving 22 to 42 days, 15.2 percent and over 42 days postpartum, 6.3 percent. The abortion rate of mares increased with increasing age, especially in mares over 18 years of age when it reached 28.6 percent. The incidence of abortion in brood mares barren for one year was 13.6 percent compared to 6.5 percent in mares that had foaled and conceived the same year. Abortion rates in mares covered by different stallions varied from 7.1 to 27.8 percent. Thus many factors can influence the incidence of abortion in mares. Further controlled, complete, competent studies on large numbers of infertile and fertile mares, as has been done in cattle, are indicated.

Abortion in Swine

Abortions in swine, as in other species, are comprised of early embryonic deaths and abortions or absorptions, fetal deaths and either abortion of the entire litter or mummification and stillbirths at term of a variable portion of the litter. The latter two categories in contrast to uniparous animals are common in swine. In a herd relatively free of infectious bacterial and viral diseases an incidence of 3 to 8 percent stillbirths and 1 to 5 percent

fetal mummification in 551 litters of over 5000 pigs in a ten year period was reported.² Abortions were uncommon. Over 58,000 pigs had an incidence of 5 to 14 percent stillbirths.⁵ Stillbirths comprise those fetal deaths occurring within the last 20 to 30 days of gestation which terminate in abortion at term; mummification comprise those deaths occurring from 35 to approximately 85 days of gestation.² The incidence of swine abortion is variable, possibly about 5 percent, and abortions usually occur from 75 to 95 days of gestation.^{2,10} Stillbirths and mummification will be discussed later in more detail but are an integral part of the porcine prenatal death loss.

About 40 to 50 percent of the causes of abortions in swine are diagnosed when investigated by competent veterinary laboratories. This level of diagnosis is only slightly better than in cattle and lower than in sheep and horses. A 1978 study of infectious agents associated with 824 abortions in swine in the midwest indicated that 38.8 percent of the fetuses revealed an infectious agent; 22 percent were viral and 16.5 percent were bacterial. Of the bacterial infections leptospiral agents were most common, 9.8 percent.⁴

Infectious Causes of Swine Abortion

Bacterial Causes

Leptospirosis first recognized in 1950 is the most common bacterial cause of swine abortion in the U.S. now that brucellosis is on the decline due to regulatory activities. The causative agent is usually *L. pomona* al-

Table 11. Summary of Causes of Abortion in Swine

Infectious causes:

Bacterial-Leptospirosis (*L. pomona*, *L. grippityphosa*, *L. icterohemorrhagiae* and *L. canicola*), Brucellosis (*Br. suis*) Miscellaneous bacterial-streptococci, *Staphylococcus aureus*, *E. coli*, *Salmonella* spp., *Mycobacterium avium*, *Listeria monocytogenes*, *C. pyogenes*, *Erysipelothrix rhusiopathiae*, *Pseudomonas* spp. *Nocardia asteroides*, *Pasteurella* spp, *Mycoplasma*, *Actinobacillus equuli*, *Actinomyces*, *Hemophilus*, *Proteus*, *Chlamydia*, *Hemophilus parahemolyticus* *Mycobacterium tuberculosis*, and *Klebsiella pneumoniae*.

Viral-enteroviruses or picornaviruses, parvovirus, pseudorabies (Aujeszky's disease)

Miscellaneous viral-hog cholera, reovirus, cytomegalovirus, vesicular exanthema virus and vesicular stomatitis virus, foot and mouth disease virus, Japanese B. encephalitis virus, hemagglutination virus, influenza virus and African swine fever virus.

Mycotic or fungal-*Aspergillus fumigatus* and other molds

Protozoa-*Toxoplasma gondii*, eperythrozoonosis, and sarcocystosis.

Noninfectious Causes:

Chemical, Drug and Plant-dicoumaral, zearalenone and trichothenes (moldy corn), pentachlorophenols (PCB's), carbon monoxide and creosote

Hormonal-estrogens, glucocorticoids, prostaglandins

Nutritional-deficiencies of iodine, vitamin A, iron, and calcium

Physical-stress and exhaustion coincident to transportation, fighting and injury

Genetic, congenital or chromosomal-anomalies, early embryonic deaths

Miscellaneous-poor management, increased stillbirths associated with large or small litters and in older anemic, fat sows.

though *L. grippotyphosa*, *L. hardjo*, *L. canicola*, *L. hyos*, *L. sejroe* (hebdomadis), *L. icterohemorrhagiae*, *L. ballum* and *L. autumnalis* have also been reported as causing abortion, stillbirths or weak pigs that die shortly after birth.^{1,2,3,4,6,7,1,2} Leptospirosis in swine due to various serotypes is widespread in the U.S., Europe and other countries throughout the world. It is more prevalent than commonly suspected because certain serotypes (serovars) produce an inapparent clinical disease.⁷ The incidence of leptospirosis in swine in the U.S. varies from 8 to 25 percent^{3b,5} with the higher incidence in Florida and Georgia.

Leptospiral organisms usually enter the body of the susceptible pig through breaks in the skin or through the mucous membrane of the nasal, conjunctival, digestive or reproductive tracts. A leptospiremia and general infection develops in which organisms invade all the visceral organs. This lasts for 5 to 10 days after which serum antibodies can be detected. The highest serum antibody titers are observed about 3 to 4 weeks after exposure and persist for a year or more. The organisms usually localize in the kidney tubules and are discharged in the urine for 1-1/2 to 6 months. In a few pigs the renal carrier state or leptospiruria may persist for 2 years. The greatest number of organisms are shed 20 to 30 days after exposure.^{1,5,7} Leptospiral organisms may be spread directly by the urine or indirectly by contaminated feed and water to susceptible pigs. As reported previously under abortions in cattle, leptospira can survive in a moist environment outside the body for a period of over a week.^{7,9} Infected boars might infect susceptible sows at coitus and have been shown to introduce the infection into a susceptible sow herd. It is possible that leptospirosis might be spread from infected boars by artificial insemination. Infection, but not abortion, was produced by infecting sows intravaginally after coitus.³ Abortions occurred only in sows infected late in the second month, during the third month or early in the fourth month of gestation. *Leptospira spp* can also be spread from cattle to swine or swine to cattle by infected urine. As in leptospirosis in cattle, wild animals such as rodents, skunks, opossums and raccoons may be a source of infection for swine.

Only occasionally do swine infected with *Leptospira spp* demonstrate acute or obvious clinical signs of illness such as hemoglobinuria. In experimental animals the incubation period is 1 to 2 weeks and inappetence, a mild fever and slight depression may be seen for several days during the leptospiremic stage of the disease but under farm conditions these signs are often not observed. Thus many leptospiral infections of swine are inapparent except for abortions that occur in pregnant females. Fol-

lowing leptospirosis in swine small widespread greyish foci are found scattered throughout the kidneys and liver.^{5,9} Some degeneration and necrosis of kidney tubules may also be present.

Abortions in susceptible sows infected with *Leptospira spp* occur 1 to 4 weeks prior to term. Of 800 aborting sows the earliest leptospiral abortions were from 72 to 78 days of gestation.⁴ Infections occurring between 55 and 88 days of gestation in sows most commonly produce abortions. Abortions usually occur 3 to 4 weeks after the initial infection of the sow. Some or all of the fetuses may be infected and deaths are due to a leptospiral septicemia. Following fetal deaths mummification of the fetus may occur.⁷ Stillbirths or deaths of fetuses late in gestation, and the birth of infected weak, "squealer" pigs that die within several days after birth are common in leptospiral epizootics in swine herds. The incidence of abortion in sows in a herd or of dead fetuses or dying newborn pigs may vary from 20 to 100 percent depending on the number of susceptible sows in late gestation and the rate of spread and virulence of the organism.⁸ Aborted fetuses may be icteric and weak live pigs may die soon after birth.^{6,7}

Leptospirosis may be diagnosed by leptospiral serum titers of 1:100 or higher in the aborting sows as determined by the microscopic agglutination (MA) test using cultures or antigens of five serotypes.⁷ Other serologic tests may be used. Low titers might indicate a prior infection or vaccination with *L. pomona* or other leptospira and abortion due to another cause. A rising titer is highly diagnostic in blood samples taken at abortion and several weeks later. *Leptospira spp* can often be isolated on culture with special media or animal inoculation from the liver, kidneys, peritoneal or pericardial cavities of aborted fetuses, stillborn or weak, ill newborn piglets. Histopathological examination of silver-stained kidney sections or fluorescent antibody stained body fluids or tissues^{6,7} from fetuses may reveal the organism. *Leptospira* often cannot be isolated from the urine of acutely infected aborting sows but several weeks following abortion leptospira can frequently be cultured from the sow's urine. Direct dark field examination of the fetal pericardial or peritoneal fluid or kidney scrapings may reveal the small, fine, filamentous, motile "spinning" leptospiral organisms.^{2,6,1} Following abortion caused by leptospira the sows are immune and resistant to reinfection with that serotype for at least 11 to 14 months.⁶

Leptospirosis in swine may be controlled by sanitation, vaccination and antibiotic therapy, but is difficult to eradicate in a herd. Maintaining a herd free of leptospirosis is possible but may be difficult due to reservoirs of infection in cattle, other domestic animals and

in wild animals, such as skunks, mice and rats. A sanitary environment free of water holes and swampy areas may aid in preventing the spread of the disease. Covered feeding and watering troughs not easily contaminated by infective urine are also desirable. Cattle and swine should not be housed together as leptospirosis may be transmitted between the species. By proper sanitation and management, frequent blood testing, segregation and isolation or measures used to produce a specific pathogen-free herd, a leptospirosis-free herd may be attained. If the swine herd is free of leptospirosis, purchased swine should be negative to the blood test, isolated away from the herd for a month and retested before placed in the herd.

Since in chronically-infected swine herds the acute disease is inapparent, most commercial swine owners routinely vaccinate their sows and gilts before the breeding season, early in pregnancy or every six months with a multivalent leptospiral bacterin that provides a good but relatively short-lived immunity against abortions due to *L. pomona*, *hardjo*, *grippotyphosa*, *canicola* and *icterohemorrhagiae*. The bacterin may also be used early in an outbreak but abortions may continue for 3 to 4 weeks in infected sows. Vaccination of swine two weeks before going to fairs or shows is recommended. Leptospirosis may occasionally develop in exposed vaccinated sows but abortions do not occur, and the number of carriers will be reduced.^{5,1} Vaccination with the bacterin produces low serum titers.

In recently infected susceptible herds, vaccination and antibiotics administered for a period of several weeks⁶ have been effective in treating the carrier state as well as the acute infection and to reduce the incidence of abortion for a period of several weeks until immunity develops to vaccination. The following regimens have been recommended: for pregnant animals in an infected herd; 400 to 500 gm. of chlortetracycline (*Aureomycin*) or oxytetracycline (*Terramycin*) per ton of feed for 10 to 14 days should be provided. For treating the chronic carrier or shedder state in pigs of all ages, chlortetracycline or oxytetracycline at levels of 400 to 500 up to 1000 gm. per ton of feed should be fed for 7 to 10 days.^{2,6,1} Individual treatment of swine may also be used with 5 daily intramuscular injections of tetracycline (*Polyotic*) at a dose level of 3 mg. per pound of body weight or a single injection of 25 mg. per kg. of body weight of dihydrostreptomycin.¹⁰

It is advisable to blood test boars or sows introduced into the breeding herd. If the breeding herd is infected, vaccination of these animals prior to entry is indicated. If the breeding herd is noninfected and the introduced animals are positive, isolation and administration of antibiotics to eliminate the carrier state is essential.

Brucellosis in swine, due to *Brucella suis*, is a much more insidious disease than brucellosis in cattle. The disease has been widespread especially in the hog-raising areas of the Midwest. In 1980 the incidence of animal infection in the U.S. was 0.08 percent and farm infection 0.87 percent.⁵ An aggressive eradication program is continuing in the U.S. under the direction of the U.S. Dept. of Agriculture and cooperating states to increase the numbers of validated (brucellosis-free) herds. Blood testing of adult sows and boars at slaughter to locate infected herds has proven highly effective in controlling and eradicating this disease. Swine brucellosis exists in all swine producing countries and occurs in wild pigs in Florida and Louisiana.⁷ In Florida infected feral swine have caused brucellosis in other swine and hunters.⁶ *Br. suis* may also occur naturally in horses, cattle, dogs, fowl and the European hare. *Br. abortus*, *Br. melitensis* and *Br. canis* may cause brucellosis in swine but clinical signs are rare and the infections are self-limiting.^{2,5,6} Brucellosis due to *Br. suis* until recently was the most common type found in humans in the United States.⁶ *Br. suis* is a facultative intracellular parasite that can survive in the host's phagocytic cells.³

Clinically the disease is endemic on certain farms. The level of resistance is high in young immature pigs nursing infected dams. Clinical signs of the disease usually occur after sexual maturity.^{2,6,4} New infections in a herd are often traced to a recently introduced boar. The organism, *Br. suis*, enters the body through the conjunctiva, nose or mouth, the latter by ingestion of feed and water contaminated by uterine discharges, urine, or feces of infected animals or by eating aborted fetuses and membranes. An important cause of infection in the sow is mating with an infected boar. Brucellosis is a venereal disease of swine. Most infected swine develop brucellosis with clinical signs and a bacteremia starting 1 to 7 weeks post exposure and continuing for 5 weeks and then in a few swine an intermittent bacteremia may last for 8 months to 3 years.⁶ A diagnostic level of serum antibody develops 10 to 21 days after exposure. Antibody levels are higher and persist longer in adult than in immature swine.

The principal clinical signs of brucellosis in swine are abortion, birth of stillborn or weak pigs, infertility due to early embryonic deaths, and less commonly orchitis in boars and posterior paralysis and lameness due to vertebral lesions. Abortions may occur at any stage of gestation.^{6,2} Nearly all brucella-infected boars had lesions in the epididymis and vesicular glands and produced normal appearing but infected semen.⁶ Pus in the semen was uncommon and fertilization was normal. Following service to infected boars abortions may occur as early as

22 days of gestation and are usually not observed under field conditions as no vaginal discharge is present. Sows or gilts infected at coitus frequently return to estrum in 30 to 45 days. Infections acquired by the sow after 30 or 40 days of gestation result in abortions from 46 to 105 days, average 65 to 80 days.^{2,6,4} Genital infection may persist from 1 to 30 months in females. The period of infertility in sows is related to the duration of the genital infection and the degree of pathology present. Many sows overcome the genital infection within one to two months and then have good conception rates thereafter. **Br. suis** may persist in granulomatous lesions and in mucosal cysts of the endometrium and catarrhal endometritis may occur. About 75 percent of susceptible gilts bred to an infected boar become pregnant and 80 percent of these have a normal gestation period. But when an infected sow was bred to a clean boar only a 35 percent conception occurred due to chronic endometrial lesions causing early embryonic deaths and prolonged periods between estrums.⁶ Nodular or granulomatous lesions containing **Br. suis** may also be found in lymph glands, spleen, liver, kidneys, testes, ovaries, and accessory male reproductive glands.

A good herd history is very helpful in a diagnosis of swine brucellosis. The disease may be definitely diagnosed by recovering the organism by cultural methods from organs, especially lymph glands, of the infected sow or boar, from the stomach contents of aborted fetuses or from the chorion of the placenta. Fluorescent antibody tests on fetal or placental tissues may aid diagnosis. The tube or plate agglutination tests may be performed on blood serum from suspected or infected swine. This test is not as reliable as the blood test in cattle. Certain swine harboring and spreading the organism may have low serum titers or be negative to the agglutination test. Most swine with localized infections and those with clinical signs of brucellosis will have an agglutination titer of 1:100 or higher on the standard tube test at some stage of the disease.^{6,4} Nonspecific antibodies to other organisms producing titers of up to 1:50 are common in swine. The blood titer in swine drops more rapidly than in cattle. Testing the herd and eliminating the reactors is not a practical method of eradicating the disease. The agglutination test is of value, however, as a herd test for indicating the presence of infection. In the adult swine herd the presence of any reactors with a titer of 1:100 or a higher indicates that the herd is infected.³ A herd with no animals with titers over 1:50 on repeated tests and no clinical signs of brucellosis is considered negative. Supplemental tests such as the acidified plate antigen test, the heat inactivation test, the Rose-Bengal test, the rivanol test, the complement fixation test and espe-

cially the Card test may be helpful in the diagnosis of carriers of **Br. suis**.^{3,6,7} In the future the ELISA (enzyme-linked immunosorbent assay) test may prove to be a superior test.⁶ A single negative blood test on one individual is of no diagnostic value. The prognosis is guarded in this insidious disease, since sterility may follow abortion and the sow may spread the disease for several months or more. In respect to the herd situation, rather drastic steps need to be taken to eradicate the disease, as there are no treatments that have proven effective in curing an infected animal or herd. No safe or reliable vaccines have been developed and in this country the present incidence of brucellosis does not justify a possible vaccination approach to control.

The methods of eradicating the disease in commercial herds consist of^{6,3} (1) selling all the stock for slaughter, cleaning and disinfecting the premises or moving to clean quarters and then restocking from known noninfected or validated herds. This has been the most successful and economical approach. (2) In valuable purebred herds in which it is desired that breeding lines be maintained, the pigs may be raised on infected sows until eight weeks of age, weaned, and moved from the infected herd, isolated, and raised on clean ground. These pigs are tested individually by the agglutination test at intervals of 1 to 2 months. Any reactors are sold for slaughter. Methods of blood collection from the anterior vena cava and the tail of swine have been described.^{2,3} When the isolated gilts are of breeding age they are bred to noninfected boars. After farrowing in isolation the gilts are retested and if they are negative their litters, when weaned at 8 weeks, are the basis of a new, clean herd. The original herd is disposed of as soon as practical. (3) Repeated blood testing at 30-day intervals together with the slaughter of reactors may occasionally be advisable and successful. In most herds this is not as satisfactory or successful as the two previous methods. If only one or two animals in a herd are serologically positive there is a question whether brucellosis actually is present in the herd.^{6,3} Chemotherapy is of no value in this disease. **Br. abortus** strain 19 vaccine does not immunize swine. Natural resistance or immunity to **Br. suis** is present in about 30 percent of swine.^{6,4} Animals purchased from herds of unknown brucellosis status should not be placed in a brucellosis-free herd.

Miscellaneous bacterial causes of abortion in swine have been described in sporadic cases or occasional outbreaks. The following organisms have been recovered in pure culture from freshly-aborted porcine fetuses: **Staphylococcus aureus**,⁹ **Mycobacterium avium**,⁶ **Listeria monocytogenes**,⁷ **Salmonella sp.**, **E. coli**, **Streptococci**,^{9b} **Coryn. pyogenes**,^{4,5} **Erysipelothrix rhu-**

siopathiae; *Pseudomonas* spp., *Pasteurella*,^{2, 1a} *Campylobacter fetus*, mycoplasma,^{16c} *Nocardia asteroides*,⁴ *Actinomyces* spp.,^{4, 5} *Actinobacillus equuli*,¹¹ *Haemophilus parahemolyticus*, *Mycobacterium tuberculosis*, chlamydia and *Proteus*.^{4, 8}

An outbreak of abortions, stillbirths and moribund neonatal pigs apparently due to streptococci and *E. coli* has been described.^{1a} The former organism was resistant to 4 antibiotics that had been used in the herd in prior years as a feed additive. The use of effective oral antibiotics, determined by sensitivity testing, for the last 30 days of gestation greatly increased the numbers of live pigs per litter at birth, 10 vs. 6, and the number of weaned pigs per litter over the untreated controls, 8.5 vs. 3.8, respectively. *E. coli* endotoxin caused abortion when injected into pregnant sows by apparently inducing prostaglandin release and luteolysis.¹² Nine of 30 sows given a live avirulent erysipelas vaccine 30 days before farrowing aborted and the organism was isolated from the fetuses.³

Viral Causes for Porcine Prenatal Losses

The major viral causes for prenatal loss in swine are parvovirus infection, pseudorabies or Aujeszky's disease and various entero-picorna (SMEDI) viruses. Hog cholera, formerly an important viral cause of abortion, has been eradicated from the United States. SMEDI is an acronym coined by Dunne³ referring to stillbirth-mummification-embryonic death and infertility associated with the above and other viral diseases of swine. Other viral agents of swine that produce signs of the SMEDI syndrome are hog cholera virus, reovirus and influenza virus.^{1, 2, 3} Of 824 porcine abortions in the midwest U.S.A. 22 percent were due to a viral agent; 10.9 percent enterovirus, 4.9 percent parvovirus, 4.4 percent reovirus and 1 percent pseudorabies virus.⁴ Dual infections with two viruses or a virus and bacteria are fairly common in swine abortions. Since the etiologic agents causing the SMEDI syndrome are now well-known and diagnostic tests have been developed, the term SMEDI should be discarded. It should be noted that leptospirosis and brucellosis may also exhibit similar signs. It is important to recognize that in swine these and other viruses may affect the developing embryos or fetuses and result in: (1) infertility or sterility related to early embryonic deaths that are aborted unseen or absorbed, (2) fetal mummification, (3) defective or anomalous fetuses (4) stillbirths (5) birth of live but poorly viable pigs and (6) birth of live normal pigs that may be carriers of the virus. Abortions of entire litters late in gestation are rare.

Enteroviruses or Picornaviruses,³ have been shown to cause occasional abortions but mainly the aforementioned effects on intrauterine embryos or fetuses in sows. (See Figure 74.) These enteroviruses are ubiquitous in all swine. The only known natural host for porcine enteroviruses is the pig. These viruses are quite resistant to disinfectants and very resistant to environmental influences.² Transmission is directly by the fecal-oral route and indirectly by fomites. Several serogroups of porcine enteroviruses are endemic in all commercial swine herds. Pigs of any age are susceptible but most adults have high antibody titers and rarely excrete virus.^{2, 4} In a tentative classification of over 40 porcine picornavirus strains isolated in North America, Japan, England and Czechoslovakia, 17 groups were determined serologically. The 5 strains of enteroviruses isolated in Pennsylvania fell into Groups 1, 6, 7 and 13.⁵ These 5 strains of enteroviruses when inoculated into cholera-immune or cholera-susceptible pregnant swine cause a similar syndrome to that caused by hog cholera, pseudorabies, parvovirus, or other viruses that will be mentioned. Susceptible pregnant gilts inoculated with enteroviruses at 25 days of gestation had embryonic deaths within 5 days of the inoculation; death of fetuses and mummification occurred 15 to 40 or more days after inoculation; and thereafter stillbirths and weak pigs dying within 6 hours after birth were observed. Fetuses in the same sow may become infected and die at different stages of gestation. If embryos die before 30 days of gestation when no skeletal development has occurred, absorption results; if fetuses die at later stages of gestation, 50 to 100 days, after skeletal development occurs mummification or stillbirths result. The position of the fetus in the uterus was not related to the time of fetal deaths. In some sows where early embryonic deaths occurred the sow returned to estrum at a varying interval following the initial service. In other cases where fetal deaths occurred at 30 to 60 days of gestation and mummification resulted, "parturition" did not take place at the end of gestation and the sow exhibited a prolonged "gestation" period. These signs are usually limited to one breeding season in a herd. Recovered immune sows have normal gestations during the next breeding season.

The virus is apparently spread through the susceptible animals in the breeding herd after its introduction by an infected animal or from contact with infected pigs. The boar may also be a temporary spreader of the virus. The virus may be isolated in suspected outbreaks from cultures of the internal organs of stillborn fetuses or weak, poorly viable, newborn pigs. Usually there are no lesions in aborted fetuses. Occasional lesions may be seen in the CNS, lungs (pneumonia) or heart (pericarditis or myocarditis). In mummified pigs the viral antigen may

be detected by immunofluorescence. Serologic tests are of no value.² Sows infected before breeding are apparently immune as are sows at the next breeding period following an episode or outbreak of stillbirths, mummified fetuses, abortions, embryonic deaths and infertility. Control measures depend on prevention rather than treatment.² Because of the many serogroups no effective vaccine is available. So gilts and fresh stock introduced into the herd should be exposed to "resident" infection by contact with the older sows, weaned piglets, or fecal material a month or more before breeding. Comingling gilts with older sows also provides nose to nose contact as well as fecal exposure and the development of a natural immunity before breeding.^{1,2}

Pseudorabies (Aujeszky's disease) due to a herpesvirus is widespread in swine in the U.S. with most outbreaks reported in the midwest. In the early and mid 1970's there was a marked increase in the number and severity of outbreaks in the U.S. In 1981 the incidence in swine based on serological testing by the USDA was 8.3 percent. The disease incidence has also increased in Europe and is found world-wide.^{3,1b,5,13} The virus apparently persists in a latent form^{3,3,5,7,11} in recovered swine and may be present in most domestic animals and many wild animals. In animals other than swine, which is the host of the virus, pseudorabies is usually a fatal disease. Humans are resistant. Up to 60 percent abortions have been reported in a susceptible breeding herd.^{5,8,12} The average live litter size was reduced from 7.7 pigs in control gilts to 1.9 pigs in the exposed gilts.⁸ Forty-one percent of porcine fetuses from sows aborting or delivering stillbirths due to pseudorabies had pinpoint to poppy-seed-sized necrotic foci in the liver and intranuclear inclusion bodies were observed.^{2,14} They also have isolated the virus from the vagina of sows and the prepuce of boars. If this herpesvirus is like others in domestic animals it is likely the boar may transmit the virus at coitus at rare intervals.⁹ The herpesvirus of pseudorabies in swine, as in virus infections in other species, such as IBR in cattle, may be transmitted in semen. Many states and the federal government have passed regulations in recent years controlling the shipping of infected swine or semen, the use of vaccines and the quarantining of known-infected herds.

The greatest mortality in susceptible pigs infected with pseudorabies virus from nasal or oral exposure is in suckling pigs, up to 90 percent, and next greatest is in weanling and fattening pigs.^{4,5} Usually fever, difficult breathing and sneezing, salivation, vomition, anorexia, ataxia, convulsions, coma and death in 1 to 2 days in the former and 6 to 8 days in the latter is observed. The mortality rate in mature swine is less than 2 percent with

mild signs of sneezing, coughing, anorexia. Blindness often is associated with central nervous signs. Most older pigs recover in 10 to 12 days.⁵ The main site of viral replication is the upper respiratory tract from which the virus invades the blood stream and the cranial nerves.^{5,7} Viremia allows passage of the virus to all organs of the body.

In pregnant swine the virus readily crosses the placenta barrier and infects the embryo or fetus. If this occurs at 30 days of gestation the embryos die and are resorbed and pregnancy is terminated. If infection occurs after 40 days of gestation and before 60 to 80 days, fetal mummification and maceration of some or all of the fetuses may occur. If infection occurs after 60 or 80 days of gestation death and maceration, premature expulsion or the birth at term of stillborn or weak infected fetuses may occur. Delayed parturition of 2 to 3 weeks occasionally occurs if all the fetuses died in the later stages of gestation. Following fetal infections and expulsion, infertility may be present at the first breeding.

Diagnosis of pseudorabies can be made by culturing tissues from infected fetuses or performing the immunofluorescent antibody (FA) test on fetal tissues.^{5,14} Serologic tests on live pigs or sows include the virus neutralization test, the enzyme-linked immunosorbent assay (ELISA) test, agar gel immunodiffusion test,^{7b} the complement fixation test and the indirect hemagglutination test. A skin test based on cell-mediated immunity has been developed. Biologic tests of animal inoculation of suspect material subcutaneously into rabbits or mice or into embryonating chicken eggs can also be performed.⁵

Treatment cannot greatly alter the course of the disease once signs of the disease are present. Eradication or control are topics being seriously debated currently between those concerned with the control and prevention of pseudorabies.^{13a} Because of the nature of herpesviruses and their ability to remain latent in the ganglions of the cranial (trigeminal) nerve^{7,11} and recrudescence under stress,^{1b} the wide-spread incidence of the virus in the swine population, the failure of diagnostic tests to indicate all carrier or infected animals, and the difficulties of acquiring a pseudorabies virus-free herd and maintaining it with the other livestock or wild animals that can carry the virus on to the farm, the author believes a pseudorabies virus-free commercial or conventional swine herd would be difficult to develop and maintain. The cost of this effort would probably not be economically possible for most swine breeders and the country.^{13a}

Attenuated (MLV) and inactivated vaccines are available^{1,5,6,10} and when used properly before breeding in young pigs will produce a good immunity and largely

prevent losses due to pseudorabies. Vaccines will not prevent infection with virulent virus and these infected animals shed the virulent virus for a period of time and often develop a latent infection that can recrudesce under stress.^{3,7,11} One bivalent commercial inactivated vaccine contains both pseudorabies and parvoviruses.¹⁰ Vaccines will produce positive serologic titers.⁶ These titers can interfere with serologic tests used to eliminate virus from a herd. Another inactivated P.R. vaccine has been combined with a multivalent leptospiral vaccine. It is recommended that cattle, sheep and dogs be kept away from infected or pseudorabies-free herds. Additions to herds should be blood tested and retested after a 4-week isolation period or purchased from pseudorabies-free herds to prevent the possible introduction of virulent virus especially when sows are pregnant or have recently farrowed. Pseudorabies vaccines have proven helpful when given to pregnant sows early in an outbreak.^{1,10}

Porcine Parvovirus (PPV), the most common cause of embryonic and early fetal loss or mummification, was first described in 1967 in England.^{1,5} Since then it has been found to be an ubiquitous virus throughout the world and is enzootic in most swine herds.⁵ It causes reproductive failure in sows with signs of embryonic and fetal death with resorption or mummification without producing any clinical signs of illness. In 1977 a study at an abattoir in Iowa found 62 of 203 pregnant sow uteri containing dead or mummified embryos or fetuses.³ Forty six or 74.2 percent of these litters were positive for porcine parvovirus (PPV) based on isolation of the virus or demonstration of the PPV antigen. Most of the fetuses (392 or 84 percent) died and became mummified before 71 days of gestation and antibody was found in nearly all of the serums of the 68 or 14.8 percent live fetuses at 81 to 105 days of gestational age. The incidence of PPV infection in pregnant uteri in abattoir material in Minnesota and Iowa was 9.4 to 23 percent.^{3,9} Porcine parvovirus is not related to other parvoviruses including canine parvoviruses, feline panleukopenia virus or mink enteritis virus.⁵

Because of the ubiquitous nature of porcine parvovirus nearly all sows in most herds have become naturally infected by the oral and nasal routes and are immune as determined by seroepidemiologic data. This immunity persists for a lifetime. The parvovirus is quite stable, and remains infectious in the secretions and excretions of acutely infected pigs for months.⁵ It is resistant to common disinfectants. Parvovirus may be spread by acutely-infected boars by several routes including the semen. Acute infection of susceptible young pigs, pregnant gilts or sows and boars is usually subclinical even though the virus is found throughout the body and can pass transplacentally to the fetuses. Thus the only clinical signs

are referable to reproductive failure with embryonic and fetal death.

Transplacental infection apparently requires 10 to 14 days from maternal exposure. Infection of the conceptus between 10 and 30 days of gestation causes embryonic death and resorption and between 30 and 70 days causes fetal death and mummification. Intrauterine spread of the virus may also occur causing deaths at different times with mummified fetuses of different sizes.^{4,5} Immuno-tolerance to PPV may develop in fetuses infected prior to 55 days of gestation and they may be born alive with no antibody but carrying the virus.⁵ After midgestation, 70 days, fetal infection also occurs in acutely infected susceptible gilts or sows but the fetus survives without clinical disease because it develops an immunologic response to the virus.^{5,6}

Even though a direct causal role of porcine parvovirus in semen in reproduction failure has not been completely confirmed, the susceptible female infected by semen may spread the virus to other swine.⁵ Conceptuses are apparently infected transplacentally during or after maternal viremia. Infected embryos or fetuses contain the virus in most of their cells at death especially in the endothelium as determined by immunofluorescent microscopy. Macroscopic lesions seen in fetuses before they are immunocompetent include congestion, edema, hemorrhage, and bloody fluids in the body cavities. Microscopic lesions include cellular necrosis and inflammation and possibly intranuclear inclusions.⁵ Meningoencephalitis with perivascular cuffing has been described in fetuses or stillborn pigs after they have become immunocompetent.

PPV may be suspected when gilts, not sows, show evidence of early embryonic deaths, return to estrus, have abortions, fetal mummification, resorptions, infertility and failure to farrow. Stillbirths or reduced numbers of pigs and neonatal deaths occur occasionally.⁵ Fetal mummification or death of all embryos and their resorption has caused prolonged gestation. Diagnosis is confirmed by fluorescent antibody test of tissues, especially the lungs, of mummified fetuses less than 16 cm in length.⁵ Remnants of autolyzed tissues of embryos may be similarly examined by immunofluorescent microscopy. Viral isolation from infected autolyzed tissues of fetuses is difficult. Serologic tests are recommended only when small mummified fetuses are not present indicating a recent infection. Maternal blood samples taken from sows or gilts if negative for PPV antibody would exclude this virus as a cause of reproductive failure. Because PPV virus is so ubiquitous a positive hemagglutination inhibition (HI) test, serum neutralization (SN) test, immunodiffusion test, or modified direct complement fixation (CF) test is meaningless.⁵ Detection of PPV antibodies

in the serum of fetuses or stillborn pigs or neonatal pigs before nursing or body fluids of fetuses would indicate fetal infection since maternal antibody cannot cross the fetal-maternal junction.²

There is no treatment for porcine parvoviral reproductive failures. Preventive measures include either the natural exposure and infection or vaccination of gilts before they are bred. Natural exposure and infection is effected by close contact or intermingling of seronegative gilts with seropositive sows, placing the former in a contaminated area or exposing the susceptible gilts to mummified conceptuses, stillbirths and placentas of recently infected aborting sows. This method of exposing gilts to PPV may inadvertently expose them to pseudorabies virus and other diseases and is not as reliable as vaccination. In herds where PPV is enzootic usually 50 percent or more of the gilts are infected and immune before breeding.⁵ In 2 swine herds with enzootic PPV, the proportion of seronegative, susceptible gilts at breeding was 40 percent and only 50 percent of these became infected during their first gestation. The incidence of mummified fetuses in pigs born previously to seropositive gilts, seronegative gilts and gilts that seroconverted during gestation was 0.6%, 1.0% and 3.0% respectively.^{2b}

By vaccination one month or more prior to breeding the swine breeder can be certain gilts are immune before conception. Both inactivated and MLV vaccines^{5,7,8} have been developed. Since seropositive sows produce antibodies to PPV in the colostrum passive antibodies in piglets persist for 4 to 6 months and interfere with vaccination immunity. Gilts should be vaccinated 15 to 60 days before breeding. The duration of immunity from the inactivated vaccine lasts 4 to 6 months and usually within this time natural exposure and active immunity will develop. Vaccination with an inactivated product is recommended for all seronegative sows and boars introduced into an infected herd. A few disease-free or other swine herds may be PPV-free but maintaining this status is very difficult and risky. Porcine parvovirus when introduced into a PPV-free herd produces very severe reproductive losses.⁵

Swine influenza due to the swine influenza virus (SIV) is primarily a respiratory disease common during the fall and winter in swine raising areas with a serologic incidence of 12 to 45 percent.^{7,5} Reproductive losses, including mummification and weak pigs, have been reported in susceptible dams infected with SIV during gestation, especially the first 30 days. Breeding sows that are more likely to have been previously exposed to SIV, in the fall for winter farrowing instead of gilts may reduce the reproductive losses.^{2,5,11} Diagnosis of swine influenza is based on the history and respiratory signs, and possibly the recovery of the virus from aborted fetuses

or careful interpretation of serologic evidence by the hemagglutination-inhibition (HI) or serum neutralizing or complement fixation test on sows or newborn piglets before suckling. Presently there are no licensed vaccines for swine influenza nor any specific treatment.¹ A recent study showed that SIV did not produce abortions, did not cross the placenta into the fetuses and was not a direct cause of reproductive failure in swine.^{1b} It should be noted that influenza viruses in cattle and horses seldom affect the fetus or reproduction. Further studies are needed to determine the role, if any, of swine influenza in reproductive losses.

Reovirus infection has been reported in 4.4 percent of 320 porcine abortions based on untyped virologic cultures.^{4,8} Sows experimentally infected between 40 and 80 days of gestation produced stillbirths, mummified fetuses and weak pigs.⁷ Clinical signs of reovirus infection in swine usually includes mild respiratory or digestive signs. No lesions have been described in fetuses or neonates. Antibody detected by the HI test is widespread but might be used for detecting antibodies in stillbirths or neonatal piglets before suckling. Reproductive losses due to reovirus requires further investigation.

Porcine cytomegalovirus (PCMV) infection is not accompanied by clinical signs in pigs over 3 weeks old but can be fatal for the fetus and newborn piglet.⁶ This ubiquitous organism is spread in the nasal and ocular secretions, urine and cervical secretions of infected pregnant sows. Active immunity usually develops between 8 to 11 weeks in piglets receiving passive colostrum immunity from the dam. Early postnatal or congenital infection of piglets occurs in association with mummified fetuses, stillbirths, neonatal deaths, and stunted pigs. Intracellular inclusions are observed in the reticuloendothelial tissues and kidney of infected fetuses or neonates. Gross fetal lesions include petechiae, pleural and pericardial effusions and edema especially in the kidney. Viral cultures and serologic tests aid the diagnosis of PCMV infections.

Hog cholera due to hog cholera virus (HCV), although eradicated from the United States, is present in many countries. Hog cholera virus strains differ markedly in virulence.¹⁰ Field strains of low virulence or attenuated or modified strains used as vaccines if inoculated into pregnant susceptible sows the first 10 to 20 days of gestation resulted in death and absorption of the embryos and fetal malformations.^{2,3} If the virus gained entrance to the sow's body from 30 to 90 or more days of gestation, mummification of fetuses, stillbirths and weak pigs were common.

The hog cholera virus in infected fetuses, stillbirths or live newborn pigs may be cultured on tissue culture media or demonstrated by the fluorescent antibody

technique^{1,2,4,10} Pigs infected **in utero** may survive and after birth become tolerant carriers of HCV. Under stress these carrier pigs may become ill and die of cholera weeks or months after birth.

Other viral causes for porcine fetal deaths, mummification and abortion include: **Japanese B encephalitis virus**, **Japanese hemagglutinating virus**, and **African swine fever virus**.^{1,4,9} The latter virus caused outbreaks in the Dominican Republic and Haiti in 1978 and Cuba in 1979. This has been the closest African swine fever outbreaks have occurred to the United States. This virus causes porcine abortions at any stage of gestation, latent carriers and possibly immunotolerant offspring. The Dominican isolate caused 7 abortions in thirteen 38 to 92 day pregnant sows 5 to 8 days postinoculation associated with the acute viremia of the sow.⁹ African swine fever virus was recovered from the aborted fetuses. Abortions have also been described accompanying acute cases of **vesicular exanthema**,⁷ foot and mouth disease and possibly **vesicular stomatitis**.^{7,4}

Mycotic or fungal porcine abortions due to **Aspergillus fumigatus**, **Nocardia asteroides** and others have been described on rare sporadic occasions.^{4,1a,b,c}

The parasitic protozoan causes of abortion in swine possibly include the agents of **Toxoplasma gondii** and **Eperythrozoon suis** and **Sarcocystis spp.** From serological evidence **toxoplasmosis** is common in swine but few clinical cases have been reported.^{1,3} Pregnant sows may abort or farrow weak or stillborn pigs.^{2,6,7} **Eperythrozoonosis**, although very common in herds in the United States, is suspected, but not proven to be associated with reproductive problems including delayed estrus, embryonic death, absorption of fetuses and abortion.^{6,5} **Sarcocystis suicanis** was carried by host dogs and raccoons and affected 16.6 percent of sows in Georgia. This parasitic protozoa caused abortions and deaths in pregnant sows in Europe,^{1a,4} when experimentally inoculated in large doses. (See sheep.)

Noninfectious Causes of Porcine Abortion

Chemical, drug or plant poisonings are rather seldom causes for abortion in swine. Dicoumarol poisoning has been cited.⁵ Wood preservatives such as the **pentachlorophenols** and **creosote** have been reported to be toxic for prenatal and postnatal pigs.¹⁴ Wood so treated should be thoroughly dried before placing sows or pigs in contact with it. Polychlorinated biphenyl (PCB) when fed to sows caused a reduction in live pigs farrowed and an increase in fetal mummification probably related to the immunosuppressive effects of the compound.⁶ **Moldy**

corn toxicosis probably due to aflatoxin B associated with penicillin, aspergillus and rhizopus molds, caused bloody diarrhea, anorexia, depression, ataxia and abortion.³ Another mold, **Fusarium spp.**, produces the mycotoxins, zearalenone and trichothenes.^{7a,b,9b,11} The former causes an estrogenic syndrome of swollen external genitalia, mammary gland development, testicular hypoplasia, infertility, constant estrus, pseudopregnancy, small litter size due to early embryonic deaths and resorption, increased mummification and possibly increased stillbirths and weak pigs. The latter mycotoxin may also cause infertility and abortion. **Ergot** was not shown to be a cause of abortion in swine even when ergotism produced necrosis of the extremities.¹ Ergot-infected feed did cause agalactia in sows and in one report lowered reproductive rates.^{3,7,9b,11} Early embryonic deaths and mummification followed the consumption by sows of a tropical shrub legume, **Leucaena leucocephala**.¹⁶

Hormonal causes for porcine abortions are uncommon. Glucocorticoids have not been reported to cause abortion in swine but severe stress conditions have been associated with premature births and abortions. Exogenous glucocorticoids in large doses such as dexamethasone and prostaglandins or their analogues have been used to induce premature or "timed" parturition by injection between 110 and 113 days of gestation.⁵ (See Chapter XI). Administration of 500 µg cloprostenol to gilts between 30 and 100 days of gestation resulted in abortion in 34 to 42 hours requiring a duration of 4 to 14 hours. Estrus occurred 9 to 10 days after abortions with 90 percent conceptions in this estrus.^{11b}

Nutritional causes of swine abortion, stillbirths and anomalous fetuses include deficiencies of iodine, vitamin A, iron and calcium.^{5,9,10,12} **Iodine deficiency** is characterized by hairlessness, goiter, edema of the fetus and a slightly prolonged gestation. This condition is rare at present because iodine is commonly added to salt in most rations. **Vitamin A deficiency** usually related to a lack of pasture, alfalfa hay and the feeding of 2 or more-year-old corn may result in weak, moribund newborn pigs or stillbirths with edema, ascites, cleft palate, anophthalmia, microphthalmia, hydrocephalus and cardiac defects. **Iron deficiency** may cause stillbirths or weak newborn pigs suffering from a severe anemia. **Chronic calcium deficiency** due to exclusive grain feeding, a lack of roughage or pasture or no mineral or tankage supplementation results a progressive increase in the number of mummified fetuses and stillbirths with each litter produced.

Physical causes of porcine abortion include stress and exhaustion due to transportation and excessive fight-

ing between sows.⁵ Abortions were associated with severe outbreaks of pneumonia in many swine herds.^{9a}

Genetic or chromosomal causes for stillbirths or moribund pigs include the congenital or genetic lethal defects described previously (See Chap. III). About 10 to 12 percent of the blastocysts from normal sows had chromosomal defects, mainly polyploidy, which may account for about 30 percent of the total pregnancy wastage in swine.⁸ These defective zygotes that die early in gestation may comprise a significant number of the ova released and fertilized that fail to result in pigs produced at parturition. This loss may be estimated by counting the corpora lutea in the ovaries at farrowing.

Miscellaneous abortions or loss of neonatal pigs may be due to **poor management** at the time of farrowing resulting in smothering, crushing or chilling of newborn pigs. These are often called "stillbirths." About 5 to 10 percent of all porcine fetuses expelled at parturition are stillbirths. These may be divided into prepartum deaths usually due to infectious causes late in gestation and intrapartum deaths associated with delayed or abnormal expulsion of fetuses.⁶ Attendance of a caretaker at farrowing is highly desirable. At parturition sows should be neither too fat nor too thin. Farrowing crates or guarded stalls and heat lamps or heated floors are very helpful in preventing neonatal losses. The larger the litter or the smaller the litter, above 12 or below 4, the greater the percentage of stillbirths that occurred.⁶ The number of stillbirths increased as the duration of parturition increased from one to 8 hours and as the age of the sow increased. Most of the dead pigs, 80 to 85 percent, were born late in the act of parturition. In large litters deaths might have been due to delays in birth associated with exhaustion of the sow or uterine inertia and anoxia of the fetus due to intrauterine rupture of the umbilical cord. In small litters the larger-sized fetuses presented may have resulted in slower expulsion. Administration of oxytocin to hasten farrowing did not reduce the mortality. If parturition is more than 6 to 7 days early or late the incidence of stillbirths increase. Weak pigs at birth may be due to hypoxia and may be revived by artificial respiration and small amounts of supplemental oxygen.^{6,15} Sows that are anemic, with hemoglobin levels below 9 gm/100 ml, have a higher incidence of stillborn pigs. Iron supplementation during pregnancy is indicated in these sows. Induction of parturition with prostaglandins so attendants may be present to supervise births has reduced the incidence of stillbirths. After about one-half or two-thirds of the litter has been born administration of frequent small doses of oxytocin or the single injection of neostigmine (5 mg/sow)^{6,15} increases the speed of farrowing and reduces the number of stillbirths.

Sows in late pregnancy were exposed for 48 to 96 hours to various atmospheric carbon monoxide concentrations such as might occur in poorly maintained gas-fired heaters in farrowing houses. There was a close correlation between the rates of stillbirths (8 to 80 percent) and the concentrations of carbon monoxide (200 to 350 ppm).^{4,17} Gross lesions in the stillborn pigs were cherry-red discoloration of subcutaneous tissues, muscles and viscera and a serosanguinous pleural effusion. Other distinctive microscopic lesions were also described.

Abortion in Swine

ABORTION IN SHEEP AND GOATS

Abortions in sheep and goats, as in other larger domestic animals, are due to a wide variety of infectious and noninfectious agents. Because of the methods of breeding and management of sheep in flocks, many animals are at the same stage of pregnancy at the same time and exposure of pregnant ewes to introduced infectious diseases is favored. When an abortion outbreak does occur in a flock it is usually possible to secure 2 to 5 or more fresh fetuses and their placentas for examination and laboratory diagnosis. For this reason, the percentage of confirmed or accurate diagnoses for abortions in ewes is higher than in cattle, about 40 to 60 percent. In most flocks an incidence of 1 to 5 percent abortion and stillbirth is considered "average" or acceptable.¹³ Higher rates of abortion or stillbirth should be carefully investigated. For this purpose fresh fetuses and placentas from aborting ewes should be collected in a clean container, chilled and promptly transported to a well-equipped diagnostic laboratory.

Infectious Causes of Ovine and Caprine Abortion

Bacterial Causes

Campylobacteriosis, Vibrionic abortion (vibriosis) due to *Campylobacter fetus* var *intestinalis* is the most common cause for epizootic ovine abortion in the United States.^{2,4,5b,8,10} *Campylobacter* abortion is rare in goats.^{5,11} It is a cause of serious economic losses in bands of sheep in the Rocky Mountain states and elsewhere in the U.S. It is widespread, occurring in nearly all the sheep-raising areas of the world. The *C. fetus intestinalis* organism in sheep is similar to *C. fetus venerealis* in cattle in some bacteriologic and morphologic characteristics. The former organism in sheep seldom spreads to or infects cows under natural conditions. *C. fetus intestinalis* (*C. jejuni*) can cause abortions in humans so it is of public health significance.⁸

C. fetus intestinalis is catalase positive and H₂S positive; while *C. fetus venerealis* is catalase positive and H₂S negative. The former will grow in 1% glycine while the latter will not. These organisms may be confused with nonpathogenic vibrios, *C. bubulus*, which is catalase negative and *C. fecalis* which is catalase positive but resembles *C. bubulus*. There are 5 whole-cell serotypes (I–V) with two serotypes I and V (C) causing most outbreaks.^{5,8,3} In recent months an intestinal strain of campylobacter called *Campylobacter jejuni* has been

recovered from feces from a number of species including ducks, goats, sheep, cattle, dogs and humans. In these species it may cause an acute diarrhea and in sheep and goats it causes abortions in late pregnancy. *C. jejuni* and *C. fetus intestinalis* are possibly identical, based on serological and cultural characteristics.^{1b,4b,11b}

In affected flocks the incidence of abortion due to vibriosis varies from 5 to 70 percent, with an average of 20 to 25 percent with deaths in about 5 percent of the affected ewes.^{8,2} These authors reported that the disease was observed uncommonly in flocks kept on range the year around, but that it was more commonly seen in sheep kept in feed lots for a part of the winter especially if sanitation was poor. Ewes will frequently smell of and lick aborted conceptuses of other ewes. The disease has been transmitted orally by feeding infective material from aborting ewes as well as by intravenous injection of cultures of *C. fetus intestinalis*. Following oral exposure of susceptible ewes, a period of bacteremia of 7 to 14 days follows as in brucellosis.^{8,11} Under natural conditions infection is probably introduced into clean flocks by carrier sheep that may carry the organisms in their intestines or gall bladder, whether they aborted or not, and shed them in their feces for weeks or months. Carion birds such as magpies and crows may also carry the organisms in their gut from one flock to another.^{13,16,17} *C. fetus* is rather easily destroyed by sunlight, heat or drying, but may remain viable for some time at low temperatures in moist surroundings. This may partly account

Table 12. Summary of the Causes of Ovine and Caprine Abortion

Infectious causes

Bacterial causes—*Campylobacter fetus* var. *intestinalis* and *jejuni*; *Listeria monocytogenes*; *Brucella melitensis*, *abortus*, and *ovis*; *Salmonella abortus ovis*, *dublin*, *typhimurium* and others; *Leptospira pomona* and others; *Corynebacterium pyogenes*, *pseudotuberculosis* and others; and *Pasteurella tularensis*, *pseudotuberculosis* and others.

Miscellaneous bacterial causes—*E. coli* and other coliforms, streptococci, staphylococci, *Clostridium fesi*, *Bacteroides fragilis* and *Mycobacterium paratuberculosis*.

Viral and rickettsial causes—Enzootic abortion (EAE) due to *Chlamydia psittaci*

Miscellaneous viral and rickettsial causes—Tick-borne fever, Wesselbron virus, Rift Valley fever, Nairobi sheep disease, rinderpest, foot and mouth disease, bluetongue, *Coxiella (Rickettsia) burnetii*, Akabane virus and Border Disease and/or BVD-MD virus.

Mycoplasma causes—*M. agalactiae*, *M. mycoides* var *capri* and ureaplasma.

Mycotic causes—*Aspergillus fumigatus*.

Protozoan causes—*Toxoplasma gondii* and *Sarcocystis* spp.

Noninfectious Causes

Drugs, chemical and plant poisonings—phenothiazine, tetramisole, carbon tetrachloride, lead, nitrate, locoweeds, lupines, Veratrum, and onion grass.

Hormonal—estrogens, progesterone deficiency, cortisol and ACTH excess, prostaglandins, and stress.

Nutritional—Deficiency of TDN, copper, cobalt, iodine, selenium, vitamin A and manganese, debility and parasitisms.

Miscellaneous—chromosomal or genetic lethals, severe physical stress, possibly twinning or greater multiples.

for the higher incidence during the winter months.

Vibriosis in sheep in contrast to vibriosis in cattle is not a venereal disease. The ram is not a factor in the transmission of the disease except as he may be an intestinal carrier of the infection.^{4,7} Infertility due to embryonic deaths is not present in ewes mated to experimentally infected rams. The disease is transmitted from infected or aborting sheep to susceptible pregnant ewes the third through the fifth month of gestation. Pregnant ewes infected prior to the third month of gestation do not abort.² There is an incubation period of 7 to 25 days. During the bacteremic period the vibrio enter the maternal placenta where inflammatory changes occur with extension of the infection to the fetal placenta and chorion. The organisms are then carried to the fetus by the placental circulation causing fetal bacteremia.⁸ Abortions may continue in a flock for 6 to 12 weeks. In campylobacter abortion there are often no premonitory symptoms. Occasionally the vulva will swell and a slight reddish discharge may be present. The fetuses are usually expelled the last trimester or 4 to 6 weeks of pregnancy. Abortions occur 1 to 3 days after the death of the fetus. In some cases lambs may be expelled prematurely as stillbirths or at term but die soon after birth. At the time of abortion the fetuses are fairly fresh and only seldom are they decomposed or mummified. The aborted fetuses usually have subcutaneous edema and reddish serum in the body cavities due to autolytic changes. The fetal membranes, especially the cotyledons, show inflammatory changes characterized by edema and necrosis. About 5 percent of aborting ewes may die due to secondary uterine infections, macerating fetuses and peritonitis.^{8,2} About 20 to 60 percent of the fetuses have characteristic necrotic areas or infarcts 1/2 to 3 cm. in diameter in the liver. These contain large numbers of organisms. The cotyledons may be necrotic and organisms may be recovered from these placental structures. **C. fetus** may be identified by stained smears or cultures from the fetal stomach, lungs, cotyledons or uterine exudate.⁸ The latter is usually necessary for a positive identification. The agglutination test on the blood has been of very limited value in the diagnosis of the disease. Fluorescent antibody technique may be of value in the rapid diagnosis of the disease.^{1,2}

Most workers agree that sheep that abort one year are usually immune the second and possibly the third year and carry their lambs normally, but immunity is probably not permanent.^{9,10} In some flocks the disease may appear two years in a row but usually the incidence is much lower the second year. Aborting ewes should immediately be removed from the rest of the flock and isolated for 2 to 4 weeks until genital discharges cease. The

fetus and membranes should be buried or destroyed. Disinfection with a cresylic compound of the infected pen or area after an abortion is desirable.¹

Other precautionary sanitary measures to prevent the contamination of feed and water by infective material is indicated. Injection of 300,000 units of penicillin and 1 gm. of dihydrostreptomycin intramuscularly for 2 daily doses or the daily feeding of 80 mg of chlortetracycline in grain until lambing if done in the early stages of an outbreak of vibriosis will reduce the incidence of abortion about 10 percent.^{6,12} Feeding of antibiotics was not highly effective unless started prior to an outbreak.¹⁰ Although additional injections of antibiotics might be indicated, it is probably not practical.

C. fetus intestinalis serotypes I and V (C) are the most common causes of ovine vibriosis. Cross immunity between these two serotypes does not occur.¹⁰ Two injections 15 to 30 days apart of a commercial bivalent, alum-adsorbed, killed bacterin before breeding or during the first half of pregnancy provided an excellent immunity if done at yearly intervals.¹⁴ Susceptible replacement ewes should also be vaccinated when entering the flock.¹⁵ Recent work has shown that an oil adjuvanted bacterin produced an immunity that lasted for 3 years.¹⁰ Vaccination has been recommended in outbreaks of ovine vibriosis. Since 10 to 14 days are required for immunity to develop, early and prompt diagnosis and administration of the vaccine is indicated for even fair results to be obtained.⁵ The combination of bacterin and antibiotic injections may be used. This disease is rare in does.¹¹

Listeriosis caused by *Listeria monocytogenes* is a worldwide disease affecting a variety of species including man with the septicemic, the encephalitic or the reproductive or abortifacient forms of the disease.^{8,12} It is uncommon to see more than one of these forms in a group of animals at one time. The septicemic form occurs most commonly in newborn or very young ruminants even though the dam may appear normal. The encephalitic form is most common in sheep and cattle. The reproductive form occurs naturally as an epizootic outbreak in occasional flocks of pregnant ewes and does. *Listeria* is a cause of habitual abortion in women. Humans can contract this disease from animals; thus it is of public health significance.

Listeriosis in sheep due to *Listeria monocytogenes* is a much less common cause of abortion than **C. fetus**. In flocks experiencing listerial abortion outbreaks, sheep were recently purchased from flocks where listeriosis had previously been demonstrated.¹² Apparently the disease can be carried latently by clinically normal sheep and excreted during periods of stress. The disease may spread from cattle to sheep on the same farm. Nearly all cases

of ovine and caprine abortions due to listeria will follow by 1 to 3 weeks some radical change in management that caused a lowering of the animal's resistance such as withholding food and water, feeding poor silage in which *Listeria* organisms might have multiplied,^{2,3,10} or heavy feeding to condition ewes for show. The incidence of abortions due to listeriosis varied from 1 to 25 percent which is lower than in vibronic abortion. Abortions usually occur late in gestation and may take place over a period of several months. A few fetuses may be aborted at an earlier stage of gestation. Sheep showing the encephalitic form of listeriosis may rarely also be observed in the flock. The mode of spread is not known but experimental abortions were produced by oral administration of the organisms.^{2,3,10} Intravenous injections of *L. monocytogenes* regularly produced abortions in 7 to 12 days.⁹ The fetuses had usually been dead for several days before expulsion. Thus autolysis and decomposition of the fetus and membranes were often present. Retained placentas were common and associated with metritis.^{2,5} Placental lesions and fetal lesions were not distinctive.⁶ However, listeric abortions resulted mainly from a placentitis.⁵

Postmortem examination of the fetuses revealed evenly distributed small foci of necrosis in the liver and edema and congestion of the meninges. Some lambs near term may be born alive but die within several days with keratitis and liver necrosis. *Listeria* may be recovered by culture from the placenta, brain, abomasum, meconium and other fetal organs.² The genital tract of infected ewes sheds organisms in the uterine discharge for several days after the abortion. Isolation of the organism may be difficult and require repeated cultures of large amounts of refrigerated material (See listerial abortion in cattle). The uterus is usually free of organisms 2 to 3 weeks after abortion. It is assumed that after one abortion the ewe is immune inasmuch as second abortions or consecutive yearly flock outbreaks due to *L. monocytogenes* have not been reported. The fluorescent antibody technique is a helpful aid in diagnosis. Serological tests have been tried with only limited success.^{13,7}

Treatment would logically call for division of the flock into small units, isolation of aborting or convalescent ewes, and proper sanitation and disinfection of premises. Silage feeding should be discontinued. Environmental stresses should be eliminated. Purchase of ewes should be confined to flocks free of listeriosis. Preliminary studies on various types of vaccines have been performed⁸ but none have been developed commercially. The value of antibiotics in an epizootic outbreak has not been determined but could be of value.¹¹

Brucellosis due to *Brucella melitensis*, *Brucella*

abortus or ***Brucella ovis*** is presently rare in the United States as a cause for abortion in sheep and goats. There are no published reports of ***Br. ovis*** abortions in goats.¹¹ In certain areas in and around the Mediterranean region of Europe and Africa, in Russia and possibly Central and South America brucellosis due to ***Br. melitensis*** is an enzootic and a common cause for abortion, especially in goats.^{4,5,8,9} Ovine abortion due to ***Brucella melitensis*** has not been reported in recent years in the United States. An outbreak of ovine abortion due to ***Br. abortus*** in Minnesota apparently contracted from infected cattle was reported. Infections and abortions persisted in this flock for more than 40 months.^{10,11} This was apparently a rare occurrence as sheep are quite resistant to ***Br. abortus***.^{10,13} The third form of brucellosis, due to ***Brucella ovis*** (ram epididymitis organism) (REO) has been reported in Australia and New Zealand, Central Europe, S. Africa and the United States where its principal pathologic effect has been in rams causing infertility. In California the incidence of infected rams was 20 to 25 percent.¹⁰ Abortion in ewes due to ***Br. ovis*** is of little importance and is seldom reported except in New Zealand where an incidence of 7 to 10 percent was noted in some flocks.^{5,14}

In brucellosis in goats due to ***Br. melitensis*** the incidence of abortion may reach 40 to 60 percent. Abortions occur the last third of gestation and weak moribund kids or lambs may be born at term or prematurely. Like brucellosis in cattle the disease is contracted by pregnant sheep or goats by ingestion of food and water contaminated with organisms from aborted fetuses and their membranes or genital discharges. After intravenous inoculation of ***Br. melitensis*** abortions may occur 10 to 21 days later. A placentitis involving the placentomes with necrosis of the chorioallantois occurs in advanced cases. The fetus is also infected with inflammatory and necrotic foci in the liver and other organs.^{2,15} Diagnosis of the disease is based on cultures of aborted fetuses or stillbirths and serologic tests, the most useful of which is the agglutination test. Following abortions or infection some ewes or does may carry the infection for months, years or a lifetime in various organs, especially the udder and uterus.^{11,12}

Control of the infection is patterned after the control of brucellosis in cattle and swine. Sanitation, blood testing by the tube agglutination, CF and card tests,^{5,11} isolation or quarantine and slaughter are necessary. Agglutination titers of 1:25 are positive. Milk tests such as the whey agglutination test have not proven as satisfactory for the diagnosis of brucellosis in goats as in cattle. As in swine serologic tests may be unreliable in individual goats but on a herd basis even one positive sample indicates a herd infection.^{5,11} Vaccines have been tried in

the control of **Br. melitensis**. **Br. abortus** strain 19 vaccine is of questionable value. Two other vaccines have been more effective; one is an oil and water adjuvanted killed vaccine of **Br. melitensis** that produces a severe local reaction and persistent titers and the other is an avirulent living **Br. melitensis** vaccine (Rev 1) recommended for use in sheep and goats at 3 to 8 months of age.^{5,11,6,7} Vaccination is not practiced in the United States since the incidence of **Br. abortus** and **melitensis** is extremely low.

In brucellosis due to **Br. abortus** in sheep and goats the signs, lesions and diagnosis are similar to those with **Br. melitensis**. The disease may rarely spread from infected cattle to pregnant sheep or goats and cause abortions the last third of gestation. The occurrence of this form is rare. It should be controlled promptly in a manner similar to brucellosis in cattle, except for vaccination. Isolation, quarantine and slaughter procedures are recommended.

Brucellosis due to **Br. ovis** in ewes is lower in pathogenicity than **Br. melitensis** or **Br. abortus**. Ewes abort only if infected during pregnancy especially the first or second month of pregnancy since it requires 1-1/3 to 3 months or more to produce severe enough lesions of edema and coalescing areas of necrosis in the placenta and intercotyledonary placenta to interfere with fetal nutrition and result in the death of the fetus and abortion or the birth of weak diseased lambs.^{9,13,16} Apparently ewes are difficult to infect with **Br. ovis** unless they are pregnant. Breeding ewes with infected rams seldom causes the disease in ewes. Ewe to ewe passage of infection is rare. Ram to ram infection occurs most commonly by a susceptible ram breeding a ewe recently bred by an infected ram and contaminating his prepuce with the **Br. ovis** organism. Oral infection from pasture, feed, or water contaminated with material from aborted fetuses, membranes or genital discharges can occur but is of little importance. The disease can be produced in pregnant ewes by the inoculation of the conjunctival, nasal or rectal mucous membranes or by parenteral injection.^{8,9} Since intravaginal deposition of infected semen, as in cattle, seldom produces the disease it has been suggested that intrarectal ejaculation of infected semen or sodomy may be a means of spread of this form of ovine brucellosis from ram to ewe or ram to ram.⁸

The incidence of abortion due to **Br. ovis** is low.^{2,4,8,9,13,14} New Zealand workers⁵ indicated a high incidence of 7 to 10 percent in 40 naturally-infected flocks. Abortions usually occur the last trimester of pregnancy. Chronic placental lesions of necrotic plaque-like thickening and edema of the intercotyledonary areas of the placenta is characteristic of **Br. ovis** infection.^{9,16} Smears

of these areas stained with Stamp's modification of Ziehl-Neelsen stain often reveal the organism.¹⁴ The organism may be cultured from the fetus, the membranes and the uterine discharges for a week after abortion or premature lambing. The complement fixation (CF) test is a highly satisfactory serological test for determining the presence of **Br. ovis** in a flock or individual.¹⁰ The fluorescent antibody technique may also be used to detect **Br. ovis** in contaminated material in the placenta or semen. Infection in ewes persists from one breeding season to the next in only a few ewes.⁸ However, rams may be chronically infected for 3 or more years. There is no evidence that lambs born from infected ewes retain infection. There is little evidence **Br. ovis** causes infertility in ewes. Infertility in rams is the major cause for losses from this disease. Since the effects of **Br. ovis** infection in the ewe are limited and the infection is transient, most control efforts are aimed at the rams. Palpation of the testes for the presence of lesions, especially in the region of the cauda epididymis will clinically diagnose most individual infected rams. The use of the CF test on all rams will detect clinically and nonclinically infected males. Repeated clinical and serological testing and the elimination of infected rams will rapidly reduce the infection rate and eliminate the infection in a flock. Replacement rams should be raised or purchased from disease-free flocks and tested prior to and after a 2 to 3 months isolation period. An effective vaccination procedure for young rams combining the simultaneous use of **Brucella abortus** Strain 19 and a formalin-killed oil adjuvant **Br. ovis** vaccine has been used widely in Australia and New Zealand.¹ A vaccination procedure consisting of injecting an alum-precipitated **Br. ovis** bacterin subcutaneously in 2 doses 30 to 60 days apart and followed by a single injection each year has been used in California.³ Because of the nature of the disease it is probably unnecessary to vaccinate ewes.⁹ Antibiotic therapy, especially in chronic cases, is of doubtful value.⁶

Salmonella (paratyphoid) abortion in sheep is principally caused by **Salmonella abortus ovis**, **S. typhimurium** and **S. dublin** and others.^{8,11,1,4,6} **Salmonella** spp. infections have caused outbreaks of abortions in goat herds.¹¹ These are uncommon and detailed clinical reports are not available. This type of infection has been described in England and Europe, especially Germany, but not in the U.S. The incidence of abortion varied from 8 to 60 percent.^{10,6} The infection is contracted orally by contamination of feed and water with aborted material or organisms from other common animal sources. An outside carrier animal added to the flock may introduce the disease. Stress situations often precede an outbreak.^{8,2} In a few cases diarrhea or other evidence of

infection of the ewe such as high fever and depression has been noted but in most cases no signs other than abortions in the last third of gestation or stillbirths at term are observed. Occasionally deaths may occur in newborn lambs and 5 to 7 percent of affected ewes.^{8,5}

The organisms are readily isolated from the internal organs of the fetus, the placenta, and the uterine discharges for a few days after abortion. An agglutination test can demonstrate antibodies in the blood serum of infected ewes or rams. Aborting ewes should be isolated and aborted fetuses and placentas should be destroyed. Contamination of feed and water must be prevented. Rodent control is essential. Although autogenous bacterins have been used very early in an outbreak, or as a preventative in reducing the incidence of abortion, their use has not been scientifically evaluated. Individual ewes may benefit from antibiotics, 10 mg/kg tetracycline daily, and supportive fluid therapy.^{8,10,2}

Leptospirosis due to *L. pomona* and *L. icterohemorrhagiae* and others is seen much less frequently in sheep and goats than in cattle and swine as they appear more resistant to infection. The disease is more common in young lambs than in older ewes.^{5,8,10,11,4}

Leptospirosis as a clinical disease of goats has been reported infrequently. Outbreaks of leptospirosis in older pregnant ewes that caused abortion in up to 20 percent of the flock have been described.² Other symptoms included icterus, hemoglobinuria and death of the ewes. An outbreak of abortion in goats due to *L. grippotyphosa* was reported in Israel.¹ Based on experimental infections, sheep may have a leptospiruria for 40 to 100 days.⁵ No fetal infections were observed before 21 days after intraarterial inoculation of *L. pomona*. *Leptospira* may be cultured from fresh fetal or placental material, and seen by histologic or fluorescent antibody (FA) techniques.⁸ In autolyzed fetal or placental tissues cultural methods may be unsuccessful. As in cattle and swine, serologic tests are of limited value in the diagnosis of the disease. Treatment of the disease with an inactivated vaccine, usually multivalent, and antibiotics should be conducted along lines similar to those employed in cattle.^{11,3}

Miscellaneous Bacteria Causing Ovine and Caprine Abortion

Pasteurella tularensis and *P. pseudotuberculosis* are sporadic causes of abortion in ewes the latter part of the gestation period.^{5,10,13,4} The latter organism was reported¹³ to produce white necrotic foci in the liver of fetuses. Tularemia due to *P. tularensis* is common in western

United States where it causes enzootic outbreaks of disease in wild rodents and can be transmitted to sheep by the common wood tick, *Dermacentor andersoni* and other ticks. Man is also susceptible to infection. The disease has been described in Europe and Japan. Affected sheep show depression, anorexia, elevated temperature, increased pulse and respiratory rates, coughing, premature births, stillbirths and abortions. One attack confers a long-lasting immunity with a persisting antibody titer. The agglutination test on the serum is useful for diagnostic purposes but may cross react with *Brucella* organisms. Injections of streptomycin or oxytetracycline produced a prompt clinical response and reduced losses. Controlling tick infestation of sheep by dipping or by keeping sheep from infected ranges is indicated.⁴

Cornynebacterium pyogenes, *C. pseudotuberculosis* and even *C. renale* and *C. equi* have been recovered from aborted ovine fetuses. *C. pyogenes* is the most common strain.^{1,3} This organism may also cause deaths in newborn lambs.

Other miscellaneous bacteria causing abortion in ewes include: *E. coli* and other coliform organisms, streptococci and staphylococci.^{9,13} Blackleg of the fetus due to *Clostridium fesi* infection following shearing wounds resulted in death of the fetus and distension of its tissues and the uterus and abortion.^{1,10,2} *Bacteroides fragilis* was described as a cause of abortion in ewes,^{13,5} as was an organism resembling *Bacillus cereus*.⁶ Johne's disease or *Mycobacterium paratuberculosis* in goats is a chronic condition resulting in debility, failure of conception, abortions and births of weak kids. There is no effective treatment.¹¹

Viral and Rickettsial Causes of Abortion in Ewes and Does

Enzootic abortion of ewes (EAE) chlamydiosis or ovine virus abortion is caused by a viral agent of the psittacosis-lymphogranuloma (PL) group (*Chlamydia psittaci*). There is good evidence that the agent causing epizootic bovine abortion, EBA, and EAE are the same.^{5,6,8,11,2,6,12} Enzootic abortion of ewes and goats has been described in Scotland and England, Europe and in Western United States. In these latter states EAE or chlamydiosis is a common occurrence in sheep and goat flocks.^{5,8,10,16} Chlamydial viruses have also been described as causing pneumonia and polyarthritis in sheep and goats.^{5,8,11,10,13} Latent persistent chlamydial infections of the ovine and caprine intestinal tract are common.^{5,10,11} Further study is necessary to determine the relationship of these chlamydial agents to each other and

to abortion in ewes and goats. Evidence indicated that all these agents caused abortion in experimental ewes. Ewes with latent intestinal *Chlamydia* spp infection showed no increased resistance to superinfection and often aborted when challenged.¹¹ The causative agent is an obligate intracellular parasite that forms elementary bodies.⁵ Chlamydiosis is characterized by abortions from 100 days of gestation to term but most commonly the last month of pregnancy. Occasionally macerated or mummified fetuses are observed. The birth of dead fetuses or weak, moribund lambs and kids is not uncommon. One fetus of twin lambs may be affected. The incidence of abortions in a flock where the disease is enzootic, is usually 1 to 5 percent but in susceptible flocks the incidence may reach 30 percent. Most abortions occur in two- and three-year-old ewes in the chronically-infected flocks. Retained placenta may occur and be associated with a brownish genital discharge. Occasionally ewes and does may die from metritis and other complications after abortion. Most ewes bred satisfactorily following abortion as an immunity was developed.^{8,10,13,12} The disease may be difficult to differentiate from campylobacteriosis (vibriosis). In fact, occasionally both infections may occur concurrently in a flock.³ This chlamydial agent causing abortion in sheep and cattle also causes abortion in goats.^{5,11,1,9}

Enzootic abortion of ewes (EAE) or chlamydiosis due to *Chlamydia psittaci* can be produced by oral feeding of the agent to susceptible ewes and does. The incubation period is about 50 to 90 days.⁸ Infection is probably most commonly due to ingestion of feed or water contaminated with infective material from aborting ewes and does. Although rams may become infected as determined by the CF test on serum there is no indication they are implicated in the spread of this disease. Ewe lambs or does born in infected flocks may later show evidence of disease during pregnancy. Susceptible ewes or does contracting the infection at one lambing period may abort during their next pregnancy. The disease is not tick-born.

The fetal membranes are grossly similar to the fetal membranes present in bovine abortions due to *Br. abortus*. The chorionic membranes and cotyledons are thickened, edematous, necrotic and leathery and often retained. The aborted fetuses usually show signs of autolytic changes that are not distinctive. Staining of placental smears and examination with the microscope usually demonstrate the elementary coccoid viral bodies in the epithelial cells. The fluorescent antibody test is reliable but staining is just as reliable and easier.^{5,8,11} The virus from the fetal membranes may be cultured in chick embryos and mice. Virus is seldom found in the fetus. Vaginal swabs taken soon after abortion are the best sam-

ples for the isolation of chlamydia.⁵ Most ewes and does show a complement fixation titer in the serum from two weeks to 4 months after abortion. The CF test is not highly accurate because some infected individual ewes and goats may show no titers. Other nonaborting ewes may carry a titer due to natural infection or due to the latent agent commonly found in the digestive tract.^{5,8,10,11,13,2}

Workers in Scotland and the U.S. produced a formalized killed adjuvanted vaccine that proved effective as an immunizing agent for EAE. The immunity lasted for 2 to 3 years after a single injection. This vaccine given prior to the first breeding and to susceptible additions to the flock has also proven of value in Idaho and California and federal licensing is expected.^{8,14} Experimentally chlortetracycline fed at a rate of 100 to 250 mg per head per day^{5,11} to exposed or inoculated ewes or does may prevent abortions. Injection of tylosin and tetracyclines might also prove helpful. However treatment is not completely effective. Once the infection was established in the placenta abortions could still occur.

Miscellaneous viral and rickettsial diseases of sheep causing abortion are as follows:

Tickborne fever is due to *Rickettsia phagocytophilia*. It has been reported in the United Kingdom and Scandinavia in goats, sheep and cattle and is transmitted by ticks, *Ixodes ricinus*.^{1,8,12,13} After inoculation of infected blood, fever developed in 4 to 8 days and lasted for 10 days. During this period abortions occurred. When susceptible pregnant animals are moved from tick-free to tick-infested pastures late in gestation abortions may occur in up to 50 percent of the ewes and does and deaths in aborting animals may occasionally reach 20 percent. The causative agent may be found by microscopic examination of the blood in aborting ewes. The inclusion bodies of this organism are seen in the cytoplasm of neutrophils and large monocytes. A complement fixation test has proven to be an accurate diagnostic serologic procedure.¹ Ewes and does reared on tick-infested pastures are apparently immune.⁸

Wesselsbron virus is a cause of abortion in sheep and death in newborn lambs in South Africa.^{12,13,11} A few affected ewes may die. The virus is transmitted by mosquitoes. Antibodies to the virus are present in the serum of sheep after recovery. The virus apparently affects and kills the fetus *in utero* and may be cultured from the aborted fetus. Presently a modified live virus (MLV) vaccine is given annually to all ewes before breeding.⁸

Rift Valley Fever virus or enzootic hepatitis, was a major cause of abortion in Kenya and South Africa in sheep, goats and cattle^{1,8} until a vaccine was developed and used extensively. Signs of abortion and deaths in

newborn lambs resembled disease due to Wesselsbron virus. Occasional deaths occurred in older ewes and goats. This disease is also transmitted by insects. As with Wesselsbron virus the disease may affect man causing an influenza-like syndrome. Viral isolation and serologic tests can confirm a clinical diagnosis of the disease.^{1,8}

Nairobi sheep disease virus in Africa^{12,13} or rinderpest and foot and mouth disease^{2,11} although not present in the United States cause abortions in sheep in countries where these diseases are prevalent.

Bluetongue virus vaccine, a live viral preparation, if used on pregnant ewes, or a natural infection occurs in ewes and goats between the fourth and eighth week of gestation cause up to 20 percent fetal losses characterized by stillbirths, mummified fetuses or spastic neonates with a variety of developmental central nervous system defects.^{1,8,3,7} Goats, like cattle, are occasionally affected by bluetongue virus but are more naturally resistant than sheep.⁸ Bluetongue has been reported in most southern and western states⁶ and in many other countries. It is spread between animals during warm weather by insect vectors, especially the *Culicoides* fly.^{8,10} The viremic stage may last for four months in sheep even though neutralizing antibodies are in the blood. Cattle may also harbor the virus and be a factor in the spread of the disease to sheep.⁴ Bluetongue (MLV or inactivated) vaccines are now available but since there are a number of serotypes of bluetongue virus a heterologous vaccine would be more effective than the homologous vaccine presently used.^{1,8,6}

Coxiella or Rickettsia burnetii or Q fever virus has been recovered from the placenta of cattle, ewes and goats in North America, Australia and Europe. In several flocks abortions occurred and antibodies were found in the blood of ewes and *Coxiella* organisms were recovered from the placenta.^{1,8,11,1,12} This rickettsial agent was not highly pathogenic for sheep and goats and seldom was a cause for abortion.^{12,9} Positive serologic tests and cultures are common where Q fever virus is endemic, even in ewes, goats and cattle having a normal birth and offspring. However when outbreaks of abortions occur in sheep and goats and this rickettsial agent is found culturally and serologically and no other cause for the abortions can be ascertained, veterinarians will believe this is the probable cause of the abortions. Possibly when infections are severe abortions can result.^{1,12}

Akabane virus causing fetal arthrogryposis and hydranephaly described previously in cattle (Chapter III) also affects ovine and caprine fetuses. It has been reported in Japan, Australia and Israel. The virus is transmitted by *Culicoides* insect vectors. It may also cause abortion, premature birth or stillbirths.¹

Border disease, "Hairy Shaker" Disease, Hypomyelinogenesis congenita in sheep and goats is caused by a virus closely related to or identical with BVD-MD and hog cholera viruses. It has been reported in the United Kingdom, New Zealand, Australia and Europe^{1,8,11} and possibly in the United States.⁵ Affected pregnant ewes and does may abort or produce defective newborn. Hair coat defects common in sheep are not observed in newborn kids with signs of CNS disease.¹¹ Pregnant sheep and goats should be separated from cattle⁸ as cattle shedding virulent BVD-MD virus in large amounts may infect pregnant ewes and does. Two studies^{5a,b} reported on "Border Disease" in California and northwest United States based on serologic tests for BVD-MD virus in ewes and lambs and the recovery of the virus from the nasal and vaginal cavities of ewes and experimental reproduction of the disease. However Ward in 1971¹³ and English workers in 1980¹⁰ showed that the inoculation of BVD-MD virus into pregnant ewes from 22 to 105 days and 25 to 40 days of gestation, respectively, resulted in 40 to 70 percent "empty" ewes at the time of lambing, up to 40 percent abortions, a few mummified fetuses and a number of stillbirths and neonates exhibiting growth retardation with hypomyelinogenesis, cerebellar hypoplasia and hydrocephalus. Border disease virus may be recovered from infected newborn fetuses and the dams' genital tract in the early postpartum period.^{1b} Border disease was produced in lambs following the artificial insemination of their dams with semen from persistently infected rams. Certain infected rams and ewes producing infected lambs may not have circulating antibodies to BD virus. There were marked differences between strains of BD and BVD viruses in their antigenicity.^{1b} Further studies are indicated on the very close relationship of BD and BVD viruses and the similar disease conditions produced in sheep and cattle.^{5b}

Inoculation of the **ovine progressive pneumonia virus (OPPV)** into the fetal amniotic sac at 45 to 85 days of gestation caused resorption, maceration or abortion of the fetus. Inoculation after 100 days of gestation had no clinical effect but the healthy lambs could be carriers of OPPV.^{1a}

Mycoplasmal and Fungal Abortions

Mycoplasma agalactiae causing mastitis (contagious agalactia), arthritis and keratoconjunctivitis in sheep and goats may occasionally be associated with vulvovaginitis and abortion.¹¹ **Mycoplasma mycoides var capri** and other mycoplasma have been isolated from goats and sheep in the United States.³ Although the former mycoplasma causes contagious caprine pleuropneumonia, myco-

plasma have been recovered from esophageal-pharyngeal fluids from dead fetuses from does. *Ureaplasma* spp has been associated with infertility and abortion in sheep in Texas.²

Aspergillus fumigatus, a fungus, has been described only occasionally as a cause for abortion in ewes and goats.¹

Parasitic Protozoal Infections Causing Abortions

Toxoplasma gondii, a protozoa, may infect all domestic animals but only in sheep and goats is it a common and serious cause of abortion. Toxoplasmosis occurs widespread throughout the world and in the United States and Canada. The infective form of *Toxoplasma gondii* is found as a coccidial oocyst in cat feces resembling that of the coccidia.^{1,5,8,11,12,4,5,6a,b,7,8,11} Experimental infections have been produced by inoculating infective material.¹¹ Control of the cat population on the farm may help prevent toxoplasmosis in sheep and goat flocks. The presence of cats on small farms make this disease more frequent in small flocks than in large range flocks.⁸ Natural outbreaks in goat flocks are uncommon.^{1,8,4} Heavy rainfall favors the spread of the disease. Stress may cause latent toxoplasmosis to become active. Occasional cases of congenital or intrauterine infections of the newborn have been described in most species of domestic animals. If antibodies are present in the dam no transmission of the infection to the fetus occurs.^{1,13} The importance of toxoplasmosis as a cause of early fetal resorption, maceration, mummification, abortion and neonatal deaths varies in different countries. In New Zealand 50 to 60 percent of abortions and neonatal deaths were due to this disease; in Yorkshire, England about 15 percent and in the U.S. only sporadic outbreaks have been reported. The incidence of abortion in a flock may vary from 3 to 30 percent. Ewes and does infected prior to breeding do not abort. Those infected from 30 to 90 days postbreeding usually have fetal resorption or mummification. Most observed abortions occur the last trimester of gestation, 2 to 3 weeks before term after infection during the latter half of gestation. The incubation period from the feeding of sporulated oocysts to abortion in sheep was 28 to 34 days.¹ One normal twin and one dead twin may be born at term. Ewes aborting due to toxoplasmosis often have a retained placenta. Affected ewes bred back and produced normal lambs the next season. Chronically infected ewes do not have abortions or diseased newborn as do acutely infected pregnant ewes.^{1,11,13} Stillbirths, living, defective, ataxic, weak and dull lambs and normal lambs, as well as aborted fetuses may carry *Toxoplasma gondii*. This organism produces a characteristic

placentitis with multiple small, 1 to 3 mm., soft white nodules amongst the fetal villi in the dark red caruncle or cotyledon. (See Figure 70.) The organism is readily identified either free or in cysts. The intercotyledonary placenta is often edematous. Fetuses or stillbirths show no gross lesions but organisms may be recovered from the liver, lungs, or brain.

The Sabin-Feldman dye test or the indirect hemagglutination method on ewe's or doe's blood detects antibody usually present at the time of abortion and the titer continues to rise for several weeks. The CF test and skin sensitivity test have also been used but the latter is of less value in the diagnosis of toxoplasmosis.^{10,12,13} The indirect fluorescent antibody test on imprints of fresh cut tissues has proven valuable.¹ Occasionally campylobacteriosis (vibriosis) or other causes of abortion are found associated with toxoplasmosis. There is no satisfactory treatment for this disease. Sulfonamides and pyrimethamine have been tried.¹ It should be noted that animal to man transmission of toxoplasmosis can occur and acute infections in pregnant women should be prevented as the organism has a great affinity for the human fetus.^{10,14} Vaccination with a nonpathogenic coccidium may prove of value to protect susceptible ewes and does against toxoplasmosis.⁵ A recent review of toxoplasmosis in humans has been published.¹⁵

Sarcosporidiosis (Sarcocystosis) caused by *Sarcocystis* spp is similar to the life cycle of toxoplasma except most carnivores can excrete the various protozoal oocysts. Sarcosporidial cysts can be found in striated muscle in sheep and goats. *S. ovis* is a parasite in the dog's intestinal tract which when ingested in large numbers by susceptible sheep or goats results in anemia, anorexia, ataxia and abortions during the period when the vascular endothelium is parasitized by schizonts.^{5,2,3,9,11,12,13b} Large experimental infections induced in pregnant ewes caused premature births and deaths of the ewes. Their lambs did not have congenital sarcocystosis.^{13b} (See swine.) Sarcosporidiosis is distributed world-wide. The *S. tenella* infection in cats can be passed to sheep but apparently it is nonpathogenic.² *Globidiosis* caused by the coccidia *Eimeria* (*Globidium*) *gilruthi* and *Besnoidia* may be transmitted in a manner similar to the above parasitic protozoa. There is no good evidence however, that they cause prenatal or neonatal deaths in fetuses or newborn domestic animals.

Noninfectious Causes for Ovine or Caprine Abortion

Drugs, Chemical or Plant Poisonings:

Although the following causes of abortion in ewes and does have been reported, some of these causes are prob-

ably questionable and require further documentation and experimentation to ascertain their significance. Some abortions may be due to a combination of causes of which only one was recorded.

Phenothiazine administered to ewes in late pregnancy may cause abortions within 4 days postworming.²⁶ The author has observed dead, emphysematous, macerating fetuses causing severe dystocia, metritis and death following this practice. This may be due to the stress of handling rather than the drug. Tetramisole and phenothiazine, but not thiabendazole has been reported to cause abortion in goats.¹¹

Carbon tetrachloride, a chemical seldom used currently in parasite control, may cause abortion if administered to pregnant ewes, and goats.^{11,12,13}

Chronic lead poisoning may cause abortion in pregnant ewes.³

Nitrate feeding in doses in excess to that occurring in forage and causing a severe methemoglobinemia may occasionally cause abortion in ewes.¹⁰

Locoweeds (*Astragalus lentiginos*, *A. pubentisimus* and *Oxytropis sericea*) caused abortions in all stages of gestation, and deformed and small weak newborn if fed to pregnant ewes and goats as hay or if grazed upon in pasture.^{11,14,16,17}

Lupine ingestion resulting in chronic lupinosis has been associated with abortions and fetal deaths in ewes as has consumption of **broomweed (*Gutierrezia microcephala*)** by goats.^{11,20} ***Indigofera spicata***, (creeping indigo) caused abortions in sheep.¹⁶

Veratrum californicum (False Hellebore) if consumed by pregnant ewes will cause early embryonic deaths, aborted fetuses and deformed lambs.^{16,23}

Ergot fed to ewes at levels of 0.1 to 0.7 percent of the ration reduced the percent of ewes that lambed by 20 percent.⁷

Onion grass (*Romulea bulbocodium*) when ingested by pregnant ewes may cause abortion.^{12,13}

Hormonal Causes for Abortion in Sheep

Estrogens—The ingestion of excessive estrogens in subterranean clover by sheep in Australia often resulted in uterine inertia, dystocia, and the birth of stillborn lambs.⁴ Dystocia and sterility remained at a rather high level even though the sheep were removed from the clover pasture because of permanent uterine damage by the estrogens. An isoflavone derivative, genistein, was the active estrogen in the clover.⁸ It has estrogenic activity equal to one-fifth that of estrone. In certain fresh-cut subterranean clovers, such as the dwalganup variety,

concentrations of 100 mg. of genistein per 100 gms of clover was found. Small amounts of hexoestrol in the grain ration the last few weeks of pregnancy caused abortion in 11 of 14 ewes.^{12,13}

Progesterone deficiency, or cortisol or ACTH excess has been reported as causes of abortion in goats and sheep. Many Angora goat farms in South Africa had over 30 percent abortions each year.²² The condition did not affect other herds of goats and so it was considered to be genetic in nature. Abortions occurred from 2 weeks of gestation to term with over 60 percent occurring from 100 to 120 days of gestation. Fetuses were partially autolyzed when expelled. A higher incidence was present in the older does. Does conceived promptly after aborting. Abortions were caused by regression of the corpus luteum, necessary in the goat to maintain pregnancy. There was evidence of a lack of luteotrophic hormone from the anterior pituitary gland. Stress, such as shearing, seemed to contribute to an increased incidence of abortion. As discussed in cattle abortion the pituitary-adrenal axis largely controls the onset of parturition in sheep and goats. In habitual abortions occurring in Angora goats²² hyperplasia of the adrenals was observed in aborting does and their fetuses.^{24,25} It was considered that selection for fleece quality in Angora goats raised for mohair production favored animals with adrenal hyperplasia.

If ovine fetuses were given ACTH, corticotropin, or cortisol abortion would occur within 3 to 7 days.^{18,25} If the former hormone was given the fetal adrenals would become as large as those in fetuses at term. Conversely if the fetal pituitary was destroyed or the fetal adrenals removed, prolonged gestation resulted. Injections of cortisol (hydrocortisone) or dexamethasone (Azium) in relatively small doses into ewes in late gestation caused the premature induction of parturition.^{2,25} Larger doses of cortisol administered to ewes during early gestation had no effect but after 85 days of gestation they proved lethal to the fetus.

Prostaglandin F_{2a} at a dose of 15 mg caused abortions in goats at 30 and 65 days of gestation and premature births at 140 or 142 days of gestation.⁵ When the prostaglandin analogue, cloprostenol (Estrumate, ICI) was injected at a dose level of 0.5 or 0.50 ml per goat IM or SC between 72 and 132 days of pregnancy abortions occurred 30 to 50 hours later.⁹

High ambient temperatures and high humidity causing adrenal hyperactivity and hydrocortisone injections shortly after breeding caused increased embryonic deaths.¹⁵ Stress factors and their effect on the pregnant ewe especially in late pregnancy may play a definite role in inducing abortions as in toxoplasmosis, phenothiazine poisoning, and reduction in energy intake or ketosis.

Nutritional Causes of Ovine Abortion

Lack of TDN or energy has been widely reported in England and elsewhere as a cause of abortion. A high incidence of up to 80 percent abortions and/or maternal deaths have been associated with pregnancy toxemia or ketosis in ewes, especially those having 2 or more fetuses, and on a restricted energy intake and lack of exercise in late pregnancy. Ewes fed only roots during pregnancy had a high abortion rate due to the reduced energy intake.^{12,13} Severe parasitism, malnutrition and exposure or a combination of these may induce abortion prior to death of the doe.^{11,20}

Copper deficiency was reported to be associated with stillbirths in ewes.^{12,13} A manganese deficiency has been associated with abortion in does at 80 to 100 days of gestation.¹¹ **Cobalt deficiency** has been reported associated with a high death rate in neonatal lambs.¹⁹

Vitamin A deficiency of long standing caused a high incidence of stillbirths or poorly viable newborn lambs and kids.^{11,12,13}

Iodine deficiency has also resulted in congenital goiter and abortion or stillbirths in sheep and goats.^{11,12,13}

Selenium deficiency in ewes in New Zealand has been reported to cause abortion or neonatal deaths of lambs with congenital white muscle disease affecting the heart. It has been associated with farms having a large number of barren ewes and reduced lambing percentage.^{12,13} Experimental diets high in sulfur caused fetal deaths and abortion with evidence of white muscle disease despite the administration of selenium and vitamin E to the pregnant ewes.⁶ The administration of sulfur probably interfered with the absorption or utilization of selenium. The administration of 5 mg of sodium selenate or selenite monthly for 3 doses before breeding and again one month before lambing was recommended.¹³ A muscular dystrophy in sheep with early neonatal deaths not associated with selenium deficiency has been described.²¹

Chromosomal, physical and miscellaneous causes

Lethal genetic defects causing fetal deaths, abortions and stillbirths have been described previously. (See Chapter III.) Severe physical stress, fright and exhaustion, such as caused by dogs chasing a flock of ewes in advanced pregnancy, has occasionally been reported as a cause of abortions or premature births. Young ewes have a higher incidence of stillbirths than older ewes.^{12,13} Ewes carrying twins or greater multiples especially if on a low protein ration were more apt to abort or have stillbirths than those carrying single fetuses.

ABORTION IN THE BITCH

Abortions in bitches are much less common than in the larger domestic animals. Most canine abortions are sporadic except for enzootic or epizootic outbreaks in kennels due to **Br. canis**. Limited experimental work has been done on other causes of abortions in small animals.

Infectious Causes of Canine Abortions

Bacterial Causes

Brucella canis is the most common cause of third trimester abortion and infertility in bitches and epididymitis, testicular atrophy and infertility in males,^{8,9c,24} It can be a serious cause for losses in breeding kennels. This highly contagious disease is widespread in the United States and other countries. The incidence of canine brucellosis, based on serologic tests, varies from 1 to 10 percent of dogs in the United States.²⁴ Since serologic tests are inaccurate the true incidence may be much lower. For example in the north midwest states 6.7 percent of 2,572 dogs were positive on the slide test, 1.5 percent^{25,72} on the tube agglutination test and only 0.2 percent positive on blood culture.³ In northeastern U.S. about 0.5 to 1.5 percent of dogs are possibly infected.^{8,24} Although initially observed in Beagles in the late 1960's, it now occurs in all breeds and in both kenneled and free-roaming dogs. The incidence is higher in states and countries where the climate is mild and free-roaming packs of dogs are common.^{7,24} The disease in dogs resembles brucellosis in swine due to **Br. suis** but is relatively mild. **Br. canis** is an intracellular pathogen morphologically similar to other **Brucella**. It cross reacts with **Br. ovis** and rough variants of other **Brucella** as well as **Actinobacillus equuli** and **Pseudomonas aeruginosa**.⁸ Canine brucellosis is characterized by abortion occurring between gestation days 30 and 57 with about 85 percent of the observed abortions occurring between days 45 and 55. Some infected bitches may carry their fetuses to near term and deliver both live and dead pups. The living pups may survive and appear healthy but be bacteremic for at least two months. Up to 30 percent of infected bitches may abort two or three litters in succession. Apparent failure of conception was also commonly ob-

Table 13a. Summary of the Causes of Canine Abortion

Infectious causes:

Bacterial causes—**Br. canis**.Miscellaneous bacterial causes—**Br. abortus** and **suis**, staphylococci, streptococci, pseudomonas, coliform and salmonella organisms.

Viral Causes—Distemper virus, adenovirus (infectious hepatitis) and canine herpesvirus (CHV).

Other infections—**Toxoplasma gondii**

Noninfectious Causes:

Drugs, chemical, poisons—O-diazoacetyl-L-serine, N-desacetyl thiocolchicine, malucidin and others.

Hormonal—progesterone deficiency, prostaglandins.

Physical—severe trauma (?)

Nutritional—manganese deficiency (?)

Miscellaneous—genetic defects, parturient conditions and stillbirths.

served and this was due to early unrecognized embryonic deaths between gestation days 10 to 25.^{8,22,24} Early abortions were largely unobserved because the affected bitches would ingest the expelled membranes and embryos. These early breeding failures may also be repeated three or four times after consecutive breeding periods.²⁴ Occasionally a bitch would abort, have a normal pregnancy and then abort again. The incidence of abortion in a susceptible kennel of dogs may reach 80 percent. Retained placentas were not observed. However, prolonged vaginal discharges were commonly seen lasting from 4 to 6 weeks after an abortion. The living pups often died and some fetuses had degrees of autolytic changes. In adult male dogs epididymitis was a consistent sign and the scrotum was hyperemic, swollen and painful resulting in scrotal dermatitis secondary to excessive licking. The epididymides were enlarged and firm and testicular degeneration and atrophy were often observed. Primary orchitis is seldom noted but the prostate is commonly affected. Semen samples are abnormal with varying degrees of oligospermia to azoospermia and containing many neutrophils and monocytes. Other lesions due to **Br. canis** include lymph node and splenic enlargement, and occasionally discospondylitis and recurrent uveitis.^{7,24} Clinical signs of pyrexia, depression, anorexia are usually absent and deaths due to **Br. canis** have not been reported.^{7,24}

Transmission of the disease can occur by inoculation of fairly large numbers of infective organisms but probably occurs naturally by oral, nasal, conjunctival or vaginal exposure to infective material.^{7,24} Aborting bitches discharge large numbers of infective organisms. The infected male can transmit brucellosis to bitches at coitus for many months by infective semen.²⁴ Organisms from the epididymis, testes and prostate are discharged intermittently in semen. The male dog might rarely spread infection in his urine.^{8,24} Spread of infection by fecal

contamination does not readily occur. When like-sexed infected and uninfected dogs were housed together transmission did not occur.²⁴

The practice of breeding popular stud dogs to large number of females from a wide geographic area or the use of artificial insemination or frozen semen could disseminate the disease widely if the stud should be infected. The aborting female can readily spread **Br. canis** throughout a kennel by contamination of food, runs, and water from aborted fetuses and membranes, genital discharges and even by her milk. Because of the prolonged bacteremia blood transfusions or even the use of contaminated syringes and needles could spread the disease.

Since dogs are the only known natural host for **Br. canis**, transmission to man probably comes from this canine source. Humans appear relatively resistant to **Br. canis** infection unless massively exposed.^{7,9c} Signs in humans vary but resemble those of undulant fever due to **Br. abortus** including intermittent fever, chills, malaise, muscle and joint pain and enlarged lymph nodes. In the U. S. seroprevalence rates in humans was 0.4 percent. Human infections have responded to treatments with tetracyclines. There have been only 18 cases of human brucellosis due to **Br. canis** reported and no known deaths.^{7,24}

Following canine exposure to **Br. canis** a bacteremia develops within 1 to 3 weeks. A generalized lymphadenitis and splenitis occurs and antibodies become detectable by the serum agglutination test. The brucella organisms persist for many months or indefinitely in many organs of the body. After one year blood cultures may become negative in some dogs but a few dogs may have a bacteremia lasting for 26 to 33 months or more. Since clinical signs other than abortion and epididymitis are not specific, a definitive diagnosis is based on serologic and bacteriologic tests, especially the latter.^{7,24}

The organisms can readily be cultured from organs of

aborted fetuses, placental tissues and vaginal discharges. Blood cultures are often positive. Current available serologic screening tests for canine brucellosis must be performed carefully and interpreted cautiously. The slide agglutination test and tube agglutination tests are widely used. The agar gel immunodiffusion test shows promise and is presently being evaluated.²⁴ The slide agglutination test is commonly performed by mixing patient serum with a rose bengal-stained heat-killed *Br. ovis* suspension. Clumping or agglutination is interpreted as suspicious of *Br. canis* infection. However 50 to 60 percent of positive test results are erroneous or false positives. While a negative test is highly reliable, false negatives are rare. Thus a positive test result **must** be confirmed by culture of the organism. The addition of mercaptoethanol to the serum will eliminate about 90 percent of the false positive results.⁶ A recommendation to destroy, castrate or spay serotest positive dogs requires the recovery of the organism by culture procedures. The false positive test results are due to cross reactions to a number of ubiquitous canine organisms. The tube agglutination test is the most widely used serologic procedure to detect *Br. canis* antibodies. The serotiters reported based on this test must be interpreted by the laboratory performing the test but usually a titer of 1:200 is considered positive. However some chronically infected male dogs may be negative by serologic testing. It is interesting to note that even though dogs have positive serologic tests indicating the presence of antibodies in the blood that these dogs may concurrently have a *Brucella* bacteremia. Antibiotic therapy for several weeks will result in a period of abacteremia and false negative serologic test results. After therapy is discontinued the bacteremia will usually recur. A single negative blood culture does not completely indicate freedom from the disease so, especially in treated male dogs, repeated blood cultures might be indicated. Since present serologic tests may not be reliable, a recommendation to destroy, castrate or spay a serotest positive dog should not be made without blood culture.^{6,7,24}

Efforts to develop an effective safe bacterin or MLV vaccine have been unsuccessful and probably is not indicated or desirable.^{6,7} Although *Br. canis* is susceptible *in vitro* to a combination of tetracyclines, dihydrostreptomycin, minocycline, rifamycin; sulfonamides or combinations of antibiotics administered to infected dogs for a number of weeks,^{15b,24,32} therapy has been unsatisfactory as only a one to three-month temporary cessation of the bacteremia resulted. A few antibiotic regimens especially if given early in the disease have apparently resulted in a cure of the disease in certain bitches.³² Such treatment was long term, very expensive and required

repeated confirmatory cultures over many months even after therapy was discontinued.^{6,7,24} Bitches naturally infected with *Br. canis* were treated sequentially for a period of 14 days each with tetracycline 20 mg/kg orally TID, dihydrostreptomycin 11 mg/kg IM, BID and trimethoprim-sulfadiazine 15 mg/kg orally BID. These bitches became abacteremic after treatment and abortions did not occur while they were bacteremic.^{15b}

Prevention and control in kennels is based on eradication by repeated monthly serologic and cultural tests of all dogs, young, old, male and female, segregation and destruction of infected animals, and concomitant sanitary measures. All dogs to be introduced into kennels should be isolated for 3 to 4 weeks and blood tested. Domestic livestock have been shown to be highly resistant to infection with *Br. canis*. There is no evidence that *Br. canis* on inoculation into cattle will cause seroconversion on tests for either *Br. canis* or *Br. abortus*. Cats are resistant to natural infections with *Brucella* spp.^{8,21,24}

Miscellaneous bacterial causes of canine and feline abortion include:

Brucella abortus,¹ *suis*¹⁹ and *melitensis*^{4,7} can cause occasional sporadic abortions in pregnant bitches when they ingest infected material. These cases may be diagnosed on culture of aborted, infected fetuses or membranes and by the serum agglutination test.^{17,22b} As with *Br. canis*, dogs infected with these other species of *Brucella* may transmit infections to humans. Nonspecific organisms such as *coliforms*, *staphylococci*, *streptococci* and *Salmonella* spp. are frequently associated with sporadic abortions especially in older bitches and often accompanied by chronic endometritis and low grade cystic endometrial hyperplasia.^{2,18,20,21,23} These abortions are usually associated with infertility, a persistent vulvar discharge, chronic metritis, and repeated abortions. Few bacteriological studies have been reported in dogs to indicate the incidence of the more common or even the occasional bacterial causes of abortion.

By the administration of large doses of penicillin and streptomycin or other antibiotics for 7 to 14 days or longer, some veterinarians have reported apparent success in preventing abortion in dogs showing early symptoms of impending abortion. Bitches with a history of repeated abortions may carry the conceptus to term if infection was controlled or prevented by treating with broad range antibiotics for several weeks before and after service. Although a few reports have linked *Leptospira pomona* with abortion in dogs, evidence indicates that they do not abort from this cause. Dogs can become urinary shedders of *leptospira*.⁴ *Salmonella* spp. has been re-

ported as a cause of occasional canine abortion and stillbirths associated with the acute disease.²³

Viral causes of abortion—In contrast to the large species of domestic animals, dogs relatively seldom abort due to viral infections of the fetuses. Abortions in dogs have been described following an acute attack of distemper. Viral agents including distemper,^{10,16,18} canine adenovirus¹⁸ (infectious hepatitis) and canine herpesvirus (CHV)^{14,18} have been isolated from aborted fetuses, placentas and neonates. Transplacental transmission of CHV to fetuses may occur late in gestation.^{14b} There is evidence that the latter two viruses may occasionally cause abortion. Canine distemper virus (CDV) can cause transplacental infections and abortion and if late in gestation may cause congenital infections in the newborn pups.^{18a} Vaccines are available for the prevention of disease caused by distemper and infectious hepatitis and should be given before breeding. Canine distemper virus (CDV) MLV or avirulent vaccines should not be administered to pregnant bitches.

Fungal causes of abortion have not been reported in dogs.

Protozoal causes of abortion in dogs are uncommon. *Toxoplasma gondii* may cause abortions, birth of premature, dead or moribund pups or living pups with congenital toxoplasmosis.^{4,8,28} Toxoplasmosis may clinically resemble other infectious diseases of dogs. As with sheep the organism may be recovered from fetal organs and placenta, especially the brain or be observed in histologic sections. The Sabin-Feldman dye test and the complement-fixation test and others are useful serologic tests for toxoplasmosis.^{4,11}

Noninfectious Causes for Canine Abortion

A number of drugs have been described that when administered to pregnant bitches caused fetal death and abortion. These drugs include: N-deacetylthiocolchicine; O-diazoacetyl-L-serine (azoserine); malucidin; a yeast extract and other nonhormonal compounds.^{12,13,27,30,31} These drugs have been suggested for mismatings but have not been generally accepted for this purpose nor proven acceptable for causing abortion in bitches.

Because the dog is highly susceptible to estrogen toxicity by bone marrow depression, thrombocytopenia and leukopenia, large or repeated doses of estrogens to produce abortion has not been attempted nor recommended. Small doses of 0.02 to 0.03 mg/kg of prostaglandin F_{2a} given 2 or 3 times per day between 33 and 53 days of gestation resulted in abortion in 4 or 7 bitches at 56 to 80 hours after treatment was started.^{9b} In some bitches not all the fetuses were expelled. Also undesirable side

effects of salivation, vomition and diarrhea occurred after the injections. A single effective dose of 1 mg/kg is too near the fatal dose of 5 mg/kg to administer. Presently 0.05 to 0.075 mg/kg is given twice a day up to 5 to 7 days to be certain all fetuses are expelled.^{9a} In preliminary studies 2 bitches pregnant 30 days and 2 pregnant 45 days were given 5 mg dexamethasone twice daily for 10 days. In the former the embryos died and were resorbed and in the latter dead fetuses were aborted one and 3 days after the end of the treatment.^{1a} Further studies are indicated. Thus in the bitch there is no satisfactory product or drug to induce abortion even in early pregnancy. The use of dexamethasone to induce abortion or cause premature births in bitches has not been adequately evaluated. Possibly the combination of dexamethasone and prostaglandin might be satisfactory but further trials are indicated. However surgical removal of the corpora lutea in the bitch will result in abortion at any stage of gestation and presently it is the only safe method for termination of pregnancy.⁵

Progesterone deficiency—Abortion in bitches with no evidence of infection may be due to hypoluteinization and occur the sixth to seventh week of gestation because of premature regression of the corpus luteum, or occur the second to fifth week of gestation due to faulty development of the corpus luteum. Five to 25 mg doses of progesterone in oil 2 to 3 times a week until the eighth week of pregnancy, or the "repositol" form could be used less often.² More work needs to be done to assess the incidence of abortions due to endocrine deficiencies.

Nutritional causes of abortion in dogs have rarely been reported. Manganese deficient bitches either failed to come into estrus or when bred, terminated gestation about three weeks later.²⁶ It is rather significant that in our motorized society that only a few abortions in dogs following severe trauma have been described. Genetic defects of the developing embryo or fetus may result in embryonic or fetal death. In bitches, as in sows, the number of developing embryos maturing to term is regulated by uterine factors and spacing of embryos. Most deaths due to these factors occur about 30 days of gestation and embryos dying at this time are usually autolysed and absorbed. Dystocia due to achondroplasia in certain breeds of dogs and lack of proper growth in young animals may cause dystocia and stillbirths.

Abortion in Queens

Abortion in queens is probably more common than in bitches¹³ but much lower than in sows, ewes, cows and mares. The true incidence is not known because of early embryonic deaths and resorption of the conceptuses and the nature of carnivores to consume aborted material or fetuses. Most feline abortions are sporadic. An increasing number of studies have been performed on the causes of abortion in queens.

Infectious Causes of Feline Abortions

Bacterial Causes

Nonspecific organisms including coliforms (**E. coli**), **Pseudomonas spp.** **Staphylococci**, **Streptococci** and **Salmonella** are associated with sporadic or repeated abortions, early embryonic deaths, mummified and still-born fetuses, in middle-aged or older queens that, as in bitches, may be associated with chronic endometritis and low-grade cystic endometrial hyperplasia. Most of these

Table 13b. Summary of the Causes of Feline Abortions

Infectious Causes

Bacterial causes—none.

Miscellaneous bacterial causes—coliforms, pseudomonas, staphylococci, streptococci and salmonella.

Viral causes—feline panleucopenia virus, feline herpesvirus (feline viral rhinotracheitis), feline leukemia virus (?).

Other infectious causes—mycoplasma, *Toxoplasma gondii***Noninfectious Causes**

Hormonal causes—progesterone deficiency (?), prostaglandins.

Physical causes—severe trauma (?)

Miscellaneous causes—genetic defects, parturient conditions and stillbirths.

abortions are observed after 4 to 5 weeks of gestation with an apparent greater incidence in short-haired queens.^{3,13,14,19,20} These reproductive failures are often accompanied by a prolonged discharge from the genital tract and a history of infertility. Although of questionable value, prompt administration of broad-range antibiotics may prevent abortion in queens exhibiting signs of impending abortion. Culture of the discharge and sensitivity testing might improve the results of treatment. Those with a history of repeated abortions might benefit from antibiotics given for several weeks before and after breeding. This above syndrome, not uncommon in queens, may be associated with immunosuppressive viruses such as the feline leukemia and possibly feline infectious peritonitis viruses¹⁴ as well as the abnormal uterine changes in older queens due to chronic hormonal stimulation associated with estrous cycling and pseudo-pregnancy and the steroid hormones, progesterone and estrogen.¹⁵

Cats are resistant to natural infection with *Brucella* spp.¹⁵ Although when infected they can become urinary shedders of *Leptospira* spp., abortions do not occur.^{1,6}

Viral Causes

Feline panleucopenia (FPL) virus, a parvovirus, causes embryo resorption, mummified fetuses, abortions, stillbirths and cerebellar hypoplasia or aplasia in neonates infected late in gestation.^{2,3,5,9,12,14} Signs of ataxia associated with cerebellar dysplasia is often not noted until the kitten is 2 to 3 weeks old. As in parvovirus infection in swine not all fetuses in a litter may become infected.

Feline panleucopenia, feline infectious enteritis, or "distemper" is a highly contagious viral infection seen world-wide in all breeds of cats. It is characterized by a marked leucopenia, fever, depression, anorexia, vomiting and a profuse diarrhea especially seen in young susceptible kittens after 2 or 3 months of age when they have lost their colostral immunity. Acutely infected animals shed virus in all body excretions and for up to one year in the urine. It is easily spread by indirect contact as the virus is very stable.

The virus may be recovered by viral isolation from aborted fetuses or demonstrated by immunofluorescence of infected tissues. The serum-neutralization test is used to detect antibody which rises rapidly to reach a high level about 10 days after the onset of illness.^{2,5,9}

The disease may be prevented by vaccination with an inactivated or MLV vaccine or combined FPL and FVR vaccines available commercially. The latter MLV vaccines should not be used in pregnant queens. After the initial series of vaccinations as kittens, once a year revaccination is recommended for maximum protection. Treatment of exposed pregnant and possibly susceptible queens should be with antiserum or normal feline serum at a rate of 1 ml/lb. to provide immediate protection.^{9,14}

Feline viral rhinotracheitis (FVR) or feline herpesvirus 1 is wide-spread and causes an upper respiratory disease that varies from a subclinical condition to marked respiratory signs and death. It is characterized by sudden onset, pyrexia, leucocytosis, sneezing, coughing, nasal and conjunctival exudate, and anorexia.^{2,3,5,12,14} Occasionally secondary bacterial pneumonia, dendritic keratitis, and vulvo-vaginitis may occur. If pregnant susceptible cats become infected about the sixth week of gestation, mummified fetuses, abortion, stillborn or congenitally infected, weak newborn may result as this feline herpesvirus crosses the placental barrier. As with other herpesviruses a carrier or latent infection in the trigeminal ganglion often results with recrudescence spontaneously or at periods of stress such as parturition.^{7,8} Carriers or acutely infected cats transmit this infection by the respiratory route. This feline herpesvirus 1 is distinct from the herpesvirus virus described as the possible cause of feline urolithiasis.⁹ Other agents such as feline calici (picorna) virus, feline chlamydial infection (pneumonitis), reovirus, and Bordetella and Pasteurella also cause respiratory disease in cats that may resemble feline viral rhinotracheitis. Diagnosis of FVR infection can be made by viral isolation from fetuses or placentae, by the fluorescent antibody test or by finding intranuclear inclusion bodies typically seen in herpes virus infected tissues on histopathological examination. Inactivated and

MLV vaccines for intramuscular use and an MLV vaccine for intranasal and conjunctival administration are commercially available. The MLV vaccines should not be used in pregnant queens. Presently commercial vaccines combining the feline viral rhinotracheitis and panleukopenia viruses are also available.

Other feline viruses such as the calici (picorna), feline infectious peritonitis (FIP), reovirus and chlamydial organisms have not been reported to cause abortion in cats.⁹

In the mid to late 1970's a wide-spread syndrome occurred in a near epizootic manner in many catteries and breeding colonies in the U.S. This kitten mortality complex (KMC) was an apparently new disease characterized by a high incidence of reproductive failures and kitten deaths including: repeat breedings and failure of conception, abortions the last trimester of pregnancy, stillbirths, congenital malformations, endometritis and pyometra with a bloody vulvar discharge, chronic upper respiratory disease and conjunctivitis, intermittent pyrexia, acute cardiovascular disease and kittens dying within a few days or weeks of birth.^{16b,18c} Careful studies failed to reveal any bacterial or viral etiologic agent. However, nearly all affected cats were serologically positive for feline infectious peritonitis (FIP). In recent years the incidence of this KMC syndrome has greatly declined.

Feline leukemia virus (FeLV) is probably world-wide in distribution and causes a number of clinicopathological syndromes including alimentary, thymic and multicentric lymphomas, leukemia, anemia, panleukopenia-like syndrome, enlarged kidneys, thymic atrophy and other FeLV immunosuppressive diseases. The FeLV virus may be transmitted horizontally, especially in young kittens, or vertically from viremic queens. More often, however, early embryonic deaths and resorptions or abortions have been reported.^{3,9,10,11,14} Thus even if feline leukemia virus doesn't actually cause abortion or resorptions it may favor disease processes that produce them. Further studies are needed to delineate the exact role of FeLV in reproductive losses.

Unless obvious disease states such as tumors are present, a diagnosis of feline leukemia-sarcoma complex requires laboratory assistance.⁹ Blood examinations, histopathological, serological and virological procedure may all be used. The most common simple rapid tests are the immunofluorescent antibody (IFA) test applied to blood smears¹¹ and the commercially-produced ELISA test that can be performed in the veterinary hospital, which detect the FeLV or antigen in the blood. This latter test is more sensitive and may detect transiently infected cats so a second test about a month later is indicated to determine the chronically FeLV infected cat.^{18b} The FOCMA (feline oncovirus-associated cell membrane antigen) test for

the presence of antibody can help assess the resistance of a cat. On the basis of these and other tests the prognosis in a given case may be determined.⁹

Although work has been undertaken on the development of a FeLV vaccine, none is presently available. The greatest numbers or incidence of FeLV-infected cats have been found in large breeding catteries; while a much lower percentage of positive cats have been found in one or two cat households or in free-roaming cats. An IFA or ELISA test positive cat is carrying the FeLV virus whether it appears healthy or diseased and is probably shedding the virus.^{9,11} By using the above tests FeLV-free colonies can be established and maintained by not allowing infected cats into the disease-free colony. This is essential for a breeding cattery.

Mycoplasmosis due to *M. gateae* has been described as a cause of feline abortions at various stages of gestation.²²

Fungal causes of abortion in cats has not been reported.

Parasitic Protozoal Causes—Toxoplasmosis due to *Toxoplasma gondii* was formerly reported in queens as the occasional cause of embryonic resorptions, fetal mummification, abortion and death of neonates, possibly due to transplacental infections.^{1,14,17,21} A more recent well-controlled study indicated that *T. gondii* is not likely to be an important cause of abortion or perinatal mortality in cats and transplacental transmission could not be demonstrated.^{3,4a,b} However cats can harbor and excrete oocysts from their intestinal tract of four coccidial parasites, *Toxoplasma*, *Hammondia*, *Sarcocystis* and *Besnoitia*.²³ Toxoplasmosis in kittens or older cats can easily be clinically confused with other feline diseases.^{4b}

Noninfectious Causes for Feline Abortion

Recurrent abortions in queens might be due to a **progesterone deficiency** when other causes cannot be determined.^{1a} These abortions usually occur from the second to seventh week of gestation. It was suggested that 5 to 25 mg doses of progesterone in oil be administered two to three times a week until the eighth week of gestation or the repositol form could be used once or twice a week. Further studies might be informative if a number of queens with habitual abortions could be examined throughout pregnancy by hormonal assays.

Prostaglandin F_{2α} at doses of 0.5 to 1.0 mg/kg once or, if necessary, twice at 24 hour intervals caused abortions in all pregnant cats over 40 days of gestation within 24 or 48 hours, respectively. Queens pregnant 55 days

or longer gave birth to live kittens, lactated normally and suckled their newborn.¹⁶ This treatment in contrast to bitches given prostaglandin, was well tolerated. Another preliminary study²⁴ indicated that PGF_{2α} alone did not cause abortion in queens in late pregnancy unless combined with ACTH. Prostaglandin did not induce abortions when administered prior to 40 days of gestation.^{18a}

Estradiol cypionate (ECP) in a single dose of 0.25 mg given intramuscularly will prevent conception if given within 1 to 5 days, preferably about 40 hours after coitus, if the time of coitus is known.¹⁴ This treatment apparently retards the passage or locks the fertilized ova in the uterine tubes where they degenerate. Signs of estrus may be prolonged. Repeated estrogenic therapy should be avoided in queens, although they are not as susceptible to estrogen toxicity with bone marrow depression and thrombocytopenia as the bitch.^{18a}

Nutritional causes of abortion in queens have not been reported. Some feline abortions have been associated with severe anemia or pregnancy toxemia.¹³ As in other species genetic or chromosomal defects can cause early embryonic deaths, abortions or defective weak neonates.

Mummification of the Fetus

Fetal death in domestic animals occurring the middle or last third of gestation that does not result in involution of the corpus luteum and abortion of the fetus within the next week or 10 days or decomposition or maceration of the fetus within the next several months, is followed by autolytic changes in the fetus, absorption of placental and fetal fluids, involution of the maternal placenta, and mummification of the fetus. Conditions necessary for the occurrence of fetal mummification include the maintenance of the dead fetus within the uterus by the presence of a normal viable fetus or fetuses or the persistence of the corpus luteum of pregnancy associated with a single, or rarely twin, bovine mummified fetuses. One or more mummified fetuses present in the uterus with one or more

Figure 71. Mummification of twin, bovine, 3-month-old fetuses. These were spontaneously aborted at four months of gestation.

normal viable fetuses is observed frequently in sows, occasionally in bitches and queens and uncommonly in ewes, does, cows and mares. Fetal mummification associated with a persistent corpus luteum is observed in the cow, doe, sow and bitch. The maintenance of pregnancy in these species is due to progesterone produced by the corpus luteum. In the other species progesterone is produced by the fetal placenta or chorion after midgestation and the corpora lutea involute. Fetal mummification apparently does not occur the first trimester of gestation because embryonic or fetal death prior to the development of the fetal bones usually is followed by resorption of the fetal and placental tissues. Fetal death the last month or six weeks of gestation with beginning fetal mumi-

fication may be undiagnosed at parturition and called a stillbirth, especially in multiparous animals. Williams¹⁹ described some of these fetuses in cows as "static fetal cadavers." Fetal mummification may occur and subsequently bacteria may invade or gain entrance to the uterus and cause secondary maceration of the uterine contents.

Two types of fetal mummification have been described in animals, the hematic type in cattle and the papyraceous type in all the other species. The process by which these two types form are basically similar. In cows as the maternal placenta or caruncle undergoes involution a variable amount of hemorrhage occurs between the endometrium and fetal membranes which after the plasma has been absorbed leaves a reddish-brown, gummy, tenacious mass of autolyzed red cells, clots and mucus. This imparts a reddish-brown color to the fetal membranes and fetus. A similar discharge of blood from the caruncles is noted in normal parturient cows 10 to 14 days after calving and is characterized by a bloody genital discharge. The similarity between the tenacious sticky reddish mucus around the membranes of the bovine mummified fetus and that found in the rectum following intussusception of the intestine in cattle is strik-

Figure 73. Death and mummification of a bovine fetus due to the displacement of the umbilical cord around the neck of the fetus.

Figure 74. Porcine fetal death and mummification at different times in gestation and a stillbirth, with abortion of the uterine contents near term. This might possibly have been due to a parvo-, entero-, or pseudorabies virus.

ing. In the other species mummification is not characterized by placental hemorrhage and the fetus is usually a brownish color and the fetal membranes are not covered with this reddish-brown tenacious material. In both types of mummification the longer the condition exists the greater the loss of fluids from the placenta, the membranes and the fetus.

Mummification of the bovine fetus is observed most often in Guernsey cattle although other breeds are commonly affected. The condition usually affects single fetuses but may occasionally involve one or both fetuses in twin pregnancies. Bovine fetal mummification occurs during the third to eighth month of gestation but most commonly the fourth, fifth and sixth months (See Figures 71, 72, 73). If the condition is undiagnosed the mummified fetus may remain in the uterus for months beyond a normal gestation period. Spontaneous abor-

tions before, near, or after the expected end of gestation are not uncommon. In one study of 32 mummified fetuses in one herd the range of the "gestation," period from conception to spontaneous abortion, was 131 to 342 days with an average of 215 days.⁵ The sex of mummified fetuses are nearly equally divided between males and females.¹¹ No premonitory signs are observed before the expulsion of a mummified fetus except occasionally those of estrus.

The causes of fetal death and mummification in cattle are often the same as causes for fetal death and abortion. The cause of fetal mummification is often impossible to determine because the time of death is not known and autolysis and mummification of the fetus and membranes makes isolation and determination of the causative agent difficult or impossible. Serologic tests of the dam weeks or months after fetal death are usually of little diagnostic significance. Fluorescent antibody staining of tissues have been helpful in some cases.

Genetic factors may be involved in bovine fetal mummification.¹¹ There is a greater incidence in the Guernsey and Jersey breeds of cattle. Certain cow families will have mummified fetuses in two to four generations of cows bred to apparently unrelated males by artificial insemination. In these and other studies the male did not seem to play a causative role in the genetic inheritance of this condition. However, one report¹⁶ suggested that abortions and fetal mummification experienced in a Holstein herd at 120 to 180 days of gestation when daughters of two popular sires were mated artificially to the other sire were due to autosomal recessive genes. In another large Holstein herd⁵ the heritability of fetal mummification was only 16 percent when the service sire was excluded and the condition was not transmitted as a simple recessive. When the owner used other bulls on these cows the losses stopped. Further evidence that this condition may be due to an inherited endocrine or other defect of certain cows is the fact that as many as 20 to 50 percent, average 30 percent, of subsequent conceptions in cows that have had mummified fetuses may result in fetal mummification whether the same or different sires were used.¹¹ The author observed one Guernsey cow that had 5 normal calves and 5 mummified calves within a period of 9 years. In such cows abortions at midgestation not associated with fetal mummification are quite common. The possibility of a latent virus or organism residing in the uterine or other body tissue or cells and causing the repeated occurrence of mummified fetuses in the same individual should possibly be considered although evidence for this has not been reported. Rare cases of mummified anomalous calves are recorded.

Other causes for bovine fetal mummification include

torsion of the umbilical cord or compression of the umbilical cord by its passing around a fetal extremity (See Figures 66 and 73). This causes fetal death. Fetal mummification may then occur instead of prompt abortion. There is evidence that fetal mummification may follow infectious causes of fetal death such as *C. fetus*, molds, leptospirosis, IBR and BVD-MD virus.^{8,9a,11} Leptospirosis and BVD-MD virus may account for the occasional epizootic outbreaks of fetal mummification in a herd. Fetal death and a degree of mummification may occur in animals in which the duration of gestation has been prolonged by progesterone or progesterone-like compounds. Torsion of the uterus and trauma are not considered to be causes of fetal mummification. Wound infection organisms causing an inflammatory response in the endometrium with possible release of prostaglandins are characterized by fetal death and prompt abortion and not by fetal mummification. Almost all mummified fetuses and uteri when examined and cultured are sterile and free of organisms and the endometrium is involuted and no inflammatory lesions are present. This is further substantiated by the observations that cows usually conceive the first or second estrum after the expulsion of the mummified fetus. The causes of fetal mummification in the other species should be noted as these might provide leads for explaining the causes of the condition in cattle.

As the fetus mummifies and fetal and placental fluids disappear, the uterine walls contract and tightly enclose the conceptus. The longer the condition exists, the dryer, firmer, and more leather-like the tissues of the fetus become. In the cow the uterine walls are fairly thick and no cotyledons are palpable. The uterine artery is small and has no fremitus. Fetal mummification in the cow is characterized by failure of estrum with a persistent corpus luteum. It is usually not suspected until late in gestation or until after the normal length of gestation, when normal development of the fetus, body and udder changes incident to parturition and calving fail to occur. Although the uterus may be drawn forward by the weight of the mummified fetus and a normal cervical seal may be present, a careful rectal examination will readily reveal the nature of the disease. If the uterus is dropped downward out of reach it may be pulled up to the pelvic cavity manually by grasping the cervix or intercornual ligament, by placing Knowles cervical forceps on the cervix and drawing the uterus back, or by having two men raise the caudal abdominal viscera by means of a pipe or bar held by each of them. Rarely a large mummified fetus may be ballotted through the flank. In cases where the uterus is examined very early after the death of the fetus and the occurrence of the interplacental hem-

orrhage, the former feels distended by a doughy mass, which is the large, soft blood clot. The fetus is not easily palpated in this doughy mass within the contracting uterus. Within a few weeks the typical changes associated with fetal mummification in the cow become apparent.

The bovine fetal mummy remains in this semi-moist state without odor or pus until spontaneous abortion results in from 1 to 2 months to 1 to 2 years, or until the condition is diagnosed, treated, and corrected, or the animal is slaughtered. If spontaneous abortion occurs, the fetus may be expelled into the vaginal cavity and a portion of the dark brownish-red stained fetal membrane hangs from the vulva until noticed by the caretaker or owner. Estrum usually occurs about the time of the spontaneous abortion and the cow will come into estrum again 16 to 24 days later. If the fetus should be large and passage through the dilated cervix is not possible then fetal maceration may occasionally result. In large fetuses tenesmus or straining, as noted in other abortions, may be observed.

The incidence of fetal mummification in cattle is low and sporadic. In three large herds the incidence was 0.43 to 1.8 percent of the pregnancies.¹¹ In some herds the incidence may be higher and in a few instances apparent epizootics of mummified fetuses may occur.

To expel the mummified fetus in the cow the simplest treatment is to administer 50 to 80 mgs. of stilbestrol or 5 to 10 mg. of estradiol intramuscularly. The injected estrogen causes contraction of the uterine muscles, relaxation of the cervix, involution of the corpus luteum and results in the expulsion of the fetus. In about 80 percent or more of the cases this single injection of an estrogen is all that is required and the fetus is expelled within 37 to 72 hours. If the fetus has not been expelled within this time, a similar dose of estrogen may be administered a second time. In unusual instances 3 or more doses at 48-hour intervals may be needed. Some veterinarians use repositol diethylstilbestrol, 100 to 150 mg., intramuscularly. In one study of 50 cows with mummified fetuses, daily injections of estrogens were given and all expelled the fetuses in 3 to 11 days.¹⁷ Occasionally examination of a cow either after treatment or before will reveal the fetus entering into or wedged in the cervical canal, with the cervix not yet dilated sufficiently to allow passage. Administration of a single large dose of estrogen at this time usually results in successful dilation of the cervix and the expulsion of the fetus within 24 to 36 hours. When the fetus is large, or mummification occurs at 6 to 8 months of gestation, or the cow is small or immature, the genital tract should always be examined within 48 to 72 hours after the injection to make certain failure of expulsion or dystocia does not occur

with secondary infection of the uterus, closure of the cervix and maceration of the fetus. Occasionally a second dose of estrogen, much lubrication, gradual traction with a snare or Knowles cervical forceps by one hand and pushing on the fetus with the other hand in the rectum, may be needed to help remove the fetus.

In recent years a number of reports have indicated that the injection of prostaglandin or its analogues in luteolytic or somewhat larger doses intramuscularly such as 25 to 50 mg of prostaglandin $F_{2\alpha}$ or 500 ug cloprostenol (**Estrumate**), caused the involution of the corpus luteum and the expulsion of the mummified fetus 72 to 120 hours later.^{7,17,18} Plasma progesterone levels dropped rapidly from about 10 ug/ml to 1 ug/ml and estradiol levels were low about 3 pg/ml during the postinjection sampling period. However in most reported cases it was necessary to withdraw the fetus from the cervix and cranial vagina by traction due to the incomplete relaxation and dilation of the vagina and vulva. Possibly the combination of estrogens and prostaglandin would be more effective in producing expulsion of the mummified fetus and relaxation of the genital tract. Further studies are indicated as in some cases after prostaglandin therapy and rare cases after estrogen therapy the corpus luteum would involute but the mummified fetus would not be expelled.^{11,17} Glucocorticoid treatment of cows with mummified fetuses failed to induce luteolysis and expulsion of the mummy. A live fetus is necessary for dexamethasone to effect abortion or premature delivery.^{1,1b,17}

Removal of the persistent bovine corpus luteum of pregnancy will usually result in estrum and evacuation of the uterus. There is the added danger of trauma and damage to the ovary by the forceful or surgical removal of the deeply imbedded corpus luteum of pregnancy. It has been found that massage of the uterus daily for several days frequently provides enough stimulus to cause evacuation of the uterus. Manual dilation of the cervix is not indicated. It has been reported that filling and distending the vagina with cotton will cause the expulsion of a mummified fetus. The author has had no experience with this method of treatment. It is possible that manual uterine massage or distention of the vagina stimulate the release of oxytocin and prostaglandin to effect expulsion. In exceptional cases in which the affected animal is a small heifer, or the fetal cadaver is very large or previous treatment has been unsuccessful, a cesarean operation through either the right or left flank is usually successful in correcting the condition.

Following treatment and expulsion of the mummified fetus, most cattle recover promptly since no infection is present to delay recovery. Conception usually occurs

within 1 to 3 months. Any cow with a history of having one mummified calf may abort at 3 to 8 months of gestation or have another one at any gestation period; hence the prognosis should always be guarded.

Fetal mummification in horses occurs seldom and has only been reported in one of twin fetuses that has died during pregnancy probably due to a lack of placental area. The equine mummified fetus remains in the uterus only as long as pregnancy is maintained by the viable twin.¹² Since spontaneous abortion of twin fetuses is common in mares the discrepancy between the size and development of the partially mummified fetus and recently dead fetus often leads to the improper diagnosis of superfetation. Mummification of both fetuses in a twin pregnancy has not been reported in the mare.

Fetal mummification in sheep is occasionally observed as affecting single ovine fetuses or one or both twin fetuses. It has been associated with and probably caused by infections in sheep causing fetal deaths and abortions. These include: toxoplasmosis, EAE (Enzootic abortion of ewes or Chlamydiosis), **Listeria monocytogenes**, possibly **L. pomona** and unknown causes associated with prolonged gestation.¹¹

In does, as in ewes, fetal mummification is uncommon but it has occurred affecting one of twin fetuses in chlamydiosis, in toxoplasmosis, in Border Disease (BVD) and possibly in Coxiella infection.^{13,14,15} Two rare cases were reported in does. One was a case of twin hybrid mummified fetuses resulting from a mating of a ram and a doe and the other in a doe that ingested a toxic dose of Japanese pieris.^{13,14}

Fetal mummification in swine is an important cause of prenatal losses. Fetuses dying *in utero* from 40 to 90 days of gestation usually mummify and are expelled at parturition along with the normal fetuses. In a herd relatively free of disease, single mummified fetuses in a litter were more common than two or more.¹⁰ In three breeds of pigs in this herd, Berkshire, Chester White and Yorkshire, the percentages of mummified pigs were 4.97 and 1.95 and 1.08, respectively. The high incidence of mummified fetuses in Berkshires in this herd accounted in part for the smaller litter size in this breed. Single mummified fetuses were more common in large litters. The presence of occasional mummified fetuses were not related to the incidence of stillbirths. The cause of these occasional mummified fetuses in certain litters is not known. Epizootic herd outbreaks of abortions, early embryonic deaths, mummified fetuses and stillbirths have been described in swine (See Figure 74). A high incidence of mummified porcine fetuses has been reported due to the following viruses: Aujeszky's or pseudorabies, Japanese encephalitis B, Japanese hemagglutination, hog

cholera, picorno or entero-viruses,^{3,4} parvovirus, reovirus, cytomegalovirus and possibly swine influenza virus. Fetal mummification also occurs due to leptospirosis in pregnant sows (see abortion in swine). In these viral diseases mummification, when it affected all or nearly all of the fetuses, occasionally resulted in a prolonged gestation period.^{1,3} Following outbreaks of the above viral diseases, affected sows usually conceive promptly and produce normal litters. A natural immunity is apparently produced.

Fetal mummification in dogs and cats is uncommon and sporadic in nature but apparently similar to that seen commonly in swine where one to three mummified fetuses are expelled with normal neonates at the time of parturition. Occasionally in the bitch and more often in the queen the uterus may rupture in late gestation due to torsion or trauma and some fetuses escape into the abdominal cavity and mummify^{1a,9b} (see Extra-uterine Pregnancies and Fetuses).

Fetal Maceration

Maceration may occur at any stage of gestation and has been observed in all species. It is described most often in the cow. (See Figures 75 and 76.) When the fertilized ovum or embryo succumbs to bacterial or viral infection or other disease or abnormality early in gestation it is usually absorbed in the uterus or a slight and often insignificant purulent uterine or vaginal discharge may be evident. The embryo is seldom observed. The interval between estrual periods may be prolonged if the embryo did not succumb until 20 to 50 days after conception. Early embryonic death and maceration are prob-

Figure 75. Maceration of a 4-month-old bovine fetus.

Figure 76. Bones of a 6-month-old macerated bovine fetus in the uterus. Note the thickened uterine wall and degenerated fibrotic endometrium (Courtesy K. McEntee).

ably caused by a variety of miscellaneous organisms that may be found in the uterus, and are of common occurrence in cows affected with trichomoniasis or vibriosis. In occasional cases of pyometra seen in trichomoniasis, fetal shreds and placental remnants are often found floating in the purulent exudate. In cases of early fetal maceration the cervix may be tightly sealed or some discharge of pus may be evident in the vagina or from the vulva. These cases usually are diagnosed and treated as pyometra or endometritis. In the former, estrus is not present; in the latter estrus may occur. In multipara, maceration of early embryos and fetuses usually ends in their being absorbed. The other fetuses develop normally or occasionally some become macerated in turn by the extension of the infection. Rarely in cows, ewes, does and mares one fetus may die the first half of gestation and macerate and be expelled with the placenta and the normal twin at parturition.

In the cow fetal maceration that occurs after the third month of gestation, by which time fetal bones are fairly well developed, may be caused by wound-infection type bacterial agents, especially *C. pyogenes*. Septic metritis of pregnancy, resulting in the death, emphysema, and maceration of the fetus in a closed uterus, is uncommon. It may be caused in the cow by the death or mummification of the fetus, followed by a dilation of the cervix and an incomplete abortion and/or dystocia usually occurring from the middle of gestation to near term. The symptoms of septic metritis of pregnancy are similar to septic metritis after parturition. The condition may be more serious or fatal due to the presence of the decomposing fetus(es), failure of the cervix and genital canal to dilate normally, and a uterine inertia.

In rare instances fetal emphysema and maceration may be associated with uterine torsion during gestation. The two factors of an open cervix and a dead fetus at body temperature cause a rapid bacterial invasion of the fetus and membranes of organisms already present in the uterus or from the more caudal portions of the reproductive tract. Fetal emphysema and maceration follow. If the bovine fetus is beyond the third month of pregnancy and if the usual expulsive efforts are not observed or are unsuccessful, the fetus develops emphysema in 24 to 48 hours and in 3 to 4 days maceration begins. If fetal emphysema and maceration develop in a fetus late in gestation, the handling or treatment of the case is the same as similar cases occurring as a sequelae to an ordinary dystocia at or near term and will be described later under the handling of dystocia.

Because of the relatively smaller size of the fetus, those cases of fetal emphysema and maceration accompanying an abortion during the middle period of gestation are treated differently. Usually these cases have a history of intermittent straining for several days accompanied by a foul, fetid, reddish-grey vulvar discharge. The temperature and pulse are often elevated. Anorexia and drop in milk production may be present. Occasionally diarrhea is present. Palpation per vagina or rectum of a distended, swollen fetus with gas crepitating in the tissues is diagnostic of fetal emphysema. In bovine abortion from the fourth to seventh month with fetal emphysema, the fetus usually may be removed by careful and gradual traction if the cervix is sufficiently dilated and much lubrication is used. In the mare the cervix may be carefully dilated manually prior to removal of the decomposing fetus. After removal the uterus should be reexamined to make certain another fetus is not present and to remove the placenta if possible. Aftercare is similar to that described for septic metritis and retained placenta. In those few cases in cattle in which the cervix is contracted and the fetus cannot be removed, heroic treatment is not indicated. Supportive treatment consisting of antibiotics and sulfanomides parenterally along with large doses of estrogens, 50 to 100 mg. of stilbestrol or 5 to 10 mg. of estradiol daily or every other day for perhaps 4 to 7 days, is administered until the cervix is relaxed enough or the fetus is macerated sufficiently to effect its removal in its entirety or in pieces without injury to the cow. With this treatment the danger of excessive traction or fetotomy causing lacerations or rupture of the cervix and uterus is avoided. Because the uterus and its contents are relatively small the development of a septic metritis and a severe toxemia is prevented by the supportive therapy. Cesarean section should be considered as a last resort in the cow, ewe and doe but is seldom required. The ani-

mal should not be rebred for at least three to four months and the outlook for her reproductive life is guarded. Aftercare and treatment of the infected uterus is necessary.

In long-standing cases of fetal maceration the acute emphysematous stage has passed, straining is seldom observed, and the cervix is usually contracted. Generalized symptoms of elevated temperature and pulse and anorexia are not present. There is often a history of a chronic, fetid, mucopurulent discharge from the vulva over a period of several weeks or months. Only rarely is the cervix sealed. There may be a history of a gradual drop in milk flow and a loss of weight. The presence of diarrhea is variable. Diagnosis in the bitch and queen is aided by abdominal palpation, for loss of fluids and crepitation, and radiographs besides observing the other symptoms. Radiographs in the bitch, queen, and possibly the ewe, doe and sow may reveal late fetal death and maceration by the presence of fetal gas and cranial bone overlap. In the bitch dead fetuses curl into a posture resembling the letter C.⁶ In the bitch and queen laparohysterotomy or hysterectomy may successfully correct fetal maceration and the former operation may be followed by conception.² In most cases no external symptoms of illness are noted except possibly a uterine discharge appearing occasionally at the vulva. On rectal examination in the cow or mare, fetal bones may be palpated in the uterus either floating in pus or crepitating against each other with some exudate around them. The uterine wall is thick and heavy and the cervix is usually large and hard. In these cases severe degenerative and sclerotic changes have occurred in the endometrium.

The prognosis is poor. Treatment in the cow is difficult. If much pus is present, treatment as for pyometra is indicated and possibly the bones may be passed through the cervix with the pus. More often the amount of pus is slight and the condition has existed long enough so that the bones are deeply imbedded in the endometrium and uterine wall. The cervix is hard and indurated and not dilatable even with estrogens and prostaglandins. Laparohysterotomy is difficult because of the small size of the uterus and its infected contents. It is seldom indicated and then only as a last resort in a valuable cow, since the future breeding life of these cattle is very questionable. The longer the condition has existed the greater the damage to the endometrium and the poorer the prognosis. In most cases in cattle, slaughter is recommended. In multiparous animals hysterectomy or hysterotomy may be performed, depending upon the circumstances.

In rare instances fetal emphysema and maceration may cause a local perimetritis or even rupture of the uterus, with the macerating fetus being walled off in the abdominal cavity where it may remain indefinitely; or the mass

may slough through the abdominal floor, into the rumen or into the rectum. In rare cases, torsion of the uterus may cause a similar condition in the cow and multipara.

Prevention of Conception after Mismating and Induced or Artificial Abortion in Domestic Animals

Induced or artificial abortion or preventing of conception is occasionally desirable in veterinary medicine from an economic or therapeutic standpoint. For example if a purebred female is bred by accident to a scrub male or a male of another breed, or if a female is bred at too young an age, induced abortion is often indicated. The earlier this abortion is brought about, the less time is lost in the female's reproductive life and the fewer complications that may arise. Abortions are often desirable in meat-producing animals upon entering the feed lots. If the owner of an animal requests an abortion there are no legal complications to consider as in human medicine. Induced abortion by the administration of hormones has also been discussed under the causes for abortion in each species. Prevention of conception following accidental breeding will now be considered.

The most conservative methods of preventing conception or producing abortion should be used. Heroic measures while often effective may adversely affect the animal's health or its future potential as a breeding animal.

Prevention of conception following an accidental or unwanted service is best accomplished in animals by the injection of an estrogen within 24 to 48 hours after the undesired service. In the cow or heifer 40 to 80 mg. of stilbestrol or 5 to 10 mg. of estradiol intramuscularly usually prevents conception. In the mare this dose should be repeated 48 hours later. In the bitch 0.1 mg/10 lb of body weight up to a maximum of 1.0 mg. of estradiol cypionate (ECP) may be given intramuscularly^{8,9} 9 to 12 days after the onset of proestrus bleeding, 3 to 5 days after the onset of estrus or within 1 to 2 days after a mismating. Rarely toxic or fatal complications due to bone marrow depression may arise even with the modest but effective dose recommended. Estrogens are probably contraindicated in valuable bitches.^{8,9,12} Estrum is usually prolonged 2 to 10 days. In the queen mismating may be treated with 0.25 mg. of estradiol cypionate (ECP) about 40 hours after coitus or from 1 to 5 days after the cessation of estrus. As in the dog this dose may be repeated but excessive doses of estrogens are contraindicated.^{7,9} Conception fails to occur after estrogen therapy due either to the locking or slowing of the passage of the fertilized ovum through the uterine tube,⁷ its too rapid passage through the uterine tube and uterus, or else to the production of an uterine environment inimicable to the development of the early embryo.

The practice of douching female animals with mild antiseptics immediately after service often fails to prevent conception because in the cow, sperm cells reach the pavilion of the oviducts in less than 4-1/2 minutes

and in other species it is apparently only a matter of minutes for some of the spermatozoa to reach the oviducts and hence out of reach of the antiseptic douche fluid. There is no need or reason for a veterinarian to attempt to "separate" copulating dogs even when this is desired by the owners. This is difficult, dangerous and often highly embarrassing. By the time the dogs are separated sperm cells have advanced into the cranial portions of the uterus.

In the bitch, a number of steroidal, usually progestational, compounds have been used to prevent pregnancy in the past, but have proven unsatisfactory because they produced uterine disease.^{3,12} Presently megestrol acetate is satisfactory for use for short periods of time at a dose level of 0.25 mg/lb. daily for 30 days to prevent the development of estrus. It is also administered at a dose level of 1.0 mg/lb. for 8 days beginning during the first 3 days of proestrus bleeding and vulvar swelling to prevent ovulation and corpora lutea formation. This latter treatment usually shortens the interval between estrous periods to 3 to 5 months.^{3,12} **Mibolerone**, a potent orally-active synthetic androgen is now approved for long term estrus prevention in the bitch. Daily administration at a dose rate of 60 to 200 ug daily is required and treatment may be continued for up to two years.^{3,4,12} Side effects are minimal and consist of enlargement of the clitoris, vulvo-vaginitis and occasionally a worsening of seborrhea if this condition is present. These effective steroidal compounds suppress the release of gonadotropins and stop the estrous cycle by preventing follicle formation, ovulation and the formation of corpora lutea.

Less research has been done with the use of steroids as contraceptive agents in queens. The administration of progestational compounds in cats causes less uterine disease than in dogs. Mibolerone (19-norandrogen) is not approved for use in the queen, although daily oral doses of 50 ug prevent estrus.^{3,4} These and even smaller doses cause thyroid dysfunction, clitoral hypertrophy and hepatic dysfunction. Megestrol acetate (**Ovaban**) at a dose of 5 mg/day for 3 days and then 2.5 to 5 mg/week has suppressed estrus in young queens for over a year. Even queens in estrus will go out of estrus after 3 days on megestrol acetate. This product should not be used in cats with infections of the genital tract.⁹ Since the queen is an induced ovulator, one can apply coital stimulus with a vasectomized tom cat or a pseudocoital stimulus with a sterile rod or swab inserted into the vagina during estrus. Also 25 units of HCG (human chorionic gonadotropin) per lb. of body weight can be administered to induce ovulation which is followed by a diestrus or pseudopregnancy that lasts for 35 to 45 days.^{3,5} Progesterone-like agents used for prolonged periods in dogs have produced cystic degeneration of the endometrium and secondary endometritis and pyometra. They are of no value

in preventing conception after coitus, in fact some of these agents actually promote conception and maintenance of pregnancy if given at this time.

Experimentally in cattle the injection of oxytocin, 100 to 200 I.U. daily from day 2 to day 7 after estrus causes an inhibition of the growth and development of the corpus luteum and its secretion of progesterone necessary to maintain pregnancy. Usually cattle treated in such a manner return to estrus in 8 to 10 days. Thus this treatment should also prevent conception in bovine animals bred accidentally.

In areas such as India where bulls and cows are not confined and the amount of feed available is limited, the value of a small stainless steel spring similar to a "bobby pin" inserted into the cervix of a heifer or cow and remaining indefinitely has been demonstrated.¹¹ Although under these conditions estrous cycles, coitus and conception may occur, abortion results due to the failure of the cervix to be able to seal itself properly. This technique was an early application of the presently widely accepted intrauterine devices (I.U.D.) used in women to prevent conception. Depending upon the species of animals the I.U.D.'s prevent fertilization, prevent implantation or interfere with normal corpus luteum development.

Intravaginal or preputial devices to prevent conception have not proven satisfactory for general use.³ Ovariectomy effectively suppresses the estrous cycle and together with castration or vasectomy prevents conception in all domestic animals.

The induction of abortion in domestic animals following conception can be accomplished in a variety of ways depending on the species of animal, the duration of pregnancy, the desires of the owner and the ease of inducing abortions by physical, hormonal or surgical procedures. Generally the earlier in gestation an abortion is induced, the simpler and easier it is for the dam and the veterinarian and fewer complications will arise. Inducing abortion after midgestation or early in the third trimester should generally be discouraged because of the difficulties in the induction and the problems of delivery and aftercare of the dam. (See Induction of Parturition.)

Douching the uterus by means of a catheter or pipette with antiseptics such as 1 to 2 percent Lugol's solution, 200 ppm. chlorine solution, dilute acetic acid or 2 to 3 percent potassium permanganate solution or even saline 7 to 20 days or longer after service in the cow or mare, is often successful, possibly by also introducing bacteria to cause an endometritis, and destroying or expelling the developing ovum or embryo. Injecting of irritating solutions such as dilute Lugol's solution around the third to sixth day after service in the cow may result in similar changes as produced by the injection of oxytocin with a

shortened time between estrous periods due to the release of prostaglandins from the endometrium resulting in luteolysis. In mares abortion may be produced readily up to 8 months of gestation by manual dilation of the cervix in a sterile manner and injecting several hundred ml. of dilute Lugol's solution or other suitable mild antiseptic. One author¹⁴ aborted over 100 army remount mares by injecting 500 ml of sterile iodized oil or physiological saline into the gravid uterus. Possibly manual dilation alone would be sufficient in the mare. Aborting mares with fetuses over 8 months of age may cause injury or result in infection or dystocia in the mare. Douching the uterus and dilating the cervix is not practical or possible in the ewe, bitch, sow or cat.

Injection of hormones to induce abortion has been reported in all species of domestic animals. The usual hormones used in early to midgestation are estrogens, prostaglandins and possibly cortisone (dexamethasone). The use of these hormones for inducing abortion has been described previously in this Chapter under abortion in the various species. Often a combination of several hormones is superior to a single product. Following these treatments the veterinarian should follow each case to be certain abortion occurred and no complications such as dystocia, fetal maceration or uterine infection developed.

Although seldom used at this time manual **removal of the corpus luteum of pregnancy** in the cow per rectum invariably results in abortion in about 3 to 5 days. Since there is some danger of hemorrhage and ovarian and uterine adhesions following manual removal or enucleation of the corpus luteum in the cow, and early involution and luteolysis is readily produced by estrogens and prostaglandins, the latter products have replaced the former hazardous procedure. Removal of the corpus luteum during early pregnancy in the mare or other domestic animals is not possible except by laparotomy and ovariectomy.

Manual rupture of the amnionic vesicle in the cow and the chorionic vesicle in the mare with destruction of the embryo or fetus is possibly by digital manipulation through the rectal wall from 30 to 100 days of pregnancy in the cow and 17 to 40 days in the mare as described previously under physical causes of abortion in the cow and mare. It was interesting to note that in single bovine pregnancies when the embryo was destroyed that "pregnancy" continued and the membranes grew for 2 to 3 weeks following the rupture of the amnionic vesicle.^{1,2} Estrus seldom occurred until 30 or more days after inducing embryonic death.^{1,2,13} Manual destruction of one of twin embryos was reported to be successful in the mare⁶ but in the cow when one embryo was manually

destroyed, the other also succumbed.¹³

The re-establishment of a normal estrous cycle within 2 or 3 months in the mare after terminating pregnancy after 40 or more days of gestation is very unlikely. The endometrial cups and their secretion of PMSG have an adverse effect on the initiation of normal follicle development, ovulation and the normal expression of regular periodic estrous signs in the mare.

The timed induction of parturition in the later stages of pregnancy by the use of glucocorticoids and prostaglandins in cows, sows, ewes and does, and oxytocin in mares have been described briefly under abortion in the various species and will be discussed in greater detail under parturition.

Extrauterine Pregnancies and Fetuses

True Extrauterine Pregnancy is characterized by a fertilized ovum, embryo, or fetus that has established nutritive relations with organs or tissues other than the endometrium and has undergone in this location a degree

of embryological development. In humans ovarian and tubal pregnancies may occur, the latter being fairly common. True abdominal pregnancies, with the fetal placenta attaching to the mesentery and omentum, have been described as rarely occurring in humans. In ovarian, tubal, and abdominal pregnancies the embryonic development proceeds only a short time and then the fetus succumbs. In human tubal pregnancy the oviduct ruptures, usually accompanied by severe hemorrhage. No authentic cases of true extrauterine pregnancies have been described in domestic animals. This difference is apparently related to the manner in which the developing zygote establishes nutritive relationships with the dam. In humans and rodents the developing zygote erodes the mucosa and buries itself in the maternal tissues while in domestic animals the villi of the trophoblast attach themselves in the maternal crypts formed in the endometrium.

False or Secondary Extrauterine Pregnancy is seen occasionally in all domestic animals and very rarely in the mare.² In this condition the fertilized ovum, embryo, or fetus develops normal placental relationships with the endometrium and the fetus reaches recognizable size. It then escapes from the uterine cavity into the abdominal cavity. This condition usually occurs the last two-thirds of the gestation period. Almost all secondary extrauterine fetuses are dead by the time the condition is diagnosed. The cause for uterine rupture, allowing the escape of the fetus into the abdominal cavity, is frequently unknown. The condition is seen in uterine torsion, fetal emphysema, chronic perimetritis with adhesions and following dystocia and oxytocin administration especially in the bitch.^{3,4} It may occur spontaneously or possibly associated with violence or trauma in advanced pregnancy. In multipara, uterine torsion may involve a part of one horn or the entire horn with the enclosed fetuses being separated from the rest of the uterus. The adhesions that take place may cause the condition to be diagnosed as an extrauterine pregnancy or fetus. In many cases in domestic animals in which a sterile fetus is released into the abdominal cavity little or no external symptoms may be evident. The fetus dies and with its membranes becomes walled off as a sterile foreign body in the ventral portion of the abdominal cavity and remains there as an inert mass for months.^{1,6,7} Often extensive adhesions between it and other abdominal viscera develop. The site of the rupture may only be a small or invisible scar after the uterus involutes. Since most of these fetuses are well-walled off, no external symptoms are usually seen. Occasionally mild digestive disturbances may be evident. In rare cases a large extrauterine fetus may be diagnosed on rectal examination in the cow if the fetus was near term when it escaped from the uterus.

A differential diagnosis must be made, considering mummification of the fetus, tumors, and fat necrosis. Diagnosis of most cases in the larger domestic animals is made at the time of slaughter. In the dog and cat abdominal palpation, radiographs and exploratory laparotomy may aid in revealing the extrauterine fetus(es) especially in an ailing animal soon after parturition. Reports would indicate that secondary extrauterine pregnancy and extrauterine fetuses occur more commonly in queens than in bitches.^{1,6} These fetuses may be or become infected, macerate, cause peritonitis and the death of the dam or rarely be walled-off and be expelled into the alimentary tract or through the abdominal wall.^{3,8}

If extrauterine fetuses are diagnosed in large animals the prognosis is guarded and the animal is usually slaughtered. A laparotomy operation to remove the extrauterine fetus would be difficult and many adhesions would remain. In the dog and cat an operation might be considered in cases of chronic, walled-off extrauterine fetuses.

In animals with uterine rupture late in pregnancy or at the time of parturition, secondary to trauma, torsion, fetal emphysema or possibly spontaneous rupture, the fetus and uterine contents escape into the abdominal cavity. If the fetus is emphysematous or grossly infected, fatal peritonitis and shock frequently follow. In rare cases the fetus may still be found alive and the dam and possibly the young can be saved by an immediate laparotomy to remove the dead or live fetuses and repair the ruptured uterus.

In the mare a rotated or compound bicornual pregnancy may be confused with an extrauterine fetus. In this condition the birth passageway is very long and the fetus may be palpated beneath the stretched vagina and uterine body and simulate an extrauterine fetus. In humans some long-existing extrauterine fetuses become quite firm and encapsulated with calcium laid down in the capsule, causing them to be spoken of as lithopedions. These well-encapsulated extrauterine fetuses in animals may occasionally be referred to as extrauterine fetal mummies.

Dropsy of the Fetal Membranes and Fetus

These pathologic conditions in pregnant domestic animals may include hydramnios, hydrallantois, edema of the allantois chorion, fetal anasarca, or fetal edema with ascites and hydrothorax. These conditions are usually found singly but on rare occasions may be associated. In hydramnios and hydrallantois in uniparous animals the abdomen is usually distended as if twins or triplets are present. All cows in which twins are suspected should

be examined promptly for these possible dropsical conditions. Of these conditions hydramnios and hydrallantois are most common with the latter occurring 10 to 15 times more frequently than the former. In 7 percent of cases both hydramnios and hydrallantois were present together.²³

Hydramnios or hydrops of the amnion is characterized by a gradual enlargement or filling of the amniotic cavity that is associated with a genetic or congenitally defective fetus. The condition is seen most commonly in cattle, occasionally in sheep, rarely in pigs and carnivores, and it has not been reported in horses.³ It may affect one of twin fetuses. At midgestation the amniotic fluid is watery and slightly yellow and in normal bovine conceptuses only increases in amount very slowly until the last month of pregnancy when it nearly doubles in amount.^{1,3,4} In normal sheep there is a sudden increase around the 100th day of pregnancy. From mid-gestation onward the amniotic fluid becomes more viscid and glairy because the early watery fluid is swallowed or possibly inhaled into the large bronchi and absorbed and a large volume of saliva is continually produced. In defective fetuses swallowing is impaired and the amounts of amniotic fluid increase gradually to 5 to 30 gallons. Hydramnios is not solely due to a failure of deglutition in the fetus as other mechanisms besides swallowing regulate the volume and composition of amniotic fluid.²⁵ During the last few months of gestation, when hydramnios becomes apparent, the amount of amniotic fluid in normal cows is only 1 to 2 gallons.

Genetic or hereditary conditions resulting in defective fetuses often associated with hydramnios are: 1) Dexter cattle pregnant with "bull dog" calves. In these animals the disease is apparent at 3 to 4 months of pregnancy.⁷

Figure 77. Jersey cow about 7 to 8 months pregnant affected with hydrops and a transverse rupture of the abdominal muscles 8 inches cranial to the pubis. The cow was unable to stand.

Figure 78. Same Jersey cow with marked ventral hernia with signs of rupture of the prepubic tendon two weeks after a cesarean section.

2) Angus cattle pregnant with small brachygnathic, defective calves with osteopetrosis. These exhibit increased abdominal enlargement the last month of gestation. 3) A muscle contracture monster associated with hydrops of the amnion has been described in Red-Danish cattle.¹² 4) Prolonged gestation in Guernsey cattle characterized by an immature defective small fetus with pituitary hypoplasia or aplasia may be associated with hydramnios. 5) A lethal muscle contracture monster in sheep accompanied by dropsy of the amnion has been described.¹⁸ Hydramnios was commonly observed with hydrocephalic fetuses in Hereford cattle.^{5a} All of the above defective fetuses have been caused by recessive autosomal genes (See chapter on Anomalies of the Fetus). Hydramnios is also seen in cattle with congenitally anomalous fetuses such as conjoined twin monsters, **Schistosomus reflexus**, and fetuses with anomalies of the cranial portions of the body. Hybrids produced by mating of an American bison bull with a domestic cow resulted in hydrops of the amnion.²⁴ Anencephaly is frequently the cause of hydramnios in women.⁶

Hydramnios develops slowly over several months during the latter half of pregnancy. If the condition causes obvious abdominal enlargement it is usually the last month or six weeks of the gestation period. Often the condition is not recognized until parturition when large quantities of syrupy, viscid amniotic fluid, occasionally containing meconium, is released. The differential diagnosis between hydramnios and hydrallantois has been described. (See Table 14.) The prognosis for the future breeding life of the dam is fair to good in hydramnios but the fetus is invariably defective and dies. Retention of the placenta and metritis are not serious problems as with hydrallantois. Abortions and premature parturitions are frequent in cases of hydramnios. Because of the enlarged

Table 14. The Differential Diagnosis Between Hydrallantois and Hydramnios in Cattle

Hydrallantois	Hydramnios
Occurs in 85 to 90% of cases of uterine dropsy.	Occurs in 5 to 10% of cases of uterine dropsy.
Abdominal enlargement develops rapidly within 5 to 20 days.	Abdominal enlargement develops slowly over weeks and months.
Abdominal wall is round, distended and tense.	Abdominal wall is pear-shaped and less tense.
Distended horns of uterus easily palpated per rectum and fill the abdominal cavity.	Uterine horns hard to palpate, not very tense and don't fill the upper and caudal abdominal cavity area.
Fetus and placentomes are not able to be palpated or ballotted per rectum or through the abdominal wall.	Placentomes and often the fetus may be palpated per rectum and the latter may occasionally be ballotted through the abdominal wall.
Sporadic in incidence.	Usually sporadic but in an inbred herd may have a number of cases.
Allantoic fluid is watery, clear and amber, with characteristics of a transudate.	Amniotic fluid usually syrupy and viscid, and often contains meconium.
Fetuses are normal but small twins are occasionally present.	Associated with a defective, small, anomalous fetus.
Placenta, especially the allantois chorion, is usually diseased and abnormal with a reduced number of greatly hypertrophied placentomes.	Placenta, allantois chorion and placentomes normal.
After removing much fluid by caesarean section or by allantocentesis, the allantoic cavity rapidly fills again.	After removing much fluid by caesarean section or by amniocentesis, the amnion does not refill in the former and only slowly in the latter.
Retained placenta and severe metritis usually occurs.	Retained placenta may occasionally occur and metritis is much less common or severe.
Sequelae such as uterine rupture, abdominal hernias and dislocation of the hips are common in severe cases.	Adverse sequelae are rare due to gradual onset and the nature of the disease.
Prognosis—guarded to poor for life and fertility.	Prognosis—fair to good for life and fertility.

uterus, uterine inertia, and defective fetuses, dystocia at parturition is not uncommon. It is usually easily handled because of the small size of the fetus. In hydramnios associated with prolonged gestation and fetuses with defective or missing pituitary glands injections of large repeated doses of glucocorticoids, prostaglandins, and estrogens might be indicated to produce abortion or parturition. If the fetus is dead, glucocorticoids are of questionable value.^{4,19,21} Combinations of these hormones may avoid repeated large doses of a single hormone. Further trials are indicated. Cesarean section, as described under hydrallantois, can also be used to terminate a pregnancy with hydramnios. The genetic implication in salvaging an affected dam should be considered. If the defective fetus and hydramnios is due to a recessive gene then the dam and sire are carriers. Such animals should be eliminated from the herd and any inbreeding in the herd should be discouraged.

Hydrallantois, dropsy or hydrops of the allantois, is the single factor present in 85 to 90 percent of the dropsical conditions affecting the bovine fetus and its membranes. This condition is seen sporadically in dairy and beef cattle. It is often associated with a diseased uterus in which most of the caruncles in one horn are

not functional and the rest of the placentomes are greatly enlarged and possibly diseased. Adventitious placenta are commonly observed. Portions of the placenta may be necrotic and edematous. Hydrallantois is seen quite commonly in cattle carrying twin fetuses or greater multiples. Hydrallantois apparently is caused by structural or functional changes in the allantois chorion including its vessels with transudation and collection of fluid, differing from normal allantoic fluid but resembling plasma.²⁰ One may remove many gallons of this transudate from the allantoic cavity with a trocar but within 2 to 4 days it has been restored. This would tend to indicate that the fetal kidneys probably seldom play a role in causing this disease. The presence of cystic kidneys, hydronephrosis, or dysfunction of the fetal renal tubules resulting in polyuria might be concerned in the pathogenesis of hydrallantois.¹⁶ The author has seldom observed such abnormalities in the fetal kidneys of fetuses from affected cows and further suggests these changes are probably secondary to the hydrallantois. Torsion of the uterus and torsion of the umbilical cord are not associated with this condition. The navel cord in the cow is short and seldom twisted. In the mare torsion of the umbilical cord may occur and be severe enough to cause the death of the

fetus but dropsy of the fetal membranes and fetus rarely occur. The author and others have observed mares with hydrops allantois that spontaneously aborted a small defective fetus. In one case there was evidence of moderate umbilical torsion with an area of adhesion between the amnion and chorioallantois. This condition appeared to be more prevalent in cattle in seasons when forage has been damaged, with a possible loss of vitamin A resulting in a lowered resistance of the endometrium to disease.^{13,24} In cases of hydrallantois associated with a reduced number of placentomes and uterine disease the fetuses are usually growth-retarded and show some edema and ascites. Hydrallantois usually affects cows 3 or more years of age although rarely the condition may be seen in heifers in which possibly a congenital lack of uterine caruncles was present. In older cows this lack of caruncles characteristic of hydrallantois may be due to prior uterine infection or even tuberculous metritis.³

The signs of dropsy of the allantois vary depending on the degree of the involvement and the stage of pregnancy. In mild cases, where the amount of fluids is moderate, 10 to 20 gallons, the condition may not be diagnosed until parturition. At this time an excessive amount of clear, watery, amber fluid with the characteristics of a transudate is expelled. The fetal membranes may be tough and rupture with difficulty. The uterus is greatly enlarged and atonic and the small, growth-retarded fetus may exhibit some edema and ascites. Dystocia may result at the time of abortion or parturition due to uterine inertia. The fetus is usually dead at birth or dies shortly thereafter. Retention of the fetal membranes and septic metritis are common sequelae to this dropsical condition. In severe cases, symptoms of hydrops of allantois may occur as early as the fifth month of pregnancy but nearly all cases develop the last 3 months of gestation.⁴ Hydrallantois usually develops rapidly within 5 to 20 days and is characterized by a distended uterus and enlarged abdomen (See Figure 77). Spontaneous abortion at 6 to 9 months may frequently be observed.^{21,23} In the more severe cases the amounts of fluid may reach 30 to 60 gallons. The fetal membranes may be heavy and edematous and the cow frequently has ascitic fluid in her abdominal cavity. Thus the weights of the dropsical fluids, membranes, and uterus frequently total 350 to 550 lbs. This excessive volume of fluid distending the abdomen causes the owner to believe his records of breeding dates are wrong or else the cow is going to have triplets. Later, digestive symptoms with anorexia, lack of ruminations, and constipation are noted. The condition is frequently misdiagnosed as indigestion, bloat, or traumatic gastritis. The cow may drink excessive amounts of water. The temperature is normal. The pulse is elevated to 90 to 140

per minute and is weak and wiry. The cow may exhibit anxiety, restlessness, and an expiratory grunt. Because of the excessive volume of fluid, the fetus can seldom be ballotted or felt per rectum. On rectal examination the uterus is greatly distended and tense. Placentomes can seldom be felt, due to the tense uterine wall, but the uterine arteries are "whirring" indicative of a live fetus. The uterus appears to fill the abdominal cavity. As the condition progresses—and it may progress quite rapidly at any time during the last trimester of pregnancy—the abdomen becomes more distended. The gait is stiff, slow, and cautious. The cow loses body condition, and eventually is unable to rise. Dislocation of the hips or backward extension of the rear limbs may occur and the cow lies on her sternum looking like a "bloated bull frog" (See Figure 77). Rarely in the cow and mare rupture of the prepubic tendon or ventral hernia may occur due to the excessive weight of the uterus. Rupture of the uterine wall has also been described.^{9,17,23} For a differential diagnosis between bovine hydrallantois and hydramnios see Table 14.

In mares hydrops allantois is rare.²² It may occur in mares of any age. The condition becomes evident the last trimester of gestation with signs similar to those observed in cows. Dystocia and retained placenta secondary to the uterine inertia caused by the greatly distended uterus is common. The fetus in affected mares is often defective, growth retarded and some may exhibit hydrocephalus but while most all are alive at delivery, they invariably die within a short time. Other dropsical conditions affecting the fetus are much less common.

Edema of the allantois chorion characterized by extensive and severe edema distending these tissues to a thickness of 4 to 6 inches has been associated with **Brucella abortus** infection causing placental disease in cattle and therefore is rarely seen at present in the United States. Hydrallantois is rarely associated with **Brucella abortus** infection.

Fetal ascites severe enough to cause dystocia may also rarely be due to **Br. abortus** infection. Slight fetal ascites and edema as well as mild placental edema is frequently associated with intrauterine fetal death and sterile autolytic changes.

Fetal anasarca or excessive edema of fetus is seen most commonly in cattle but may affect sheep. It may develop in a single fetus or one of twins. It is also rarely observed in one or two of a litter in swine or carnivores. Rarely mild hydrops of the amnion and/or allantois and edema of the placenta may accompany fetal anasarca. Abortions of affected fetuses are fairly common from 4 to 8 months of gestation in uniparous animals. The condition has been described affecting Ayrshire cattle.⁸ This

is caused by a recessive autosomal character. Most anasarctic fetuses were expelled dead. In all of these latter conditions with the possible exception of edema of the allantois chorion, enlargement of the abdomen is not noted.

The prognosis for hydramnios is fair to good for the dam unless she is a carrier of a recessive gene responsible for the defective fetus producing the condition. Salvage of the defective fetus is usually impossible. In many of these cases following induced abortions or caesarean section the placenta is often expelled or if it is retained, metritis associated with uterine inertia is not as severe as that following hydrallantois. The prognosis in cases of hydrallantois is poor. In advanced cases in which the cow is unable to rise, the prognosis is often hopeless. Even if the fetus can be removed, the mortality in cows is high, because the uterus is very atonic, the membranes diseased, and shock or severe septic metritis usually follows the expulsion or removal of the fetus. If the cow should survive, its future reproductive life is questionable. In almost all cows with hydrops except the occasional slight or moderate one that goes to term and spontaneously delivers, the fetus dies *in utero* or soon after birth. Milk production in dairy cows for the next lactation after either hydramnios or hydrallantois is usually poor. Dropsy of the allantois at term is often associated with dystocia due to a dead edematous fetus in an abnormal position or posture, uterine inertia, and a cervix that may fail to dilate completely. If the dystocia is not handled promptly emphysema of the fetus soon develops. In the rare cases of hydrops allantois seen in mares the prognosis is guarded but better than in cattle unless rupture of the prepubic tendon occurs. The prognosis in rare cases of edema of the allantois chorion is similar to hydrops allantois. In both severe fetal ascites and fetal anasarca, dystocia usually results at the time the overly large fetus enters the birth canal, whether the fetus is aborted or expelled at term.

The treatment or handling of cases of hydramnios and hydrallantois varies with the duration and severity of the condition. In mild cases undiagnosed until the time of abortion, premature birth or at normal parturition, excessive volumes of fluids are observed accompanied by the presence of a poorly viable, small, growth-retarded or defective fetus, dystocia related to the diseased or dead fetus, and uterine inertia secondary to the uterine distention. Mutation and forced extraction of these fetuses is usually easily effected. In mares about one-half of the cases terminate by spontaneous abortion or birth at or near term.²² In cases of fetal anasarca or ascites greater amounts of traction and lubrication may be needed. In a few cases fetotomy might have to be resorted to in

order to mutilate the fetus to allow the excess fluid to escape. Retained placenta and a secondary severe metritis frequently follows hydrallantois and edema of the allantois chorion but is less frequently observed and is less severe in hydramnios. Early treatment for these conditions with parenteral and local antibiotics and ecbolics such as oxytocin, stilbestrol and ergonovine are indicated.

In severe cases of hydramnios and hydrallantois occurring during the gestation period with a closed cervix, the prompt termination of the abnormal pregnancy is usually desired. In some slowly developing cases late in gestation it may be expedient to observe the cow or mare and wait for or induce parturition. In other severe cases an early decision to slaughter the cow while she is still in good physical condition is often the best method of handling these cases when all factors are considered. Daily administration of large doses of stilbestrol, 50 to 120 mg., or estradiol, 8 to 10 mg. for 4 to 7 days alone or together with large doses of prostaglandins, and glucocorticoids and antibiotics may frequently result in cervical dilation and abortion.^{4,14,15,19,21,23} Precipitating abortion is more successful with hydramnios than hydrallantois. Because the uterus is atonic and distended and the cervix usually dilates poorly, the cow should be watched carefully. The abortion should be aided when necessary. Pituitrin or oxytocin may be given but its effect may be negligible because of the atonic, stretched, and diseased uterine wall.

In the mare abortion or premature birth may be induced by manual dilation of the cervix, rupture of the usually thick, tough allantois-chorion and very slow drainage of the allantoic fluid to prevent shock. Oxytocin, 50 units, in a liter of saline given slowly intravenously, and repeated if necessary, to aid uterine contraction and delivery as well as promote expulsion of the placenta has been recommended.²² Injection of estradiol, 20 mg., 24 hours before induction of abortion might be indicated to promote relaxation of the cervix and genital tract. Manual removal of the fetus is usually necessary. Cesarean section has been attempted in many cases with success but in some the cow succumbs. Various authors^{5b,10,16} have recommended the use of a sterile trocar or plastic tube inserted by a surgical procedure through the abdominal and uterine walls to draw the fluid off gradually at a rate of one liter per minute before the Cesarean is performed. This helped to avoid possible shock from removing too much fluid too rapidly. The draining of 25 to 50 liters of allantoic fluid often induces abortion within one to three days. In a few cases it may be indicated to repeat this treatment.^{5b} Since most severely affected cows are very dehydrated with marked electro-

lyte imbalances, appropriate fluid therapy in large volumes is indicated before, during and after the operation. Once the cow is down and unable to rise due to the weight of the fluid, any treatment is usually unsuccessful because of complications such as abdominal hernia, severe myositis and nerve damage or dislocated hips. Following the relief of these severe dropsical conditions metritis usually associated with retained placenta almost invariably follows. The severity of this metritis varies with the severity of the condition and is a common cause for the high mortality. In all hydrops cases the treatment for septic metritis should begin before or at the time the condition is relieved with supportive fluid therapy, antibiotics, both parenteral and locally in the uterus and frequent injections of ecbolics. Since treatment of this condition is not very successful, most of the more severe cases are sent to slaughter as soon as they are diagnosed. This is especially true if the cow is of only moderate value. Three cases of hydrops allantois were successfully corrected by Cesarean section after slowly draining off 20 to 30 gallons of allantoic fluid in the one-half hour before the Cesarean operation.^{4b} The pulse and respirations were monitored and Ringer's solution with dextrose was administered intravenously during the operation. Subsequent treatment with estrogens, antibiotics and further supportive therapy was necessary to control metritis as the placenta was retained for up to three weeks. It was recommended that the cows not be rebred. If more than 1 or 2 cases of hydramnios occur in a herd the hereditary nature of this disease should be suspected and investigated, and further inbreeding prevented.

An interesting observation is that after terminating hydrops of the allantois by cesarean section the uterus may continue to fill with transudative fluid for about 48 hours and require further draining.¹⁵

Abdominal Hernias Resulting in Hysterocele

The pregnant uterus may drop into, or be present in, umbilical, inguinal, perineal, diaphragmatic, or ventral hernias. In cases of rupture of the prepubic tendon, the pregnant uterus will drop into the sac formed by the skin and cutaneous muscles. This may cause dystocia or death of the fetuses or dam or both.

Umbilical and inguinal hernias may, if large enough, contain a portion of the uterine horn and developing fetus. **Umbilical hernias** have been described as hereditary in all species of animals. In cows most of them are small. Such animals should not be used as breeding animals. Umbilical hernia in cattle, especially Holsteins, is probably an autosomal dominant with low pene-

trance.^{4b} Most female animals with large umbilical hernias are not bred. In males an umbilical hernia may prevent copulation. **Inguinal hernias** are hereditary or acquired and are described as common in the bitch, and rare in the queen, sow and mare. They have not been described in the cow or ewe. Bitches over 5 years of age are most commonly affected.¹⁰ Spayed bitches given large amounts of estrogen developed inguinal hernias within 90 days.⁸ One bitch with an inguinal hernia was spayed through a midline incision and the hernia was left intact. One year later the hernia had spontaneously disappeared. These observations indicate a close relationship between estrogen production by the ovary and the development of inguinal hernia in bitches. Inguinal hernias may be bilateral or unilateral, usually the latter, and are characterized by a swelling in the inguinal region. This becomes larger as pregnancy progresses if a portion of the pregnant uterine horn is present in the hernial sac. In the bitch one to three fetuses may develop in the hernial sac. If pregnancy is allowed to progress it results in the death of the fetuses or in dystocia at the time of parturition. In the bitch this condition should be differentiated from a mammary neoplasm and a local abscess. **Diaphragmatic hernia** is usually secondary to trauma in the bitch and other multiparous female animals and in rare cases a pregnant uterine horn may be present in the thoracic cavity.^{6,9} A **perineal hernia** containing a portion of the fetus has been described in the goat.¹ **Ventral hernias** are usually traumatic in origin and may occur in all species. In the mare they may occur at the time of parturition in the caudal, ventral abdominal area just lateral to the midline. If possible, surgical repair should be delayed several months or more until the edges of the hernial rupture have healed and organized.⁷ If they are large a portion of the uterine horn and fetus may develop therein. If ventral hernias in large animals are extensive they are difficult if not impossible to repair. Fortunately, in large animals the uterus in early pregnancy does not drop far enough downward or forward to drop into most hernial sacs and in later pregnancy the uterus is too large to enter them.

In the bitch, an inguinal hernia containing a portion of a pregnant horn can be handled surgically early in pregnancy by reducing and repairing the hernia, if necessary by enlarging the ring and/or using a synthetic mesh for a lasting support. From midpregnancy to near term, hysterotomy can be performed and the fetus or fetuses removed, the uterus replaced in the abdominal cavity, and the hernial ring sutured. Occasionally the portion of the herniated uterine horn containing fetuses may be removed by a partial hysterectomy. In other cases ovari-hysterectomy may be indicated. The rare cases of um-

bilical or ventral, diaphragmatic or perineal hernias encountered containing a portion of the pregnant uterus could be handled in a manner similar to the repair of inguinal hernias.

Extensive unilateral ventral hernias in large animals occur occasionally in advanced pregnancy in cows, ewes, and does, but rarely in mares. These hernias are usually due to trauma. The greatly increased weight of the gravid uterus and fetus, and possibly other changes, weaken the abdominal floor. These extensive hernias are seen most commonly in ruminants on the right side of the abdominal floor. They are observed most often on the left side in the mare.² In rare instances they may be associated with twins or greater multiples or with hydrops of the amnion and allantois. Large unilateral ventral hernias are characterized by a unilateral ventral sagging of the abdominal floor, 6 to 8 inches or more below that of the normal side. Calving or foaling may be difficult because of the inability of the abdominal muscles to contract equally and strongly and force the fetus toward and through the birth canal. Following calving, the abdominal floor of the affected side may retract in some cattle and the abdominal contour become nearly normal. This may occasionally remain normal during subsequent pregnancies. However, it usually recurs during the latter stage of each gestation period. The involvement is so great that treatment or operations other than those outlined under rupture of the prepubic tendon are not indicated.

Rupture of the prepubic tendon or prepubic desmorrhaxis of pregnancy is seen most commonly in the mare, and rarely in the cow and ewe. This condition is seen most frequently in the draft mare that is idle and well-fed, and infrequently in light mares. It is rare in

Figure 80. Acute rupture of the prepubic tendon in a mare.

cattle because the subpubic tendon, a structure that does not exist in horses, gives added support to the prepubic tendon.⁴ (See Figures 78, 79, 80.) Rupture of the prepubic tendon occurs during the last 2 months of gestation. In the mare and occasionally the cow it is often preceded by a marked tense, painful edema, 6 to 14 cm. thick, on the abdominal floor, starting at the udder and extending to the xiphoid region. Severe edema of the abdominal floor in the mare in advanced pregnancy should always be viewed seriously. Physiological edema of the abdominal floor in the cow is common and does not indicate a possible weakness or rupture of the abdominal floor as in the mare. Rarely massive hematomas in the region of the bovine udder may be mistaken for rupture of the prepubic tendon.⁵ (See Figure 81.)

The rupture is predisposed by the increased weight of the gravid uterus on the abdominal floor and possible degenerative changes due to the edema and the weight. Occasionally, due to violence or trauma, the condition

Figure 79. Impending rupture of the prepubic tendon in an old mare. A proper support has been applied.

Figure 81. A massive hematoma cranial and dorsal to the mammary gland of a pregnant cow resembling a rupture of the prepubic tendon.

occurs suddenly without the development of edema. Twins or greater multiples,³ hydrops of the fetal membranes, fetal giants in prolonged gestation, as in *Veratrum* poisoning in ewes, favor rupture. In this condition there is a transverse rupture of the prepubic tendon, the ventral abdominal muscles, abdominal tunic, and peritoneum letting the viscera and gravid uterus drop downward into a sac formed by the skin and cutaneous muscles. Only very rarely does complete eventration occur. In rupture that occurs suddenly due to violence, besides the sudden enlargement in the ventral abdominal region and the sinking of the flanks, there usually occurs intense pain and colic together with a cold sweat, fast respirations, rapid weak pulse, and a tendency toward collapse due to shock, and possible hemorrhage (see Figure 80). Occasionally a mare and her intrauterine fetus will perish at this time despite supportive treatment of blood, saline, stimulants, and support for the abdominal wall. In most cases the onset is more gradual, with a preceding painful edema of the abdominal floor, a stiff, careful, cautious gait, and refusal to lie down. After rupture has occurred the udder and teats are stretched forward and downward on the abdominal floor. The attitude is a typical "saw-horse" one, with an elevation of the tail head and the ischial tuberosities and a lordosis. The pelvis is tilted backward because the prepubic tendon is not intact to maintain the pelvis in its proper relationship to the spinal column.

The prognosis in rupture of the prepubic tendon is always poor, as most mares and foals succumb before foaling occurs. If foaling should terminate successfully the mare's condition will improve, and she might do light work; but usually the mare is so unsightly that she is destroyed. Rebreeding these mares is definitely not indicated. Affected cows are usually sold after calving and lactation because of difficulty in milking and because rebreeding is contraindicated.

Treatment is usually unsatisfactory, once rupture of the tendon has occurred. Preventive treatment of mares showing marked edema of the ventral abdominal floor and a stiff cautious gait should consist of confining the mare in a large comfortable box stall and restricting exercise. Large bulky feeds should be withheld and a light concentrate ration should be fed. In some mares mild laxatives might be indicated. A suitable heavy, wide canvas webbing should be tightened securely with straps around the abdomen, to transfer the weight of the abdominal viscera to the spine. Padding over the back usually is necessary to prevent pressure necrosis. (See Figure 79.) The mare should be watched closely for the beginning of parturition so that aid may be given at once and the fetus withdrawn by traction. This aid is neces-

sary since abdominal contractions are very weak and parturition cannot take place without aid and direction. In most cases uterine contractions and cervical dilation may take place but since the fetus does not engage or enter into the pelvic cavity, abdominal contractions, or labor do not begin. Periodic vaginal examinations may be necessary. In some cases the wide band in a horse sling to support the abdominal viscera may be useful and the mare can be kept standing. Possibly parturition should be induced in the mare in late pregnancy by the injection of estradiol and 30 to 40 units of oxytocin. Another possibility in these mares is cesarean section which, though often successful permits the fetus to be saved, while the affected mare is usually destroyed. This latter procedure is indicated in sudden rupture, with impending collapse and death of the mare. In the cow abdominal support or slings are not tolerated. Induction of premature birth by the administration of large, repeated doses of glucocorticoids, prostaglandins and estrogens in the cow is usually successfully accomplished with fewer complications than a cesarean operation. By confinement and careful observation, the fetus may be promptly withdrawn by traction. In the cow cesarean section is more successful than in the mare and may occasionally be indicated in this condition. In relieving dystocia due to rupture of the prepubic tendon, rolling the cow or mare on its side or back will aid in bringing the fetus to the pelvic inlet for removal. If the mare is in a standing position, horse slings may be applied and tightened to bring the fetus near the pelvic inlet.

Torsion of the Uterus

Torsion of the uterus may occur in all species of animals. Uterine torsion is usually defined as the revolution or twisting of the uterus on its long axis. This might be true in the mare, where torsion of the uterus is uncommon due to the dorsally attached broad ligaments that tend to prevent torsion. In other species of animals such as the cow, ewe, and doe, the gravid horn is in the shape of an arc or a U-shaped loop with the vagina and ovary at the respective ends of the arc. Torsion involves the rotation of this arc on its transverse axis, similar to an intestinal volvulus. This same type of torsion occurs in multipara when one horn rotates at its base. A modification of this same volvulus type of torsion occurs in multipara when only a portion of one horn, containing usually only one fetus, may be twisted or rotated. In unipara, because of the strong intercornual ligament and the distention of the uterine horns and body with placenta and fluid, both gravid and nongravid horns are in-

volved in the torsion. Torsion involving both horns of the uterus cannot occur in the bitch and queen.²

Torsion of the uterus is most commonly observed in dairy cows and is occasionally seen in beef cows, bitches, queens, ewes, does and mares and rarely seen in the sow.^{4,15} Two rare cases of torsion of both uterine horns in sows were reported.¹⁵ Uterine torsion was reported to be more common in draft mares than in light mares.¹ The incidence of uterine torsion in dairy cattle was 7.3 percent in 1555 dystocia cases treated over a 10-year period in the Ambulatory Clinic of the New York State Veterinary College. The incidence of uterine torsion may vary from 1 to 3 percent in Australia to 18 to 25 percent of referred cases in England, Germany and Switzerland.^{5b,10} Uterine torsion is rare in the *Bos indicus* type of cattle.

The possible causes for torsion of the uterus in the cow are many. The lesser curvature of the uterus in advanced pregnancy is supported dorsal laterally by the mesometrium. The greater curvature lies free in the abdominal cavity resting on the abdominal floor and supported by the rumen, the viscera, and the abdominal walls. The ovarian end of the gravid horn of the bovine uterus is a relatively small or narrow base upon which the uterus rests. If the nongravid horn is small or nonfunctional the instability of the uterus is increased. This anatomical arrangement, together with the manner in which the cow lies down, with the fore quarters going down first, and rises, by elevating the rear quarters first, so that each time the cow lies down or rises the gravid uterus is suspended in the abdominal cavity, means that a sudden slip or fall in either lying down or rising could cause torsion. Other factors aiding torsion of the uterus in advanced pregnancy are lack of fetal fluids, and violence such as sudden falls or rolling. In bitches and queens this latter factor is probably important. Confinement in stables for long periods favors torsion in the cow. The incidence of torsion as a cause of dystocia in pastured cattle was 2.7 percent and in stabled cattle 8.6 percent.¹⁶ In the experience of many veterinarians in New York State most of the cases of uterine torsion occur during the early spring months after cows have been stabled for 4 to 6 months. Torsion is observed more commonly in pluriparous than in primiparous animals. A lack of tone of the pregnant uterus—a condition composed of a lack of fluids, flaccid uterine walls, a small nongravid horn, a long flaccid mesometrium—favors uterine torsion. A deep capacious abdomen predisposes to uterine torsion. Twins in ruminants tend to prevent torsion by making a broader base for the uterus to rest upon and by filling the abdominal cavity. However, 5 of 10 cases of uterine torsion in ewes were in bicomual twin pregnancies^{5b} even though the ovine

mesometrial attachment is sublumbar as in mares.¹ In some cases strong movements of the fetus in the early stages of parturition probably can cause uterine torsion.

Uterine torsion is observed most commonly in advanced pregnancy. However, cases of uterine torsion in the cow have been observed from 70 days of gestation to term. Torsions occurring before the seventh month of pregnancy in the cow are unusual. Several cases in cows¹⁶ and queens¹² have been recorded in which uterine torsion occurred in nonpregnant uteri containing purulent exudate. Most bovine torsions occurred during the early part of the second stage of labor or the latter part of the first stage.¹ This conclusion was based on observations that the cervix is found to be dilated immediately after the torsion is relieved in most of the bovine dystocia cases due to torsion of the uterus. In only occasional cases is there a severe edema due to venous congestion or other circulatory disturbance in the uterus or its contents. In cases diagnosed early the fetus may still be alive. Uterine torsion at this time may be favored by unequal contractions of the uterus or by active movements of the large bovine fetuses.¹ These movements are greatest during the first stage and early second stage of parturition. One mare developed uterine torsion immediately after a period of intense fetal activity.⁸ Probably other factors may be involved in the torsion, as it appears difficult for either uterine contractions or fetal activity alone to produce torsion.

Uterine torsions of cattle of 180° may occasionally be present for days or weeks without clinical symptoms until labor begins and dystocia results. In these cases¹⁶ and the occasional similar cases observed by the author, no evidence of circulatory interference was present. If circulatory interference of the blood supply to the uterus was present, acute clinical symptoms and death of the fetus would probably occur. During pregnancy 45° to 90° torsions or rotations of the uterus are rather frequently found on rectal examination. These often appear to correct themselves before or at parturition.

For the above reasons this writer believes that some cases of bovine uterine torsion of 90 to 180° occur during the last few months of gestation, persist for days, weeks or months and only become evident at the time of parturition. In unusual instances torsion of the uterus may involve a 360° or more rotation of the uterus. One author cited a case involving two complete turns.¹⁶ In torsions of greater than 180° to 240° the birth canal at parturition is usually tightly closed, so that the cervix and the fetus are not palpable per vagina. These severe torsions may cause obstruction of the blood supply to the uterus, with resulting congestion, edema, shock, death of the fetus, and even gangrene of the uterus. In neglected cases

transverse rupture of the uterus or vagina, emphysema and maceration of the fetus, shock, collapse, and death may occur. In rare cases one of the large uterine vessels may rupture, followed by severe hemorrhage into the abdominal cavity. In the bitch transverse rupture of the twisted segment of the uterus often occurs at parturition when the uterus contracts and the fetuses are released into the abdominal cavity. Rarely uterine torsion may be associated with mummification of the fetus late in gestation, instead of emphysema and maceration.

In torsion in cows, ewes and does the cephalic portion of the vagina is usually twisted. Occasionally in a uterus lacking fluid or tone the torsion may occur cephalad to the cervix and in severe torsions at the time of parturition the twist may actually involve the cervix. In multiparous animals, since there is no intercornual ligament, usually one entire horn rotates at the point of its junction with the body and the other horn. Occasionally only a portion of the horn is involved, the twisted portion may occur anywhere throughout the horn. In rare cases in multipara in which both uterine horns are involved in the torsion, the cranial portion of the vagina is twisted. There are a number of reports in the literature on multipara in which the twisted portion of the horn or the entire horn with its fetuses separated completely from the body of the uterus during pregnancy. The fetuses may rupture from this blind sac into the abdominal cavity at the time of parturition, or this separated portion of the horn may be walled off as a passive body in which the fetus or fetuses may macerate or mummify.

Torsions in uniparous animals are either torsions to the right (clockwise) or to the left (counter-clockwise). Most authors agree that left torsion occurs more often than right.^{1,5b,10} If the right horn is gravid the torsion is apt to be to the right.¹⁰

The signs, prognosis, and handling of torsions causing dystocia at the time of parturition will be discussed later. The following paragraphs will deal with the symptoms and prognosis of severe torsions during the gestation period that may be recognized prior to parturition. Although treatment of these antenatal torsions will be mentioned at this time they are similar for torsions resulting in dystocia and so will be discussed in detail in Chapter 10.

The symptoms of torsions of the uterus in the cow prior to parturition may be completely lacking if the torsion is of a mild degree, 45° to 90° or even 180°. When the torsion is 180 degrees or more, definite signs of abdominal pain usually may be noted, such as anorexia, constipation, lack of ruminations, weak and slow rumen contractions, rapid pulse rate, restlessness or colicky symptoms, treading, and tail switching. These symp-

toms may be confused with traumatic gastritis, indigestion, pyelonephritis, or intestinal intussusception. Uterine torsion during pregnancy in the ewe is characterized by a stiff, stilted gait and a stretched, "sawhorse" attitude resembling signs of peritonitis and intussusception or volvulus.⁶ Whenever any cow over six months pregnant shows these suggestive symptoms, a rectal examination should always be made to determine if torsion of the uterus is present. In right torsion the right broad ligament is pulled strongly downward and under the twisted uterine body or vagina, and the left broad ligament is pulled tightly across over the top of the cervix, the body of the uterus, and the vagina, toward the right side. In counter-clockwise, or left torsion the location and direction of the two broad ligaments is reversed, with the right broad ligament crossing over the top of the twisted portion of the birth canal (See Chapter X). The uterine arteries on both sides are tightly stretched. The amount of tension on the broad ligaments and arteries will help determine the severity of the torsion. The fetus is often difficult to palpate but the position of the fetus in the uterus in advanced pregnancy may further indicate the degree of torsion. A dorso-pubic position of the fetus usually occurs when the torsion is 180°. A rectal examination is preferred over a vaginal examination because occasionally the twisted portion of the genital tract may lie cephalad to the cervix in the region of the body of the uterus and not extend back into the vagina. In most cases of torsion of the uterus in cows the cephalic portion of the vagina is involved, the vaginal walls are spirally twisted and a stenosis of the vagina is present. Starting from the dorsum of the vagina, if the folds spiral forward and downward to the left, or counterclockwise left torsion is present; and if the folds spiral downward and forward to the right or clockwise it is a right torsion of the uterus. Rarely torsion may be suspected on external examination of the vulva by the dorsal commissure being pulled forward to the left or right. This is more noticeable in advanced pregnancy when the vulva is relaxed and edematous. In severe cases of torsion occurring in late pregnancy the blood supply to and from the uterus is severely restricted or cut off. In these cases marked symptoms of complete anorexia and constipation, fetid diarrhea, complete lack of ruminations and rumen activity, very rapid and weak pulse, rapid respirations, expiratory grunt, normal to subnormal body temperature, cold extremities, shock, collapse, and death may occur within 24 to 72 hours. In other cases the fetus may die, become emphysematous and macerate or rarely become mummified and the cow develop only slight or mild symptoms. A rectal examination may reveal chronic adhesions, perimetritis, or even an extrauterine fetus if

the uterus has ruptured. This latter condition usually occurs at the time of parturition. In ewes symptoms are similar to those in cows. In multipara, symptoms of abdominal involvement in advanced pregnancy should always cause suspicion of torsion of the uterus. An exploratory laparotomy in ewes and multipara is often indicated.

In a review^{5a} of uterine torsions in mares, most cases occurred from 8 months of gestation to term, average 9 months, with torsions of 180 to 360 degrees. Unlike torsion in the cow, uterine torsion in the mare rarely involves the cervix and vagina. Thus vaginal examination as an aid to the diagnosis of equine uterine torsion is seldom of value. In the cow over 90 percent of uterine torsions are recognized at term while in the mare nearly all uterine torsions are recognized late in gestation with very few mares being in labor when the torsion is diagnosed. All pregnant mares exhibiting signs of colic in the last trimester of gestation should be examined rectally for evidence of uterine torsion as revealed by the location and tension on the twisted broad ligaments and a narrowing of the lumen of the small colon. In the mare torsions to the left or right are reported with near equal frequency.^{5a} If possible the fetus should be palpated to determine if it is alive or dead. Also if mares show severe colic, uterine rupture or incarceration of a portion of the intestine in the torsion may have occurred. The method preferred by some veterinarians of correcting uterine torsion in the mare is the standing laparotomy operation in the flank region on the same side as the direction of the torsion. The alternate lifting and pushing or rocking of the uterus by grasping the fetal limbs through the uterine wall greatly facilitates the correct replacement of the uterus. By this procedure over 50 percent of the fetuses and 70 percent of the mares survived.^{5a} This is possibly a higher recovery rate than the simpler Schaeffer technique of rolling the mare under sedation or anesthesia preferred by the author. If complications are present, alternate surgical approaches should be considered.

The prognosis in torsion of the uterus prior to parturition depends upon the degree of torsion, the severity of symptoms, and the length of time it has existed. In mild cases without symptoms—found by accident on rectal examination—in which the torsion is occasionally 180° but usually 90° or less, the prognosis is good, since the torsion seldom worsens, and treatment is often not necessary. In 180° to 270° torsions causing definite symptoms that are diagnosed and treated early, the immediate prognosis is usually good for the dam and fetus, but the torsion may occasionally recur prior to parturition. In advanced, severe, and neglected cases the prog-

nosis is poor for the life and reproductive life of the dam and usually the fetus is dead.

Depending upon the circumstances the two treatments most apt to be successful in antenatal cases of 180° to 270° torsions in which the condition is diagnosed promptly are: rolling of the cow or mare by Schaeffer's method described by Arthur^{2,7} or correcting the torsion manually by means of a laparotomy. This latter technique was highly satisfactory by a flank approach in either the recumbent or standing mare.^{5a,9,13,14} These authors reported that 5 of 10 mares in which torsion of the uterus was corrected by rolling died;^{3,14} this technique was apparently more dangerous than a laparotomy. The author and others have successfully corrected uterine torsion in mares by rolling.^{3b} Attempts at correcting torsion by manipulation through the rectum or vagina or both in cows in which the cervix is sealed are usually not successful. Hoisting the rear parts of the cow to effect reduction of the torsion is crude and unnecessary, but may be effective in the ewe.¹ In rare cases cesarean section may be indicated when pregnancy is near term. Extrauterine fetuses, fetal maceration, or mummification associated with torsion are handled as described previously.

In advanced severe cases in which gangrene of the uterus is present, laparohysterectomy is indicated in the bitch and queen but is usually unsuccessful in the cow. Further detailed description of the handling of uterine torsions is discussed in Chapter 10 under handling of torsions causing dystocia.

Vagino-cervical Prolapse

Prolapse of the vagina usually involves a prolapse of the floor, the lateral walls and a portion of the roof of the vagina through the vulva with the cervix and uterus moving caudad. Not infrequently the entire vagina and cervix are prolapsed through the vulva. Vagino-cervical prolapse is seen in all species of domestic animals but most commonly in the cow, especially Herefords and Santa Gertrudis and the ewe. The incidence of ovine vaginal prolapse was reported to be about 0.5 percent but in some flocks this may reach 20 percent.¹⁶ In dairy cattle it is observed most often in the larger dairy breeds such as Holstein and Brown Swiss. In young, brachycephalic dogs prolapse of the vagina at the time of estrum is fairly common. It is practically unknown in cats.⁴

The causes of prolapse of the vagina and cervix are probably multiple. It is observed in the cow most commonly the last 2 to 3 months of gestation when a large amount of estrogenic hormone is being secreted by the placenta. This causes a relaxation of the pelvic ligaments

and adjacent structures and an edema and relaxation of the vulva and vulvar sphincter muscles. When the cow lies down the intra-abdominal pressure especially in late pregnancy is transmitted to the flaccid pelvic structures tending to force the relaxed and loosely attached vaginal floor and walls through the vulva. The vesico-genital pouch is the least restraining part of the pelvic structures and when subjected to increased abdominal pressure the bladder and other viscera are forced against the most yielding part—the floor of the vagina.¹¹ Why this condition affects certain cows and not others is not known but it can be theorized that certain cows produce more estrogens and develop a greater relaxation of the pelvic structures earlier in pregnancy. Conformation may favor prolapse. Prolapse of the vagina may be influenced or due to hereditary or genetic factors in Hereford cattle and sheep and Boxers and Bulldogs.^{4,16,29,38} Since prolapse of the vagina is observed more commonly in pluripara than primipara, injuries or trauma of the caudal vagina and vulva at the first or subsequent parturitions may predispose to prolapse during later gestation periods. This is probably a very common predisposing cause in older cattle especially if they were immature or poorly grown heifers and required great traction to relieve dystocia occurring at the first parturition. The condition is favored by close confinement especially in stanchions in which the cow's rear parts project over the gutter and in sheep, especially those confined on lush pastures and carrying twins.^{1,2} It is seen less commonly in pastured cattle. Overdistention of the abdomen or excessive amounts of loose pelvic fat favor the condition by increasing the intrapelvic pressure. These factors are not important unless the pelvic and vulva structures are relaxed enough to allow the vaginal wall to prolapse. An hereditary cause is suspected occasionally in cattle if a dam and her daughter both develop vaginal prolapse. The high incidence of this condition in Hereford cattle may indicate a possible hereditary factor in this breed.

This condition is occasionally observed in dairy cattle following parturition. At this time it is often associated with cystic ovaries, another condition characterized by excessive estrogen production.

In dogs, especially noted in Boxers and the larger breeds, most cases of vaginal prolapse occur during proestrus and estrus and regress during metestrus, only to recur again at the next estrus. Protrusion of the hypertrophied vaginal mucosa or prolapse may occur. The latter is usually due to heredity, excessive estrogens and their relaxing effect on pelvic and perineal structures, tenesmus, forcible separation of the male before the end of coitus and disproportion in size between the two sexes. In a few instances the ration may play a role in the cause

of this condition. In swine and occasionally cattle the feeding of moldy corn or barley containing an estrogenic mycotoxin, may cause edema of the vulva, relaxation of pelvic ligaments, tenesmus, and prolapse of the vagina and even the rectum. Young swine and cattle are more often affected.^{17,20} This condition has been called vulvovaginitis and is generally considered to be due to a high estrogen content in the moldy feed.²¹ Certain types of legumes such as subterranean clover in Australia may contain a high level of estrogens and produce permanent sterility in ewes due to cystic degeneration of the endometrium, marked mammary growth and development, great enlargement of the bulbo-urethral glands in wethers, uterine inertia and dystocia, as well as a high incidence, 10 to 12 percent, of prolapse of the vagina in nonpregnant ewes.³ The development of vaginal prolapse ceased after removing the ewes from the subterranean clover pastures.²⁸ Proper fertilization and rotation of pastures to maintain a certain percentage of grasses largely prevented this condition in sheep pastured on this type of clover.⁷ The former use of stilbestrol or estrogens in fattening lambs in the United States produced vaginal prolapse.⁸

Once prolapse of the vagina or cervix has occurred the exposed mucous membranes as well as the vulvar and vestibular mucosa become very edematous, inflamed, irritated, infected, and occasionally necrotic. The bladder may prolapse through the vulva within the vaginal floor and continue to fill with urine. These factors tend to prevent the return of the prolapsed structures when the cow rises, and favor tenesmus, or straining, that may lead to prolapse of the cervix and the rectum and to exhaustion. In most cases occurring during the late gestation period, the symptoms usually cease after parturition. There is no relationship between prolapse of the vagina and cervix prior to parturition and prolapse of the uterus after parturition. Prolapse of the uterus is no more likely to occur when prolapse of the vagina has preceded parturition than in cows not affected. Prolapse of the vagina and cervix will invariably recur and become more severe during subsequent pregnancies.

The symptoms of vagino-cervical prolapse are obvious and the condition is often spoken of by the farmer as "casting of the wethers." In the cow this condition is usually observed the last 2 to 3 months of gestation with an increasing incidence as parturition is approached. Occasionally it is seen as early as 4 to 5 months of gestation. In a few cases it is observed after parturition in the cow. In the ewe and other species of domestic animals it seldom occurs other than a few weeks prior to parturition except in the dog. Prolapse of the vagina in the bitch is seen most commonly at the time of estrus. The

Figure 82. Prolapse of the vagina in a first-calf heifer.

symptoms may vary from a mild protrusion of the vaginal mucous membrane through the vulvar lips when the cow lies down, to a severe necrotic vagino-cervical prolapse containing a greatly distended bladder and complicated by a prolapse of the rectum due to the constant tenesmus (see Figures 82, 83, 84). In mild cases the prolapsed vaginal wall returns to its proper position when the cow rises. The degree of vulvitis, vaginitis, and cervicitis will vary depending upon the length of time the condition has existed and the type of mechanical, thermal, or infectious agents acting upon the prolapsed mucous membranes. The symptom of straining or tenesmus may be absent, intermittent and mild, or severe and nearly constant, depending upon the degree of the prolapse, the degree of inflammation, edema and irritation involving the genital canal, and the degree of distention of the bladder. Edema of the prolapsed vagina and cervix occurs because of the irritation and trauma to the exposed mucous membrane, and because this portion drops over the ischial arch thereby causing a passive venous congestion. This edema tends to accumulate in the submucosa and cause a separation of the mucosa from the under-

Figure 83. Prolapse of the vagina, including the bladder, in a cow.

lying thin muscular vaginal wall. The cervical seal usually remains intact; although if the cervix is prolapsed and inflamed, the external portion of the seal may be absent. Occasionally the cervix relaxes, the cervical seal is lost and abortion or premature parturition occurs within 24 to 72 hours. If breeding records are not available, a rectal or vaginal examination should be made to see if the fetus is still alive and to determine the approximate stage of gestation. These factors are important in the prognosis and treatment. If the fetus is alive, the uterine artery has its characteristic "whirr," or fremitus, and the fetus moves when its foot or eyeballs are pinched or its leg or jaw is pulled. In some recently purchased cows vulvar scars may be found indicating previous treatments for vaginal prolapse during other pregnancies. In ne-

Figure 84. Prolapse of the vagina and cervix with a secondary prolapse of the rectum in a cow.

glected, severe cases the exposed mucous membrane may be necrotic resulting in a toxemia and septicemia. This together with exhaustion caused by the constant straining may cause a fast, weak pulse, anorexia, rapid loss of weight, general body weakness, death of the fetus, possible uterine infection and death. Necrosis or gangrene may even involve the cervix and the caudal portion of the uterus secondary vascular insult and thrombosis. If prolapse of the vagina occurs postpartum, the ovaries should always be examined for the presence of cysts and if no cysts are present the vulva should be examined for injuries. In the ewe suffering from prolapse of the vagina or cervix, death and maceration of the fetus followed by the death of the dam is not uncommon. Severe infections of the birth canal associated with prolapse of the vagina may result in uterine infections or retained afterbirth following parturition or abortion. Differential diagnosis should rather easily distinguish between prolapse of the vagina and cervix, and cystic Bartholin's glands, hematomas of the vulva, tumors of the vagina or vulva, prolapse or eversion of the bladder, rupture of the vagina and prolapse of perivaginal fat, and thick heavy fetal membranes. Cows will usually calve without assistance in nearly all uncomplicated cases. After parturition the prolapse is usually immediately relieved.

The prognosis in prolapse of the vagina and cervix depends upon the severity of the condition and the length of time it has existed. Except in extreme or severe cases, the prognosis is generally fair to good for the life of the animal and the fetus if treatment is prompt and aftercare is good. The condition will recur at subsequent gestation periods unless suitable procedures are followed to prevent it. In the more extreme conditions complicated by prolapse of the rectum, death of the fetus, impending abortion, septic metritis, severe necrosis of the prolapsed organs, exhaustion, septicemia and toxemia, marked debility of the patient, or constant and violent straining, the prognosis is guarded to poor. Slaughter should be considered after parturition or weaning of the newborn because of the tendency for this condition to recur and the possible hereditary nature of the condition. In sheep the prognosis is more guarded, since 10 to 20 percent of pregnant ewes may die or expel dead fetuses.

The method of treatment selected for handling prolapse of the vagina and cervix will vary with the species and breed of animal, the severity of the condition, the stage of pregnancy and the ability of the owner to care for and observe the animal until after parturition. Early prompt treatment often permits the use of simple conservative methods and obviates the necessity of using more heroic techniques. Many methods of handling prolapse of the vagina are available. These will be discussed

in order from the conservative to the more heroic methods used in cattle and then the handling of prolapse in the other species will be mentioned. The operator should select the most conservative method possible under the circumstances and caution the owner that as pregnancy progresses other methods may need to be used to control the condition. Combinations of methods may be used.

Of the 16 procedures or techniques described in the second edition (1971) to correct prolapse of the vagina and control straining or tenesmus, 4 have been eliminated in this third edition because they have not been generally accepted by practicing veterinarians even though some beneficial effects were originally ascribed to them. They are: (1) the use of progesterone injections to control vaginal prolapse in mild or early cases,³⁷ (2) the technique for removal of large deposits of perivaginal fat;^{12,13} (3) the use of artificial pneumoperitoneum to control tenesmus,^{10,31} and (4) the technique of unilateral pudendal neurectomy.^{9,33} Although the vaginal reefing operation for chronic vaginal prolapse¹¹ may only occasionally be used, the author has briefly described it because it may be of value in chronic vaginal hypertrophy and prolapse in bitches.

(1) In mild cases in cattle in which only a slight prolapse occurs when the cows lie down, the cow should be removed from the stanchion and placed in a box stall. In slightly more advanced cases (2) one may elevate the rear parts of the cow in a stanchion by means of an inclined platform that raises the rear quarters 2 to 6 inches higher than the front quarters. In a stall this may be done by building up the bedding under the rear quarters or digging out the soil under the front quarters. This practice has been frequently followed in many of the mild cases of prolapse without any untoward effects with the exception that the rear quarters of the dairy cow have been difficult to keep clean. This simple procedure has prevented many mild cases from becoming more severe and has circumvented the use of trusses or vulvar sutures. It is most practical in dairy cattle.

In replacing the prolapsed bovine vagina and cervix epidural anesthesia using 5 to 8 ml. of 2 percent procaine or xylocaine solution is very helpful and usually necessary particularly in the more severe cases where tenesmus is present. Blocking the internal pudendal nerves in cows, in the manner described for bulls,¹⁹ anesthetizes the vulva and vestibular structures without affecting any motor nerves which is often observed in epidural anesthesia. It is advisable to have the animal standing, preferably with the rear parts elevated to facilitate replacement of the prolapsed organs. In smaller animals the lifting or even suspending of the rear parts off the ground is easily accomplished and greatly aids replacement. The

prolapsed portions should be washed free of dirt and debris with a mild, nonirritating antiseptic solution or physiological saline. If irritation, infection, or straining is present a bland antiseptic oil, or sulfonamides or antibiotics in oil or ointment, might be of value when applied to the prolapsed vagina before replacing, and injected into the vagina once to twice daily for several days or more after replacement. If difficulty is encountered in replacement of the prolapsed vagina with the distended bladder inside it, the prolapsed portion may be raised dorsally to reduce the sharp kink in the urethra, thus permitting the urine to escape. In exceptional cases it may be necessary to trocarize the bladder through the prolapsed vagina wall with a large-gauge needle. Once the vaginal floor and walls are replaced the normal circulation is restored and the edema in the vaginal walls and mucous membrane is rapidly reduced. If the vagina is badly infected the animal may have an elevated body temperature. In these cases or those in which the cervix is relaxed and dilated and abortion appears likely, a course of antibiotic or sulfonamide therapy is indicated to control infection and septicemia, and if abortion does occur to prevent septic metritis.

(3) The vulvar truss is of practical value in controlling prolapse of the vagina in dairy cattle confined in stanchions or box stalls where the owner is able to check and adjust the truss as needed. These trusses may be made of rope, leather, or metal. An aluminum rod truss²⁶ held in place with ropes is easily molded to fit the individual cow. These trusses are held in place by ropes or leather straps securely fastened to a surcingle around the cow's chest and neck. The truss, as it fits over the vulva, may be padded with toweling or burlap to prevent abrasions or necrosis where it lies against the ischial arch. When the cow arches her back to urinate or calve the truss will loosen. Cows have been reported to have calved with the truss in place. Many dairy farmers prefer these simpler, less drastic methods, 1 through 3, for handling vaginal prolapse. Most cases are mild and when treated early the results are satisfactory. The above techniques are not usually satisfactory when tenesmus is severe or vagino-cervical prolapse is marked.

(4) Pessaries which are popular in Europe consist of a long narrow wine bottle or similar blunt round object inserted into the vagina after replacement. Pessaries are held in place by a narrow piece of wood or metal placed into the bottle with a ring or loop on the end projecting out of the vulva. A rope is fastened through this ring similar to ropes that hold a metal, plastic or leather truss in place. A light metal rod or plastic pessary shaped like a hairpin with long lateral arms containing eyes so it could be fastened to the wool of ewes has been described and

is available commercially in the United States.¹⁶ Pessaries have not been popular in the United States because an object placed in the vagina tends to cause straining and expulsion of the pessary.

(5) Vulvar sutures that do not pass through the vulvar lips are often a satisfactory method of treating vaginal prolapse for a limited period especially the last 2 to 3 weeks of gestation. The sutures should be located at least 2 to 3 inches lateral to the vulvar lips in the hair line. This affords a much tougher and thicker skin for the suture, which does not tear out as readily nor cause as much irritation as one in the vulvar lips. It is desirable to use a type of suture that can be untied or released, so that if a cow appears to be near or in the first stage of parturition the vulvar sutures can be unfastened, so that calving can occur. If the calving time has been misjudged and prolapse again results, the prolapsed vagina may be washed and replaced. If prolapse does not occur, the sutures can be retied. This is not possible with the simple horizontal figure-eight or horizontal mattress sutures that do not pass through the vulvar lips or deep horizontal mattress sutures, usually of double thickness one-eighth to one-quarter-inch thick umbilical tape, that have been passed through each lateral wall of the vulvar vestibule and including the vulvar lips. Another advantage of the type of suture that can be untied is that if there is some possibility of postpartum prolapse of the vagina, or even the uterus, the sutures can be retied after parturition and left for several more days. Although some suppuration occurs around these stitches they may be left in place for as long as 6 to 8 weeks. The vulva-suturing technique preferred by the author is one employing 4 to 5 small separate loops of doubled 1/4-3/8 inch umbilical tape or heavy nylon on either side of the vulva in the hair line from the level of the anus to about opposite the lower commissure of the vulva.¹² About 2 feet of 1-1/2-inch to 3-inch gauze bandage, doubled, is used to lace up the loops in a manner similar to lacing a shoe. This gauze may be removed or replaced as desired. A similar but crude technique is the use of hog rings instead of umbilical tape loops. These tend to tear out or work out of the skin. A metal skewer type of needle with large wooden buttons to hold the vulvar lips together and other metallic clamp-like devices have been advocated by European veterinarians and are available commercially. Some veterinarians prefer quill, button, or deep horizontal mattress sutures of umbilical tape, through the vulvar skin, muscle, and mucous membrane.^{18,32}

(6) A buried or "hidden" purse-string type of suture, Buhner's method, for the vulva following replacement of a prolapsed vagina has been described.^{1,6,27} This technique may be used in chronic postpartum prolapse as

well as prepartum prolapse. Under epidural anesthesia and with a near-sterile procedure, two one-half inch incisions are made one to two inches above the upper commissure and below the lower commissure of the vulva, respectively. With a long eye-point needle similar to a seton needle, an 18-inch piece of one-eighth inch thick nylon cord, heavy "Vetafil" or nylon sashcord is passed within the tissues from one incision to the other near the hairline lateral to one vulvar lip. The needle is withdrawn and reinserted in the opposite direction lateral to the opposite vulvar lip to the lower incision site and again withdrawn. The purse-string suture around the vulva is tightened sufficiently to allow 4 fingers in the vulva, and a bow knot is tied with long ends. Thus, the farmer may loosen this suture if parturition is imminent and if necessary tighten and retie the suture after calving.

(7) A vulva-closing technique modified from the Caslick operation in mares has been of great assistance in the treatment of chronic prolapse of the vagina 2 months or more before parturition or in postpartum prolapse in cows. It has also proved very valuable in controlling tenesmus associated with "windsucking" and a highly inflamed vaginal and vulvar mucous membrane. The drawing of air into and forcing it out of a highly inflamed vagina appears to stimulate and produce violent straining. This operation is performed under epidural anesthesia. After replacement of the prolapsed structures, the caudal 3/4 inch of mucous membrane of both vulvar lips from and including the superior commissure to about 1-1/2 inches above the ventral commissure is removed with scissors. These raw areas of both vulvar lips are sewn together with interrupted vertical mattress sutures of fine catgut, nylon or silk suture closely spaced. One or two deep horizontal mattress vulvar sutures of umbilical tape are placed through the skin 2 or 3 inches lateral to the vulva and through the vulvar muscles and mucous membrane to prevent the vaginal wall being forced against the fine sutures in the vulvar lips and thus tearing them out if tenesmus occurs (see Figure 85). After 10 days all sutures may be removed. The vulvar opening is then so small that the vaginal wall cannot prolapse and air cannot gain admittance to the vaginal lumen. Just before or at the time of calving it is necessary to slit this adhesion between the vulvar lips to prevent its tearing out. Because of the tendency to repeated prolapse at each gestation period, resuturing is advised immediately after calving if artificial insemination is employed or after breeding if natural service is used.

(8) Minchev's method^{14,23} for controlling prolapse of the vagina by surgically fastening the cranial portion of the vaginal wall through the dorsolateral wall of the sacroscopic ligament, muscles and skin of the croup was

slightly modified⁵ to place the stay sutures dorso-cranial to the lesser sciatic foramen.^{14,15,25} After replacement of the prolapsed vagina under epidural anesthesia the anterior portion of the vagina is fastened to either side of the pelvic cavity preventing a prolapse by means of anchoring devices including gauze rolls, heavy plastic buttons, large overcoat buttons or 3/16th inch thick pads of industrial belting. In securing the vaginal walls to the pelvic walls with these anchors inside the vagina and outside on the skin of the croup, heavy suture material such as 1/4 or 3/8 inch umbilical tape doubled or heavy Vetafil or nylon cord so that if straining does occur the vaginal wall will not be lacerated freeing it from its attachment to the pelvic wall. The sutures fastening the vaginal and skin buttons together may be inserted under local anesthesia by making small incisions in the skin of the croup over the sacroscopic ligament and inserting a small rumen trocar or a crochet-type hook into the vaginal cavity to guide or carry the suture material fastened to the vaginal button to the outside button on the skin. One may also do this by carrying a 4 to 6 inch needle threaded on the suture material attached to the vaginal button into the vagina and forcing the needle dorsolaterally through the skin. In inserting the needle or trocar care should be taken to avoid the rectum, the pudendal nerve and vessels and the sciatic nerve that can be palpated medial to the sacroscopic ligament. The authors originally describing this technique recommended that the sutures be removed in 10 to 14 days at which time the vaginal wall was firmly adhered to the pelvic wall. Firm attachment frequently does not occur by this time and prolapse of the vagina may again recur. For this reason many veterinarians leave the buttons and sutures in place until after calving.

(9) Another recently introduced technique (Winkler) for handling prolapse of the vagina is fixation of the cervix to the prepubic tendon, cervixepxy.^{24,36} This procedure minimized tenesmus, required no aftercase during gestation or at parturition, prevented recurrent prolapse at subsequent pregnancies and could be used in all types of cases. Under epidural anesthesia the prolapsed vagina is carefully cleaned and replaced. A 3 or 4-inch half circle cutting edge suture needle is bent into a U-shape and threaded with 36 to 48 inches of heavy 3 or 4 nylon or "Vetafil," noncapillary suture material. Material such as umbilical tape should not be used. The needle and suture material are carried into the vagina. The bladder is pushed laterally away from the midline. The needle is passed through the floor of the vagina beneath the external os of the cervix in a lateral to medial direction just cranial to the pubic symphysis and just to the right or left of the prepubic tendon and through a small lateral portion of

Figure 85. A technique for the control of chronic prolapse of the vagina. (Left) Under epidural or local anesthesia a three-quarter inch strip of mucosa is removed from just inside the vulvar lips. (Center) An interrupted vertical mattress suture is used to draw the wound edges gently together. (Right) If the animal is straining a deep mattress suture is placed through both vulvar lips cranial to the suture line.

the thick prepubic tendon, and then back up through the vaginal floor. This suture should include 1-1/2 to 2 inches of vaginal floor and 1/4 to 3/8 inch of prepubic tendon. The needle is then passed through the ventral half of the cervix at least one-half inch cranial to the external os. The suture is tied outside vulva and the knot carried forward so the cervix is fastened closely to, but not necessarily tightly against, the floor of the pelvis. It may be desirable to pass a catheter into the bladder to make certain it was not included in the suture. These latter two operations (10 and 11) avoid placing sutures in the region of the vulva which is richly supplied with sensory nerves and thus tenesmus is minimized. The suture is left in place indefinitely as it does not interfere with breeding or calving. This operation is performed most easily several months after calving when the uterus has involuted. Cervopexy through a laparotomy in the left paralumbar area may facilitate placing the fixation suture.²⁴

(10) Another surgical "reefing" technique for correction of chronic vagino-cervical prolapse, particularly adapted to selected cases in beef cattle has been described.¹¹ This consists of a submucous resection of the edematous, devitalized mucous membrane from the prolapsed portion of the vagina. If the prolapsed portion of the vagina is large due to the presence of a distended bladder this should not be reduced before the operation as it will make surgery more difficult. Surgery can be

performed under epidural anesthesia. Adrenaline injected or applied locally may aid in reducing hemorrhage during the peeling-off of the diseased, often necrotic, edematous mucous membrane. The sleeve of vaginal mucous membrane that is peeled off is narrow at the dorsum and wide ventrally, as more of the floor of the vagina is usually involved in the prolapse. Incisions on the prolapsed vagina are made in the normal mucous membrane near the cervix caudally and near the urethral orifice or hymen cranially. As the diseased mucous membrane is peeled off, mostly by blunt dissection, No. 3 or 4 chromic catgut suture is used to approximate the two cut edges of normal mucous membrane, as the operation progresses. This is done to control hemorrhage, which is usually quite severe but of a capillary oozing type, and to get most of the incision sewed before the prolapsed vagina begins to drop back into its proper intrapelvic position. In most operations traction applied to the cervix is necessary to keep the vagina retracted and outside the vulva until the suturing is completed. The vagina is greatly shortened by this reefing operation so that the cervix is nearer the vulva. Since the excess vaginal wall is thereby eliminated, the prolapse will not recur during that particular gestation though in rare cases it may during subsequent ones. Tenesmus ceases after the operation. The muscular coat of the vaginal wall is drawn up in folds under the suture line that joins the cephalic and caudal edges of normal vaginal mucous

membrane. In operating on cows in which most of the vagina is prolapsed, care should be exercised in removing the mucous membrane on the dorsal surface of the vagina not to cut too deeply and enter the recto-genital pouch of peritoneum, that extends about 5 inches caudad on the dorsal surface of the vagina. Care should also be used to prevent incising the urethral opening or urethra. Obviously this operation should not be performed if the cow is due to calve within 3 to 4 weeks or if abortion appears likely. This is not an operation to select as a last resort in a neglected case, with the patient exhibiting symptoms of toxemia and exhaustion. The type of case indicated for this operative should be selected carefully. The prolapse should have occurred relatively early in the gestation period or be a chronic postpartum prolapse. The cow should be in good condition for the operation. It is particularly indicated in that type of cow, usually beef, in which regular observation and care of the cow is not possible.

In the bitch, no treatment of mild cases of vaginal hyperplasia and prolapse is indicated, as the condition corrects itself after estrum. In breeding dogs the removal of the prolapsed mucous membranes by a reefing technique similar to the one described in the cow gives good results.^{11,22,32} Episiotomy in the dorsal position may be necessary as an aid in resection of the mucous membrane in the dog.¹⁴ In nonbreeding dogs ovariectomy results in a permanent cure.

(11) In chronic prolapse in postpartum cows treatment with a gonadotrophic hormone or GnRH is indicated if cystic ovaries are present.¹² In unusual cases other methods of handling might be indicated such as a cesarean section late in gestation.

If prolapse of the rectum occurs along with prolapse of the vagina the prognosis is more grave and either a purse-string suture to retain the rectum, a reefing operation, or amputation of the rectum might be indicated, along with feeding or administering mild laxatives or large amounts of fluids to prevent constipation. Prompt slaughter of many animals affected with severe prolapse of both vagina and rectum is advisable as persistent tenesmus is common in these animals.

If constant tenesmus after replacement is a problem, repeated use of local epidural anesthesia at one to two hour intervals may be helpful if accompanied by intravaginal infusions of bland, protective antiseptics in oil. In certain beef cattle some veterinarians have injected 3 to 8 ml. of benzyl, ethyl or isopropyl alcohol epidurally that destroys the nerve tissue resulting in anesthesia to the perineum and paralysis of the tail lasting from 2 to 6 months. This technique is not desirable for dairy cattle for sanitary reasons. The old technique of a tracheotomy

operation to prevent straining is rarely, if ever, necessary or recommended. Recently some of the local anesthetics such as benzocaine, nupercaine, and cyclaine have been incorporated into ointment bases. The application of these ointments to the vaginal and vulvar mucous membranes have been recommended to control local surface irritation and the resulting tenesmus. However, the author has not found these local anesthetic ointments very effective.

Paraplegia of Pregnancy

There are numerous causes for paraplegia, or paresis, during pregnancy. Most of these conditions occur in, or are aggravated by, advanced pregnancy, during which period there is very rapid growth of the fetus and an increase in weight of the gravid uterus as well as a progressive relaxation of the pelvic ligaments and an increase in the size and development of the udder. The factors, and several may operate together, that may cause a cow to exhibit paresis in advanced pregnancy are:

Nutritional deficiencies and starvation—A lack of minerals such as phosphorus and calcium may result in debility, pica, bone and joint lesions, and even an increase in incidence of fractures. A lack of trace minerals, principally copper, cobalt, and iron, has been reported as resulting in anemia and debility, which if extreme may cause weakness and inability to rise. In certain areas such as Florida with high molybdenum levels in the soil and forage, chronic diarrhea coupled with a lack of copper, iron, and cobalt favor debility. Lack of vitamin A in the ration may lower resistance and favor uterine infections. Most nutritional deficiencies are multiple, including a lack of minerals, proteins, carbohydrates, and fats. The classic symptoms of severe underfeeding or starvation are debility, cachexia, weakness, and finally inability to rise; and in advanced cases, death of the fetus, and abortion. In certain areas of the country specific deficiency diseases occur commonly and are known by the local veterinarians. In the high-producing dairy cow it is usually desirable to supply additional minerals to the ration as well as offering them free-choice to compensate for the loss of minerals in the milk and the developing large fetus.

Ketosis—Pregnancy disease in ewes due to a lack of carbohydrates is a common cause for debility and paraplegia in ewes and does in advanced pregnancy. Twin or triplet pregnancy is a predisposing factor. Usually the fetuses die and the ewe often succumbs. If the fetuses are aborted promptly the ewe may recover; or treatment administered early in the disease may bring about recovery. Therapy for ketosis consists of glucose intra-

venously, propylene glycol or glycerol orally and glucocorticoids in small doses parenterally. Large doses of glucocorticoids may induce premature parturition or abortion in late pregnancy. In a valuable ewe near term, cesarean section may be indicated. The carbohydrate intake of the rest of the pregnant ewes in the flock should be increased by feeding grain or molasses. Provision for increased exercise may be helpful. This condition may be observed in the cow and bitch prior to parturition.^{2,4,5}

Grass tetany is seen in pregnant cattle on lush pasture, such as wheat pastures, particularly in the fall or early spring. In areas with soil deficient in calcium and magnesium, it may occur at any time of year even in stabled animals. It is apparently due to a lack of calcium causing hypocalcemia and/or magnesium causing hypomagnesemia. Some believe it is associated with the high potassium or high vitamin A levels of the lush, green immature forage. Mineral feed or feeding of good-quality alfalfa or clover hay rich in calcium, magnesium and phosphorus tends to prevent the condition. It is probably best to remove the stock from the lush pasture for a time. The paretic cases usually respond to calcium therapy, or if paresis and nervous symptoms are present both calcium and magnesium therapy are indicated.

Milk fever or parturient paresis may occur just prior to parturition in the high-producing dairy cow, at which time it is called preparturient milk fever or paresis. Most preparturient cases occur during the first stage of parturition, when milk letdown is favored by the action of the oxytocin released at that time. Following treatment, active labor and calving will often follow within 4 to 6 hours. In a few cases preparturient milk fever, or hypomagnesemia due to a sudden drop in blood calcium and/or magnesium may be observed 24 to 72 hours before parturition. Transport stress in cows late in pregnancy may precipitate this condition.⁶

Puerperal tetany, or eclampsia in dogs and rarely cats associated with a hypocalcemia characterized by nervousness, restlessness, whining, and then staggering, stiffness of the legs, and finally collapse with clonic spasms, labored respirations, salivation, and elevation of temperature, may be seen occasionally prior to parturition although it is far more commonly observed the first 2 weeks after parturition.

Dropsy of the fetal membranes and fetus—This may occur from 5 months to term as has been discussed previously and is associated with a great increase in abdominal weight and size and the inability to rise. The increased abdominal weight may lead to injury such as dislocation of the hips.

Joint and tendon injuries, especially to the rear limbs, may render the animal unable to rise. Dislocation of the

hip is common in the cow in advanced pregnancy, especially after slipping on concrete floors or ice in the barnyard. Dislocation or subluxation of the stifle are occasionally observed. Separation of the ligaments of the ilio-sacral articulation is infrequently observed. Sometimes painful lesions of the joints, due to chronic arthritis of the stifle or hip or suppurative lesions of the hock or coffin joint, may cause reluctance to rise; in time, stiffness, myositis, neuritis and weakness and paresis may result with inability to rise.³ Sudden rupture of the prepubic tendon in the mare or rupture of the gastrocnemius tendon, usually secondary to Zenker's muscle degeneration in the cow, may occasionally be causes in these animals of their being unable to rise or rising with difficulty.

Fractures of the rear limbs or spine—Fractures of the femur and pelvis are the most common of those occurring in advanced pregnancy. They may occur when a cow in advanced pregnancy is mounted by another cow. Osteomalacia due to a prolonged mineral deficiency favors fracture. Excessive relaxation of joints and ligaments due to estrogens present in advanced pregnancy may also lead to fractures. Spinal injuries or fractures in the lumbar region with severe posterior paresis, may occasionally occur. If a cow or bull mounts the pregnant animal, the impact of the sternum on the coccygeal and sacral vertebrae may cause a subluxation, dislocation, or fracture of these vertebrae and subsequent posterior weakness and paralysis of the tail.

Septic or infectious processes associated with advanced pregnancy may cause paresis. They may be any of the following: septic metritis of pregnancy with death and maceration of the fetus; rupture of the uterus with severe peritonitis secondary to an emphysematous fetus; traumatic gastritis with diffuse peritonitis; severe torsion of the uterus with gangrene and shock, or death of the fetus and rupture of the uterus; severe pyelonephritis aggravated by advanced pregnancy; or septic mastitis.

Other conditions that may cause paresis or paraplegia in animals at any time may affect the pregnant animal. These are as follows: rupture of a large uterine vessel with hemorrhage, toxic indigestion, diseases of the central nervous system, such as rabies and listeriosis; severe prolonged illness resulting in debility such as: Johnes disease, severe mange or pediculosis, advanced actinomycosis of the jaw, and senility; tumors especially of the brain and spinal cord, such as lymphocytoma; severe septicemic diseases such as: anthrax, blackleg, pasteurellosis, leptospirosis and anaplasmosis; and severe foot lesions.⁶

If an animal is down, struggles to rise, but remains down for a period of time particularly on a hard concrete

floor, decubital injuries, contusions, abrasions, joint muscle, nerve and tendon injuries, and exhaustion are common. These cause progressive soreness, stiffness, awkwardness, and even greater difficulty in rising. Many so-called malingers or "downer" cows^{2,3,6} have arthritis, myositis, neuritis or tendonitis painful and debilitating enough so that they refuse or are unable to rise. These animals might benefit from good nursing, a dirt floor or heavily bedded box stall, and slings to get them up periodically so as to restore movement and circulation to the legs. Occasionally butazolidin or similar drugs to control inflammation and pain are of value. The further handling of these animals in advanced pregnancy depends upon their value for food, their sentimental value, the value of the offspring, the nature and severity of their diseases or injuries, and the owner's ability, means, and interest in nursing these paraplegic, paretic or "downer" animals.

Miscellaneous Accidents of Pregnancy

Hemorrhages of pregnancy—The most common hemorrhage of pregnancy is that associated with hematic mummification of the bovine fetus. This occurs in the utero-chorionic space of a sealed uterus. Slight hemorrhages occur between the maternal and fetal placenta that may be noted on examination of the placenta after parturition. In the cow "uterine sand," occasionally found in the utero-chorionic space, is dried or inspissated granules of serum about 1/64 to 1/16 inch in diameter. Occasionally due to trauma or violence causing rupture of the larger vessels, hemorrhage or large blood clots sufficient to cause death may be found around the vagina or in the broad ligament in the cow or mare in late pregnancy. Mares should not be transported or subject to violent exercise in late pregnancy for this reason. Hemorrhage or bleeding from the genital tract appearing at the vulva during pregnancy is rare in domestic animals. It may be noted in pyelonephritis, in a traumatic injury to the vagina, vulva or bladder or in tumors of the vulva or vagina that bleed readily. In mares recurrent slight bleeding from a ruptured varicose or surface vein in the vagina or hymenal region is common but not serious; it may heal spontaneously or be corrected by cautery or by surgically ligating the lesion. Bleeding usually ceases after parturition. A reddish-brown vulvar exudate containing free blood may be associated with beginning abortion and a dead fetus or a septic metritis of pregnancy with an open cervix. Hemoglobinuria due to leptospirosis and other acute hemolytic diseases may be confused in the pregnant animal with bleeding from the genital tract.

Rupture of the gravid uterus—This may occur either spontaneously due to unknown causes, or secondary to abortion, dystocia, emphysematous fetuses, chronic peritonitis with uterine adhesions, torsion of the uterus, dropsy of the fetal membranes and fetus, and extreme violence and trauma in advanced pregnancy.

Strangulation of the large colon by the gravid uterus—A mare with unexplainable symptoms of digestive distress proved to have, on postmortem examination, a displacement of the large colon beneath the gravid uterus.⁷ Obstruction of the bowel may also occur associated with uterine torsion.

Strangulation of the pregnant uterus by a pedunculated lipoma—A case of a 4-month pregnancy in a cow was cited in which a pedunculated lipoma wrapped around the uterus.¹

Chapter VI

PARTURITION

Parturition encompasses the various physiological processes involved in the birth of young including the delivery of the fetus and placenta (fetal membranes) and the involution of the uterus. Prior to parturition the dam should have been fed a properly balanced ration in amounts sufficient to provide the necessary carbohydrates, protein, fat, vitamins, minerals, and water so that at the time of parturition she is neither fat nor thin. Most livestock men prefer to feed their animals approaching parturition a light, slightly laxative feed. Under most systems of management the pregnant animal is provided adequate opportunity for exercise. For the last 2 to 3 weeks prior to parturition violence and excessive exercise or work should be avoided. The animals should be segregated from the rest of the herd in clean, sanitary, comfortable, quiet surroundings.

One of the best locations possible for parturition of farm animals is a small pasture free of woods, steep slopes, wet or brush areas. This location is clean and the newborn are not exposed to the common barn or barnyard diseases. The principal disadvantage of such a location is that frequently close observation or supervision of parturition cannot be followed. During periods of adverse cold and wet weather, a dry, relatively warm building or shed supplied with heat is desirable for parturition for all domestic animals. A satisfactory place often used for parturition of the large domestic animals is a clean, well-bedded, roomy, disinfected box stall. Clean, fresh, dry straw, shavings or sawdust are usually available as bedding but are not ideal because they readily contaminate the fetus, membranes and genital tract. A strong, sterilized, rubberized or plastic covering securely anchored over the above bedding material would be highly desirable. Facilities for sanitation and isolation at the time of parturition or abortion are of prime importance in most herds. A reliable birth detection system for animals, other than the time-consuming repeated checking of those near parturition, has not been developed although preliminary studies have been conducted.^{52b}

In swine in which heavy death losses of 20 to 30 percent of the newborn are frequently experienced during parturition and the following 48 to 72 hours, many life-saving innovations have been introduced. The farrowing

pen should have guard rails. The bedding should not be too deep. Farrowing crates are highly desirable. Constant watch should be kept on farrowing sows to prevent them from lying on the newborn pigs. In many cases the newborn pig is removed immediately after birth. After farrowing is completed, the pigs are returned to the sow. To prevent the newborn pigs from becoming chilled, farrowing houses are built singly and small, or larger farrowing houses are artificially heated. The use of heat-lamp-type brooders placed in the corner of the pens not only prevents chilling but provides a safe place for pigs when they are not nursing. In some farrowing houses heating cable is placed in the concrete floor to provide heat for the pigs. The optimum environmental temperature for newborn pigs is 85° to 95° F. This temperature must be maintained for 3 to 6 weeks as piglets are unable to maintain a normal body temperature when the ambient temperature is low. For dogs, the owner should set aside a whelping place or box about two to three feet square with six to eight inch sides for medium-sized dogs. If possible the bitch should be kept in this familiar environment for at least a month before whelping.

It is important that veterinarians be familiar with normal parturition as it occurs in the various domestic animals so that there may be immediate recognition of any pathological symptoms. Assistance or interference with the birth process, occasionally necessary to save the fetus or dam, must be performed at the proper time. The time of parturition is one of the most critical stages in the life of any animal. It is one of the periods of highest death rate in animals. It can be a period in which not only the fetus, but also the dam, may be severely damaged or injured and thus affect its future reproductive and productive efficiency. This period, therefore, is of vital concern to the farmer who has a large economic investment in his animals.

Symptoms of Approaching Parturition

The signs of approaching parturition in domestic animals are somewhat similar but vary in certain important respects. The symptoms are inconstant between individ-

ual animals and between consecutive parturitions. These symptoms therefore do not permit an accurate prediction as to the exact time of parturition in a certain animal but they are useful indications as to the approximate time parturition may be expected. The practicing veterinarian is frequently asked to examine and predict the time of parturition of an animal in advanced pregnancy. Although the following discussion will be helpful in this respect, he should refrain from making too positive or definite a statement concerning the exact time of parturition, as subsequent events will more often than not prove him wrong.

The breeding date, if known, is helpful in predicting the approximate time of parturition. Breeding records are necessary on the well-managed farm. Just prior to parturition most animals tend to segregate themselves from the others. The sow, bitch, and queen attempt to make a suitable bed. Changes in the pelvis, genital organs, and mammary glands take place.

In the cow the pelvic ligaments, especially the sacro-sciatic, become progressively more relaxed, causing a sinking of the croup ligaments and muscles. The caudal border of the sacro-sciatic ligament between the coccygeal vertebrae and ischial tuberosity becomes less cord-like and tight, and more relaxed and flaccid. Relaxation of the pelvic ligaments, cervix and possibly the structures around the perineum is due to edema and changes in the collagen fibers in connective tissue probably caused by an increase in estrogen from the placenta. Relaxin may also play a role. In most cows the presence of very relaxed ligaments indicates that parturition will probably occur in 24 to 48 hours. This relaxation of the ligaments is also noted by the elevation of the tail head. The vulva becomes progressively edematous and more flaccid until it is 2 to 6 times its normal size. The udder becomes enlarged and edematous. In heifers this udder enlargement begins about the fourth month of gestation. In older, pluriparous cows it may not be noticeable until 2 to 4 weeks before parturition. In high-producing, younger cows, the amount of edema in the udder may be extensive and cause difficulty in walking. Edema may extend forward on the abdominal floor to the xiphoid region and be 2 to 6 inches deep. In the region of the navel it may resemble an umbilical hernia. It may extend caudally above the udder and involve the region of the escutcheon and even the vulva. This edema may occasionally be severe enough to interfere with circulation in the skin between the udder and legs or in the region between the fore quarters of the udder, resulting in areas of necrosis at these sites. Just prior to parturition the udder secretion changes from a honey-like dry secretion to a yellow, turbid, opaque cellular secretion called colostrum. At this

period the udder and teats are so distended with colostrum that in "easy milkers" it may leak out. The cow usually exhibits a tenacious, whitish, stringy type of mucus coming from the cranial part of the vagina, starting about 7 months of pregnancy. This mucus becomes more profuse as parturition approaches. Just prior to parturition the amount of mucus increases markedly and the cervical seal liquefies. During the last few hours before calving the cow may exhibit anorexia and restlessness. Heifers may show signs of abdominal discomfort with kicking at the abdomen, treading, raising and switching their tails and lying down and rising. A majority of cows, 67 percent, calve during the night hours.⁹² Other studies indicate that calvings occurred equally between day and night. However, feeding beef cows at night for 1 to 3 weeks before calving altered the calving pattern so 85 percent of 1331 cows calved during the daylight, 6 am to 6 pm, hours when they could more easily be observed.^{60,62b} Further studies are indicated.

In the mare somewhat similar symptoms of approaching parturition are present. The sinking of the sacro-sciatic ligaments is not so pronounced, due to the heavy croup muscles. The vulva does not become as edematous as in the cow but edema and flaccidity are noted the last few weeks of gestation. No discharge of vaginal mucus prior to foaling is noted in the mare. The udder starts to develop noticeably about 3 to 6 weeks before foaling. In most mares the udder and teats become filled and distended with colostrum about 2 days before foaling, and oozing of this colostrum from the teats, called "waxing," is usually observed in 95 percent of mares 6 to 48 hours before foaling. In a few cases no waxing is observed before foaling and in rare cases milk may leak from the teats up to a week or so before parturition. Within 4 hours of parturition slight sweating in flank region and behind the elbows is frequently noticed. Anorexia occurs only within 1 to 2 hours of foaling. As the first stage of labor advances the mare becomes restless, shows slight colicky symptoms, raises and switches her tail and lies down and gets up frequently. These symptoms become progressively more marked until the allantois chorion ruptures and the second stage with actual labor begins.

The mare greatly prefers solitude and quiet at parturition and seems more able than other animals to control or suppress parturition until the night hours, when stable activities are at a minimum. Of 367 foals, 59.8 percent were born from 6:00 p.m. to midnight, 23.4 percent from midnight to 6:00 a.m. and only 16.8 percent from 6:00 a.m. to 6:00 p.m. Thus about 83 percent of the foals were born during the night. Other studies confirmed this percentage of nighttime foalings.^{6,85,99}

In the ewe and goat the conditions are similar to the

cow with the exception that udder development is not so great. **In the sow and queen** the symptoms are somewhat similar to those in the bitch. As pregnancy progresses, **the bitch** becomes quieter and as parturition approaches the vulva becomes flaccid, enlarged, and edematous. The mammary glands also become enlarged and edematous and milk may be present in the udder several days before parturition. The bitch becomes restless and shows anorexia for a few days before parturition. This becomes more noticeable 12 to 24 hours before whelping. During the first stage of labor, the bitch may pant or exhibit an increased respiratory rate. During the latter stages of pregnancy in the ewe, sow, and bitch a mucoid vulvar discharge is usually evident. Environmental disturbances, especially those caused by other dogs, will delay or interrupt the birth process in bitches.¹¹ Seventy-three percent of farrowings occurred between 2:00 pm and 4:00 am.⁵

The Initiation of Parturition

In recent years the exact mechanism concerned with the onset of parturition after a rather regular and definite length of gestation for each species of animals is becoming much better understood. Hormonal factors are of prime importance, as parturition can take place without innervation of the uterus.^{21,33,47,49,60,85}

As described in Chapter IV progesterone from the corpus luteum is necessary throughout gestation in the cow, doe, sow and bitch. Ovariectomy at any stage of gestation in these species results in abortion or premature birth. While in the ewe, queen and mare progesterone from the corpus luteum is necessary to maintain pregnancy only during the early stages of gestation. Ovariectomy may be performed without affecting pregnancy after 55 days of gestation in the ewe, 50 days of gestation in the queen and 70 to 150 days of gestation in the mare. In these latter species, progestogens or progesterone are produced by the feto-placental unit to maintain pregnancy after luteal function ceases.^{21,33}

Estrogen levels, arising from the embryo or fetus and the placenta, are much lower than progesterone levels during pregnancy. In the cow, ewe, sow, doe and queen the estrogen levels rise very slowly during early and midgestation and then rise more rapidly the third trimester and an especially sharp rise in estrogen levels occur the last few days of gestation, except in the queen. In the sow there is a temporary rise in estrogen levels around 12 to 30 days of gestation and in the mare from 150 to 250 days of gestation. In the mare this rise corresponds to the increase in size of the fetal gonads. In the mare and bitch estrogen levels in the dam's plasma declined slightly the latter stages of gestation.

Initiation of parturition in the ewe, doe, sow, cow, bitch and probably the queen starts in the hypothalamus of the fetal brain, possibly from stimuli such as placental aging, nutritional and uterine restrictions to growth and the accumulation of waste products, followed by release of ACTH from the pituitary gland and the elevation of adrenal cortisol in the fetal and then maternal plasma.^{21,33,49,97,98} The manner in which the different species respond to this elevated cortisol level differs. In ewes the placental enzymes cause the placental progesterone to be made into estrogen. Blood levels of progesterone fall rapidly and placental estrogen causes the synthesis of PGF_{2a} and uterine contractions occur. In cows, does and sows, cortisol stimulates placental estrogen production causing uterine release of PGF_{2a} and the rapid involution or luteolysis of the corpora lutea, with a rapid decline in progesterone levels and subsequent uterine contractions. Cortisol production by the fetus late in gestation is essential for rapid lung maturation and pulmonary surfactant production necessary for the survival of premature or mature fetuses.¹⁹ In the mare a somewhat similar pattern may exist but a pronounced rise in fetal plasma cortisol levels just prior to parturition has not been shown to occur.^{21,47,54,64,76,85} Further studies are needed. At the time of parturition in the mare the blood progestagen level is quite high, as in the woman, but drops rapidly within 24 hours after birth. In the bitch progesterone levels fall sharply just prior to parturition and cortisol levels reach a peak during the day prior to the onset of parturition. There was sharp fall of 0.8° C in body temperature of the bitch during the 24 hours prior to parturition.^{22,23} In the bitch and queen there is need for further studies to determine the exact sequence of events that initiate parturition. Prostaglandin E₂ as well as prostaglandin F_{2a} is found in the fetal fluids and plasma during the latter stages of gestation in the mare and other animals. The former prostaglandin probably plays an important role in maintaining the fetal vascular system including the patency of the ductus arteriosus^{60,85} and dilation of the cervix.^{63b}

It is likely that a synergistic action between the rise in estrogens and relaxin, the rapid decline in progestogens and the rise in prostaglandins (PGF_{2a}) precipitate peristaltic uterine contractions, cervical dilation and parturition. In sows a large amount of relaxin from the lutein cells of the ovaries is released the last few days of gestation. Prostaglandin stimulates release of relaxin that dilates the cervix, increases the pelvic area and facilitates the expulsion of the fetuses.³⁶ Relaxin levels in plasma rise rapidly late in gestation and just before parturition from 4.2 to 7 to 8 ng/ml. in the mare,^{94c} from 2.7 ng. to 42 to 257 ng/ml. in the sow^{90b} and in the cow.^{77b}

These levels decline very rapidly after parturition. During the second stage of labor in all domestic animals high levels of PGF_{2a} are present and as the fetus engages in the birth canal oxytocin is released. The latter hormone from the posterior pituitary gland does not initiate parturition as previously believed but augments it by stimulating the release of large amounts of PGF_{2a} .^{49,51,77a,98} However it is important, together with PGF_{2a} , in causing peristaltic uterine contractions to assist in delivery of the fetus(es) and the placentas. Two to 3 IU oxytocin i.v. intensified normal myometrial activity in sows within 20 seconds but 10 IU caused uterine spasms for 10 to 15 minutes.^{12b} Recent studies established that estrogens are important for myometrial sensitivity to oxytocin. This is accomplished by the regulation of the concentration of oxytocin receptors in the myometrium by estrogens.^{41b,93} Within 24 hours after birth, progesterone and estrogen levels in maternal plasma drop to very low levels in all domestic animals.

Postponement of parturition can be achieved by progestins in cows, ewes and sows for a few days to a week but dystocia and poor viability of the neonate often occurs. For short term postponement of parturition for a few to 18 hours, long-acting sympathomimetic, betamimetic or tocolytic agents such as clenbuterol or isoxsuprine may be used to produce myometrial quiescence.^{6b,c} These agents are not currently available to veterinarians in the U.S. (See Dystocia.)

Induction of Parturition (and Abortion)

The great increase in knowledge in recent years of the endocrine control of parturition has enabled veterinarians not only to produce abortions at nearly any stage of gestation in most domestic animals (See Chapter V) but to induce essentially normal parturitions by the timely injection of certain hormones. The stage of pregnancy at which parturition is induced, although not critical for the dam, is very critical for the welfare of the neonate.^{33,35} When parturition is induced prematurely more than 3 days in the sow, 5 days in the ewe and doe and 7 to 14 days in the cow satisfactory lactation and neonate survival and growth is severely affected. In the mare the mammary glands should be enlarged and developed and secreting a milk-like colostrum, the mare should be at least 330 or more days into gestation and the cervix and pelvic ligaments should be relaxed before parturition is induced.^{54,55,78,84} Because there are very few reasons for induction of parturition in the bitch and queen, few studies have been performed.

The principal reasons for inducing birth is to terminate the pregnancy and to allow delivery of the fetus(es) dur-

ing the daytime when trained skilled assistance is available. Other indications might include: a history of prior poorly viable neonates, prolonged gestation, abdominal hernias or severe edema, severe arthritis, possible injury or obstructions of the birth canal, fetal death or mummification and dropsy of the fetal sacs. There is no evidence to suggest that induced parturition can be more normal than natural birth. Therefore veterinarians should be both cautious and selective in their cases before recommending it and then carefully monitor the process. As animal owners are understandably prone to be highly critical should any adverse incidents occur to the dam or offspring during or for a long period after the induced birth (See Chart 2).

In mares the site for induced foaling should be in a clean, disinfected, quiet, isolated location. The most common technique or method is the injection of 20 to 100 IU of oxytocin into the mare with the criteria noted above.^{55,78} Forty to 60 I.U. given intramuscularly will usually result in a foaling within one hour. Recent studies have shown that much lower doses are probably safer even if a second or third dose at 30 minute intervals are needed to initiate the second stage of labor.^{77b} In mares ready to foal oxytocin in a dose as low as 0.5 to 10 IU caused the rapid release of endogenous PGF_{2a} and the initiation of labor within 90 minutes. Thus large doses greater than 10 IU may be unnecessary and even dangerous.^{77a} Large doses might cause uterine and muscle spasms,^{12b} premature placental separation or malposition of the fetus. The fetal membranes are usually noted at the vulva within 30 minutes. The fetus may be checked at this time or earlier to note and correct, if necessary, the position and posture of the fetus. The hormonal patterns produced by induction with oxytocin are similar to those occurring during a normal parturition.⁵⁴ Retained fetal membranes or subsequent infertility has not been experienced after inducing foaling in mares when the proper procedures were followed at full term.

As described in Chapter IV, the hormonal pattern at the termination of pregnancy in mares is very similar to that in women and different from the other domestic animals. A recent report on parturition in humans, causes one to speculate on a similar pattern in mares.^{41b} Namely, under the influence of estrogens during pregnancy there occurs a dramatic increase in myometrial oxytocin receptors. This lowers the threshold so rather small doses of oxytocin probably from the fetus activates myometrial activity and contractions as well as producing prostaglandin from the placenta where oxytocin receptors have also greatly increased. Prostaglandin release is essential for the dilation of the cervix and both hormones further promote uterine contractions and birth through the relaxed cervix.

Chart 2a. Hormones Used Effectively for the Induction of Parturition**

Species	Corticoids		Estrogens	PGF _{2α} and analogues	Oxytocin
	single administration	multiple			
Cow	+++*	+++ ¹ *	+	+++*	0
Ewe	+++*	n.n.	+++*	+++	0
Doe	++	n.n.	+++*	+++	0
Sow	±	+++	n.t.	+++*	0
Mare	±	+++	n.t.	+	+++*

¹May be necessary to assure the delivery of fetus; can be replaced by a single dose of a long-acting corticoid.

n.n. = not necessary; single injection fully effective.

n.t. = not tested.

*Presently most preferred technique.

Dose levels: Corticoids: Two to three times the optimal therapeutic dose.

Estrogens: Large therapeutic doses, repeated if not long-acting.

PGs: Equivalent or larger than the luteolytic dose in cycling animals.

Oxytocin: 20–100 I.U., repeated small doses, 5 to 10 I.U. preferable.

Legend: +++ = 90–100% effective; ++ = 70–90% effective; + = 60–80% effective; ± = ca 50% effective; 0 = not effective.

**Modified from W. Jöchle.⁶¹

Chart 2b. Condition of the Fetus and the Maternal Endometrium and Response to Hormonal Induction of Parturition (close to term, in delayed, or in pathological gestations) in the Cow.*

Condition of the conceptus ²	Condition of the maternal endometrium	Corticoids	Estrogens	Prostaglandin F _{2α} and analogues
Fetus alive, normal developed, approaching term.	normal	+++	+	+++
Fetus alive, normal developed, delivery delayed	normal	+++	+	+++
Fetus dead (shortly before term).	unknown	0	+++	+++
Dropsy of the fetal sacs: hydrallantois and/or hydramnios.	unknown	+++ ¹	+++	+++
Fetus died and is mummified.	normal	0	+++	+++

Legend: +++ = 90–100% effective; + = 60–80% effective; 0 = ineffective.

¹Depends on stage of gestation and viability of fetus.

²When fetal viability is unknown or fetus is dead, combined therapy of 2 or more hormones is probably indicated.

*Modified from W. Jöchle.⁶¹

Ordinary to large daily doses, 10 to 40 mg., of the glucocorticoid, dexamethasone, for 4 to 5 days did not induce foaling in mares late in the gestation period. However, when massive doses of 100 mg. of dexamethasone were given daily for 5 days from 321 to 324 days of gestation parturition occurred 3 to 7 days after the first injection.³⁴ Estrogens to induce foaling in mares has not been adequately investigated. Estrogen and dexamethasone given 24 hours before giving PGF_{2α} to mares between 325 and 354 days of gestation with none showing impending signs of foaling resulted in induced normal parturition 3 hours after the third dose of PGF_{2α} given

at 12 hour intervals.¹⁰² The prostaglandin analogue, fluprostenol, when given intramuscularly to mares (1000 ug) or to pony mares (250 ug) not showing imminent signs of foaling, produced the first stage of labor within 30 minutes and normal foaling occurred within 90 minutes in mares that were apparently hormonally ready for induction.⁸⁴ Further study on the use of prostaglandins to induce foaling in mares is indicated but presently oxytocin is the drug of choice.^{77a}

In sows induction of parturition may be produced by exogenous dexamethasone or PGF_{2α} or prostaglandin analogues.³⁵ Injection of dexamethasone results in a con-

siderable variation and a longer time period to produce delivery. While the prostaglandins, 10 to 12 mg PGF_{2a} , 175 ug **Cloprostenol** or 5 mg **Prostalone**, if given on days 111, 112 or 113 of gestation, preferably the latter two days, results in delivery of pigs in an average time of 33 hours.^{35,42,50,56} About 80 percent of the sows treated with PGF_{2a} farrowed within the predicted 12 hour period and 95 percent within 48 hours. When parturition was induced before day 111 of gestation in sows, unacceptable neonate losses resulted due to prematurity and poor viability.^{33,35} Thus if accurate breeding records with identified sows are available, treatment early one morning results in nearly all sows farrowing during daylight hours the next day when attendants are available. Farrowing could be planned for groups of sows 3 days a week, avoiding weekends and holidays. Cross-fostering of pigs would be more efficient. Induced farrowing might aid in reducing the incidence of M.M.A.^{16b,26} The prostaglandin analogues in sows, as in mares, produced less side effects of restlessness, rubbing and gnawing, salivation and increased respiration rates, defecation and urination than PGF_{2a} .²⁷ Following the administration of prostaglandins, progesterone levels decline rapidly due to luteolysis of the corpora lutea. During the day after the injection of prostaglandin about two hours after a stream of milk could be expressed from the teats or 28 hours after the injection of **Cloprostenol**, 50 IU of oxytocin will markedly shorten the time to birth.¹⁰⁵

In cows 16 to 30 mg of dexamethasone or 5 to 10 mg of flumethasone induced parturition after day 265 of gestation in over 80 percent of the cattle. The time from treatment to parturition ranged from 30 to 60 hours. Fifty to 90 percent of the cows had a retained placenta.^{33,60,104} Evidence would indicate that the glucocorticoid stimulated the release of estrogen from the placenta followed by the release of PGF_{2a} by the uterus which caused luteolysis. Treatment with estrogen, 25 mg of estradiol, before or at the same time as the injection of a glucocorticoid increased the percent of cows delivering, tended to shorten the time to delivery of the fetus and somewhat reduced the incidence of retained placentas.^{12,88} However the problem of estrogen residues in milk limits the use of this hormone in dairy cattle. The local treatment and manipulation of the retained placenta accompanying most cases of induced parturition in cattle should be avoided but parenteral injections(s) of antibiotics were indicated. The fetal membranes dropped from the uterus within 10 days and subsequent delayed conception and infertility was not a problem.^{33,60,104}

The injection of 20 to 40 mg of prostaglandin F_{2a} into cows after 265 days of gestation induced parturition in 90 to 100 percent within 57 to 100 hours. The time from treatment to delivery was longer with prostaglandin F_{2a}

than with the glucocorticoids.^{33,60,63} The incidence of dystocia was somewhat higher, the percent of live calves slightly lower and the incidence of retained placenta about the same as with the glucocorticoids. Estrogens will also induce parturition in dairy cattle but high doses of 100 to 150 mg of diethylstilbesterol or its equivalent must be used and residue problems would occur.⁶⁰ Combinations of a glucocorticoid, 25 mg dexamethasone, and PGF_{2a} or prostaglandin analogues, 500 ug **Cloprostenol**, have been used to produce abortions within 4 to 6 days in 93 to 100 percent of heifers from 1 to 8 months of gestation.^{6c} In New Zealand over 1 million late-calving dairy cows were induced to calve up to 3 to 5 weeks before term for economic and managerial reasons by the injection of a slowly absorbed corticosteroid formulation of betamethasone. Treated cows were observed carefully for parturition and periparturient disease problems. Retention of the placenta was commonly observed. It was determined there was no economic benefit to such a practice unless the cows were normal, young and healthy and advantages were indicated beyond the first lactation.^{71b} **Cloprostenol (Estrumate)** at a dose of 500 ug IM in cows and heifers from 250 to 300 days of gestation induced parturition in 95 percent of 64 animals within 0 to 60 hours, average 47 hours. It was desirable to induce parturition within one week of the expected calving date. Retained placenta occurred in 62 percent of the cows and 91 percent of the calves were viable.^{61b}

Thus both the glucocorticoids and prostaglandins reliably induce parturition in cattle after 265 days of gestation. Until further extensive comparative trials are conducted the glucocorticoids appear to be more desirable and safe in producing shorter gestation periods, none or very slight, increase in calving difficulty, slight reductions in birth weights, healthy viable calves and a reduced udder edema in dairy heifers and cows.⁸⁸ Heifers tended to have a shorter time interval from treatment to delivery than cows.⁶³

In ewes given 20 mg of estradiol benzoate at 142 to 148 days of gestation 65 percent lambd within 48 hours and 84 percent lambd within 96 hours.¹⁶ This treatment could not be recommended because of the high incidence of lamb mortality in the 16 percent of the ewes that did not respond to the treatment. In another trial ewes were given either 2 mg flumethasone or 15 mg prostaglandin F_{2a} on day 141 of gestation.⁵² Eighty nine percent of ewes treated with flumethasone and 33 percent treated with PGF_{2a} lambd within 72 hours after treatment. The average or mean hours from the flumethasone treatment to lambing was 50.9 hours for those ewes lambing within 72 hours. Another study in which 2 mg of flumethasone was given to ewes on days 138 through 144 of gestation, 67 to 89 percent of ewes injected on days 140 to 144 of

gestation lambled within 72 hours after treatment. Of those ewes injected on days 138 and 139 of gestation only 31 to 41 percent lambled within 72 hours.⁸¹ These studies further emphasized the need for more trials with prostaglandins and the importance of accurate breeding dates and records. Although further evaluation is needed, the use of 10 to 20 mg of dexamethasone in ewes 140 days pregnant induced parturition, and pregnancy toxemia losses were reduced.^{2,57}

In does the administration of 15 mg PGF_{2a} at 140 to 142 days of gestation resulted in induced parturition within 36 to 70 hours. Retention of the placenta for up to 24 hours with secondary metritis occurred in a number of does.¹³ Induction of parturition in goats has also been produced with estrogens and glucocorticoids but because of a lack of economic interest extensive studies in the doe have not been made.^{33,60} The doe responds to the above hormones in a manner similar to that of the cow to produce luteolysis and a rapid drop in progesterone levels with subsequent delivery. Live birth only occurs when estrogen and PGF_{2a} treatments are given after day 139 of gestation.³³

The Stages of Parturition

Although the act of parturition is continuous, for purposes of definition it is usually divided into three stages or phases.

First Stage—This stage is characterized by the relaxation of the cervix and active contractions of both the longitudinal and circular muscle fibers of the uterine wall. In ewes, does, and possibly the other domestic animals, the collagenous structural nature of the cervix probably requires a mechanism involving an enzymic degradation of collagen to cause cervical relaxation and softening. This is apparently brought about by a declining progesterone level, an elevated estrogen level and an elevation of prostaglandins. The latter are probably within the cervix.³⁶ In the sow and possibly the other species relaxin also plays an important role in cervical relaxation.^{21,33,49} The elevated levels of estrogen and prostaglandin and reduced progesterone induced in most species by an elevated level of glucocorticoids in the fetus result in uterine contractions. Oxytocin is seldom released from the hypophysis prior to the second stage of labor so is not essential for the induction of parturition or labor.^{21,38,49,69,101} Uterine peristalsis starting in the apices of the uterine horns is initiated by circular muscle contractions synchronized by propagation of the action impulse through the longitudinal muscles. Uterine contractions perform 90 percent of the work of parturition and

these contractions are directly proportional to fetal resistance. There is a greatly increased activity of the uterine musculature the last 1 to 2 hours before birth. The average prepartum amplitude of uterine muscle contraction was 80 cm. of H₂O. Uterine contractions force the fetal membranes and their fluids against and into the relaxed cervix. The external os of the bovine cervix relaxes sufficiently a week or so before calving to accommodate 2 to 4 fingers.⁴ The cervix of heifers remained tightly closed until the day before parturition. In the first stage of parturition the cervix was not dilated by the allantois chorion but was pulled open by the contraction of the longitudinal uterine muscles. For most of the first stage the cervix easily contained the allantois chorion that projected into it. True dilation of the internal os started 2 to 4 hours after the external os had reached a diameter of 8 to 12 cm and by 6 to 12 hours the whole cervix was 12 to 15 cm wide and the cervix and vagina were a continuous canal filled with the distended allantois-chorion. Once cervical dilation is complete, the bovine fetus is expelled within 2 to 4 hours unless fetal or maternal causes for dystocia are present.⁹²

During the first stage in the cow, uterine contractions occur about every 10 to 15 minutes and last 15 to 30 seconds. As the stage advances they increase in frequency, strength, and duration until contractions occur about every 3 to 5 minutes.^{8,46} In uniparous animals the contractions start at the apex of the cornua while the caudal part does not contract but rather dilates from the pressure of the fetus and fluids forced caudally. In this stage in the mare^{4,85} and probably the bitch the fetus is rotating from its dorso-pubic or dorso-lateral position into the dorso-sacral position. As it passes through the cervix into the birth canal the legs and head are extended. In the bovine and ovine fetus no rotation is necessary, as it is already in a dorso-sacral position. By the end of this stage the cervix is completely dilated.

The multiparous animals have a more complex mechanism of uterine contractions.^{4,8} The contractions of the uterus occur just cephalad to the most caudad fetus forcing it through the cervix into the birth canal, while the rest of the uterus remains quiescent. Then the same process is repeated for the most caudad fetus in the other horn, or the fetus immediately cranial to the one just expelled. This may help explain why in the second stage two fetuses may be born nearly simultaneously. The longitudinal fibers of the parts of the horn just emptied contract, but the circular fibers remain relaxed, so that the next fetus may pass through. This shortens the uterus as parturition progresses, so that each fetus in turn is brought back nearly to the cervix. This is important in multipara so that the fetuses at the apex of the uterine horn do not have to traverse a long uterine horn after the placenta

has been detached or the navel cord ruptured. The normal and abnormal behavioral patterns, or ethology, of the various species of animals before, during and after parturition has been described.^{39,40}

During this first stage of parturition which lasts about 1 to 4 hours, straining or labor is not exhibited in the mare. The symptoms of restlessness, anorexia, colicky pains, slight sweating behind the elbows and around the flanks, lying down and getting up, tail switching, elevating of the tail, repeated periodic sudden complete arrest in motion even chewing, repeated stretching as if to urinate, frequent small bowel evacuations, and looking at the flank are characteristic of abdominal discomfort in the mare during the latter part of this period. Usually the pulse and respiratory rates are accelerated. During the latter part of the first stage just prior to labor the mare may roll back and forth in an apparent effort to rotate the fetus into a dorso-sacral position. Both fetal and maternal activity and movements result in the turning or rotation of the fetus.⁸⁵ The mare may crouch, go down on her knees, rise again and be highly restless. The body temperature may become slightly lower than normal during this period.⁴

In the cow and ewe the symptoms of abdominal pain or discomfort may not be evident especially in pluriparous animals. In heifers, colicky symptoms and restlessness usually are observed and may last for 1 to 24 hours. The cow and ewe will show anorexia, stand with an arched back and raised tail, strain occasionally, and ruminate irregularly. The cow may lie down and get up frequently. Pulse and respiratory rates increase but lowering of the body temperature is inconstant.

In the bitch, sow, and cat nervousness, anorexia, and an increase in pulse and respiratory rates usually occur. In dogs this may result in panting. The signs of various stages of parturition in the bitch have been described.⁴¹ Occasionally vomiting is observed. This stage usually lasts for about 2 to 12 hours. In the dog there is usually a sudden drop of 1 to 2° F in body temperature to below 100° F just before or during this phase of parturition.

A drop in body temperature of 1 to 1.5° F just before parturition in cows, ewes, sows and bitches has been reported.^{22,23,30,31,32,107} This decline in temperature is related to the decline in progesterone levels. However because of its variability under field conditions, this fall in body temperature is of little practical value in predicting the onset of parturition in the cow, sow or ewe. In all animals in which a drop in body temperature occurs during this first stage, the temperature afterwards rises and reaches a peak during and shortly after parturition due to exertion.

This first stage is apparent for longer periods in pri-

miparous than pluriparous animals. During this stage in some animals of all species, milk or colostrum may drip or run from the udder. Usually toward the end of this first stage the allantois chorion ruptures as it is forced through the dilated cervix into the vagina. After the allantois chorion ruptures, the amnion pushes into and through the cervix, and the fetus—because of the shortening and contracting of the uterus and dilation of the cervix—passes into the cervix and vagina. Once a portion of the fetus enters the pelvis, reflex stimuli result in straining or labor. This is produced by contractions of the abdominal muscles and diaphragm together with a closing of the glottis; and the second stage of parturition begins.

Presentation, Position and Posture of the Fetus—

It is essential for the sake of accuracy to describe the various presentations, positions, and postures a fetus may assume at the time of its entrance into the birth canal or pelvis. These definitions were established by Williams¹⁰⁶ and are commonly used in the description of both normal and abnormal births.

The **presentation** includes: (1) The relation of the spinal axis of the fetus to that of the dam. Presentations are either longitudinal or transverse. (2) The portion of the fetus that is approaching or entering the pelvic cavity or birth canal. This portion of the fetus is anterior or posterior in the longitudinal presentation, or dorsal or ventral in the transverse presentation.

The **position** includes: (1) The relation of the dorsum of the fetus in longitudinal presentation, or the head in transverse presentation, to the quadrants of the maternal pelvis. These are the sacrum, the right ilium, the left ilium, and the pubis.

The **posture** signifies the relation of the extremities, or the head, neck, and limbs, to the body of the fetus. The extremities may be flexed or extended or retained beneath, on the right or left side, or above the fetus.

In outline form the presentation and position include all possible variations of the manner in which the fetus may enter the birth canal at parturition.

Presentations	Positions
Anterior, longitudinal	Dorso-sacral Right dorso-ilial
Posterior, longitudinal	Left dorso-ilial Dorso-pubic
Transverse ventral	Right cephalo-ilial
Transverse dorsal	Left cephalo-ilial

The normal presentation in uniparous animals is the anterior longitudinal presentation, dorso-sacral position with the head resting on the metacarpal bones and knees of the extended fore legs. Birth can take place without assistance if the fetus is in the posterior longitudinal presentation, dorso-sacral position. Unless the fetus is small, other positions result in dystocia. The transverse presentation is seen only rarely in ruminants and multipara. It can occur in the mare, in which the fetus develops in both horns, rather than in the body and one horn. Dystocia invariably results. The posterior longitudinal presentation, dorso sacral position, with the hind limbs retained or extended beneath the body, is commonly spoken of as **breech presentation**. Two old terms, only rarely used, are "sterno-abdominal" presentation, which is a transverse ventral presentation in the mare, and "poll" presentation which is an anterior longitudinal presentation, dorso-sacral position, with the head flexed beneath the neck. The position of the fetus in the uterus was discussed in Chapter 4. Thirty to 40 percent of the fetuses of multipara are presented posteriorly and this is considered normal or physiological. Because of the short neck of swine fetuses, the head and neck are seldom deviated. Since the limbs in multipara are small, short and flexible, their posture is of no importance. They may be extended beneath or in front of the body or flexed without resulting in dystocia. In ewes 69.5 percent of fetuses were in normal anterior presentation with the extremities extended and 17.8 percent of the fetuses were normal except for one retained or flexed leg.⁴ In sheep, fetuses may be expelled without assistance in anterior presentation with one fore limb extended beneath or alongside the body. When both forelimbs are retained beneath the body dystocia usually results.

The Second Stage—This stage is characterized by uterine contractions, the entrance of the fetus or fetuses into the dilated birth canal; rupture of the allantoic sac; abdominal contractions, or labor; and the expulsion of the fetus through the vulva. In the cow abdominal contractions occurred only after the feet of the fetus were in the cervix or vagina.⁴⁶ Breaking of the allantoic sac caused a sudden increase in abdominal contractions that were superimposed on the crest of each uterine wave with amplitudes of 80 to 320 cm. H₂O, average 180 cm. H₂O. In the cow and mare following the rupture of the allantoic sac, the amnion is pushed through the cervix and may appear at the vulva as a translucent distended membrane.⁸⁵ During this second stage of labor, uterine contractions occurred in the cow about 4 to 8 times every 10 minutes and lasted 80 to 100 seconds.^{8,46} Intermittent tenesmus or straining continues and the feet of the fetus appear at the vulva. As the feet pass through the vulva

the amniotic sac usually ruptures. Point pressure rather than diffuse pressure such as that exerted by the allantoic sac is the stimulus to abdominal contractions. Passage of the head, shoulders and hips of the fetus through the pelvis caused an increase in abdominal contractions. The fetal head starts through the vulva and at this point the greatest and strongest abdominal straining in the birth process usually occurs. In the larger uniparous animals as the head is being forced into the vulva, the chest is entering the pelvic canal. Often after the head passes the vulva the dam will rest for a few minutes before beginning straining again with strong abdominal efforts as the chest passes through the birth canal and vulva. The hips usually follow through the birth canal fairly rapidly but occasionally the hind limbs may remain in the vagina until the fetus or dam moves.⁸⁵ In goats and cows during the passage of the fetus through the birth canal and when the vagina was dilated there was a great increase in the levels of oxytocin in the jugular blood over that present during the first and early second stages of labor when in general it was similar to the very low blood levels present during pregnancy.^{38,101} The release of oxytocin during most of the second stage of labor was continual in contrast to spurts in the release of oxytocin during the milking act. Oxytocin causes the release of prostaglandins which further increases uterine contractions and cervical dilation.^{47,51,85} The levels of oxytocin in the blood plasma of goats, sheep and cows during the second stage of labor was 77 to 381, 5 to 3000, and 400 to 1000 microunits per ml., respectively. The half life of oxytocin in the blood is one to one and one-half minutes. In the goat the posterior pituitary gland contains about 9 to 13 units of oxytocin and about one-tenth that amount is released during parturition.^{38,101} Passage of the fetus through the birth canal not only causes the release of oxytocin but also the release of prostaglandins in the mare⁸⁵ and probably the other domestic animals.

Almost all animals lie down as soon as straining commences. The foal or calf may be born with the dam standing in only about 1.5 percent of mares and cows.^{85,92} The mare and sow usually lie out flat with the legs extended, whereas the cow, bitch, and ewe are more likely to lie on their sternum. In the mare straining is usually characterized by several, 2 to 5, strong expulsive efforts followed by 2 to 3 minutes of rest. This procedure is repeated at fairly regular intervals. In the mare one foreleg of the fetus precedes the other by 6 inches as the fetus passes through the birth canal.⁴ This indicates that one elbow and shoulder enters the birth canal before the other. The foal's cheek is usually lying on the limbs with its muzzle midway between the knee and fetlock joints. Although parturition is quite rapid in the mare it is ac-

companied by such great expulsive efforts that the mare is usually exhausted and will lie on her side for 15 to 30 minutes before rising.^{83,85} Since the umbilical cord in the mare is long it often does not rupture as the fetus passes through the birth canal. It will remain attached to the fetus for an average of 8 to occasionally 30 minutes until the mare or foal moves, when it breaks at a point about 3 to 5 cm from the foal's body. Pulsations can usually be felt in the umbilical artery for one to 9 minutes. If the umbilical cord is separated immediately 400 to 1,500 ml of blood is lost to the fetus.⁸³

In the cow the straining is not as forceful or as frequent as in the mare. During the early part of labor the cow may remain standing. Its body temperature may increase to a high normal level and the pulse and respiration rate will rise due to the exertion, as is observed in other animals. In the ewe the second stage of birth is similar to that in the cow. Once the second stage begins the abdominal contractions develop with gradually increasing frequency and intensity until birth has occurred. The periods or bouts of abdominal straining occur every 2 to 3 minutes and consist of 5 to 8 abdominal contractions in the cow. These abdominal contractions will increase and resting time decrease as the fetus enters and passes through the birth canal.⁹² If these contractions become reduced in number or intensity usually assistance will be necessary to deliver a live fetus, as this condition does not occur in normal deliveries. Once the feet have passed through the vulva they should stay there and not appear and disappear at each abdominal contraction. This same pattern is followed in other domestic animals.

In the bitch the amnion as it appears at the vulva before the first pup is usually broken by the bitch as she licks the vulva. In the bitch the delivery of the head through the vulva requires the greatest expulsive efforts. The umbilical cord, which is still intact at birth, is usually broken by the bitch. After the birth of each pup the bitch rests, licks the pup and her vulva. When the fetal membranes are expelled—in about 10 minutes after the birth of the pup—they are eaten by the bitch. It is probably best to let the bitch eat only 2 or 3 placentas and then remove the rest, as consumption of too many placentas may cause vomiting and diarrhea. The greenish-black fluid that is discharged following the fetal membranes is normal and is due to the breakdown of blood resulting in the presence of bile-like pigments, uteroverdin, around the edges of the placental zone of attachment. Straining begins again after 0.5 to 1 hour or more and another pup is expelled. Although it may take about 1 hour of labor for the first pup to be born, the periods of straining for the second and third pups are usually progressively shorter. The rate of expulsion of the fe-

tuses is very irregular. Some bitches may not expel the second fetus for several hours after the first. Then the next 2 or 3 may be expelled rapidly within 10 to 30 minutes of each other followed by another delay. Rarely are the pups expelled rapidly in a short time. They may also be expelled at somewhat regular intervals. The sow and queen have a second stage of birth similar to that in the bitch. The period of time between the expulsion of pigs varied from 3 to 45 minutes or rarely longer. The longest intervals were observed between the first and second pig and before the last pig.^{4,61,69} About three-quarters of the pigs were born with the umbilical cords intact and it took 2 to 6 minutes average time before rupture. After farrowing the sow usually urinates copiously.

In multipara the fetuses are expelled in an irregular and random manner from each horn, that is, one fetus may be expelled from one horn and then 2 or 3 from the other and then 2 from the first and one from the second, and so forth. In the bitch, but not the sow, the horn containing the most fetuses expelled the first fetus.⁹⁵ About half of the pigs born came from the same horn as its predecessor and the other half from the opposite horn.^{25b} In some sows most of one horn would empty and then all of the other and the remainder of the first horn and etc. In general porcine and canine fetuses came randomly. Porcine fetuses occasionally passed each other within the horn or uterine body and as many as 20 percent of the fetuses changed their presentations in late gestation or during parturition.⁹⁵ In 73 canine fetuses marked by transuterine injections at laparotomy between 45 and 54 days of gestation, 56.2% were in anterior and 43.8% were in posterior presentation. Between marking and birth 6.9% changed from posterior to anterior presentation. At no time did a canine fetus located more tubally pass another fetus located closer to the cervix. After the birth of one pup, the next pup came from the contralateral horn in 78.2% of the births. Therefore the two horns did not alternate in presenting a fetus into the birth canal. In the 14 bitches in their first to third parities the average duration of gestation was 62.3 days and the duration of parturition from the first to last pup ranged from 100 to 875 minutes (1.6 to 14.5 hours). Eight of the 14 bitches were given 1 IU oxytocin during parturition with 33.3%, 66.6%, 71.4% and 88.1%, of the pups born within 30, 60, 90 and 120 minutes, respectively of its predecessor.^{101b}

The presence of a dead fetus may delay the emptying of that horn. Occasionally in the mare, bitch, and only rarely in the other domestic animals, the fetus may be born with the amnion or a portion of it wrapped around its head. In the mare this may cause suffocation of the foal if not promptly removed. In carnivora, death is not

likely from this cause since the bitch and queen promptly licks and eats the amnion.

During this stage the contracting and shortening uterine walls force and direct the fetus into the birth canal and pelvis and abdominal contractions, or labor, drives the fetus through the birth canal. The intra-uterine pressure in the cow was 66 mm. of Hg between uterine contractions during the second stage of labor. The pressure reached about 170 mm. of Hg at the time of abdominal contraction. Thus the total pressure at the opening of the pelvic inlet is about 150 to 170 lbs., or about what one man could apply by traction on the fetus.⁷

The intra-abdominal pressure, caused by contraction of the abdominal muscles and diaphragm and closure of the glottis, is equal in all directions. The uterus is necessary to direct the fetus into the path of least resistance—the pelvic canal. If a large hernia is present abdominal contractions could force the uterus into the hernia. Not uncommonly traumatic gastritis or displacement of the abomasum may occur as a sequelae to parturition, due to the abdominal pressure. A healthy fetus, intact abdominal walls and a healthy uterus are necessary for normal birth.

In uniparous animals the large fetuses pass through an arc from the abdominal cavity upward into and through the pelvis and then downward again as they pass through the vulva. In the cow the fetus must pass over the high ischial tuberosities. This arc-like direction of the fetus as it passes through the pelvis causes stretching of its dorsal and pelvic muscles and a relaxation of the linea alba and abdominal muscles. The latter is important because it allows the pelvis to be extended backward on the fetal sacrum, thus reducing the sacro-pubic diameter of the fetal pelvis. The downward direction of the cranial portion of the fetus as it passes the vulva tends to push the fetal pelvis high in the maternal pelvis, where the bisiliac diameter is greater. This helps prevent a hiplock condition frequently encountered when traction is incorrectly applied. In hiplock the greater trochanters fail to pass between the shafts of the ilia.

The time for this second stage of birth in the cow is from 0.5 to 3 to 4 hours. In pluriparous cows this second stage usually requires 0.5 to 1 hour. Primipara may take longer, up to 3 hours or more. In ewes and goats the second stage of labor is completed in about 1 hour, range 0.5 to 2 hours, or slightly longer if twins or triplets are present. In mares this second stage is normally completed in 5 to 60 minutes with an average of 20 minutes.^{4,83,85} In multiparous or polytocous animals the length of the second stage of birth is variable, often depending upon the number of fetuses in the uterus. In the bitch the expulsion of the first pup may take up to 1 hour and

a variable time for each fetus thereafter. The average total time for the second stage of parturition in a bitch is 3 to 6 hours. Twelve hours would certainly be near maximum. In the sow the second stage is usually completed within 1 to 5 hours but occasionally may last up to 8 hours. In the sow the interval between the birth of pigs averaged 15 minutes but ranged from 1 minute to 3 hours.⁸⁶ A longer time interval between pigs often precedes the expulsion of a stillborn fetus. In the queen the time required to complete the second stage of labor is usually 1 to 2 hours with several minutes to an hour interval between kittens. In some cases delivery of fetuses may occur several days apart.²⁰ In the sow and bitch after the second stage of parturition is completed they actively nurse their young, cease straining, and are quiet and content.

When the umbilical cord ruptures, the two umbilical arteries together with the urachus retract into the abdominal cavity of the fetus. By the contraction of the arteries into the body tissues, provision is made for the prevention of bleeding from the navel. The umbilical vein collapses, the blood drains from it and the fluids in the umbilical cord drain out, often aided by the licking of the cord by the dam. The umbilical cord becomes necrotic, dries up and drops away in 7 to 21 days.

The Third Stage—The third and last stage of parturition is the expulsion of the fetal membranes and the involution of the uterus. These two conditions are discussed separately because the expulsion of the fetal membranes is normally completed within a few hours after the expulsion of the fetus, whereas involution of the uterus to its normal nonpregnant state may take more than a month in some species.

Fetal maturity is synchronized with parturition by the decline in progesterone and the elevation of prostaglandin and cortisol in the doe and ewe and the other animals. This alteration in hormone levels late in gestation also results in placental "maturation" and the initial early changes which after fetal birth result in the rapid separation of the fetal and maternal tissues at the microvillous junction and the initiation of lactation.^{24,94,98}

Expulsion of the Fetal Membranes—With the birth of the fetus, the vessels in the fetal placenta collapse and the villi become small and shrunken. After the expulsion of the fetus the uterus still contracts strongly for 48 hours and less vigorously, but more frequently, thereafter.^{46,62,92} This is necessary to prevent hemorrhage and to aid in the expulsion of the fetal membranes. These peristaltic and contraction waves besides reducing the size of the uterus and aiding in forcing the placenta and membranes into the birth canal probably markedly reduce the amount of blood circulating in the endometrium. This

causes a dilation or relaxation of the maternal crypts. The shrinking of the villi and the dilation of the maternal caruncular crypts probably play a major role in the separation of the fetal trophoblast and cryptal epithelium of the maternal placenta. No maternal tissue is shed in the afterbirth of cows. However a few fetal villi may be caught and left in the maternal crypts.¹⁰ The middle uterine artery immediately contracts following parturition. The artery becomes thickwalled and the characteristic thrill of "whirring" is absent although it may be several weeks or more before it involutes to near its normal size. In exceptional cases an aneurism of this artery may occur and a thrill or "whirr" may be palpated over a portion of the artery for several weeks or longer following parturition. The uterine contractions during this third stage produce movement of the uterine wall and caruncles that may aid in freeing or separating the fetal placenta. There is no muscular tissue in the caruncles. The weight of the amnion and the portion of the allantois chorion in the birth canal tends to help remove the afterbirth from the uterus. The incidence of retained afterbirth was much higher in buffalo in which the young were not allowed to suckle, 22.7 percent, than when the young were allowed to suckle, 4.9 percent.¹⁰³ It is well-known that suckling stimulates the release of oxytocin from the pituitary gland. A lack of progesterone during the last month or so of pregnancy resulted in the occurrence of parturitions 10 to 20 days earlier than normal together with a high incidence of retention of the placenta.^{69a,69b} Early parturition, twin pregnancy or a shortened gestation period have frequently been observed associated with retained placenta. In these instances infection may play a pathogenic role. This will be discussed further under retention of the fetal membranes. Normal expulsion of the fetal membranes can be said to be a complex process involving both mechanical and hormonal factors, although the exact mechanism is still not completely understood.

In bitches and queens the fetal membranes are usually expelled irregularly between the fetuses; or one fetus may be expelled with its own placenta and that of a fetus expelled earlier. In rare instances expulsion of a few placentae may be delayed for 12 hours or more. In the sow, since a number of the allantois chorions may be fused, the fetal membranes may be expelled at only 2 to 3 intervals during parturition. Most porcine afterbirths were expelled from 20 minutes to 12 hours, average 4 hours, after the birth of the last pig.⁶¹ Occasionally placentas were retained with no observed ill effects. The fetal membranes of the last fetuses in the bitch are usually expelled shortly after the birth of the last pup. This third period of labor is characterized by relatively short, infrequent, and mild periods of straining usually at the time

the larger mass of membranes are expelled or when much of the placenta is hanging from the vulva especially in uniparous animals. In most unipara the amnion and umbilical cord start through the birth canal first and as the allantois chorion separates from the endometrium at the apex of the horn due to peristaltic waves starting there, the chorion or fetal placenta is inverted and the allantoic surface is outside as the membranes are expelled from the uterus.⁶² If placental expulsion is delayed for a longer period of time than normal the chorion of fetal placenta may be exposed when it falls from the vulva. Occasionally when fetal expulsion is delayed the fetal placenta may separate, and later both the dead fetus and the fetal membranes are expelled or withdrawn together. Unlike the mare, placental separation in the cow is slower than in most other species of animals, so that the second stage of labor can be prolonged without the danger to the fetus. The umbilical cord of the bovine fetus is ruptured as the fetus passes through the birth canal. In the cow the length of time required for the expulsion of the fetal membranes is normally 1/2 to 8 hours. The ewe is similar to the cow. The mare normally expels its fetal membranes within 0.5 to 3 hours after the birth of the foal. Generally, the healthier the animal the more prompt is the expulsion of the fetal membranes. Domestic animals, with the exception of the mare, will usually eat the expelled fetal membranes. Instances of cow's choking and suffocating while eating their placentas have been reported.^{100a,106} Ruminants will not eat their fetal membranes if the membranes are decomposed. Multipara usually eat the fetal membranes as well as any fetal cadavers. The act of eating the fetal membranes is not known to be beneficial in any way. In ruminants the placenta may lie in the rumen and slowly macerate or decompose over a period of several weeks or more and is occasionally suspected of causing indigestion. This is questionable, since nearly all cattle eat their fetal membranes and symptoms of indigestion or toxemia rarely occur. Occasionally the cow may begin eating her fetal membranes before they have dropped away from the uterus. After the expulsion of the fetal membranes in a normal birth, the cervix secretes a rather thick tenacious mucus that tends to seal the cervix and thus helps prevent infection gaining entrance to the uterus.

Involution or regression of the uterus in domestic animals, with the exception of the cow and the ewe, has not been extensively studied. In multiparous animals and the ewe, rebreeding the female within the next 1 to 6 months is seldom practiced. In the bitch, sow, and queen estrus usually does not occur until after the young are weaned. In the sow signs of estrus may be exhibited about 3 days postpartum but if copulation is allowed the conception rate is extremely low. In the mare, commonly

bred 9 to 30 days after foaling, relatively few studies have been made on the involution of the uterus. Regression of the mare's uterus proceeds at a rapid rate.^{3,94b} The endometrium, however, had seldom completely involuted by the onset of the foal heat. In many mares the endometrium must be largely restored by the third to fifth day after foal heat or 12 to 17 days postpartum when the early embryo enters the uterus. Conception often occurs from service at this estrum. By 13 to 25 days after parturition the endometrium was fully restored in all normal foaling mares. At the time of onset of foal heat the subepithelial areas of glandular epithelium were highly disorganized and contained large number of leukocytes. This would indicate the uterus was not yet in a completely involuted and normal state. However, after placental separation the uterine epithelium is relatively undamaged and by 7 to 10 days after a normal foaling involution of the endometrium is largely completed.^{94b} By the end of foal heat both the gross and microscopic involution was nearly complete.^{48b} The mare may discharge a slight amount of grey to brownish lochia for about one week postpartum. Involution appears more rapid in primiparous mares than in pluriparous mares. Exercise appears to hasten involution. The rapid involution of the endometrium in the mare and sow is probably related to the simple diffuse placental attachments. The genital tract of all mares became infected, usually with streptococci, at the time of foaling or within one to three days. In normal mares this infection was overcome soon after the onset of foal heat or about the sixth to tenth day after parturition.¹⁴ Pregnant sows from 30 to 100 days of gestation may be aborted within 34 to 42 hours by a single dose of 500 ug. cloprostenol, a prostaglandin analogue. Estrus occurred in these sows within 9 to 10 days and breeding on this first heat resulted in 90% conception.^{78a} Therefore uterine and endometrial involution in the sow is rapid as in the mare.

In cows the involution of the uterus has been carefully studied.^{7,15,17,66-68,73,74,79,92} Following the expulsion of the fetal membranes in the cow the uterine contractions and peristalsis continue as strong rhythmical waves that gradually diminish through the fourth day. In the cow the uterine muscle cells shortened from 750 microns after parturition to 400 microns one day later. From the fourth to eighth days there are only irregular undulations of the horn.⁷

The maternal placenta involuted by the necrosis of the caruncular stalk due to vasoconstriction, leucocytic infiltration and by the dissolution of the uterine caruncle by fatty infiltration, solution, sloughing and detachment of the entire superficial layer of the caruncle that became part of the uterine lochia.^{43,68,79} The caruncle and its stalk were necrotic by the fifth day after parturition. The dis-

solution and sloughing of the caruncle was generally completed by the twelfth day leaving a raw surface with protruding blood vessels where the stalk was attached. The caruncles had returned to nearly their original size by the second or third week. This delayed loss of maternal placental tissue through necrosis would lead to the observation that cattle and sheep are not true nondeciduate animals. By about 25 to 30 days postpartum, epithelium covered the caruncles and repair was complete. Thus a 70 gm. caruncle by 48 hours after birth reduced its size and weight to 26 gms. and was quite small 5 days later. Even when the caruncles are nearly normal in size at 30 days postpartum a large vascular bed of vessels remains. These feel rather fibrous and are present for a long period even if the animal does not become pregnant. The intercaruncular epithelium may be eroded by bacterial lysis but is normally repaired by 20 days postpartum.^{65,67}

The lochia in the bovine uterus the first 48 hours after parturition was greatest in amount of any period, about 1400 to 1600 ml. By the eighth day postpartum the amount had decreased to 500 ml. and by 14 to 18 days there were only a few ml. of lochia. The amount of lochia discharged from the vulva was variable. Most primipara discharged about 50 ml. Some primipara discharged almost no lochia but absorbed it from the uterus. Some pluripara discharged from 800 to 2000 ml. of lochia. Usually this discharge of uterine lochia, consisting of mucus, tissue, detritus, and blood, commenced about 3 to 4 days postpartum and increased until the ninth day. The detritus was light yellow-brown to red in color. After the ninth to tenth day postpartum, there was an increased amount of blood mixed with the lochia. This apparently originated from the surface of the caruncles. This bloody lochia usually ceased about the twelfth day. Hyperleukocytosis was found only the first 2 to 3 days postpartum. The process of normal involution took the course of an aseptic process. However, in the examination of apparently normal cows. A spontaneous puerperal infection causing a massive bacterial growth in the uterine lochia was often observed.⁷⁹ About 93 percent of bovine uteri were infected from parturition to 15 days postpartum, 78 percent between 16 and 30 days, 50 percent between 31 and 45 days and 9 percent between 45 and 60 days.²⁹ Lymphocytes were extremely numerous in the endometrium of infected uteri and only moderate in most bacteriologically sterile uteri.⁴⁴ In puerperal cows infections due to *C. pyogenes*, *E. coli*, staphylococcus, *Pseudomonas aeruginosa*, streptococci, or mixed infections were most commonly cultured. These infections in cows resulted in the lochia assuming a white, yellow-white or grey mucopurulent character toward the latter part of the puerperal period. Vaginal exudates of 5 to

200 ml. volumes in 30 to 35 percent of all cows were reported 10 to 20 days postpartum but only 2 to 5 percent had this volume at 30 to 50 days.⁹⁶ These latter cases were probably those with persisting infections.

Plasma levels of prostaglandin metabolite were high for 7 to 23 days postpartum. Cows with postpartum uterine discharges had longer periods of prostaglandin release, 16.7 days, and longer periods for the completion of uterine involution, 39.6 days, than the cows with a normal postpartum uterine involution 13.5 and 29.6 days, respectively. Progesterone levels remained at baseline levels in the postpartum period until the prostaglandin release had ceased.^{64a} The interval from parturition to complete involution of the uterus averaged 29.6 days (range 16 to 50 days). Prostaglandin increased uterine tone and promoted involution.^{64a} Presence of ovarian cysts had little or/no effect on uterine involution.

The involution of the bovine uterus and cervix based on rectal palpation during the postpartum period was reviewed and reported upon.^{73,74} The size of the bovine uterus decreased slowly between the fourth and ninth days postpartum. By the tenth day the involuting uterus could be completely defined by rectal examination. A marked decrease in uterine size and an increase in uterine tone occurred from days 10 to 14 coinciding with the onset of the first estrus in normal cows and the voluminous discharge of the uterine lochia. Fluid or lochia could be detected in the uterus by palpation on days 7 to 12 postpartum in many cows. During this period of 10 to 14 days postpartum the size of the postgravid uterine horn declined from 12 cm to 7 cm in diameter. The rate of uterine regression was quite rapid from 14 to 25 days postpartum. There was a decreased rate of involution between days 26 and 39. Between days 40 and 50 there was little change noted. Prior to day 20 postpartum the diameter of the cervix, 4 to 7 or more cm, was smaller than the horn and after days 22 to 25 the cervical diameter, 3 to 4 cm, was greater than the horn diameter.^{73,74,96} The following postpartum regression in the weight of cows' uteri was 10 Kg. at parturition, 5 Kg. at 6 days, 2 Kg. at 12 days, 1 Kg. at 25 days and 0.7 Kg. at 50 days.^{65,68} Within 24 to 36 hours after a normal parturition the hand could not be passed through the cervix and by the fourth day postpartum only two fingers could be introduced. If a retained placenta was present the rate of closure of the cervix was delayed and the hand could still be inserted at 48 hours and often at 72 hours postpartum. In general the major gross palpable or physical involution of the uterus occurred by 25 to 30 days postpartum. Changes after 30 days were much less marked and more gradual. A summary of reports on bovine uterine involution as determined by palpation showed the time for involution varied from 26 to 56 days post-

partum with a majority of authors reporting complete regression between 42 and 47 days.^{73,74,92} Clinical and rectal examination of the genital tract and ovaries of normal post partum dairy cows revealed the first estrus to occur about 15 days after calving with the second estrus occurring about 33 days postpartum after a somewhat shortened estrous cycle. Subsequent estrous cycles were a normal length. Great variations were observed in high-producing cows and those with abnormal parturitions. Silent estrus occurred in 77 percent of the first postpartum ovulations, 54 percent of the second and 36 percent of the third ovulations.⁷⁴ Hormonal profiles of individual dairy cows during the postpartum period of 40 to 78 days varied greatly but correlated fairly closely with clinical findings. The first preovulatory LH peak occurred at an average of 17 days (± 10 days) and the first estrus occurred on postpartum day 28 (± 16 days).^{88a}

During the spring and summer months cows' uteri involuted more rapidly than cows calving during the fall or winter months. Cows suffering from periparturient diseases such as retention of the afterbirth had a slightly slower rate of uterine involution. The normally regressing uterus did not become histologically normal until 50 to 60 days postpartum or about 20 days after the uterus had returned to a clinically normal or involuted state. Following a retained placenta leucocytic infiltrations occurred in large numbers and remained for 20 to 30 days beyond the normal histologic involution in normal parturition or until about 70 to 90 days postpartum. Corpora albicantia replacing the corpora lutea of pregnancy usually are larger, containing more connective tissue, than are corpora albicantia replacing corpora lutea that were active for only a short period of time. In some cows these may persist for a number of years. In nearly 20 percent of the cattle, resorption of the corpora albicantia occurred after the fourth pregnancy.^{25a}

Postpartum involution of the canine uterus is a prolonged process extending over a 12 week (3 month) period. Although the interplacental area returns to normal within a few weeks, the placental sites require many weeks to involute and heal.^{2b} But as late as 3 months after parturition, when the uterus is the size and appearance of the normal diestrous uterus, slight pigmented ring-shaped stripes may be observed in the endometrium indicating the former placentation sites. The bitch discharges much dark, mucoid, green lochia after parturition. This green pigment is uteroverdin and comes from the "green border" of the placenta.³⁷ This color is produced by the breakdown of hemoglobin. This decomposition product is the same as bilirubin and biliverdin. In the cat the placental border is brown. The first week the lochia is amber to red in color and by the second week it should be normal, clear mucus. The walls of the gravid horn

remain slightly thickened. In primipara and other young animals the uterus never returns to its pregravid size.

The rate of involution in the other animals is not as well known but in sows a lochial discharge may be observed for about a week and involution of the uterus was fairly rapid.⁷ The uterine mucosa of the ewe was completely involuted by 30 days after parturition and the process was described in detail.^{100b} The uterine weight of postpartum ovine uteri was 700 gms at 3 days, 200 to 250 gms at 7 days, 60 gms at 21 days, and 30 gms at 35 days.⁷⁰

Artificial Interference in Normal Parturition

If parturition is a normal one there is no need or necessity for outside aid by attendants. Such aid is ill-advised. In the artificial environment under which many domestic animals are kept certain sanitary and preventive precautions may be necessary. Valuable animals should be observed during the act of parturition so that injury to the newborn is not caused by the dam or the surroundings, such as a mare or cow trying to give birth with its rear quarters wedged into a corner of a box stall. The afterbirth of ruminants should be removed after its expulsion so that the dam will not eat it or choke on it. Following parturition it is highly essential that the dam and newborn not be disturbed for several hours so that close "bonding" between them can occur.^{56b} If the dam becomes excited after parturition, or for some other reason attacks the newborn, they should be separated. This condition is seen occasionally in the sow, the "berserk" sow, and in rare cases in the dog, in which the dam kills and even eats her young. The young cow may rarely attack her newborn offspring. Upon arising and feeling the placenta against her hocks or heels the mare may become excited, kick, and possibly injure the foal. Some horse men tie up the amnion to the umbilical cord so the membranes are not stepped on and torn.^{83,85} Occasionally in young mares, heifers, gilts, and ewes the udder may be so sensitive, edematous, and sore that they will not allow the newborn to nurse. After dystocia or for other unknown causes, females may reject, ignore, or fail to accept and nourish their young. In these cases the dam must be restrained or given a sedative or tranquilizer to allow the newborn to suckle or colostrum must be given and the newborn placed on a foster mother or fed milk replacer. If the cow or mare gave birth in a box stall, the wet, contaminated straw should be removed and replaced with clean, dry straw. If parturition took place in an unsanitary environment the navel requires disinfection.

It is desirable to have a comfortable, quiet, isolated,

sanitary place in which the animal can give birth. The dam and the newborn should be left alone unless the course of parturition is definitely abnormal. Close observation and knowledge of the normal course of parturition is necessary. If the first stage of parturition in the cow, doe and ewe is over 6 to 12 hours, in the mare over 4 hours, in the bitch, queen and sow over 6 to 12 hours; or if the second stage of parturition in the cow, doe and ewe is over 2 to 3 hours, in the mare over 20 to 40 minutes, in the sow, bitch and queen is over 2 to 4 hours, outside help is indicated. If at anytime the normal progression of the fetus(es) into and through the birth canal fails, assistance is usually needed. This should be obtained at once if severe injury to the dam or death of the fetuses is to be prevented. This aid to the dam is indicated if the frequency or intensity of abdominal contractions declines before the birth of the young or if the feet of the fetus in unipara appear and disappear with each labor contraction without progress in the passage of the fetus. In posterior presentation in primiparous, uniparous dams, outside traction may be desirable to avoid asphyxiation of the newborn. The help or assistance provided at parturition should be competent and experienced.

During the act of parturition it is not desirable or necessary to rupture the fetal membranes, either the amnion or allantois. It is not desirable to apply traction in physiological birth when the fetus first appears at the vulva. Such traction is likely to result in laceration and trauma of the dorsal commissure of the vulva or the perineum. Traction if applied too early before the cervix, vagina, or vulva is fully dilated, pulls these structures caudally and makes the lumen or diameter of the birth canal smaller, requiring trauma or rupture of the structures if birth is to be accomplished with traction. Williams stated, "In an experience exceeding 60 years I do not recall vulvar or perineal laceration in physiological birth in a domestic animal when not tampered with by attendants." There is no indication for or advantage to the administration of oxytocin before or after normal parturition. The umbilical cord should be allowed to break of its own accord in the mare. In the cat and bitch the dam usually bites it off or it breaks off naturally by traction. Ligation of the umbilical cord in animals is usually unnecessary and frequently predisposes to umbilical infection.

Care of the Newborn and the Dam

At the time of the birth of the young especially in the mare, an attendant should be present to remove the amnion that may be wrapped around the muzzle and nose and cause asphyxiation. The onset of fetal respiration

may begin before the fetus is completely expelled in some parturitions, especially those that are delayed. In normal parturitions respiratory movements in the fetus are initiated by several deep inspirations about 10 to 60 seconds after expulsion. In the foal this will often occur before the umbilical cord has ruptured. It is believed that either a rise in the CO₂ levels in the fetal blood,⁷ an increased hydrostatic pressure in the fetal vessels when the cord ruptures, or removal of the amnion from over the nostrils, or a combination of these factors initiates breathing in the newborn. If respiration in the newborn is delayed various procedures should be used to stimulate this activity. The mucus should be removed from the nose and mouth. The newborn should be laid on its side on straw, not loose chaff or shavings that might be inhaled, with the head and fore quarters slightly lower than the hind quarters. Vigorous rubbing of the newborn with straw, hay, towels or shaking its head, or tickling its nostrils, will help bring about respiratory activity. The use of an oxygen tank and an attached short rubber tube has proven useful in saving some weak newborn. The tube is passed into the pharynx and the nostrils and mouth are closed tightly. Oxygen under moderate pressure distends the lungs. Opening the nostrils and pressure on the chest collapses the lungs and the process is repeated as often as necessary. A positive pressure "Bird" respirator may also be used. A warm oxygen tent or chamber may help save some weak pups or kittens. In recent years several simple resuscitators with attachments for an oxygen tank are commercially available. These actively remove excess mucus from the lungs and provide oxygen. Other practices, such as artificial respiration, have not proved very satisfactory or saved many weak newborn animals. Electrocardiographic studies showed a rapid rise in the heart rate occurred at birth, from 54 to 60 to 108 to 216 beats per minute in the equine newborn and from 72 to 108 to 96 to 120 per minute in the newborn calf.¹¹⁰ Some veterinarians advocate dipping the pup or kitten in cold then hot water to stimulate respiration. Other workers advise holding the young up by their hind legs to aid cleaning mucus from the larger bronchi, throat, and nose. If this is done in the newborn calf a copious flow of mucus is often passed from the nose and mouth. Most of this mucus obviously must come from the stomach. It has been observed by the author that in the handling of nearly all newborn which at expulsion are so weak that respirations do not begin normally within 1 to 2 minutes, any treatment of a drastic nature is often unsuccessful, although such efforts are usually indicated and are appreciated by the owner.

Umbilical disinfection may not be necessary if births occur on clean pasture. The licking of the navel and the

absence of barn or barnyard infections usually ensure the rapid and normal healing of the newborn's umbilicus. If parturitions take place in a barn or barnyard, particularly if navel infections are prevalent on the farm, careful disinfection of the navel may help prevent disease. It is doubtful if a hasty, careless application of a disinfectant or antiseptic to the navel will be of any value. To be effective an antiseptic should be carefully applied 1 to 3 times daily for the first two days following birth. Tincture of iodine, 1:1000 solution of alcoholic sublimate, 5 percent tannic and 5 percent salicylic acid in 70 percent alcohol, 10,000 ppm. neutral iodophor solution, 40,000 to 50,000 ppm. sodium hypochlorite solution with a very low hydroxide content, or any similar antiseptic, may be applied by carefully soaking the navel stump and squeezing it with cotton soaked in the antiseptic. Some prefer to use a powdered astringent such as alum or tannic acid and an antiseptic. This is carefully dusted on the navel stump to hasten dessication. In foals it is often advisable to administer a prophylactic dose of tetanus antitoxin. Two foals developed tetanus even though the dam received a booster injection of tetanus toxoid during pregnancy.⁸³ A contributing factor may have been that both mares leaked milk for a week before parturition. In a valuable newborn, antibiotics such as penicillin, streptomycin, tetracycline, ampicillin or chloromycetin may be administered for several days to prevent navel infection or septicemia. Clean, sanitary, well-bedded stalls for the calf and parturient cow help greatly in preventing navel infections. On farms or ranches where large numbers of females give birth in a confined area sanitation practices and facilities are highly important to prevent navel infections, infectious diseases of the newborn as well as retained placenta, metritis and mastitis in the dam. If young calves are placed together they may suck the umbilical stumps and cause navel infection. In countries with the screwworm, *Cochliomyia americana*, infestation during the warm seasons, it may be necessary to treat the navels of newborn animals with a fly repellant to prevent screwworm infestation of the navel stump.

The newborn should nurse and thus get colostrum within 1 or 2 hours after birth. From birth to suckling averaged 111 minutes, range 35 to 420, in the foal⁹³ and an average of 10 to 35 minutes, range 3 to 153, in the pig.⁶⁰ In the sow this may be slightly delayed if the pigs are removed as they are born—to prevent their injury by the sow—and returned after parturition is completed. The great importance of globulins in the colostrum, which are only absorbed from the gut 12 to 36 hours after birth by the newborn animal, has been discussed under placental transfer of immunity. This does not occur in domestic animals except to a slight degree in the dog and

cat.⁵⁰ Under highly unsanitary or infected environmental conditions, it is desirable to get colostrum into the newborn promptly, within 15 to 30 minutes after birth. If necessary this may be given by stomach tube. The amount of colostral antibodies absorbed and available to the newborn is in direct proportion to their levels in the colostrum and the amount of colostrum consumed within a few hours after parturition. Premilking in cows, sometimes practiced to avoid severe edema of the udder, may reduce the immunoglobulins available to the newborn calf because of their dilution in large quantities of milk stimulated by this practice. The principal transfer of globulins from the blood to the milk occurs the last 3 days of the gestation period.⁹³ Besides the important immune bodies absorbed from the colostrum by the intestines during the first 24 to 36 hours of life there are laxative properties in the colostrum. In the cow the colostrum is about five times as high in protein, two times as high in fat and minerals, ten times as high in iron as ordinary milk. In the newborn lamb this first feeding of colostrum is essential to getting it on its feet, and making it strong and active. Clipping of the udder in heavily fleeced ewes may aid the lambs to find the teats and nurse promptly. If for some reason, such as preparturient leaking of milk, colostrum from the dam is not available, another source may be indicated. Colostrum may be frozen and stored for such emergencies. In calves and foals 1500 to 2000 ml. should be given in divided doses the first 12 hours after birth.^{22b} The amount of immunoglobulins absorbed from the colostrum is directly related to the susceptibility of the newborn to the neonatal diseases of scours, septicemia and pneumonia. In 300 baby calves purchased at auctions, deaths occurred in 16 percent of calves with 1 to 6 percent of the serum protein comprised of gamma globulins while only 1 percent deaths occurred in calves with 19 to 46 percent gamma globulins in their total serum protein fraction.⁵³ Eighty to 90 percent of neonatal foals with failure of colostral immunoglobulin transfer developed infections and died or required therapy. This was largely due, as in cattle, to low colostral immunoglobulin content.⁷⁷ If colostrum is not available a transfusion of plasma or of dam's blood or blood from an animal of the same species is indicated to provide the necessary antibodies.^{33b} Dam's blood should not be used in newborn where hemolytic diseases are suspected. In large animals 500 to 800 ml. of blood or serum is usually administered subcutaneously,^{22b} as large amounts of fluids are difficult to inject intravenously and the process frequently causes violent struggling in the newborn. In the smaller animals 20 to 100 ml. of blood or serum may be given. Lyophilized immunoglobulins may be prepared and stored and given by stomach tube to the newborn animal.^{33b}

The use of the antibiotics have been of further help in bringing these animals lacking immune bodies through the first few critical weeks of postnatal life. The newborn of animals except dairy cows and goats suckle the dam until weaned. In the sow each pig selects its own teat, the stronger often getting the better mammary gland, so that in a week or two there are only as many functioning glands as there are pigs. This teat preference occurs in kittens but not in pups.^{45,46} The other glands, that are not being suckled, involute. In uniparous animals the young suck all teats. There are many methods of managing the newborn calf to prevent digestive upsets or diarrhea, after he has suckled the dam for the first 12 to 24 hours.

The Problem of Handling and Feeding of Orphan Animals is occasionally presented to the veterinarian when the dam dies at parturition or fails to give sufficient milk. It is well known that the young of a species thrives best on milk of its own kind. Therefore having the orphan adopted by another postparturient female of the same species is indicated. This is fairly easy and can often be done in all domestic animals when such an animal is available. Occasionally it is necessary in the sow to make the young smell like the foster dam's offspring by rubbing her fetal membranes or genital discharges over the orphan, or sprinkling the entire litter of orphans and sow with a material having a similar strong odor such as a weak cresol solution or an aerosol deodorant. In sheep it is a common practice to cover the orphan with the hide of the dead offspring or the wool of the ewe that is to be its foster mother. In the large animals, as in cows, the foster mother usually adopts the orphan fairly promptly but occasionally she may have to be restrained for a number of times to permit feeding. In the dog most postparturient bitches will readily adopt the newborn of another. The problem is more difficult when a foster mother is not available. All domestic animals can be raised with proper care and attention by artificial nursing and feeding.

In calves the problem is simple, since cow's milk is nearly universally available. In the other animals the problem can be solved to a great extent by referring to Table 8 on the composition of the milk from the various animals. From this table it is noted that milk of the ewe, doe, and cow are nearly similar in composition. The milk of the sow is richer in fat. Mare's milk is similar in composition to human milk and foals therefore thrive on formulas for human babies. After foals are several months of age, cow's milk might be satisfactory; but younger foals may develop a stubborn diarrhea when fed cow's milk.⁸⁸ Pigs, pups and possibly kittens may be raised on rich cow's milk, evaporated milk, or prepared formulas.^{6b} Presently there are fortified powdered milk prod-

ucts for foals, "Foal-lac,"* for pups, "Esbilac,"* for kittens, KMR, and for pigs, "SPF-lac."* These are mixed with the proper amounts of warm water and fed as are the synthetic or formulated starters for calves. The milk should be warm and fresh. The newborn animal should be fed every 1 to 3 hours for the first week or so and then every 4 or 12 hours thereafter. The amount of milk fed daily to the young of cattle, horses, sheep, goats, and swine should be about 10 percent of the body weight, divided into the aforementioned number of feedings. In dogs and cats the feeding of orphan young is discussed in Chapter 9 following cesarean section in the bitch. All animals can be fed by nipple bottle with either calf, lamb, human, or doll nipples. At an early age most animals except lambs usually may be taught to drink milk from a shallow pan or bucket. If symptoms of diarrhea develop, the amount of milk should be reduced markedly for 24 to 48 hours and oral and parenteral antibiotic, electrolyte and supportive therapy should be instituted. In some cases one may increase the amount of milk gradually to more than 10 percent of the body weight after the first week or so of age. It is hard to starve a young animal, but easy to overfeed it. Orphan pigs may be reared on special commercial pig starters or formulas containing antibiotics.

The orphan young should be encouraged to eat solid food as early as possible so that the amount and frequency of milk feeding can be reduced. In general for the first 1 to 2 months of life the orphan young will not appear as well nourished as animals that are not orphans, and will more often have digestive disturbances. Care and nursing are of utmost importance in the proper rearing of orphan young on artificial diets; otherwise artificial feeding is not particularly difficult. In some cases the addition of vitamins, especially A and D, may be necessary or advisable. In pigs, iron may be provided by injections of an iron dextran product intramuscularly, painting the sow's udder with a weak solution of iron, or supplying clean soil to prevent anemia.

A Persistent, Patent or Pervious Urachus is invariably seen with infection of the navel either as a cause or a result of an open urachus. This condition is seen most commonly in the newborn foal and rarely in cattle. Since it is often followed by pyemia, septicemia, and navel or joint ill, the condition should be viewed seriously. Antibiotics administered over a period of 10 to 14 days is indicated together with local treatment of the navel with antibiotics or disinfectants. If, after several days, the urine continues to flow through the urachus keeping the navel and the surrounding skin moist, the lower 4 to 5 inches

of the urachus should be cauterized with a small swab containing Lugol's solution or the instillation of about 2 to 5 ml. of 5 to 10 percent formalin solution. This or similar treatments will usually swell and close the urachus.

Retained Meconium—In the newborn foal the meconium in the rectum may be found in hard pellets from 1/2 to 2-1/2 inches in diameter that within 24 or 36 hours after birth become impacted just cranial to the bony pelvis. The condition is seen more often in colts than in fillies. The diameter of the bony pelvis is very small in the newborn foal. The affected foal usually nurses normally but within 24 to 48 hours after birth exhibits symptoms of colic and persistent to intermittent straining, frequently getting up and lying down, elevating the tail and assuming a straddled attitude similar to that assumed during defecation. Colicky symptoms may become more severe, and anorexia occur. Impaction may be confirmed by inserting a lubricated finger into the rectum and palpating the mass of hard pellets of meconium. This disease is not uncommon in foals, and for that reason many veterinarians recommend that all newborn foals be given an enema soon after birth. This enema may be of physiological saline, mineral oil, olive oil, castor oil, mild soap and water, or several ounces of glycerin in a pint of soapy water; the author has found the commercial obstetrical lubricants like "Lubrivet" very satisfactory and nonirritating. About 4 to 6 ounces are introduced at a time through a soft rubber horse catheter. This may be repeated as often as necessary. In cases of impaction of meconium with colicky symptoms this may have to be repeated frequently at intervals of 10 to 30 minutes until the condition is relieved. Oral administration of laxatives such as castor oil, or the injection of "Lentin," is not usually indicated as the fecal material in the rectum and small colon behind the hard meconial pellets is soft. Gentle, persistent treatment usually results in recovery. Heroic or drastic treatment with a looped wire or forceps is dangerous and rarely necessary.

Rupture of the Bladder or Urachus may occur in rare instances in the newborn foal. This probably occurs due to a full bladder especially in male foals at parturition or when the navel cord is ruptured. The foal appears normal for 12 to 24 hours; but by the second to fourth day the foal is depressed, pulse and respirations are increased, and the abdomen is slightly to markedly distended.^{39,76,115} Tapping the abdominal cavity with a needle in a sterile manner will release the urine and confirm the diagnosis. Blood tests show a rise in blood urea nitrogen. Laparotomy on the midline, and repair of the ruptured bladder is indicated. Supportive and antibiotic therapy with good nursing often results in a successful termination.

*Borden Chemical Co., Box 419, Norfolk, Va. 23501 and other suppliers.

Many Congenital or Hereditary Conditions such as atresia ani, cleft palate, edema, undershot jaw, contracted tendons, blindness, cerebellar hypoplasia, and combined immunodeficiency (CID) and others may affect newborn animals. (See Chapter III). Some of these defects such as umbilical and scrotal hernias and cryptorchidism noted at birth may spontaneously recover within a few weeks to months. The observation and study of anomalies in the newborn is interesting. It may be of value to the owner, if the condition has occurred several times in a herd, to check carefully for inbreeding and for a hereditary recessive factor causing the condition. If the veterinarian is acquainted with the reported hereditary defects or anomalies in the newborn he may be able to advise his client properly even though only one defective individual has been produced. If the defects or anomalies are recognized early, treatment is possible in some; but in others slaughter must be recommended. Many anomalies or defects are observable at birth or cause noticeable symptoms to develop within several days after birth. Others may not be diagnosed for months or years.

Infections of the Newborn Contracted in Utero are rather uncommon compared to the infections contracted after parturition due to contact with virulent organisms in the outside environment. Many diseases of the newborn such as various septicemias, enteritis, pneumonia, and others may develop shortly after birth. A few of these diseases may be contracted **in utero** or in the birth canal at parturition. Probably most of them are contracted after birth from infected surroundings either through the raw umbilical or navel area, by ingestion or by inhalation. Many diseases of the newborn are favored by improper nutrition, management and housing facilities. The numerous infectious, managerial and nutritional problems affecting the newborn will not be discussed in this text inasmuch as they are not directly associated with parturition or gestation.

Most of the organisms known to cause placental and fetal disease with abortion may cause disease or infection of the newborn. Many of the organisms mentioned under causes for abortion may be present in fetuses born at term and cause their early or delayed death.

In cattle these include *Brucella abortus*, *Leptospira* spp., *Listeria monocytogenes*, *E. coli*, *Streptococci*, *Toxoplasma gondii*, *Aspergillus* spp., and *Salmonella* spp. Antibody titers for brucella, leptospira and IBR-IPV, influenza, BVD-MD and other viruses in the serum of newborn calves that have never suckled have been reported. This indicates a prenatal exposure and response by the fetus to these organisms whether the organisms can or cannot be recovered from the fetus after birth. There is evidence^{67,71,110} that *Mycobacterium*

paratuberculosis may be transferred **in utero** from an infected cow to its fetus and be carried into the postnatal period. Bovine leukemia virus, similar to feline leukemia virus may occasionally pass to the fetus **in utero** although most spread occurs horizontally.^{43,112}

In horses the fetal infections contracted **in utero** causing abortion, as well as early neonatal deaths after premature abortion, as well as early neonatal deaths after premature or term births, include: *Streptococcus zooepidemicus*, *E. coli*, *Actinobacillus* or *Shigella equi*,³³ *Leptospira* spp, *Salmonella abortus equi*, and rhinopneumonitis or herpesvirus 1.¹⁷ It may be difficult to determine in some infections, such as the first two, whether the fetus was infected before birth, during birth or whether the foal became infected soon after birth. If the newborn animals are visibly ill at the time birth or within a few hours then the infection was probably prenatal especially if retained placenta or metritis develops in the mare. Only 7 of 3,346 aborted fetuses yielded *Actinobacillus equuli* on culture but if postnatal death occurred within 24 hours of birth the *Actinobacillus* infection probably occurred prenatally.^{5,91,92} Intrauterine infection of fetuses with equine infectious anemia virus has been occasionally reported.

In swine prenatal infections that may cause neonatal infections or death include: *Leptospira* spp., *E. coli*, hog cholera virus,^{19,42} parvovirus, pseudorabies virus, *Toxoplasma gondii*⁹⁵ and *Eperythrozoon suis* (?).¹¹ Newborn pigs may become chronic carriers of the last five organisms. Poxvirus was recovered from pustular skin lesions in a newborn pig.⁸¹

In sheep and goats intrauterine infections that may be present in newborn lambs and kids include: *Vibrio fetus* var *intestinalis*, *Brucella melitensis*, *Salmonella* spp., *E. coli*, enzootic abortion or *Chlamydia*, *Toxoplasma gondii* and *Mycobacterium johnei*.¹⁰⁸ The latter organism is not a cause for abortion in sheep. Occasional intrauterine transmission of ovine progressive pneumonia virus and caprine leukoencephalomyelitis virus has been reported.^{22,28}

In dogs and cats neonatal infections that may be contracted **in utero** include: *Streptococci* spp., *Staphylococci* spp., *E. coli*, *Pseudomonas aeruginosa*, *Leptospira canicola*,^{64-66,70} canine herpes virus infection or "fading pup syndrome,"^{20,23} distemper virus, infectious canine hepatitis virus,⁷⁰ *Haemobartonella canis*,⁷⁰ and *Toxoplasma gondii*. The latter protozoal infection of prenatal fetuses has been reviewed in dogs and cats as well as in swine, sheep and cattle.^{95,102} In cats panleukopenia virus and leukemia virus may occasionally be transmitted **in utero**. The horizontal spread of these viruses in young and older cats is much more common.^{82,85}

Parasites Transmitted in utero from the Dam to the Fetus include:

In horses—*Strongylus vulgaris* larvae.¹³ This is very rare.⁹¹ A verminous aneurysm in a 2 day-old fetus was infected with *Actinobacillus equuli*. *Babesia caballi*.¹¹¹

Strongyloides westeri larvae may be transmitted to the foal in the dam's milk as early as 5 days after parturition. Anthelmintic treatment of mares with **Cambendazole** within a few days after foaling prevented infection of the foals for several weeks and reduced the incidence of "foal scours."⁷³ As noted below strongyloides in swine and hookworm and ascarid larvae in dogs may also be transmitted to the newborn in the colostrum.

In cattle—*Neoascaris vitulorum*,⁸⁷ *Theileria annulata*,¹¹¹ *Anaplasma marginali* (?),¹¹¹ *Cysticercus bovis*,⁷⁹ *Trypanosoma theileri*,⁹⁷ and *Fasciola hepatica*.⁸⁶ Many other bovine parasites may be transmitted to the fetus in utero.⁵⁶

In swine—*Strongyloides ransomi* and *Stephanurus dentatus* or swine kidney worm.^{8,104} Although a few reports indicated that *Ascaris suis* infection of fetuses may occur, several studies⁸⁴ proved that this does not occur.

In dogs—*Toxocara canis*,^{38,68,70} *Ancylostoma caninum*,^{1,70} and *Dirofilaria immitis*.^{70,75} *Demodex canis* infection of pups probably occurs the first few hours of life as there was no evidence it was acquired in utero.⁴⁸ Several therapeutic regimens used to obtain ascarid-free pups have been described.^{21,49} There is presently no treatment to prevent *Toxocara* larvae from migrating from the dam to the fetus during pregnancy.

Thus many bacterial, viral, fungal, parasitic and other diseases may be transmitted in utero resulting in the birth of infected neonates. In fact even rabies virus may pass transplacentally to fetuses of infected skunks.⁵⁵

Neonatal Isoerythrolysis, or Hemolytic Icterus of the Newborn, has been described in the horse, pig, dog and cattle. In 1948 this condition was described in foals.^{12,15,16,34-37} Many workers have done much to clarify the causative factors and describe methods of diagnosis and treatment.²⁴ An incidence of 1 percent affected mares was reported in the New Market area in England. Neonatal isoerythrolysis of foals occurs when mares become isoimmunized to certain types of erythrocytes either through (1) placental breakdown and absorption of the antigens from placental tissue or fetal blood at previous gestation periods or (2) by transfusions of blood or (3) injection of fetal tissue vaccines. When these mares are bred to stallions which transmit to the fetus the type of erythrocyte to which the mare was previously immunized the disease develops. The icteric condition occurs when the apparently normal foal suckles and receives in

the dam's colostrum large amounts of antibodies composed of hemagglutinins and hemolysins. Hemolytic icterus has very rarely been observed in foals from primiparous mares. It is usually not observed in foals until the mare's third or fourth parturition. Although most mares apparently become sensitized from the placenta of their foals. An early equine-fetal-tissue vaccine used for vaccination against virus abortion caused certain mares to be immunized to the erythrocytes in the vaccine.³⁶ Since vaccines prepared from equine tissues are not now used the incidence of neonatal isoerythrolysis has declined. Neonatal isoerythrolysis in foals is not due to an Rh-like factor as in humans but is caused by an isoimmunization of pregnancy due to intraspecies blood group factors (red cell antigens).

Recent studies^{4b,105b} on equine neonatal isoerythrolysis have shown that blood factors A and Q account for nearly all cases, especially in Thoroughbred and Arabian horses.^{105b} Brood mares possessing both blood factors A and Q are at low risk in producing affected foals. While mares lacking one or both factors and with a titer of anti-A or anti-Q of about 1:8 or 1:16 within 14 to 28 days of foaling are at high risk of having their foal develop this disease. Prognostic tests for these blood factors and their corresponding antibodies are now commercially available.^{4b,105b}

The symptoms, which may resemble foal septicemia, usually develop rapidly after the foal begins nursing, with mild to severe clinical symptoms occurring from 12 to 96 hours after birth. These include: somnolence; anorexia due to weakness; usually no rise in body temperature; increased pulse and respiration rate; slight to marked jaundice and anemia; and in severe cases prostration and hemoglobinuria. Foals which die rapidly have little icterus but an acute anemia. Foals that die of this disease after several days of illness usually show icterus and have severe liver and kidney damage.²⁴ Icterus is also seen in foals that do not show illness until several days after birth. Hemoglobinuria and hemoglobinemia are unusual symptoms. The red blood cell count drops from a normal of 10 to 12 million, down to as low as 2 to 3 million in the most severe cases. In severe cases the death of the foal may result in 24 hours or less. In slight or mild cases where the amount of antibody from the ingested colostrum is minimal, recovery may occur without treatment. The condition should be carefully differentiated from septicemia of the newborn usually characterized by elevation of temperature, injection and congestion of the conjunctiva with icterus being absent or slight. Cases of septicemia, if treated fairly early, usually respond to treatment with parenteral antibiotics while cases of neonatal icterus do not respond to antibiotic therapy. The

red blood cell count does not fall below 5 to 6 million in septicemia of the newborn.

The laboratory diagnosis was described by Bruner.¹² The technique of testing the blood of mares and their foals, and stallions to which the mare was to be bred is relatively simple with proper equipment such as a centrifuge and microscope. In agglutination tests, using the serum of mares and a 50 percent suspension of carefully washed red cells of the foal or his sire, if the serum titer of the mare is no higher than 1:2 and the colostrum titer no higher than 1:4, the foal may safely nurse its dam. If the serum titer of the mare is 1:4 or the colostrum titer 1:8 the foal is likely to develop icterus and may or may not recover without treatment. If the serum titer in the mare is higher than 1:4 or the colostrum titer is 1:16 or higher it would be dangerous for the foal to nurse its dam. The development of an hemolysin titer of 1:10 or more is apparently necessary to produce marked symptoms of the disease. The serum of sensitized mares may be tested against the red blood cells of a stallion and if a titer of 1:2 or less occurs the mare may safely be mated with that stallion. The prognosis in hemolytic icterus depends upon how early the condition is diagnosed and the promptness with which treatment is instituted. Advanced severe cases often die.

The treatment of clinical cases consists of promptly removing the foal from the mare or muzzling it. If symptoms are mild and the condition was not noted until the third to fifth day following foaling, treatment is unnecessary. In severe cases several blood donors should be obtained and the blood of the dam and foal tested against various donors' blood. If they are compatible, a large blood transfusion of 1500 to 2000 ml. of blood or more should be given the affected foal by injecting the blood into one jugular vein and removing an equal amount from the other by means of a 14-gauge needle. Occasionally another 500 to 1500 ml. of blood may be given the next day. In less severe cases 500 ml of blood may be transfused once or twice daily to carry the foal through the critical period of the disease which usually lasts only one to three days.²⁴ Transfusions are usually necessary when the symptoms of the disease are exhibited within 24 hours of birth; when the foal is weak and unable to stand; and when the red blood cell number drops below 4,000,000 per cmm. or 8 gm. of hemoglobin per 100 ml. of blood. Up to 7000 ml. of blood may be transfused in a large exchange transfusion in severe or critical cases. In practice this is often not possible and usually only about 50 percent of the foal's original blood is removed. The blood volume of horses and foals is 8.11 to 9.7 percent of the body weight or in the average foal about 4000 to 6000 ml. The administration of antibiotics and confinement to

prevent excessive exercise is advisable. The foal's dam should never be used as a blood donor. Because of the low incidence of blood factor A in Shetland ponies they should be considered as potential blood donors.^{105b}

The dam should be milked out frequently by hand or by allowing another older foal to nurse her.^{15,37,94} The newborn foal can absorb antibodies from its digestive tract for only about 36 hours after birth. It had been shown in earlier work that the first colostrum had the highest titer and that this titer dropped rapidly in 12 to 18 hours with frequent milking even though slight amounts were secreted for several weeks postpartum. Most authors reported that after 48 hours postpartum it is safe to allow the foal to nurse if the mare has been milked out frequently.

This disease in foals can usually be prevented if the sensitized mare is recognized because of having previously produced an icteric foal, or by testing the mare's serum against the red cells of the stallion to which it is to be bred. A positive test indicates that the disease will probably occur. A negative test is not significant as the mare may have become sensitized during pregnancy to the stallion's red cells. A better procedure is to test the mare's serum against the stallion's red cells the last month, or preferably the last week, of pregnancy.²⁴ Even if the stallion's blood is compatible with the mare's serum when tested before breeding, the foals of sensitized or isoimmunized mares should not be allowed to nurse until its red blood cells are tested with the mare's colostrum or serum. This is the most practical test. This may be done by immediately muzzling the newborn foal until the test is completed. If the foal's erythrocytes agglutinate in a 1:4 dilution or higher with the dam's serum or 1:8 or higher with the dam's colostrum, the foal should be fed either "Foal-lac," a human baby milk formula, low-fat cow's milk to which some sugar syrup and possibly lime water have been added at a rate of 1 ounce syrup and 1 ounce lime per pint. The foal may be placed on another mare for several days. On the larger farms banks of frozen colostrum permit the foal to be provided needed colostrum after first crossmatching the red blood cells of the foal and the milk. These foals should be given prophylactic treatment with antibiotics for 4 to 6 days. The dam should be milked out thoroughly at frequent intervals by hand or by an older foal. After 48 hours the dam's foal may be unmuzzled and allowed to suckle. Some veterinarians prefer to give the foal 500 cc. of compatible donor's serum to replace the antibodies lost to the foal by not nursing its dam the first 48 hours after birth. In the convalescent period injections of iron dextran intramuscularly may aid recovery. Once a mare produces a foal affected with neonatal isoerythrolysis, sub-

sequent foals are apt to be affected especially if the mare is bred to the same stallion. Recent further reviews on hemolytic icterus in foals have been published.^{37,58,90,94}

A similar condition has been described in dogs previously immunized by blood transfusions.^{44,107,116,117} Natural isoimmunization of the bitch during pregnancy is apparently rare. Although there are 7 blood types, A through G in the dog, only A is of significance in regard to incompatibility. In blood transfusions especially in breeding females, only A-negative donors should be used to avoid producing hemolytic disease in the pups after nursing. Leakage of blood from affected pups during parturition and subsequent uterine absorption may be one way of sensitizing the bitch.⁴⁴ The signs of hemolytic anemia in affected pups are similar to those in foals. Most severely affected pups die within 72 hours of birth. Not all pups in a litter are usually affected, only those with type A positive blood. Treatment involves withdrawing 10 to 15 ml of blood from the jugular vein of affected pups and replacing it with a similar amount of A negative blood. In affected bitches the pups should be fed formula and not be allowed to nurse the bitch for 36 hours after birth. After this period their gut will not absorb the antibodies present in the colostrum and they may be returned to their dam for nursing.^{66,99}

Neonatal isoerythrolysis also occurs in pigs from 1 to 7 days after farrowing.¹⁴ Similar signs to that in foals and pups of weakness, depression, paleness of mucous membranes, anemia, icterus, prostration and occasionally hemoglobinuria are noted in some pigs, but not all, in a litter. As in dogs this condition may only rarely occur naturally. Most porcine cases have been due to vaccination of sows with crystal violet or swine tissue vaccines against hog cholera. In a few cases mildly affected pigs recover without treatment. Probably several blood group antibodies can cause the condition in swine.⁴ Other excellent reports on this disease in swine have been published.^{18,79}

Bovine neonatal isoerythrolysis has been reported in Australia and the United States associated with the use of a vaccine that contains red blood cells as a preventive for tick-fever and an anaplasmosis ("Anaplaz") respectively.^{98,105} The proper use of the latter vaccine, that is, vaccinating only nonpregnant cows, reduces the incidence to a very low level while still providing a degree of immunity to the disease. Hemolytic disease of the newborn has not been described in sheep, goats and cats but is a possibility.

Nutritional deficiencies causing disease in the newborn animals include: (1) copper deficiency causing enzootic ataxia, swayback of demyelinating encephalop-

athy in lambs in Colorado, Peru, Australia, New Zealand and Great Britain. This is characterized by a progressive locomotor incoordination and partial or complete paralysis. Feeding additional, minute amounts of copper sulphate to the pregnant ewes prevents this condition.⁵⁹

(2) Iodine deficiency or excess causing enlargement of the thyroid glands or goiter is most frequently observed in foals. This may be prevented by feeding iodized salt and by avoiding the excessive feeding of iodides especially in the form of seaweed.⁶

(3) Selenium deficiency causes congenital white muscle disease or myopathy in newborn lambs in New Zealand and other countries.⁵¹ This condition has also been described in dogs,⁷⁴ and calves.⁶⁹ Myocardial degeneration and degeneration of skeletal muscles, especially of the neck, jaw and tongue are causes for weakness, inability to nurse and early death.

(4) Vitamin A deficiency causes increased susceptibility for infectious diseases. This may occur rarely in newborn animals whose dams have been on a vitamin A deficient diet for many months. The teratogenic effects of vitamin A deficiency on fetal development have been described previously.

Neoplasms of newborn animals are rare and have been reviewed.⁸⁰ Tumors of the skin included papillomas of equine fetuses, and subcutaneous melanomas; a subcutaneous mixed tumor and subcutaneous mixed tumor and a subcutaneous lymphangioma in bovine fetuses. Abdominal tumors included mesotheliomas of the peritoneum, a sublumbar lipoma and a retroperitoneal chondrosarcoma in bovine fetuses. As in adult animals, mesotheliomas of the abdominal cavity produced ascites and resulted in dystocia that was relieved by caesarian section. Neoplasms of the gonads included adenomas of the testicles and granulosa cell tumors of the ovary of bovine fetuses.⁶¹ Congenital lymphoid leucosis often with skin involvement has been reported most often in bovine fetuses and newborn calves, and occasionally in a newborn piglet and a feline fetus.¹⁰⁹ Other tumors included reticulosarcomatosis, carcinomatosis originating in the liver, nephroblastomas, a fibrosarcoma,²⁵ and teratomas. Congenital leucosis has been reported in fetuses in cattle and cats. Most cases of leukemia are caused by the horizontal spread of the virus between animals.

Miscellaneous diseases or causes of death of newborn animals include:

Persistent bleeding from the navel stump. This occurred more often when the cord was cut with a sharp instrument instead of being broken by traction. If ligation of the cord is necessary to prevent excessive bleeding then the newborn should be placed on parenteral an-

tibiotics for 3 to 7 days and the ligature removed in 24 to 48 hours. Repeated disinfection is indicated. A hemorrhagic disease of calves was reported⁴⁷ in which the dams were normal but had been fed sweet clover hay during the gestation period. Four newborn male and female calves from one dam bled severely from the navel after birth. Three of the calves died but one survived after repeated transfusions. These calves suffered from a multiple coagulation defect of their blood. A possible hereditary nonsex-linked character might have been present.¹⁰ Hemophilia in foals and pups have been previously described as affecting the male newborn in these species.

Fibroelastosis of the heart valves due to an unknown cause has been described in pups and kittens and rarely in calves causing enlarged hearts and deaths of the newborn within 2 to 3 months after birth.⁴¹

Respiratory distress syndrome and convulsions in Thoroughbred newborn foals have been described.^{93,94} These foals have been called "barkers," "dummies," "convulsives" and "wanderers" depending upon the signs exhibited. Several different etiological factors or diseases were present in these foals including asphyxia, trauma (cerebral hemorrhage) and fetal stress. The respiratory distress syndrome was described^{93,94} indicating the affected foals were normal for 24 hours. Respiratory distress began on the second day and became more severe. The respiratory rate went from 25 to 85 per minute. Inability to stand developed and extensor spasms occurred by the third day with death of the foals by the end of the third day or early on the fourth day. The lungs were atelectic and edematous with an absence of the surface-active lung lining or hyaline membrane. Thus this disease in foals resembled the respiratory distress syndrome in human infants and piglets. A lethal autosomal recessive condition in swine characterized by respiratory distress ("barkers") and hypothermia soon after birth together with hypothyroidism, hairlessness, myxedema, reduced adrenocortical activity and immaturity of lung tissue with a surfactant deficiency has been reported.^{115b} This syndrome resembles the condition in foals and humans but a genetic component has not been reported in these latter species.

Management and environmental conditions may cause or predispose the newborn to death or disease. Based on extensive and careful records 6 percent of calves die at parturition or within 25 hours of birth, 3 percent in multipara and 14 percent in primipara.¹¹³ There was a higher mortality rate in male calves and more abnormal parturitions associated with male calves. Calf mortality was eight times higher in moderately to severe abnormal parturitions or dystocia than in normal parturitions. The incidence of abnormal parturitions was twice as high for

male calves than for female calves. Certain sires produced calves having a higher mortality rate at parturition in primipara, 18 to 19 percent, than other sires, 8 to 10 percent.¹¹³ These sires should not be used on heifers. Dennis has reviewed the incidence and causes of perinatal mortality in cattle, sheep and horses.^{30,31} Martens^{75b} and Rosedale and Ricketts⁹⁴ have further reviewed the diseases and therapy of newborn foals. In a survey of 790 feline litters 10 percent of the fetuses were stillborn and 27.1 percent of the live kittens failed to survive to one year of age. Malformations occurred in 6.8 percent of the kittens.^{97b} In a study of inbred matings, calves from certain sires had a much higher postnatal mortality rate than calves from other inbred sires.²⁶ A higher than normal mortality rate occurred within several days after birth in Brahman cows calving on range during cold wet weather.³² A greater number of male beef calves were lost at parturition; these losses were greatest in primiparous cattle, 9.5%, and least in pluriparous cows, 2.4%.³

Pups, pigs and lambs, in fact all newborn animals, have a poikilothermic nature and are often unable to respond to cold by increasing their metabolic rate until 3 to 7 days of age. This is most noticeable in thin, underweight, malnourished, "runty" newborn animals where nutritional reserves are not present. Many of these neonates appear immature. As high as 30 percent of baby pig losses after birth were due to chilling.²⁷ It was also an important cause of death in pups.^{45,46} Hypoxia was the principal cause of 75 to 85 percent of stillbirths in swine.^{47b} High death losses in newborn lambs occurred when the weather was cold and especially when the lambs were small and undernourished.² Lambs weighing 4 pounds or less at birth suffered 65 percent or greater death losses compared to 5 to 8 percent losses in lambs weighing 10 to 14 pounds.^{54,100} High environmental temperatures during gestation and underfeeding caused the birth of smaller lambs. The mortality in twin lambs with lower birth weights is 30 to 40 percent higher than in single births. Other causes for mortality in the newborn is lack of vigor due to inbreeding, prematurity, lack of nutrition for the dam during the gestation period and a failure of the dam to own or accept her newborn.¹⁰³ Rarely certain Hereford cows may have such large teats that a small weak calf is unable to obtain colostrum. Occasionally postpartum dams suffer from agalactia due to disease, such as mastitis or endocrine causes and the newborn must be raised as an orphan. Disease factors causing mortality in lambs was carefully reviewed.⁹ Subcutaneous edema associated with low serum protein levels was commonly present in all pigs for the first two days after birth. This edema disappeared after the ingestion of colostrum raised the serum protein levels of the pigs.⁴⁰ Supplying artificial heat to the newborn and seeing that

colostrum is ingested early to supply both energy and antibodies will save many weak neonatal animals.

Injuries to the fetus during normal parturition are rare, but in dystocia forced extraction may result in **fractures of the fore or hind limbs**, especially in cattle. Fractures most often occur in the metacarpal or metatarsal bone in the region of the "break joint" or epiphysis, due to applying the chain or rope above the fetlock and placing a severe strain on the leg by twisting, jerking, or excessive traction. If the fetus is dead this is of no consequence but if the fetus is alive the fracture may be highly embarrassing for the veterinarian. By bandaging the leg and padding it well after correction of the displaced ends of the bone, and applying a plaster cast, the calf or young animal can walk. In 5 to 6 weeks this may be removed, and complete healing usually results. If a compound fracture occurs the prognosis is more guarded and antibiotics locally and parenterally are indicated.

Fracture of the jaw may result from excessive traction or twisting. Occasionally the snare or chain may slip forward and fracture the bony plate holding the incisor teeth, thereby causing them to point forward. In cattle these fractures are difficult to hold in place after correction. Frequently slaughter may be advised if both halves of the mandible are broken through the body, although surgery and wiring or pinning may be successful in selected cases. If only the incisor teeth are involved in the fracture, the animal will usually nurse satisfactorily or will drink from a pail, and healing occurs promptly even though the teeth may be at a more acute angle than normal.

Fractures of the ribs occur in foals due to injury of the fetus in its expulsion through the birth canal or due to the dam accidentally stepping on the foal. Dyspnea often develops within a day or two with a jerky painful respiration and an audible grunt on expiration. The foals move slowly and stiffly. Death often results. Occasionally taping the chest snugly with wide adhesive tape may be helpful if the lungs are not damaged.

Dennis²⁹ reported 174 hepatic ruptures and 1 splenic rupture in 4,417 lambs necropsied. Similar ruptures might occur in other species but they are rarely reported.

Dislocation of the hip joint is very rare in the newborn of the larger domestic animals. If excessive traction or twisting is applied to the rear legs in posterior presentation dislocation is possible in the pup. In anterior presentation of the fetus when the head protrudes through the vulva and the fetal body is wedged in the birth canal, twisting or excessive traction on the head may cause dislocation of the occipital joint and the death of the canine or feline fetus.

Subconjunctival hemorrhage is occasionally observed in newborn calves due to trauma during birth. If

the cornea is not injured, therapy is not necessary and recovery occurs in about 7 to 10 days.¹¹⁴

Edema of the tongue is common in calves in anterior presentation, in which the normal passage of the fetus is delayed and the head is retained for several hours in the birth canal or protruding through the vulva. This edema of the tongue and often of the entire head is due to passive congestion caused by the intrapelvic pressure exerted on the calf's neck interfering with or blocking venous circulation from the head. Edema of the forelimbs is observed frequently in prolonged dystocia when the forelimbs are extended so the fetlocks are outside the vulva. If the young is still alive the edema disappears within 3 to 24 hours after birth and the fetus can then suckle in a normal manner.

Intertwined or twisted umbilical cords and straw in the nest of kittens may result in their starvation and death due to inability to move about freely. Occasionally the umbilical cord looped around a kitten's leg may cause a slough. This may be due to the queen not properly cleaning the kitten and eating the long umbilical cord.

Injury or death of the newborn caused by the dam— Occasionally the dam, usually a primiparous female, may become excited, belligerent, or vicious, and injure or destroy the young soon after birth. This is a further reason for having a quiet environment to which the animal is accustomed, and an attendant present during parturition. It occurs rarely in the cow or mare but is seen occasionally in sow and bitch. When the cow attacks, butts or kicks its calf, the calf should be removed or the cow restrained or tranquilized until it becomes reconciled to and accepts the calf. In a few mares colic associated with uterine involution and expulsion of the fetal membranes may be quite severe. A sedative or tranquilizer is indicated and in some instances the foal should be removed from the stall for several hours to prevent accidental injury by the dam. Occasionally a mare will refuse to allow a colt to nurse and kicks him away from her flank. The mare-foal bond is established at birth by appearance, sound and smell. The latter comes from the fetal fluids. If the dam is highly nervous or exhausted from a painful or difficult birth and this bond does not occur soon after birth, it may not develop.^{55a} This calls for restraint and tranquilization of the mare at regular intervals even to an attendant employing a twitch to allow the foal to nurse. Between nursings the foal should be confined in a partitioned part of the box stall. The dam may accept the foal after 1 to 2 days when the congestion and soreness has left her udder.

In swine this viciousness may be marked and the primiparous or young sow will attack and kill her offspring. About one percent of the pigs farrowed in Iowa, Illinois, and Indiana are eaten by sows.⁶³ The sow may kill her

pigs as they are farrowed or farrowing may be normal and then the sow kills the entire litter at one time. Some pigs are eaten but most are merely killed thus this condition is not a true "cannibalism." This condition rarely occurs after 24 hours after farrowing. The "berserk" sow may even attack the owner. Obviously it is necessary to have this type of sow farrow in a farrowing crate or for the attendant to remove the pigs immediately after birth. Nutrition as a cause of this condition is doubtful since usually only one sow in a drove fed the same ration is affected. It may be due to an inherited or congenital excitability, psychosis, or viciousness. Gilts from affected or related sows may also develop a similar aggressive attitude after farrowing. The hereditary or genetic nature of this condition has not been proven but seems more likely than the nutritional theory as the cause of this condition. Quiet sows and gilts should be selected for breeding.

In order to attempt to induce this type of sow to accept her pigs the surroundings should be quiet. Some owners and veterinarians truss the sow up and allow the pigs to nurse at regular intervals. Spontaneous recovery may occur at any time. Often the sow is given a sedative or narcotic dose of chloral hydrate, pentobarbital or other strong sedative before the pigs are placed on her.⁶³ Along with this, some veterinarians advise the injection of 2 to 5 ml., or 20 to 50 units, of oxytocin, but its value is questionable. The sow and her pigs should be closely watched, since as soon as they regain consciousness some sows will again attack their pigs. If this viciousness is pronounced and the sow refuses to accept her pigs in 1 to 2 days they should be placed on other dams or hand fed. Treatment frequently fails. This undesirable inherent disposition was aggravated by parturition. This type of sow is usually sent to slaughter.

The same condition is also observed in bitches, especially Cocker Spaniels, and rarely in queens after parturition. Occasionally the dam, especially in primipara, will totally reject her offspring and not clean or nurse them. Their surviving offspring usually have to be reared as orphans.^{46,52} Animals should not be reared from such unstable psychotic dams for fear of perpetuating such individuals.

Care of the Postpartum Dam—Following parturition the dam should be allowed to lick and nurse her young. All undue excitement, noise, or unusual happenings should be eliminated or prevented. Rest and quiet following parturition is imperative. The roughage fed to large animals should be of good quality. The grain ration should be rather laxative and light, such as bran, oats, and a little linseed meal. In most animals the amount of grain should be increased gradually during the first three weeks after parturition. In the dairy cow it may have to

be increased more rapidly, to prevent ketosis. In the sow the light grain feed should be continued for a week and then gradually increased. If it is increased too rapidly the pigs may get too much milk, and diarrhea may develop. In the mare a bran mash or two following foaling may be of value if the mare is constipated. Some veterinarians routinely administer one gallon of mineral oil to mares soon after foaling to help prevent constipation due to the pain occasioned by the act of defecation the first few days after foaling. Milk yield in mares, as in cows, was maximal, 11.8 kg., at 30 days postpartum and declined to 9.8 kg. in late lactation.^{47b} The cow should be watched carefully for several days after calving for symptoms of milk fever. Excess edema of the udder should be controlled by massage, frequent milking, or preferably diuretics such as the carbonic anhydrase inhibitors with or without the glucocorticoids as described under lactation. Udder suspensories may be indicated in some cows to help support the edematous udder. Although urticaria due to the absorption of milk proteins into a sensitized animal occurs most commonly at the time of drying off, especially in Guernsey and Jerseys, it may occasionally develop after parturition if milking is limited in order to prevent the occurrence of milk fever. In most animals it takes about 10 to 14 days to return the dam to full feed. Moderate and light daily exercise is advisable in animals after parturition. Mares should be turned out for about one hour a day for the first week and then for longer periods thereafter. Draft or saddle mares can begin light work in two weeks.

In domestic animals retention of the fetal membranes occasionally occurs. The membranes are considered as being retained if they are not expelled within 8 to 12 hours in the cow, 3 to 6 hours in the mare, and 8 to 12 hours in the ewe. Retained placenta occurred twice as frequently in cattle when the calf died at birth than in normal parturitions and these cows had a lower conception rate.¹¹³ In multipara, membranes usually cannot be observed hanging from the vulva and they frequently go unnoticed until they are expelled in 1 to 2 days or decompose and a mucopurulent discharge is noted in 4 to 10 days. It is desirable, especially in the cow and mare—in which species retained placenta occurs most commonly—to have this condition treated by a veterinarian. Veterinarians prefer to treat retained placenta in the cow within 1 to 3 days after parturition. Mares should be treated earlier, within 12 to 24 hours, to avoid septicemia, toxemia, and possible parturient laminitis (See Chapter XI).

If genital discharges persist beyond 14 to 20 days postpartum or if they are abnormal in amount or purulent in nature, the genital tract of the animal should be examined and treated as described under uterine infections.

It is desirable especially in valuable cows to examine the genital tract about 30 days postpartum even when the calving and the postpartum period were apparently normal. In mares a vaginal examination and possible uterine culture should be made about 6 days postpartum if breeding is to be at the foal estrum, or early in the second estrum if the mare is to be bred at that estrum. Early treatment of uterine infections or pathology or repair of vulvar lacerations after parturition is essential if the animal is to conceive promptly.

Occasionally animals develop an acute septicemia from uterine or mammary infections within 24 to 48 hours postpartum. The symptoms may be severe and death result. The dam may be so severely affected that lactation is greatly suppressed and the young may perish or must be raised as orphans. Any illness occurring immediately after parturition should be treated promptly.

Agalactia, or a lack of milk after parturition, may be due to the failure of milk let-down or failure of milk production. In the former condition adrenalin, due to stimuli such as pain and fright, is thought to be secreted. This hormone antagonizes or prevents the let-down of milk by the posterior pituitary hormone, oxytocin. This condition is noticed occasionally in heifers with a greatly congested, edematous, painful udder; injections of pituitrin or oxytocin intravenously or intramuscularly cause rapid and complete milk let-down. Sometimes repeated injections at each milking are required. The failure of milk production, if not caused by diseases such as: acute metritis, acute or chronic mastitis, traumatic gastritis, indigestion and others, is due to a hormonal deficiency or to defective development of the mammary gland with a lack of secretory tissue. Prolactin from the anterior pituitary gland apparently is important in initiating lactation, while the growth or somatotrophic hormone is responsible for the maintenance of proper and high secretory levels. Injections of crude anterior pituitary extract have been used by veterinarians with questionable success as a possible aid in stimulating lactation. With the commercial production of the separate hormones of the anterior pituitary gland, such as prolactin and growth hormone, the therapy of these animals with low production of milk after parturition, may be improved in the future. Marked agalactia in sows and mares was associated with the feeding of ergot the last few weeks of pregnancy.¹⁰¹ Mortality in piglets due to starvation was high. At present the treatment or correction of severe agalactia is unsatisfactory and usually the newborn must be reared as orphans. In most cases with no obvious cause, rebreeding is questionable and affected food-producing animals should be slaughtered.

Occasionally it may be desirable to hasten mammary involution in animals that have lost their newborn young,

or in bitches in pseudopregnancy. Cessation of milking; application of mild liniments, such as camphorated oil, to the udder; withholding or drastically reducing water and TDN intake, and injections of estrogens, in larger animals at repeated intervals if necessary, are valuable in reducing udder size and suppressing milk secretion.

Chapter VII

DYSTOCIA—ITS CAUSES

When the first, or especially the second, stages of parturition is markedly prolonged, becomes difficult or impossible for the dam without artificial aid, the condition is termed **dystocia**. The term dystocia comes from the Greek and means difficult birth. **Eutocia** is safe, easy, natural or physiological parturition. There is no clear line between normal parturition and dystocia. Dystocia is one of the most important obstetrical conditions with which the veterinarian must cope. Because of the many variable managerial and genetic components the incidence of dystocia in the various species is not satisfactorily recorded. Of the domestic species dystocia is most common in cattle, especially in primipara and in the larger breeds.^{1,11,28,29,37} The overall incidence of bovine dystocia ranges from 3 to 25 percent. Dystocia in beef cattle corrected by means other than cesarean section reduced their future reproductive performance 5 to 16 percent while in cases corrected by the latter operation it reduced performance 30 to 40 percent.^{8a} The incidence of dystocia in mares and sows is about 1 to possibly 2 percent and slightly higher in ewes due to twinning. In dogs it is highest in the Boston, Scotch Terrier, Pekinese, Sealyham, and other small brachycephalic breeds. It is lowest in the more natural breeds such as the hounds and mongrels. In queens the incidence of dystocia is probably slightly lower than in bitches. It is obvious that the incidence of dystocia is highest in the more specialized breeds and those kept under greatest confinement in the most artificial manner. Dystocia is much more common in primipara than in pluripara. The incidence of dystocia is greater in pregnancies that terminate early due to uterine disease, fetal death, and twinning, or that terminate after a prolonged gestation period due to excessive size of the fetus.

The causes of dystocia may be divided into the basic and the immediate causes. The basic causes should be studied for the purpose of obtaining knowledge that will help prevent the occurrence of dystocia. If basic causes are known and recognized, dystocia may largely be avoided; or if unavoidable the veterinarian and owner will know in advance that dystocia is highly probable. The latter circumstance requires certain preparations and precautions so that if dystocia should occur, prompt ob-

servance and handling may prevent injury or death of either or both the dam and fetus.

The Basic Causes of Dystocia

The basic causes of dystocia may be divided into the following categories: hereditary, nutritional and managerial, infectious, traumatic, miscellaneous, or combined causes. Many cases of dystocia may have two or more basic causes.

Hereditary Causes—The hereditary causes for dystocia may be divided into those that have produced defects in the dam which predispose to dystocia, or those hidden or recessive genes in the dam and sire which may produce a defective fetus.

Those hereditary defects in the dam predisposing to dystocia are inguinal hernia; persistence of the median wall of the Mullerian duct with a large band in, or caudal to, the external os of the cervix; double uterus or uterus didelphys; hypoplasia of the vagina or vulva, such as rectovaginal constriction in Jerseys, twinning; and inherited breed characteristics. Inguinal hernia as a cause of dystocia especially in the dog has been discussed previously. Persistence of the median wall of the Mullerian or paramesonephric duct may cause dystocia by obstructing the passage of the fetus if one leg should pass on one side and the other leg on the other side of this strong band. In a true double uterus in the cow the placental area is limited to only one horn. A severe dystocia may result from overlooking a twin in the other horn. Hypoplasia of hereditary origin is only rarely a cause for dystocia, as the hypoplasia often affects the uterus and ovaries, and conception does not occur. Twinning in uniparous animals is usually associated with double ovulation. Monozygous twins are uncommon. The release of two or more ova at one estrum is usually predisposed by the dam's hereditary constitution or may be associated with cystic ovaries in cows and the nutritional status of ewes. Twinning may be influenced to a lesser degree by the season and the age of the dam. Twin bicornual pregnancy in cows and ewes often results in dystocia because the long extremities frequently cause wedging

of the fetuses in the pelvis. In twinning, uterine inertia associated with unicornual twins, posterior presentation of one fetus, death of one or both fetuses, and premature twin birth or abortion also favor dystocia. Certain breeds of cattle, such as Brown Swiss and Charolais with a long gestation period and large fetuses; and certain brachycephalic or dwarf breeds of dogs, such as Bulldogs, and other breeds with a large, broad head and a relatively small pelvis and underdeveloped or weak reproductive systems, are more prone to dystocia. Scotch Terrier fetuses have a tendency toward premature hardening of the skull bones that may lead to dystocia. Most of the hereditary defects of the dam resulting in or predisposing to dystocia, with the possible exception of the inherited breed characteristics, are favored by inbreeding or close breeding practices.

The hidden and usually recessive genes in both male and female animals may produce a variety of pathological conditions affecting the fetus or fetal membranes, thus causing dystocia. Most of these are lethal genes, as they usually result in the death of the fetus. The known genetic lethals for cattle and the other domestic animals have been outlined in Chapter III. Dropsy of the fetal membranes and fetus may be caused by mating hybrids such as the bison with the domestic cow or zebu. Inbreeding in Dexter and Tux-Zillertaler cattle and others has resulted in **achondroplastic calves** and occasionally hydramnios. Certain types of muscle contracture monsters may be associated with hydrops of the amnion. If this condition should go to term it usually is associated with uterine inertia and a weak or dead fetus. Both of these conditions favor fetal emphysema and dystocia. Achondroplastic and "ankylosed" calves have been produced without dropsy of the fetal membranes by inbreeding animals with the recessive gene for those conditions. Dystocia often results at parturition due to the increased size of the fetus or certain of its parts. Hereditary lethals causing amputated limbs of fetuses, **Acroteriasis congenita**, **hydrocephalus**, and stillborn fetuses frequently may cause dystocia. Hydrocephalus in cattle is frequently associated with deformed limbs. The early death of these fetuses at the time of parturition, and abnormal postures more common in defective fetuses, increase the incidence of dystocia. An hereditary condition called congenital dropsy resulting in large, anasarctous fetuses or calves occasionally causes dystocia in Ayrshire or Swedish Lowland cattle when carried 200 days or longer. An autosomal recessive gene causing a **prolonged gestation** of 300 to 370 days in Holstein cattle and terminating in severe dystocia due to the oversized, giant calves has been described. In this case the fetuses were already dead, died at birth, or were killed during the difficult delivery. The dam's life was greatly imperiled and a

number of the dams died as a result of the dystocia. Mummified fetuses in cattle occasionally may be hereditary. Dystocia may result at the time the mummified fetus is expelled, especially in cases of fetuses that mummify after the fifth month of gestation. Muscular hypertrophy or "double muscling" in cattle is an hereditary condition that when present in fetuses, especially in primipara, often causes severe dystocia. Muscular hypertrophy has been described in Charolais, Holstein, South Devon, Hereford, Angus and Piedmont cattle. Fifty percent of oversized fetuses in Belgium causing dystocia were double-muscled.³³ Some of these lethal conditions causing dystocia affect bone development. The so-called muscle contracture monsters are usually produced by general functional ankylosis with an abnormal development of muscles and tendons, causing an immobility and extreme rigidity of the affected limbs. In sheep inherited lethals of general ankylosis and amputation and in swine general ankylosis have been described. There are many other inherited lethal genes such as cerebral hernia, epitheliogenesis imperfecta, and short spine that might contribute to dystocia because the fetus is weak and usually dies at the time of parturition. This factor of a dead or weak fetus at parturition favors abnormal postures of the fetus even though its size may be small, and its shape normal or nearly normal. A recessive hereditary condition should be suspected when several similar abnormal fetuses or dystocias are seen in related animals, over a period of several years.

Nutritional and Management Causes—The nutrition of a pregnant animal and its management at parturition are closely associated and may be the basic causes of many dystocias. Dystocia due to the small size of the dam is frequently observed in primipara. One study³ measured the area of the pelvic opening in 3-year-old heifers. As the pelvic opening increased in size from 200 sq. cm. to over 279 sq. cm. the incidence of heifers with a normal birth rose from 44 to 100 percent. Almost all severe dystocias were in heifers with pelvic areas of 200 to 240 sq. cm. or less. Improper nutrition of the growing heifers was the most important factor in retarding body and pelvic growth. This study was further confirmed by a similar one in younger heifers.²⁷ This condition may be caused by breeding the female at too young an age or by breeding a poorly grown, under-fed female that may be old enough to breed but the body growth has been greatly retarded due to poor nutrition, parasitism, or disease. Most domestic animals reach puberty before their body growth is great enough for a normal gestation and parturition. Dairy calves may show estrum at 3 to 12 months of age. Range calves still nursing their dams may occasionally come into estrum and be bred by a bull that is running with the herd. Many cases of severe dys-

tocia have been reported in cattle 13 to 18 months of age. Twenty-six percent of 2 year-old range heifers had dystocia as compared to 4 percent of the older cows.³¹

Well-grown, well-nourished heifers are usually not bred before 12 to 20 months of age, mares 3 years of age, gilts 6 to 8 months of age, ewes 1 to 1.5 years of age, and bitches 1 year of age. Dairy heifers should be bred by size or weight rather than age.⁷ Holstein or Brown Swiss heifers should be bred when they weigh 750 pounds; Ayrshire and Guernsey heifers when they weigh 600 pounds and Jerseys when they weigh 500 pounds. Depending on the levels of energy intake these weights may be reached from 10 to 19 months of age. The optimum feeding levels produce heifers of these weights from 13 to 17 months of age. During the gestation period animals should be fed sufficiently well to maintain their rate of growth so that at calving Holstein and Brown Swiss heifers weigh about 950 to 1000 pounds, Guernseys and Ayrshires 700 to 725 pounds and Jerseys 670 to 690 pounds. Restricting growth by underfeeding frequently results in dystocia and other periparturient difficulties. The breeding of animals that are immature or otherwise unfitted for a normal parturition is usually the result of an accident or gross carelessness in management. If discovered soon enough steps may be taken to prevent or terminate pregnancy.

Animals that are stunted frequently develop dystocia at parturition. This delayed development may be due to a low nutritive plane or to chronic diseases such as enteritis, pneumonia, severe pediculosis, mange or internal parasites. Stunting of a young female animal's growth is not permanent unless continued for a long period of time. In many young animals the stunting effects of a low plane of nutrition may be overcome by a high plane of nutrition for 6 months or more. Many farmers in dairy sections stunt the growth of their young stock by feeding milk substitutes improperly and by limited grain feeding, by feeding poor hay, pasturing the young stock on poor pastures, and by housing the young stock under unfavorable environmental conditions. Thus at the time of parturition the heifers are thin, small and weak. Dystocia is invited by the small pelvis and underdeveloped, juvenile genital tract, the lowered resistance to disease, and the lack of strength to expel the fetus in a normal manner. Growth and development in young animals should proceed normally from birth to puberty, from puberty to conception, and during the gestation period, if parturition is to be physiological. A proper nutritive level and efficient management are necessary to secure this goal.

High feeding levels may favor dystocia, especially in heifers, by excessive deposition of fat in the pelvic region, predisposing to difficult parturition. The influence

of over-and underfeeding of pregnant animals and its effect on increasing or decreasing the weight of the newborn has been demonstrated.¹⁸ Many owners try to compensate for low levels of feeding and poor growth in their young stock by high feeding levels during the last third of pregnancy. This is particularly true in dairy cattle, in which lactation is of major importance. This practice is of questionable value and may even be harmful, as it is during this last third of pregnancy that the fetus grows rapidly and the high feeding levels may favor the development of a larger fetus while increase in body size and growth of the immature dam occurs much more slowly. The balance between fetal size and pelvic or genital tract diameters, fetopelvic disproportion, and dystocia is favored. Overly fat, under-exercised sows and bitches often develop dystocia possibly due to uterine inertia.

Fetopelvic disproportion caused by the large size and weight of the fetus or the small size of the pelvis of the dam or both are the two greatest factors in dystocia of animals, especially beef cattle. Sires, especially those bred to young immature dams should be selected for the ease of birth of their offspring.^{21b} Male calves because of their larger size, partly due to their slightly longer gestation period, are most often associated with dystocia. Immature females should be managed and fed so that at the time of breeding and parturition they are healthy, not overly fat or thin, are of sufficient size and with a pelvic area large enough to give birth without assistance.^{4b,37b}

Failure to keep animals approaching or beginning parturition under close observation may not actually be a cause of dystocia but this neglect may cause a relatively early and simple dystocia to become more severe, with danger to the life of the fetus and the dam. During parturition all animals should be watched closely but not disturbed. No reliable birth detection system has been developed (see Parturition). Prompt aid may thus be given if parturition is not normal. This aid may prevent secondary uterine inertia, death of the fetus, rupture of the uterus or birth canal, fetal emphysema, septic metritis, retained placenta, and injuries, such as obturator paralysis. Feeding or grazing pregnant animals on plants that may damage the fetus such as ewes on *Veratrum*, should be prevented in an effort to control fetal losses and dystocia that may accompany such losses.

Pregnant animals which are not exercised and are kept in close confinement are more prone to difficulties such as torsion of the uterus and uterine inertia than those kept under more natural conditions, as on pasture. Exercise increases body tone, strength, and resistance and results in stronger labor contractions, less fatigue, shorter duration of parturition, less uterine inertia, and more prompt

recovery. Pregnant animals closely confined for long periods are more prone to abnormalities in the function of smooth muscle including prolapse of the vagina and uterus, intussusception, torsion of the cecum and displacement of the abomasum. In the first stage of labor the limbs of uniparous animals are flexed while during the second stage of labor they are extended. The strong contractions of the myometrium initiated active fetal movements and righting reflexes resulting in extension of the limbs.¹ Thus uterine disease as well as fetal disease may greatly influence the incidence of dystocia.³⁷

Infectious Causes—Any infection or disease affecting the pregnant uterus and its contents may cause abortion, uterine inertia, fetal death, and occasionally septic metritis of pregnancy. In any severe infection of the uterus the uterine wall may lose its tone or ability to contract—a condition resulting in incomplete dilation of the cervix and uterine inertia. In the latter instance the second stage of labor may be abnormally delayed. Death of the fetus prior to parturition or premature birth renders the fetal extremities prone to postural abnormalities, and may result in a dorso-pubic position of the fetus in the mare. The relation of uterine disease to hydrops of the allantois and edema of the fetus has been cited and may be a cause for uterine inertia and dystocia. Infections may be the immediate cause of conditions that predispose to dystocia, or they may be responsible for chronic uterine damage such as loss of caruncles, or a nonfunctional uterine horn, either of which may result in abortion, uterine inertia, hydrops, torsion, rare transverse pregnancies, and other abnormalities at subsequent pregnancies. All known infectious reproductive diseases such as brucellosis, leptospirosis, vibriosis, salmonella, viral, and other septicemic or infectious diseases should be controlled according to our best knowledge at the present time so that late abortions or premature births, in which dystocia is common, will be kept at a minimum.

Traumatic Causes—Traumatic causes for dystocia are not common. Ventral hernia and rupture of the prepubic tendon late in gestation may occur from traumatic causes. These injuries predispose to dystocia by rendering the abdominal wall incapable of strong contractions, with a resulting inability of the dam to force the fetus through the birth canal. Torsion of the uterus may be caused by sudden slipping, falling, or rolling in advanced pregnancy. This is not the only factor but it is an important one in the etiology of torsion. Fractures of the pelvis with secondary deformity and exostoses is seen most commonly in small animals struck by motor vehicles. These may result in a stenosis of the birth passage, resulting in a severe dystocia.

Miscellaneous Causes—The causes of certain minor

abnormalities in posture, such as a flexed knee or lateral deviation of the head and neck, resulting in dystocia with a live fetus and an apparently normal uterus, are difficult to explain except as an accidental catching of the nose or foot on the brim of the pelvis or in the soft structures of the birth canal during the early stages of parturition. A degree of uterine inertia or disease of the fetus may also be important factors. As the second stage progresses and more of the fetus enters the birth canal the deflection of the extremity is further increased. The causes of posterior presentation of the fetus, a relatively common cause for dystocia in uniparous animals, have not been satisfactorily explained. The exact causes or even satisfactory theories are not given to explain transverse pregnancies in domestic animals. Previous uterine disease in mares may predispose to transverse pregnancy and dystocia.³⁷ However another worker disagreed and reported that in 11 cases of bicornual pregnancy in mares there was no previous history of uterine disease.³⁴ In multipara a fetus may be located transversely in the uterine body, with the two ends of its body in separate horns. This may occur in polytocous dams having only a single fetus or it may be due to a fetus being misdirected during birth into the opposite horn rather than the vagina. In multipara with only about one-third the normal-sized litter the fetuses are often larger than normal due to increased nutrition and available uterine space. This may result in dystocia at parturition. In swine the most important factor determining the birth weight of pigs was the number of pigs in a litter, the larger the litter the smaller the pigs.¹⁸ Improper hormone balance of estrogens, progesterone or relaxin, or failure of the normal release of oxytocin may result in delay of the first stage or second stage of parturition, and in uterine inertia.²⁴

Uterine Inertia is defined as the lack of normal physiologic uterine contractions during or after parturition. Two types of uterine inertia are recognized, primary and secondary. **Primary uterine inertia** is seen most often in the bitch, occasionally in the cow and sow and rarely in the mare or ewe. The following conditions may be factors causing primary inertia or lack of uterine tone and feeble contractions at the time of parturition. It is observed more often in animals that are closely confined and hence lack exercise. It is more common in dairy than beef cattle. Obesity may be a possible factor in bitches and other species. Certain brachycephalic breeds of dogs tend to develop uterine inertia despite the size of the litter.^{15,16} Overstretching or overloading of the uterus in hydrops and twin pregnancy in cows, and a large number of fetuses in small bitches and sows may predispose to uterine inertia. It is observed more often in older dairy cows and bitches. It is frequently associated with nutri-

tional debility or debilitating diseases. It may be associated with disease or degeneration of the uterine wall due to uterine infections or secondary to peritonitis such as traumatic peritonitis. It may be associated with an improper hormonal balance during the complex process of parturition or the response of the genital tract to the various hormones. Further studies in this important area are needed. A primary uterine inertia in dogs associated with a small number of fetuses where symptoms of parturition are absent and the fetuses die has been described.⁶ This is probably due to a hormonal disfunction. A combination of the above factors may be present.

Secondary uterine inertia, which is seen in all species, is the result of or follows dystocia and is due to exhaustion of the uterine muscle. In multiparous animals it may follow dystocia with one fetus; the remaining fetuses may not be expelled when the fetus causing the dystocia has been removed. Certain "sensitive" dams will refrain from vigorous labor because of apparent pain or discomfort and secondary inertia may ensue. In other multiparous animals lacking body condition or strength several young may be born and then the dam and also the myometrium appears exhausted. After several hours rest the birth process will again proceed or may fail and outside aid will be necessary. Secondary inertia is frequently followed by uterine infection, septic metritis, retained placenta, and a failure of the normal involution of the uterus. In prolonged dystocia in unipara and possibly multipara, the uterine muscle may become fatigued and produce contraction or retraction rings, also called Bandl's rings, that contract tightly around the fetus or caudal to it. This may further complicate the relief of the dystocia or if not recognized it may result in rupture of the uterus if forced extraction is applied to the fetus. A condition in bitches—especially Scotch Terriers and toy Dachshunds and sows is described that is intermediate in character between primary and secondary uterine inertia.^{6,28} In these cases the bitch may have 1 or 2 fetuses and then labor ceases with a number of fetuses still in the uterus. There is no apparent cause for the dystocia. Many cases of secondary uterine inertia may be avoided by careful observation of the female during parturition so that proper help can be given as soon as difficulty arises.

Fetal monsters other than those described under hereditary causes for dystocia are considered accidental occurrences at the present time. Many of these are double monsters, with doubling of parts or nearly all of the fetus. These double monsters apparently arise from incomplete development or separation of monozygotic twins in the early embryonic period. Single fetal monsters may have a portion of the fetus that is too large to readily

pass through the birth canal. Since these more extreme monsters occur sporadically as a cause for dystocia and since their origin is so early in the gestation period little is known of their basic causes.

During the past 10 to 20 years many studies have been conducted on dystocia or calving difficulties in dairy and especially beef cattle because of the large economic losses in calves, cows, labor and infertility or delayed rebreeding produced by such difficulties. Although similar extensive studies on the other species of domestic animals have not been conducted, probably because the incidence of dystocia in these animals is much lower than in cattle, there are common significant correlations and observations that apply to all species.^{1,11,20,21,23,26,29}

Fetopelvic disproportion is the most common cause of dystocia in cattle, particularly in primipara beef cattle. About 30 percent of all bovine dystocias are due to this cause, with an incidence of 50 to 75 percent in beef cattle and 15 to 30 percent in dairy cattle.^{29,32} In beef cattle practice in the midwest U.S. about 90 percent of dystocias are due to fetopelvic disproportion.² The occurrence of dystocia is primarily related to the size or weight of the fetus and the pelvic area of the dam.

Fetal size, weight and conformation are dependent on: **Genetic factors** including sex—male calves at birth are 4 to 6 more pounds heavier and have larger body measurements of heart girth, pelvis width and length and head width.²⁶

Length of gestation—this is a function of the genotype of the fetus. Male fetuses are carried several days longer than female calves and both the sire and dam contribute to the length of gestation. A positive correlation between gestation length and birth weight of the calf exists. The larger breeds have a longer gestation period.²⁶

Breed or genotype of sire and dam—both parents contribute significantly to the size or weight of the fetus, dystocia and resulting calf mortality especially in heifers. Calves sired by the large breeds, Charolais, Simmental, Limousin, South Devon, Holstein and Brown Swiss bulls were larger and heavier than calves sired by the small breeds, Angus, Jersey and Hereford bulls.^{1,26,29} Heterosis or crossbreeding also contributes to increased calf birth weights. Conversely inbreeding, especially at high levels, decreases calf birth weight and also increases dystocia and calf mortality.²⁶ Even within a breed there are genetic differences between bulls in the transmission of size or weight and viability of the calf at birth. Many artificial insemination centers publish this information for bulls of the larger breeds so that farmers breeding heifers can select sires producing smaller calves and avoid sires producing large

calves.^{8b,c,9,23,25,32} This reduces calf mortality, calving costs, reproductive failures and generation interval. Another genetic trait of double muscling seen in the beef breeds affects the conformation of the fetus and often results in severe dystocia even though the weight of the fetus is average. However crossbreeding between mature Jersey or Guernsey cows and Charolais or double-muscled bulls resulted in only a slight increase in dystocia.^{19,22} Thus genetic effects between certain breeds crosses seem less hazardous **and non-genetic factors** including **age of dam or degree of maturity** and growth are reflected in the size of the pelvis and genital tract. Evidence was cited to indicate that the incidence of dystocia in cattle under 2 years of age was over 70 percent, and this decreased to 66 percent in 2 year-old and 44 percent in 5 year-old primipara and to 13 to 20 percent in adult pluriparous cows.²⁹ Birth weight of Hereford and Holstein calves increased up to 7 or 8 years of age and then decreased slightly.²⁶

Nutrition—different levels of energy intake low, medium or high, for 90 days before calving affected calf weight with about a six pound differential between the low and high levels.²⁶ But there was no significant effect on dystocia.⁴ However excessively high energy intakes producing overly fat heifers caused an increased incidence of dystocia due to excess pelvic fat decreasing the size of the birth canal.^{23,29} Excessively restricted energy intake also resulted in an increased incidence of dystocia due to weakness and debility even though the fetus was not large.¹⁴ In the latter instance a delayed return to estrous cycling was a concurrent problem. Larger better grown heifers usually had larger pelvic areas but breed also had a significant effect on pelvic size. The larger the pelvic area the lower the occurrence of dystocia.^{20,21,26} With Hereford heifers with less than 200 cm² having a 69 percent incidence of dystocia, heifers with pelvic areas of 200 to 229 cm² and 230 to 269 cm² had a 30 and 25 percent incidence, respectively.

Miscellaneous factors—more dystocia is observed in the winter months possibly because the cows were in better condition in the summer or because more cows are confined and were observed and aided in calving in the winter.²⁵ Confined heifers had a higher incidence of dystocia and stillbirth, often characterized by vulvar constriction,¹² than did heifers in yards or paddocks. Possibly excessive disturbance during parturition influenced these results. Dystocia caused a 15 percent reduction in estrous recycling during the AI period postpartum and a 15 percent lower postpartum conception rate.²¹

Experiments using artificial insemination by which

Shire horses and Shetland ponies were mated to each other—Shire stallions on Shetland mares and Shetland stallions on Shire mares—proved that foals by a Shire stallion out of Shetland mares were not appreciably larger than pure Shetland foals.^{18,36} Foals by Shetland stallions out of Shire mares were three times as large as pure Shetland foals but not quite as large as pure Shire foals. This difference in size was greater in horses and less in the other species because the length of gestation in horses was longer and thus the influence of the maternal environment was greater. The foal is born in the most advanced state of physiological development while the pig is the most immature of the large domestic animals. At birth the foal weighs 9 percent and the pig less than 1 percent of their mature weight.¹⁸

The basic causes for dystocia are multiple, but by properly applying our knowledge its incidence may be kept at a minimum. In general all elements that lower resistance or otherwise unfavorably affect the general health and vigor of the dam or fetus increase the possibility of dystocia.

The Immediate Causes of Dystocia

Attendant upon dystocia are many forms of interference with physiological birth. The veterinarian handling dystocia is largely concerned with correcting or relieving the immediate interferences to birth, which may be divided for convenience into maternal and fetal types of dystocia; some overlapping may occur in certain conditions. In 95 cases of dystocia in cattle 25 percent were due to maternal causes and 75 percent due to fetal causes.³⁹ In 60 dystocia cases in goats 28 percent were maternal and 75 percent were fetal causes.^{27a}

The Maternal Causes of dystocia are largely those factors that produce a narrowing or stenosis of the birth passage or prevent the normal entrance of the fetus into the birth canal. These include: fractures and exostoses of the pelvis; small size of the pelvis due to breeding at too young an age, or due to improper rearing with resultant stunting of body growth; hereditary or congenital hypoplasia of the birth canal or vulva; compression or stenosis of the cervix, vagina, or vulva by indurations caused by scars and connective tissue usually from injuries at previous parturitions; intrapelvic hemorrhage; excessive perivaginal fat; impaction of the colon or distension of the bladder in bitches and sows; tumors such as chondrosarcoma of the pelvic bones, fibromas, lipomas or leiomyomas of the uterus, cervix or vagina, or lymphomas of the large pelvic lymph glands; torsion of the uterus; folding of the uterus just cranial to the pelvic brim, especially in deep bodied older sows;²⁸ persistence

of the medial wall of the Mullerian duct; failure of the cervix to dilate or "ringwomb" in ewes; uterine inertia; hydrops of the fetal membranes, inguinal, diaphragmatic or ventral hernias; rupture of the prepubic tendon; transverse presentations; uterine infections resulting in uterine inertia, death, abortion, or emphysema of the fetus; and twinning. In uniparous animals twinning is considered a maternal cause for dystocia since it is usually due to double ovulation.

The Fetal Causes of dystocia are more numerous and are due in general to abnormal presentation, position and posture and to excessive size of the fetus. (See Figure 86.) These include: certain posterior longitudinal presentations in uniparous animals and all transverse ventral and dorsal presentations; dorso-ilial or dorso-pubic positions; flexion of the limbs beneath the fetal body in unipara and in large fetuses in multipara; ventral, lateral or dorsal flexing of the head and neck; fetal anasarca, ascites, large fetal tumors, distention of any hollow organ such as the brain, liver^{11b} stomach, cutaneous sac in **Schistosomus reflexus**, kidneys and ureters; fetal giantism in prolonged gestation; and fetal abnormalities or monsters such as mummified fetus, general ankylosis, double monsters, achondroplastic fetuses, and others.

The incidence of dystocia in posterior presentations of the fetus in unipara is high. In 800 births in Holsteins 4.5 percent were posterior presentations but 47.2 percent of these were accompanied by dystocia.⁵ A Hereford sire used on an inbred line of cattle produced a high incidence of posterior presentations suggestive of an hereditary factor conditioning such a malpresentation.³⁸ Up to 30 percent or more of the fetuses in multipara are commonly expelled in posterior presentation without dystocia occurring. Some equine fetuses in longitudinal presentations may develop a wry or ankylosed neck.³⁴ It is possible but unlikely that an equine fetus that developed transversely in both uterine horns might rotate into a longitudinal presentation. If a fetus is presented in a dorso-ilial or dorso-pubic position, torsion of the uterus may be present. Many of the abnormal postures resulting in dystocia undoubtedly arise during the first and second stages of labor, with the fetal extremities catching on the pelvic brim or soft structures in the birth canal. These abnormal postures may often be predisposed by a weak or dead fetus.⁶ Lateral deviation of the head and neck is seen occasionally in all species except swine.

The Common Forms of Dystocia in Domestic Animals

In the mare dystocia is most often caused by an abnormal presentation, position or posture. The long ex-

trémities of the fetus tend to predispose the mare to dystocia. Abnormal posture of the head and neck is one of the most common causes of dystocia in mares. At birth the equine foreleg from the fetlock to the elbow is 73 percent of its adult length.¹⁸ Dystocia due to monsters or to disproportion between fetal size and pelvic diameters is rare. Transverse ventral presentation is not uncommon, whereas transverse dorsal and rotated bicornual or transverse pregnancies are very unusual. (See Figure 86.) The ratio of transverse to longitudinal presentations in mares at foaling was 1:1000.³⁴ Dorso-ilial or dorso-pubic positions are occasionally found in the mare due to the fetus failing to rotate into the normal dorso-sacral position early in parturition. All forms of abnormal posture may occur in the mare. One or both of the long forelimbs may become lodged over the neck of the fetus. Wry neck is seen most commonly in the equine fetus which may or may not be associated with transverse pregnancy. Wry neck is characterized by an ankylosis and atrophy and contraction of the neck muscles, thus causing the head and neck to be fixed in a lateral direction alongside the body, similar to a severe, long-standing case of torticollis. It cannot be straightened even after the fetus is delivered. The abnormal positions and postures, together with violent labor contractions, frequently result in wedging of the fetus in the pelvis or in laceration of the vagina, rectum or vulva. Only a very small percentage of equine abortions are due to maternal causes such as torsion of the uterus.³⁴

In the cow disproportion between the fetal size and pelvic diameters are common, especially in primipara.¹ Fetal giantism, hydrops of the fetal membranes and fetus, and fetal emphysema are not uncommon. The incidence of monsters such as achondroplastic fetuses, **Schistosomus reflexus**, **Perosomus elumbis**, double monsters and fetuses with general ankyloses is higher than in other species. Transverse pregnancy is rare. Uterine inertia and failure of the cervix to dilate are occasionally noted. Twin dystocia and dystocia due to uterine torsion are common. Breech presentation, lateral deviation of the head and neck, and postural abnormalities of the limbs are often observed.

In the ewe and doe postural abnormalities and twin or triplet dystocias are common. Marked disproportion between fetal size and pelvic diameters are uncommon. About 70 percent of Romney ewes delivering lambs weighing over 10 pounds had dystocia.³⁰ Fetal anasarca or emphysema are occasionally seen. Relative oversize of the head is seen as a cause for dystocia in certain crosses in sheep.¹ In 50 cases of dystocia in goats 7 were triplet and 21 were twin births; 3.5 percent were in transverse presentation, 15.3 percent in posterior and 81.2 percent in anterior presentation. In the anterior presen-

Figure 86. Normal and abnormal presentations, positions and posture in bovine and equine births. I Normal anterior presentation, II Posterior presentation, III Anterior presentation with the rear legs extended beneath the fetus ("dogsitting" posture), IV Posterior presentation with the rear limbs extended beneath the fetus (breech presentation), V Anterior presentation with the head and neck extended over the fetus, VI Transverse ventral presentation of a foal. (as adapted from Diseases of Cattle U.S.D.A., 1942, Harm's Textbook of Veterinary Obstetrics, and Veterinary Obstetrics, 2nd Ed., G. H. Arthur).

tation 31.5 percent had a deviated head and neck. In posterior presentations 80 percent of the single births had one or both hind limbs flexed.⁴⁰ In 1200 dystocias in ewes 65 percent of the fetuses were in anterior presentation, many with a lateral deviation of the head or with one or both forelegs flexed; 27 percent were in posterior presentation and two-thirds of these were in breech presentation; and 8 percent were in a transverse dorsal presentation. Failure of the cervix to dilate occurred in 15 percent of the cases.^{13,17}

In the sow the incidence of dystocia caused by uterine inertia is about 40 percent.²⁸ Small litter size tends to cause larger fetuses that may predispose to dystocia. Dystocia in immature or poorly grown gilts is occasionally observed. Abnormal fetuses such as cyclops and hermaphrodites are uncommon and seldom cause dystocia. Double monsters and hydrocephalus are rare, about 0.5 percent.²⁸ Stillbirths are high in sows with dystocia.¹ (See Figure 46.)

In the bitch disproportion between fetal size and pelvic diameters is common in toy and achondroplastic breeds. In the latter the large size of the head is the principal cause of the dystocia. Oversized fetuses are occasionally seen when there are only one or two fetuses.¹ Uterine inertia, either primary or secondary, is a frequent cause of canine dystocia. Nervous voluntary inhibition of parturition may occur due to excitement, a strange environment or pain.¹⁶ A prolonged first stage of birth may occur in posterior presentation of the first fetus because of failure of the head to engage in the pelvis and stimulate uterine and abdominal contractions.¹⁵ Poll presentation and lateral deviation of the head and neck are causes of dystocia. Postural abnormalities of the limbs are of little importance. Dorso-ilial and especially dorso-pubic positions are seen as a cause of dystocia. Monsters are rare except for occasional cases of hydrocephalus.¹⁶ Transverse presentation is rare and usually occurs only with bicornual pregnancy with a single fetus. A complete review of the causes of canine dystocia have been listed.^{6b}

In the queen dystocia may be due to postural abnormalities of the head and neck and to breech presentation. Only rarely are two fetuses wedged in the pelvis. Uterine inertia, hydrocephalus and a large calvarium in primiparous Persians have also caused dystocia.¹⁰

Chapter VIII

PROCEDURES PRELIMINARY TO THE HANDLING OF DYSTOCIA

Dystocia cases are handled promptly as emergency calls but it is essential to a successful outcome that the animal be given a routine careful examination to establish the correct diagnosis so that a sound course of action can be outlined.

The History of the Case

As the preliminary examinations and preparations for handling the dystocia are being made, the history of the case as well as certain other information should be obtained from the owner or by observation. This information should include: the age of the female; the breed or information on the sire of the fetus; the dates of service and the duration of gestation; the previous breeding history; whether dystocia or any other abnormal condition was present at previous parturitions; whether the animal had exhibited any illness or unusual symptoms during the two months to the last few hours prior to parturition; the length of time the animal has been acting uneasy and shown anorexia or restlessness, or the length of time the animal has been in active labor. What is the nature of the straining—strong or weak, intermittent or regular, increasing or decreasing in frequency? Has the allantoic sac ruptured, the amnionic sac appeared at the vulva, or has any portion of the fetus appeared? In multipara have any fetuses been expelled and if so were they living or dead? Has any assistance such as traction been used by the owner, his neighbors, or even other veterinarians? Is the animal primiparous or pluriparous? Has the animal been able to get up if recumbent? This information is useful and necessary for the intelligent examination and handling of a dystocia case. The answers to some of these questions may have been obtained at the time the veterinarian was called or can be gotten along with the general examination of the patient.

The General Examination

The general examination of the patient with dystocia should include its physical condition, whether it is thin and emaciated, too fat, or in good condition. If the animal is recumbent the veterinarian should determine the

following: Is it able to rise or is it exhausted? If it is a heifer is it affected with obturator paralysis usually seen in hiplock conditions. In older dairy cows parturient paresis or other conditions causing paraplegia of pregnancy may be present. It is much better to diagnose the presence of such conditions as obturator paralysis and inform the owner before the operation. Afterwards, if this has not been done, the owner often will blame the veterinarian for having produced the paralysis during the relief of the dystocia. The pulse and temperature should be noted. In most dystocia cases the pulse is moderately elevated and the temperature may be slightly higher than normal due to the efforts at parturition. The degree of abdominal enlargement should be noted. Dystocia in dogs is often characterized by depression and futile laboring during which the bitch's mouth is open and its head is repeatedly thrown back. In exhausted prostrate animals the color of the mucous membranes should be noted for evidence of internal hemorrhage or shock due to rupture of the uterine vessels or rupture of the uterus. The general appearance and attitude of the animal should be observed, since some cattle affected with rabies frequently show tenesmus that might be confused with labor. Particular attention should be paid to the vulva. The nature of the vulvar discharge, whether it is watery, mucoid, bloody, or fetid will often indicate the condition of the fetus. If much fresh blood is present, injury to the birth canal has probably occurred due to the intervention of the owner or someone else. The character of the fetal membranes if hanging from the vulva are of further assistance in determining the condition of the fetus and the length of time the dystocia has existed. If a portion of the fetus protrudes from the vulva its condition and position and posture should be observed. The vulva itself should be noted to gain information on the amount of edema or trauma present as an indication of the length of time the dystocia has existed and whether someone has already been trying to deliver the fetus.

The Specific Examination and Restraint

The specific examination consisting of the detailed examination of the genital tract and fetus should be un-

undertaken only after the animal has been properly confined and restrained, as the obstetrical operations usually follow immediately after this examination.

If the animal is on pasture it is usually advisable, especially at night, in rough country, or during inclement weather to advise the owner, at the time he calls, to take the animal to a box stall in the barn, or to a shed near the dwelling house. This will usually insure light, easy access to hot water, and fairly comfortable working conditions. These are definitely desirable if a clean, careful obstetrical procedure is to be followed. It may avoid chilling and exposure of the operator as well as the patient. Aftercare and proper nursing are facilitated if the animal is near the owner's residence. A clean pasture lot or even a well-bedded stanchion stall are better locations in which to work than is a dirty, dark, cramped or too-small box stall. These suggestions are only common-sense practices and precautions but often if the veterinarian does not suggest or insist upon them the owner will neglect to provide satisfactory surroundings for the patient and operator. Working in the hot summer sun, on "the north-side of a barbed wire fence" in winter, knee-deep in water or filth, or in a dusty, dark, low swine house is not conducive to proper surgical cleanliness or technique. If a good supply of hot water is not available the veterinarian should take it with him.

If possible the animal should be standing at the time of the examination. A satisfactory examination and the handling of dystocia are much more difficult in the recumbent patient, with the viscera and fetus forced toward the pelvic cavity. Most animals rise promptly when urged. Others may be fatigued or may not wish to stand, and more vigorous methods are required such as; prodding them over the loins and rump with a sharp object, rolling the tail, sudden thumping of the ribs over the chest with the operator's knees, the use of the electric prod, or the intravenous injection of central nervous stimulants. Occasionally a cow which has refused to rise will do so after a small dose of anesthetic epidurally has relieved the pain. If the animal fails to get up, its rear parts should be raised above the front by lowering the front parts; or the rear parts may be placed on bags of straw, or elevated on a door or a plank resting on blocks and the animal held in place by a breast-harness. The rear parts may be hoisted by means of a figure-of-eight knot of rope around the hocks, which places the animal on its back, or by passing loops of rope around each leg up to the crotch and hoisting the animal's rear parts. If this latter method is used, the animal often falls sideways if it struggles. The judicious use of commercially available hip slings may be helpful in these cases. In nearly all cases of dystocia a standing position or the elevation of

the rear parts is necessary in order that the veterinarian may work with relative ease and effect a prompt correction of dystocia. It is therefore desirable that the animal be placed in this position prior to the examination.

The animals should be properly restrained so that they do not injure the operator at the time of the examination or operation. In mares a twitch usually should be applied to the lip and one foreleg held up. In range cattle a well-constructed chute is desirable, or cows might be fastened securely with a rope halter in a corner of a large box stall. If they kick, a nose lead will often divert their attention. In sheep the rear parts should be elevated by an assistant straddling the ewe. This position minimizes straining, aids repulsion and the introduction of a lubricant.⁶ Sows can be fastened securely by a strong rope with a loop around the upper jaw and behind the canine teeth. The sows may be secured or placed in a farrowing crate. Restless sows may be restrained by a short obstetrical chain around the metacarpus of the left foreleg and above the hock on the left rear leg and laying the sow on her left side.¹¹ Dogs should be muzzled or have their jaws tied together and cats should be held firmly by an assistant. The use of epidural anesthesia, tranquilizers or slight or deep narcosis may be necessary to properly restrain some animals.

In doing obstetrical work on large animals, the most satisfactory dress is: rubber boots, the type that slip on over the shoes; a pair of rubber pants or overalls; in warm weather a sleeveless cotton shirt or jacket and in cold weather a rubber jacket with no sleeves and the armholes cut or adjusted with elastic to fit tightly over the upper arm. Rubber or plastic gloves and sleeves can be worn, when indicated, to prevent infection and odors from contaminating the arms of the operator. These rubber or plastic gloves and sleeves are often damaged by instruments if fetotomy is employed. The long obstetrical gown is generally undesirable because it is extremely hot in the summer and does not provide proper protection to the lower portion of the operator's body when he has to kneel to work on the recumbent animal.

The animal's external genitalia and the surrounding structures should be washed thoroughly with warm water and soap. In sheep and long-haired dogs it is necessary to clip the wool and hair in the perineal area. The tail should be held to one side by an assistant or tied with a tail rope over the back to the opposite elbow. In the mare the tail should be bandaged or covered by a plastic sleeve. Adding a sanitizing detergent like the quaternary ammonium compounds and a wetting agent to the water used in washing the rear parts of the dam will aid in thoroughly cleansing the area. In cattle epidural anesthesia is helpful in preventing frequent defecation of loose

feces that contaminate the perineal area as well as the operator's arm. In some cases, however, epidural anesthesia might not be desirable, as it would cause a cessation of straining or labor. This straining may be helpful in the withdrawal of a normally-presented fetus. During the examination and obstetrical operation the perineal area should be kept washed and clean at all times. The operator should wash and lubricate his arms with water and soap or other nonirritating lubricant before making an examination of the birth canal and fetus. In the queen and bitch, after giving an enema and catheterizing the bladder, the rear parts may be cleansed and covered with a sterile drape; the veterinarian should wear sterile rubber gloves.

If the history of the case leads the veterinarian to know or suspect that others have been examining and attempting to relieve the dystocia, it is extremely important that the birth passages and caudal portions of the uterus be examined very carefully for evidence of trauma. In the middle of an obstetrical operation it is highly embarrassing to find a tear in the vagina or uterus which was present or had been produced before the operation was begun. If this injury causes the death of the animal, the owner might accuse the veterinarian of having injured the animal. The veterinarian would not be able to prove his innocence. The birth canal should be examined to see if it is dilated, twisted, moist or slippery, inflamed, swollen, dry, necrotic, contains pathological bands, stenotic areas or tumors, or contains gummy mucus indicating that parturition has not yet begun or is in the early stages. The degree of dilation or relaxation of the cervix should be noted as well as whether there is any evidence of torsion. The size of the pelvic inlet, vulva, and vagina in relation to the size of the fetus should be checked. Any other abnormalities of the birth canal should be noted. The canine or feline patient might benefit from radiography of the fetuses and pelvis of the dam to determine the fetal and pelvic sizes and if the fetuses are dead.^{7b}

The fetus should be examined to see if it is dead or alive as this will alter the prognosis and make a difference in the manner in which the case is handled. If the fetus is alive, grasping the foot and pulling or pinching it will cause movement of the limb. Pinching the eyeballs will cause the live fetus to shake its head. Placing the fingers in the mouth of the fetus may cause sucking or movements of the tongue and jaw. Putting fingers in the anus in breech presentation will cause contraction of the anal sphincter. If the fetus is dead the degree of decomposition or autolysis should be accurately assessed by the amount of subcutaneous edema or emphysema, whether or not the hair is sloughing and whether or not

a putrid, fetid odor is present. When fetal emphysema and sloughing of the hair is present the fetus has been dead for 24 to 48 hours or more depending on the degree of changes noted. After a dead fetus has been removed from the uterus, if no emphysema is present, the length of time death has existed may be approximately determined by the degree of cloudiness, turbidity or greying of the cornea. After the fetus has been dead 6 to 12 hours the corneas are grey and opaque.

The fetus should be carefully examined to determine any abnormality of presentation, position, and posture, or any teratologic defects. In a breech presentation the tail is often observed hanging from the vulva or lying in the birth canal. If the head is not in the birth canal in anterior presentation its location can be determined by finding the neck, the mane of the equine fetus, or the ears and head, by swinging the arm and hand around the cephalic part of the fetus. If the feet are lying in the birth canal it should be determined whether they are front or hind feet. Inexperienced students frequently confuse the front and hind legs by mistaking the hock for the elbow or the elbow for the hock. Front limbs have two joints, fetlock and knee, between the hoof and elbow, while hind limbs have only one joint, the fetlock, between the hoof and hock.

If the feet are protruding through the vulva with the soles ventral then the fetus is in either anterior longitudinal, dorso-sacral position or posterior longitudinal, dorso-pubic position. The latter rarely occurs. If the soles of the feet are dorsal then the fetus is in either posterior longitudinal presentation, dorso-sacral position; or anterior longitudinal presentation, dorso-pubic position. This latter condition is only rarely observed. In fetal monsters the differentiation into the various types may be quite difficult, as ankylosis and marked distortion are frequently present. Most of these abnormal fetuses have severely atrophied muscles of the limbs, making them feel thin, very firm, and rigid. If no part of the fetus is in the vagina of the mare the condition is probably a transverse dorsal or rotated bicornual pregnancy. In the latter condition the birth canal is very long and the fetus can be touched only at arm's length. Occasionally the amnion may not yet be ruptured, in which case if the birth passageway is dilated sufficiently the amnion may be ruptured with the fingers or a knife, so that palpation of the fetus may be facilitated. If more than two limbs are in, entering, or are near the pelvis, the condition should be examined carefully to differentiate between twins that are wedged in the pelvis, a *Schistosomus reflexus*, a double monster, an anterior presentation with the rear limbs of the fetus extended over or under the body, or in the mare a transverse ventral presentation.

It may occasionally be necessary to repel the fetus out of the birth canal and into the uterus in order to diagnose accurately the cause of the dystocia. If the animal is straining severely, epidural anesthesia should be given at once so that the examination can proceed without interruption. Sometimes examination is difficult, especially in a protracted dystocia in heifers, with swollen mucous membranes, a dry, dead fetus, and a uterus contracting tightly around it, making it impossible to repel the fetus. In mares and occasionally other animals, where the owner has applied traction, the fetus may become firmly wedged in the pelvis. A similar examination is made with a finger *per vaginam* in the bitch. Strict cleanliness is necessary, as in other species. If more than one fetus is palpated in the abdominal cavity and the bitch has suffered a prolonged dystocia, inertia has probably developed and cesarean section may be indicated. The importance of this complete examination cannot be overstressed, as it is the basis of the prognosis and procedures that follow in the handling of the case. It should be thorough and accurate to be professional, to save time and effort in useless and often harmful procedures, and to determine in severe cases whether or not outside help or consultation is needed.

Prognosis

The prognosis in dystocia varies widely between the different causes and species affected. For this reason the prognosis in the various types of dystocia will be considered as each type is discussed. In general the more prolonged the dystocia, the poorer the prognosis. The greater the trauma, irritation and infection of the birth canal caused by inexperienced laymen attempting to relieve the dystocia, the graver the prognosis. The prognosis in horses is graver than other domestic animals because the fetus usually dies within 30 to 40 minutes after the commencement of labor. The mare's pelvis is longer, and the fetal extremities are longer, making correction of the dystocia more difficult. Labor contractions are violent and powerful, predisposing to impaction of the fetus in the pelvis, lacerations of the birth passages or rupture of the uterine vessels. Lastly, the mare is more susceptible than other animals to trauma, irritation, infection, and inflammation of the birth passage and to peritonitis. It is difficult to save the life of a mare if she has been in labor for more than 24 hours and the fetus is emphysematous. The same is true of other animals but the prognosis is usually better, as other species are more resistant to infection. The fetus in the cow usually dies after 6 to 12 hours of labor and emphysema sets in about

24 to 36 hours after the onset of labor. In the bitch the first fetus usually dies within 6 to 8 hours³ after the onset of labor and may become emphysematous in 24 to 36 hours. But some of the other fetuses may still be alive. After 48 hours of labor no living canine fetuses are found. In sows the first pig usually dies after 4 to 6 hours of labor. The other pigs may survive for 24 hours. After 24 to 36 hours of labor all fetal pigs are invariably dead. The ewe is similar to the cow.

Williams very aptly described the handling of dystocia as resembling a salvaging operation on a "ship on the rocks." If it is possible, the following should be salvaged:¹⁵

1. the value of the surviving dam—its future breeding life, its food value for milk or meat, or its value for work.

2. the value of the newborn.

3. the sentimental value of the dam or newborn.

In the prognosis of a case of dystocia these values or credits should be weighed against the:

1. veterinary fees

2. mortality risk of the dam and the newborn

3. cost of labor and feed until the dam has recovered her value for milk, meat, work or breeding.

When these factors are considered and discussed with the owner after a careful examination of the patient, the prognosis and handling of the case will be understood by the owner. In the large farm animals whose value is usually entirely economic and not sentimental, the veterinary fees will then be paid more willingly. If the prognosis is correct these fees should not exceed the salvage or slaughter value. Many young veterinarians have labored diligently and corrected a severe dystocia, visited the animal several times subsequently to provide necessary care and drugs, and then presented the bill only to have the owner exclaim, "That's more than the heifer is worth." This embarrassing position would have been avoided if the above factors had been discussed fully with the owner before the veterinarian undertook the correction of the more severe dystocia cases. Thus the prognosis should take into consideration more than just the life of the dam or fetus unless the sentimental value is of prime importance.

Obstetrical Equipment and Anesthesia

The best guarantee of the proper and satisfactory handling of dystocia is the operator's correctly applied knowledge and experience. Good help and equipment may be available, but if the problem presented in each dystocia case cannot be perceived, the several methods

of handling it are not evaluated, a practical and logical approach and procedure are not developed, and the ability to follow the outlined procedure calmly and confidently to a successful termination are lacking, the case will probably end in failure, with a dissatisfied or disgusted owner. The best obstetrical equipment available should be used. Poor or makeshift equipment is not conducive to good surgical procedures. The instruments should be kept clean and sterile. Chrome or other types of plated or stainless steel instruments are desirable. During obstetrical operations surgical procedures of cleanliness should be followed in so far as this is possible. A plentiful supply of hot water, soap and lubricant are usually necessary. If possible a table should be provided and covered with a sterile sheet upon which the obstetrical instruments may be placed during the operation. Since this is usually lacking a clean pail of water to which an antiseptic has been added can be used and in which instruments may be placed or kept to prevent contamination. If the operation must be performed in a barn on a recumbent animal a sterile rubber sheet placed under the rear parts of the cow may help reduce contamination. In practice these sheets are difficult to hold in place. Epidural anesthesia may be necessary to control defecation. If the surroundings are poor the animal should be moved to a more suitable place.

It is not necessary to have all of the following obstetrical equipment for the handling of dystocias. Certain veterinarians become quite adept at using particular instruments while others prefer different ones. The type of practice in the various areas of the country also determines to a large extent the type of equipment that is accepted and used (see Figure 87).

Obstetrical Instruments for Traction on the fetus include:

Chains and handles: Gibbons' handles, while more bulky than the smaller Muir's handles, are better as they provide a longer, wider hand hold and do not cut into the hands. Obstetrical chains are preferred to sash cord or baling twine because they may be recleaned and sterilized, provide easier attachment for handles than does cord or twine. They are more professional in appearance. Obstetrical chains are strong, easily applied, and do not cause injury to the fetus or the genital tract of the dam. They are made in 10-, 21-, 30-, and 60-inch lengths. Lengths of 1- or 2-inch wide sterile gauze may be used for traction in dogs and cats.

Hooks may be long or short but should always be blunt. Sharp hooks are frequently the cause of injury either of the operator or the dam. Blunt hooks can do anything sharp hooks can, but without the added danger. The short hooks have an eye at their base, through which a cord

is run. The long hooks have a handle on the end opposite the hook. In general the long hooks are easier to apply because they can be turned or pushed from outside the vulva, but they occupy slightly more room than do the short hooks. The hook should be at a 45° angle from the shaft so that when traction is applied the hook tends to sink deeper into the fetal tissues. Another hook that is useful is Krey's hook or tongs. These may readily be applied to the orbits or other portions of a fetus when traction is desired during fetotomy operations. Krey's hook does not require guarding with the hands, as do other hooks that might pull out of the fetus and injure the birth canal or uterus.

A **fetal extractor** consisting of a mechanical hoisting or jacking device on the end of a long metal rod fitted into a broad metal breech plate, has proven very useful when used judiciously. When obstetrical chains are fastened to the fetus and to the hoist or jack, traction is applied and the fetus is gradually withdrawn. This instrument has great advantages over the block and tackle and wire stretchers used previously, because it allows traction to be regulated and applied upwards, downwards, or to either side. The older block-and-tackle method of traction allowed traction to be applied in only one direction and was much less professional than the fetal extractor. This device must be used with judgement and caution and with epidural anesthesia to control pain because of the great pressures it can produce on the fetus and dam. If the fetus is alive and breathing it should be used intermittently with periods of rest to prevent asphyxia from excessive tension on the respiratory muscles.

Forceps and snares of a wide variety are used to relieve dystocia in ewes and sows, bitches and queens. Knowles' cervical forceps are very satisfactory in swine as are certain wire forceps or snares. These same snares work well in many dystocias in ewes. Snares made of thin twisted wire with a long thin handle are valuable in securing the lower jaw, the limbs or the head and neck since they tighten securely and are much less apt than are chains to slip off and injure the teeth or hooves. The author has found that in an emergency clean hemp twine used for baling hay may be used after disinfection as a snare for the lower jaw or limbs. If a large knot is tied in the cord outside the vulva an obstetrical handle may be used for traction. In dogs "clam shell" forceps, sponge forceps, Roberts' snare forceps, or Hobday's type of forceps are useful.³ The clam-shell type of forcep in which there is a small offset in the handles so that the hinge does not fit tightly and cannot pinch the mucous membrane was preferred.¹⁰ Forceps or snare delivery in multipara is necessarily limited to those fetuses that are in

the pelvic canal or the body of the uterus just cranial to the pelvic inlet. Great care must be used in applying rigid metal forceps or snares to the extremities of living fetuses as lacerations or injuries to the fetus or birth canal are easily produced.

Instruments for section are used in fetotomy to reduce the size of the fetus. These instruments should be kept sharp and in good operating condition. The number and type of instruments are many and each veterinarian usually develops his preferences. Williams stated that there is no place in surgery in which familiarity with an instrument is more important to the operator than in fetotomy.

Knives—A heavy scalpel and a Bard Parker knife are useful in removing a portion of the fetus that may be outside of the body of the cow, as for example, in the operation of decapitation. The hoe or hook-bladed castrating knife is useful within the uterus, particularly the former as it does not cut so deeply into the fetus and is therefore easier to use. These castrating knives are easy to guard with the hand while in the uterus.

Williams' long cutting hook with a blunt point is very useful for cutting ribs.

Long cutting chisels are of three types: Williams, with a slightly concave flat blade; Guard's, with a V-shaped head; and the Ames chisel, resembling a nasal septum

chisel. The usefulness of chisels is limited.

Fetatomes of many types, especially in Europe, are used to protect and guide the fetatome wire.^{1,3,5,12} The two most widely used in America are the Benesch Universal and the Utrecht fetatomes. Fetatomes have the advantage over most chain saws or wire saws in that they can cut at different angles and not just in one caudal direction. The fetatomes use a stiff wire threader or guide to place the wire through the fetatome. There are several types of handles for the fetatome wire. The best type is the one in which the fetatome wire is placed between two interlocking rows of "teeth" that firmly secure the crimped wire when the handles are closed. Large forceps are also satisfactory. Several types of heavy metal rings or an obstetrical chain can be used as a guide or leader to carry the fetatome wire around the fetus. The wire should be of the best grade obtainable; it should be kept clean and free from rust, and after having been used for one fetotomy operation should not be used again. Kinking of the wire should be avoided.

In applying and using the fetatome, the fetatome wire should be securely fastened to the guide or an obstetrical chain unless a loop of wire is used. The guide or chain should always be introduced over the top of the fetus, or dorsally and then downwards or ventrally to take advantage of gravity to help carry the weighted guide around the part of the fetus to be removed. If a chain is used a large handful should be coiled in the hand and introduced as far around or over the fetal part as possible before being released. Otherwise the chain may follow the operator's hand and arm as it is pulled back, thus making it impossible to reach when the hand is passed under the fetal structure to pick it up and complete this phase of the operation. This procedure should always be done against the fetal hair, so that fetal membranes will not interfere with nor complicate the prompt placing of the wire. Occasionally the guide or chain will drop into the nongravid horn, making recovery of it impossible when the hand is passed under the fetus or fetal part. If the fetatome wire is already threaded in the fetatome and a loop of this wire is to be slid up and over an extremity, the head of the fetatome should precede and help guide the loop of wire into place. In sectioning the fetus with a fetatome, the head of the fetatome should be held tightly against the fetus, and the handle of the fetatome held or braced with the other hand and arm placed across the chest or hip as the sawing proceeds.

The newer Utrecht or similar models of fetatomes have a chain fixation plate or hooks behind the handle for attaching obstetrical chains fastened under tension to the fetus. The older Benesch universal fetatome can be modified by welding a chain fixation plate or hooks for at-

tachment of chains to the handle. With these fetatomes the head of the fetatome is located in its desired position and the wire is placed properly and tightened. Before cutting with the wire the head of the fetatome is held in place on the fetus by obstetrical chains, and Krey's tongs if needed, attached to the fetatome handle under tension. This innovation greatly facilitates accurate positioning of head of the fetatome and reduces the expenditure of effort by the operator.

The operator performing the sawing should maintain a constant strong tension on the wire with both arms, and use long, smooth strokes. If bone is encountered the wire will become hot and may break; therefore the position of the wire cutting through bone should be changed frequently, or sawing should be intermittent in order to allow the wire to cool. Breaking of the wire occurs most often on angular cuts. Care should be used in placing the fetatome, to see that the wires are not crossed between the fetatome and the fetus, as this generally results in immediate breaking of the wire. The fetatome wire should be kept taut at all times to prevent coiling, kinking and breaking. If the progress of the sawing is to be investigated, the assistant who is manipulating the wire should be warned so that the operator's hand or fingers will not be cut.

Wire Saws—There are several wire saws that cost less than the fetatome but they usually cut only in one direction, that is caudally. The pipe or guard used to protect the birth passage from the fetatome wire has no specifically designed head or end of hardened steel. Many other types of wire saws protected by metal spiral tubes or tubular pipes have been designed in Europe. The spiral types may be used to cut in more than one direction.^{3,12}

Other more elaborate instruments for section have been devised and used in Europe.³ The widespread acceptance of the fetatome has made for infrequent use of the earlier long blunt-pointed cutting hooks, chisels, and wire saws.

Instruments for Repulsion and Rotation—In repelling the fetus from the pelvic cavity, examining the fetus, or making room for manipulation of the fetus or its extremities, epidural anesthesia and the operator's arm are most commonly used.

Williams' crutch repeller, with or without the removable spike, is very useful when the fetus is firmly impacted in the pelvic inlet. It allows the operator's assistants to provide the strength to repel the fetus, and thus conserves the operator's strength. By use of this crutch the fetus can be repelled downward and forward, upward and forward, or laterally and forward. Kuhn's crutch is strongly advocated³ for the relief of dystocia but it has not become popular in America. Most of the

operations performed by these repelling instruments can be performed with greater facility by the operator's hand and arm.

The fetal rotators or uterine detorsion rods are of a number of types and are used to rotate the fetus when it is in longitudinal presentation in an abnormal position. This abnormal position may be due to a mild to moderate, 90° to 240°, torsion of the uterus. As in repulsion the operator's arms or proper direction of traction on the obstetrical chains will correct many torsions of the uterus or dorso-sacral or dorso-pubic positions of the fetus in large uniparous animals. The so-called Cornell detorsion rod is simple and requires only a 60-inch obstetrical chain and handle to make it complete. Other metal rotators, such as Erikson's, resembling a long-handled twitch with snares and chains to fasten the leg to the handle of the instrument have been used to advantage. In Europe Cammerer's torsion fork is popular and requires two canvas sleeves.³

It is highly desirable that all long-handled instruments, such as the long blunt hook, the blunt-pointed cutting hook, and chisels be solid and rigid, as they often have to be twisted within the uterus. If they are jointed the instrument can be twisted or rotated in only one direction.

In difficult or prolonged dystocia proper **lubricants** for the genital tract are essential. When the mucous membrane of the vulva and vagina is dry, mild, non-irritating soap, such as Ivory soap flakes, and water or bland liquid soap may suffice in cases needing slight lubrication. In cases requiring much lubrication epidural anesthesia is necessary to prevent the animal straining and throwing out the lubricant, and to cause sufficient relaxation so that the lubricant can flow about and cover the fetus and uterine, cervical, vaginal and vulvar walls. Mineral oil, 1 or 2 quarts, is only fairly satisfactory. Older practitioners used linseed infusions or lard or more recently canned cooking-fat preparations like "Crisco." A blended mixture of white vaseline and 10 percent boric acid has been recommended especially for fetotomy operations.⁵ To remove this tenacious greasy lubricant from the arms and hands a good detergent or mechanic's soap is recommended. The newer commercial lubricants such as **Lubrivet** and other lubricating jellies in tubes or jars or carboxymethylcellulose solutions^{39a} are good. These solutions or lubricants may be rubbed on the fetus and walls of the birth canal after being pumped in with a stomach pump and tube. In smaller animals the rear parts may be elevated so that the lubricant runs in by gravity. In severe, prolonged operations the lubricant may have to be applied 2 or more times or as frequently as the fetus or birth canal becomes dry. In rotation of the fetus

on its long axis lubricants are essential. They help to protect the mucous membranes from irritation, infection, trauma, and even rupture, besides making obstetrical manipulations and operations easier in the prolonged "dry" cases of dystocia associated with a dead or emphysematous fetus.

Other equipment for obstetrical operations should consist of two clean enamel, stainless steel or plastic pails, soap, several types of antiseptics, common surgical instruments including syringes, needles, scalpels, scissors, forceps, suture needles, and various types of sutures, sterile drapes and towels, sponges, razor, cotton, oxytocin, anesthetics for local and epidural anesthesia, tranquilizers and general anesthetics.

Epidural Anesthesia or Analgesia

Epidural anesthesia in the cow and mare is one of the most useful tools for aiding the operator and relieving pain in the patient suffering from severe dystocia. Prior to this useful tool straining was combatted by a noselead, twitch, sharp object pressed down on the back and even tracheotomy. The former pain-producing techniques are very imperfect or only shortlived. The technique of epidural anesthesia was introduced into the United States by Benesch in 1926.² In obstetrical work epidural anesthesia is used frequently because it stops abdominal straining and makes mutation of the fetal extremities, repulsion of the fetus, correction of breech presentation and uterine torsion much easier. It abolishes or reduces all pain and is therefore more humane and should be administered when great power is used as in some forced extractions. It greatly increases the speed, ease, and safety to the operator and patient in fetotomy operations. With proper epidural anesthesia the animal stands quietly without moving about or lying down, which is helpful to the operator. Often the cow that is down and refuses to stand will rise and stand normally following the administration of epidural anesthesia. Defecation is suspended. The animal does not rapidly expel lubricants pumped into the uterus. When used in cesarean section it controls straining and prevents intestinal prolapse through the operative incision. It is used to aid replacement of prolapse of the vagina, cervix, uterus, rectum, or bladder. By controlling straining, it may prevent prolapse of the uterus immediately after a difficult parturition. It alleviates symptoms of straining caused by severe vulvitis or vestibulitis. The use of epidural anesthesia is nearly free of danger and is seldom if ever contraindicated. Normal involution of the uterus is not interfered with and epidural anesthesia does not cause or fa-

vor retained placenta. Epidural anesthesia is not required in every dystocia case. In those cases in which a rapid and normal course of parturition is expected or a simple easy manipulation can correct the dystocia, it need not be used.

The technique for administering epidural anesthesia, particularly in the cow, is simple and easily mastered. Most veterinarians use a 16- or 18-gauge 1-1/4" to 2" needle. The site for insertion of the needle is determined by elevating and lowering the tail and feeling where the vertebral joints are located by the depression and movement between the vertebrae. The joint between the first and second coccygeal vertebrae is the most moveable in the cow. In palpating caudally from the sacrum, the first vertebrae joint in which movement can usually be felt is between the last sacral and first coccygeal vertebrae. After properly shaving and disinfecting this site, the needle is inserted in the cow between the first and second coccygeal vertebrae or the first coccygeal and last sacral vertebrae. The author prefers the latter site in the cow. The needle is introduced at a 10 degree angle caudally from the perpendicular, and strikes the bottom of the vertebral canal of the last sacral vertebra. This readily determines the depth at which the anesthesia should be injected. Between the first and second coccygeal vertebrae the needle may go entirely through the spinal nerves and joint. Inserting the needle in the mare is more difficult. It is introduced at a slightly greater angle caudally, 30 degrees from the perpendicular, than in the cow, about one inch cranially to the long coarse tail hairs. The veterinarian should be careful to insert the needle directly on the midline. In the cow the needle is inserted about 3/4 to 1-1/2 inches deep, depending on the size, amount of fat and the thickness of the tail. In the mare the needle is usually inserted 1-1/2 to 2-1/2 inches deep. If the needle is inserted carefully one can often feel the point of the needle "pop" through the thick connective tissue sheath covering the nerve. When the needle point has reached the proper location the anesthetic solution flows easily out of the syringe into the epidural space. If the needle is not at the proper site the solution is injected with difficulty. If the anesthetic does not contact the nerve the tail does not become flaccid, and anesthesia of the perineum is not produced. If anesthesia of the motor nerves of the tail is not evident within 3 minutes, the anesthetic was not injected properly. Occasionally the needle strikes the artery or vein ventral to the nerve, and blood will flow from the needle. This should be of no concern except that it indicates the needle is at the proper site for injection, or just below the nerve. It should be noted that this epidural injection is a nerve block and not a spinal anesthesia. The injection is out-

side the dura mater caudal to the end of the spinal cord. The spinal cord, containing the spinal fluid, terminates between the second to fourth sacral vertebrae in the cow and the first to third sacral vertebrae in the mare.¹

The amount of anesthetic solution to be injected varies with the type of solution, the weight or size of the animal, the species of animal, and the degree of anesthesia desired. In most obstetrical cases the solution should be injected in repeated small injections, so that the animal remains standing. If too much is given the animal will stagger, and possibly fall and injure itself. The author prefers to use a 2 percent lidocaine or procaine solution in 5 to 10 ml. amounts for 600-pound to 1300-pound cows and mares. Lidocaine produces a more rapid and deeper sensory anesthesia than procaine. If 1 percent procaine solution is used the amount of solution injected should be nearly doubled. This anesthesia will last about 1-1/2 to 2 hours. This time may be nearly doubled by adding 0.5 to 1 ml. of a 1:1000 solution of epinephrine. Two percent procaine penicillin in 5 to 8 ml. amounts produces satisfactory epidural anesthesia. When the animal is recumbent and the operator desires it to remain so, the animal should be placed on its sternum and as much as 20 to 50 ml. of 2 percent procaine or its equivalent may be injected epidurally without any adverse effects and with good sensory and motor anesthesia of the rear quarters. The larger amounts of anesthetic solution are forced cranially to anesthetize the motor nerves to the rear limbs.

Products containing benzyl alcohol, propylene and polyethylene glycol when injected into the epidural space produce a prolonged anesthetic effect lasting for 4 to 40 days or more by destroying the nerve fibers. In dairy cattle or horses this is very undesirable; as the animal's rear parts and tail become covered with fecal material because the tail cannot be elevated at the time of defecation and micturition. In rare instances when prolonged destruction of the nerve is desired, 5 to 10 ml. of 70 percent grain alcohol may be injected epidurally. In these instances recovery may be delayed 6 months or more. During the summer months flies and maggots may become a problem if the perineal region is not cleaned regularly.

Epidural anesthesia in sheep and goats is practical but seldom used as the abdominal contractions are not strong enough to interfere greatly with manual manipulations of the fetus. Using an 18-gauge needle 1 to 1-1/2 inches long, the operator may inject 2 to 4 ml. of a local anesthetic solution between the last sacral and first coccygeal vertebrae or between the last two sacral vertebrae.

Epidural anesthesia is seldom used in multipara except

for cesarean section because of the number of fetuses and the long period of parturition together with the resulting interruption of labor which would require a prolonged period of observation and assistance for each fetus as it entered the pelvic cavity. Epidural anesthesia or analgesia is obtained in dogs and swine by entering the lumbosacral space with a short-beveled, 2 to 5 inch, 18 to 20 gauge, spinal needle with stylet. The space is located on the midline a short distance caudal to a line at right angles to the spinal column and at the level of the crests of the dorso-iliac spines.^{7,8,9} After proper shaving and disinfection of the site, local subcutaneous anesthesia may be administered with a small needle. The spinal needle is passed perpendicularly into the lumbosacral space. When it penetrates the ligamentum flavum or the interarticular spinous ligament a distinct "pop" is felt as the point of the needle enters the epidural space. The stylet should be removed and aspiration applied on the needle to be sure the needle did not penetrate a blood vessel or the subarachnoid space containing the cerebral spinal fluid. This is unlikely as this space is small or not present at this level and is difficult to enter in bitches and sows. The dose of 2 percent lidocaine for epidural anesthesia in the dog is 1 ml per 7.5 to 10 pounds of body weight and for swine is 1 ml per 20 pounds of body weight. If 4 percent procaine is used in swine the dose is 1 ml per 10 pounds of body weight. In dogs 2 percent procaine at a rate of 1 ml per 5 pounds of body weight is recommended.^{7,8,9}

In recent years European veterinarians have reported on the extensive use of sympathomimetic agents and blockers of parasympathomimetic receptors resulting in a tocolytic effect and relaxation of uterine muscle in a variety of obstetrical cases in all species of animals. These have included dystocias due to abnormal postures and positions of the fetus, uterine torsion, fetotomies and cesarean sections. The advantages in using these agents, clenbuterol (**Planipart**) or isoxsuprine (**Hanigif**) are especially indicated in prolonged dystocias with dead fetuses. The nonsurgical management of dystocia was greatly facilitated with no increase in calf mortality retained placentas or adverse effect on postpartum uterine involution. These tocolytic agents act rapidly after injection with muscle relaxation lasting for several hours.^{1a,8b} It is hoped that these tocolytic agents will soon be available to veterinarians in the U.S.

Other Forms of Obstetrical Anesthesia

General anesthesia is often indicated in the mare with severe dystocia when extensive mutation, fetotomy pro-

cedures, rolling of the mare to relieve torsion of the uterus or a cesarean operation must be undertaken. General anesthesia is often begun by administering a tranquilizer, such as **Rompun**, followed by a short-acting intravenous anesthesia such as 5 to 10 percent dextrose solution to which thiamyl sodium or thiopental sodium have been added or ketamine HCL. After anesthesia has been induced additional amounts of the former may be given intravenously to maintain anesthesia.¹³ These products have largely replaced the older chloral hydrate and pentobarbital intravenous solutions for equine anesthesia. In the more modern equine clinics inhalation anesthesia of halothane may be used since this product is safe and relatively nontoxic even when given over a prolonged period of time. If the fetus is alive and saving it is desirable, tranquilizers, epidural or local anesthesia should be used. On occasion the intravenous or inhalant anesthetics may be used when the fetus is alive, even though the anesthetics cross the placenta, if the fetus is removed immediately after these anesthetics are administered. If the mare is to be given general anesthesia this should be done in a location large enough to work in with ease. With the mare anesthetized, its feet should extend away from the body in a normal manner so that no pressure is placed on the abdominal cavity. The mare may be rolled from one side to the other, to help the operator. For example, if the head and neck of the fetus is retained along the right side of the fetus in anterior presentation the mare should be laid on her right side so the head and neck of the fetus are located above and not beneath its body, where the weight of the fetus would make correction of the deviated head and neck difficult or impossible. Assistants may apply backward pressure to the fetal head through the relaxed upper flank of the mare.

For cesarean section in the cow, tranquilization, epidural, paravertebral, or local anesthesia or combinations of these may be used. When rolling to correct torsion of the uterus in the cow, 1.5 to 2 ounces of chloral hydrate may be given orally in capsules or by stomach tube, or 0.5 to 1 ounce given intravenously to narcotize the animal is still useful.

For cesarean section in the sow, a tranquilizer followed by local anesthesia of the operative site may be used.^{12b} Spinal anesthesia has been administered to sows and bitches by injection of procaine or lidocaine into the epidural space of the spinal cord at the lumbo-sacral articulation.^{7,8,9} Presently atropine is given as a premedication followed by an ultra-short acting barbiturate and a light plane of halothane or methoxylflurane anesthesia. **Innovar**, a neuroleptanalgesic, has also been used and followed by **naloxone** after the cesarean operation to reverse its action in the bitch and pups. Local anesthesia

may be used in the bitch in either of the above procedures to reduce exposure to the anesthetic. **Doxapram**, a respiratory stimulant, may aid recovery of pups or foals with a small amount given under the tongue or parenterally.¹³ In the bitch and cat an ether, morphine and atropine combination was formerly used as a general anesthetic during cesarean operations. In general the long-acting barbituates are not desirable because of their depressing effect on live fetuses.

The proper use of tranquilizers and local and general anesthetics in dystocia and other obstetrical operations is frequently necessary and results in easier, safer, and more rapid handling of birth-related problems, to the great benefit of both the animal and the operator.

Chapter IX

OBSTETRICAL OPERATIONS

In handling dystocia there are numerous operations or procedures that the veterinarian should be able to perform or use. Following a careful examination, the most conservative procedures should generally be undertaken in the interest of the owner, the veterinarian, the animal, and the fetus. The principal purpose of obstetrical operations is to deliver a viable fetus and to prevent injury to the dam. After a careful assessment of each obstetrical case the procedure selected should best achieve this purpose. Radical and heroic handling of dystocia is seldom necessary and then only when more conservative treatments have failed or when examination indicates the condition is such that ordinary routine methods or a combination of them will not effect relief. In most cases of dystocia one or more combinations of the major obstetrical operations are performed. The plan of operation should be carefully made with alternatives in case one procedure is not successful. If assistance or consultation is needed it should be obtained as soon as possible. In performing obstetrical operations on large animals it is necessary for the veterinarian to conserve his strength by working with both arms and by using lay assistance whenever possible. If the fetal membranes interfere with the obstetrical operations the offending portions of the membranes should be removed manually. The obstetrical operations may be divided into four major classifications: mutation, forced extraction, fetotomy and cesarean section. Laparohysterectomy is only performed in occasional instances in the bitch or queen. For excellent illustrations of various mutation and fetotomy techniques the student is referred to the following reviews.^{2-9,39a}

Sloss⁴² reported the incidence of bovine dystocia on 1600 properties involving 126,790 Australian dairy and beef cows as recorded by 13 country veterinary practices and the results of different methods of handling the 2480 dystocias. Mutation and forced extraction were most commonly employed in dairy cattle and comprised 77.8 percent of the cases of dystocia. While fetotomy and cesarean section were more commonly used in beef cattle and comprised 16.6 percent and 4.7 percent, respectively, of the total number of dystocias. These figures were nearly similar to those cited by other authors. The maternal death rate was 6 percent with a rate of 3.1 per-

cent in operations involving mutation and traction, 16.6 percent after fetotomy and 17.9 percent after cesarean section. Thirty two percent of the dystocias in dairy cattle were in heifers while 70.6 percent in beef cattle were in heifers.

Mutation

Mutation is defined as those operations by which a fetus is returned to a normal presentation, position, and posture by repulsion, rotation, version, and adjustment or extension of the extremities. Normal birth will proceed in uniparous animals only with the fetus in anterior or posterior longitudinal presentation, dorso-sacral position, with the head, neck and limbs extended. Most multipara can have a normal birth with the fetal limbs folded alongside of or beneath the body, since the limbs are small and flexible. In multipara, fetuses may be in a dorso-ilial or dorso-pubic position and be born without difficulty. In unipara only premature or very small fetuses may pass through the pelvis in dorso-ilial or dorso-pubic position or with a flexed limb or limbs. In ewes, the fetus may often be born without assistance in anterior presentation with one forelimb retained beneath the body. After the veterinarian has brought each part of the fetus into its normal posture, the cause of dystocia is usually relieved and the fetus will be expelled normally, or parturition aided or completed by traction.

Repulsion, sometimes called retropulsion, consists of pushing the fetus out of the maternal pelvis or birth canal into the abdominal cavity and uterus, where space is available for the correction of the position or posture of the fetus and its extremities. In nearly all cases in which expulsion is used, epidural anesthesia is indicated since repulsion frequently produces violent straining on the part of the animal. When repulsion is used, the portion of the fetus engaged in the pelvis is pushed cranially. Because the fetus and uterus are in the form of an arc in the cow, the opposite end of the fetus may be pushed somewhat nearer the pelvis. Repulsion is usually necessary because the birth canal or pelvic cavity is so narrow and so confining that it is impossible to correct deviations in po-

sition or posture without providing more room in which to manipulate the fetus or its long extremities. Besides its common use for repelling a portion of the fetus out of the pelvis, repulsion may also be used to force a portion of the fetus—usually the proximal portion of an extremity and the part of the body to which it is attached—cranially, dorsally, ventrally, or laterally in the uterine and abdominal cavity so that sufficient room is provided to extend the flexed extremity with facility.

Repulsion may be accomplished by the operator's arm, the arm of an assistant, or by a crutch repeller. If the latter instrument is used it should be guarded by having the operator's hand on the crutch part of the repeller as force is applied, so that slipping of the crutch and possible uterine laceration or rupture is avoided. In anterior presentation the crutch or hand of the operator is usually placed on the fetus between the shoulder and chest or across the chest beneath the neck. In posterior presentation it is placed in the perineal region over the ischial arch. Epidural anesthesia is of great value especially in large animals, because the fetus after being repelled is not immediately forced back into the pelvis by straining, and therefore it is easier for the operator to correct the abnormal posture or position. If the crutch repeller is used and left in place the person applying the outside force should be properly braced and balanced so if the crutch slips or becomes displaced it will not be forced cranially, possibly through the uterine wall. If it slips it should immediately be withdrawn or replaced. It is somewhat safer to use an assistant and under the operator's direction have him repel the fetus with one arm while the operator's arm corrects the abnormal posture. The only disadvantage to this method is that in heifers with a small birth canal, room for two arms is restricted. In ewes, does, and sows, repulsion is performed by the arm and hand, or by the finger in bitches and queens.

Having the animal standing or with its rear parts elevated if it is recumbent, is essential to make room available for repulsion. Repulsion is difficult or impossible in the recumbent animal resting on its sternum, as the abdominal viscera are forcing the fetus back toward the pelvis. If the animal is recumbent it should be laid on its side with its four legs extended. In ruminants the dam should be resting on the left side so the weight of the rumen does not press on the fetus and uterus. Excessive repulsion may be dangerous, especially in cases in which dystocia has existed for some time, because the uterine wall is often tightly contracted around the fetus. The uterine cavity thus nearly ceases to exist, and hence rupture of the uterus is liable to occur. In other countries uterine relaxants and spasmolytic drugs have been advocated and used.² These have not been available for use

in the U.S. In cases of neglected dystocia or of emphysema of the fetus, the repulsive force should be carefully controlled. Frequently satisfactory repulsion is impossible and this is the reason why the handling of prolonged dystocia cases is difficult and the prognosis is guarded to poor. In large animals, early diagnosis of minor abnormalities causing dystocia may preclude the need for epidural anesthesia and with the animal standing the fetus can be repelled and its posture or position corrected between abdominal contractions.

Rotation is the turning of the fetus on its long axis to bring the fetus into a dorso-sacral position. This position is necessary in all but very small fetuses in uniparous animals and is the usual presenting position even in multiparous animals. In the latter species an abnormal position of the fetus seldom causes dystocia due to the small size of the fetus compared with the size of the pelvic cavity or inlet. In the cow the presence of the fetus in a dorso-ilial or dorso-pubic position frequently is accompanied by a 90- to 180-degree torsion of the uterus.⁵⁶ In 90-degree torsion of the uterus twisting of the birth canal is often not noticeable. It seems very unlikely that an 180-degree torsion with its accompanying marked twisting of the birth canal would go unnoticed by an experienced veterinarian. In the dorso-pubic position of the fetus in the cow, a rectal examination and examination of the relation of the broad ligaments and the uterine arteries to the uterus, would reveal whether torsion of the uterus existed and indicate the direction for rotating the fetus in correcting the twisted uterus. **In the mare** and multiparous animals in which the fetus lies in the uterus in a dorso-pubic or dorso-ilial position during pregnancy with the navel cord extending laterally or dorsally toward the uterine attachment of the broad ligament and uterine wall, the fetus must rotate 90 to 180 degrees before entering the pelvic inlet in a dorso-sacral position. If rotation is not complete by the second stage of parturition, dystocia may result. In multiparous animals with the fetus in a dorso-pubic position the nose of the fetus may catch on the pelvic brim in anterior presentation, or the buttocks may catch on the brim of the pelvis in posterior presentation. These positions and postures are common causes for dystocia in dogs.²⁵

To relieve dystocia in unipara by rotation of the body of the fetus, it should be repelled cranially out of the pelvic cavity. If this cannot be done, due to the contracting uterus, it indicates that the dystocia has existed long enough to also result in a dry mucous membrane of the birth canal. In this case much careful lubrication of the birth canal and fetus is necessary to make rotation of the fetus within the confining structures possible and easier without injuring the uterine or vaginal walls. In

dorso-iliac positions repulsion is often not necessary but may be helpful. Lubrication of the fetus and birth canal, caudal and downward traction on the extremities, and rotation of the fetus with the operator's arm in the birth canal, readily corrects this mild abnormal position. After the body of the fetus in anterior presentation, dorso-pubic position, is repelled out of the pelvis, leaving the fetal limbs in the pelvic cavity, chains are fastened to the fetlocks and cross-traction is applied by two assistants. Depending upon which way the fetus is to be rotated one leg is initially pulled upwards, then horizontally to the left or right and then downwards while the other leg is being pulled underneath the first leg downward and obliquely to the right or left. This type of traction causes a rotation of the body of the fetus that is aided by the operator placing his arm and hand under the withers or body of the fetus and elevating it to the level of the pelvic brim, using the pelvis as a fulcrum, and then pushing the fetus obliquely to either the left or right.

To prevent the hip-lock condition in anterior or posterior presentation Ball^{3,39a} recommended rotation of the fetus so that the fetal hips engaged the maternal pelvis in an oblique manner to take advantage of the widest pelvic diameter. (See Figure 1.) This could be accomplished by applying moderate traction to the fetus and inserting the arm between the fetal legs, and over the neck in anterior, and between the rear legs in posterior presentation, and rotating the fetal body and pelvis the desired angle. The fetus is withdrawn by caudal and lateral traction, first one hip and then the other, through the pelvic girdle of the dam.

In occasional prolonged cases of dystocia in anterior presentation, the head and neck may be an obstacle to rotation and have to be amputated before rotation can be accomplished. In posterior presentation the fetus is rotated in a like manner, with the operator's hand and arm under the buttocks. This method of cross-traction is superior to placing traction directly backward on one limb and twisting the opposite limb around the fulcrum thus established. This latter technique causes the fetus to become impacted in the maternal pelvis and thus resist rotation, and a great strain is placed on the joints and ligaments of the leg that is twisted around the one to which traction is being applied. In the former techniques impaction of the fetus in the pelvis is reduced to a minimum, and elevating the body of the fetus makes correction of the abnormal position rapid and easy. If correction of the position is difficult in one direction, torsion may be present, and the direction of traction may be increasing the degree of torsion. If this is the case, the fetus should be rotated in the opposite direction. In mild cases diagnosed early in parturition or where the fetus is small,

the fetlock protruding from the vulva may be flexed and used as a means of exerting a moderate twisting action on the leg to assist rotating the fetus.

In a few cases, rotation may require the use of the detorsion rod or Cammerer's fork as described under torsion of the uterus. In these cases the rod is fastened to the two limbs after lubrication of the fetus and the birth canal and by repulsion and rotation the position is corrected. In ewes and sows the hand and in bitches and queens the finger applied to or alongside the chest or buttocks after lubrication will usually repel and then rotate the fetus into a normal dorso-sacral position. In these smaller animals forceps may also be used with care to rotate the fetus.

Version is the rotation of the fetus on its transverse axis into an anterior or posterior presentation. This is done most often in the mare in transverse ventral presentation and in rare cases in the cow, ewe, doe and bitch in transverse presentation. Transverse presentation in the mare occurred about 1 in 1000 pregnancies.⁴⁴ Version is usually limited to 90°. By repulsion on the cranial or caudal end of the fetus and traction on the other end, the transverse presentation is changed to a longitudinal presentation. If possible the fetus should be turned into a posterior longitudinal presentation, as that prevents the head and neck from complicating the correction of the abnormal presentation or posture. In the mare partial fetotomy is often indicated before version is attempted in transverse ventral presentation. Often version is only through a relatively small arc if the fetus is lying obliquely rather than in a true transverse presentation. In the tubular type of uteri in domestic animals, version through a 180° arc such as from posterior to anterior presentation is rarely possible and should not be attempted.

Extension and Adjustment of the Extremities is the correction of abnormal postures usually due to flexion of one or more of the extremities causing dystocia. Flexion of the head and neck causes dystocia in all species. Flexion of the limbs usually results in dystocia in uniparous animals but only rarely in multiparous animals. Corrective procedures are difficult and often impossible within the confines of the pelvic cavity. The fetus must usually be repelled out of the pelvis into the larger uterine and abdominal cavities to have sufficient room for the correction of abnormal postures. This is particularly true in the large uniparous animals, in which the fetal extremities are long. Many of these abnormal postures may be caused by the distal portion of the fetal extremity being caught on the pelvic brim, and are aggravated when the body of the fetus passes over this extremity, thereby resulting in greater flexion of the extremity and even its extension beneath the body. The act of repulsion of the fetus cranially into the uterine and abdominal cavities

tends to correct the deviated extremity or abnormal posture. Three basic mechanical principles are necessary to effect a prompt, easy correction of a flexed extremity (see Figure 88).

(1) **Repulsion of the Proximal Portion of the Extremity** such as the shoulder or chest is performed in anterior presentation in the correction of a flexed fetlock, carpus, elbow, or shoulder joints with the forelimb extended beneath the body; or the head and neck flexed alongside, beneath or over the body of the fetus. In posterior presentation repulsion is performed on the buttocks, stifle, or tarsus when the hind limbs are flexed at the stifle, tarsus, fetlock, or hip. In the latter condition the legs extend beneath the fetus, a breech presentation.

(2) **Lateral Rotation of the Middle Portion of the Extremity, Carpus, Tarsus, or Neck**—Lateral rotation and repulsion of the flexed tarsus, carpus or neck into the cranial and lateral flank region provides adequate room in most cases for the medial extension of the fetlock or nose into the pelvic cavity. In small equine or bovine fetuses, if the operator firmly grasps the metacarpus or metatarsus, he can with the same motion perform both repulsion and lateral rotation as well as extension of the fetlock into the pelvic cavity. In larger fetuses the operator may require a crutch repeller, or even better an assistant's arm, to force the tarsus or carpus laterally and cranially while the operator brings the fetlock medially and caudally into the pelvic cavity. This latter procedure allows the operator to cup or flex the pastern in his hand so that as the limb is extended the hoof of the fetus will not catch, tear, or lacerate the wall of the birth canal as the foot is drawn into the pelvic cavity.

(3) **Traction on the Distal Portion of the Extremity** such as the pastern, the lower jaw or, until these distal structures can be reached, the structures between the body and the distal portions of the extremity, is applied to extend the limbs or head and neck. This traction may be applied by the hands and arm, a chain, Krey's tongs or a snare. When the fetus is in breech presentation with the legs extended beneath the body, the fetus is repelled cranially out of the pelvic cavity and into the right or left flank. The hand and arm is slid down the tibia on the opposite leg and by traction the leg is pulled into a hock-flexed posture and then handled as described. In cases in which the head and neck are deviated alongside the anteriorly presented fetal body the fetus is repelled cranially and laterally into the flank of the cow on the side opposite to the head so that as much space as possible is provided in the other flank to allow correction of the deviated head and neck. By traction with the fingers in the orbits, around the lower jaw, in the angle of the mouth, by a snare around the lower jaw or small hooks in the orbits, the head can usually be pulled lat-

erally back to the pelvic inlet without twisting the neck. The head is then returned to its normal posture by manual traction, elevation or rotation of the head, and lateral repulsion on the neck. During these procedures the muzzle of the fetus should be guarded to make sure the lower incisor teeth do not lacerate the uterus, or the lower jaw catch on the pelvic brim of the dam, especially if the type of traction applied causes the mouth to gape. When the dam is recumbent the deviated fetal head should be located in the upper flank before mutation procedures begin. Otherwise the weight of the fetal body resting on the head and neck would make correction nearly impossible.

The combined use of these three mechanical principles will relieve almost all abnormal postures. In rare cases, in order to obtain more room in which to perform these maneuvers when the uterus is contracted tightly around the fetus, a partial fetotomy may be necessary, such as amputation of a forelimb. In multipara, mutation of the fetus is not generally required except in deviation of the head and neck in anterior presentation, impaction of a large fetus in the pelvis in breech presentation or in dorso-pubic position when the nose or buttocks of the fetus may catch on the pelvic brim of the dam as the fetus enters the pelvis. By using the finger in the vagina and manipulating the canine or feline fetus through the abdominal wall and floor with the opposite hand these abnormal postures may usually be corrected. Occasionally forceps or snares may be indicated. In a few cases dystocia in cattle is observed due to the impingement of the elevated tail on the dorsal border of the pelvic inlet in posterior presentation. Repulsion of the fetus, holding the tail against the perineum and applying traction to the rear limbs corrects the dystocia. Kuhn's crutch was very useful in various mutation operations in the mare and cow.³ Although the theoretical uses of the instrument are many, it has not proved useful in the author's practice.

Mutation of the fetus must be performed carefully, cautiously, and in a gentle manner in all animals. These manipulations can take place only at the level of or just below the pelvic brim. The earlier the dystocia is diagnosed, the easier is mutation of the fetus accomplished; conversely, the longer aid is withheld or delayed, the more difficult or impossible it is for mutation to be successful. This is true, but to a lesser extent, in the other major obstetrical operations.

Forced Extraction

Forced extraction is defined as the withdrawal of the fetus from the dam through the birth canal by means of the application of outside force or traction. Traction should

Figure 88. Procedures followed in mutation of deviated fetal extremities: A. Lateral view of a breech presentation of a bovine fetus. B. By repulsion on the buttocks and traction on the tibia the leg is drawn into a hock-flexed posture. C, D and E. caudal and lateral views show how, by upward repulsion and lateral rotation on the hock and medial and caudal traction on the fetlock and pastern, the leg is extended into the pelvis.

be applied only when the abdominal muscles of the dam are contracting and pulling the pubis cranially to provide the greatest pelvic diameters for the passage of the fetus. If traction on the fetus is applied when the abdominal muscles are relaxed the pelvic floor is pulled caudally reducing the size of the pelvic opening.^{3,39a} This intermittent traction may prevent asphyxiation of the fetus if he should be breathing and it is also less stressful for both the fetus and the dam. Since the widest diameter of the bovine fetal pelvis is between the greater trochanters and the widest portion of the maternal bony pelvic inlet is the dorso-pubic, not the bisiliac, diameter (See Figure 1), this information is used to assist withdrawal of a large fetus through the birth canal by rotating the fetus so the greatest diameters of the fetal and maternal pelvis coincide.^{39a}

Manner and Dangers of the Application of Traction Instruments to the Fetus—In anterior presentation obstetrical chains may be applied to the pasterns or above the knee or elbow. If the fetal membranes prevent the prompt application of the chains or snares they should be broken, ripped away, or pushed to one side. The chain should be tightly fastened around the pastern before applying traction or it may slip down over the coronary band of the hoof and when traction is applied the hoof may be pulled off. Applying the chains above the fetlock may be satisfactory in almost all cases but in rare cases excessive traction and tightening of the chain over the epiphysis or "break joint" may fracture the leg. For these reasons many veterinarians place the noose of the obstetrical chain above the fetlock and place a half-hitch around the pastern. This prevents the chain from sliding down over the coronary band and distributes the force over the two sites. Some place the large terminal link in the obstetrical chain ventral to the pastern and pass the chain between the claws of the bovine fetus. This raises and extends the toe and may avoid its catching on the brim of the pelvis.

In anterior presentation a snare may be applied around the lower jaw and tightened firmly so that with traction it will not slip and fracture the dental plate. Obstetrical chains around the lower jaw will not tighten sufficiently, and generally slip off, often damaging the incisor teeth. Excessive traction on the jaw should be avoided, as the jaw bones are not strong and fracture may occur. Moderate traction applied by one man is all that can safely be used on the lower jaw of a bovine fetus. A loop of obstetrical chain around the neck behind the head is used occasionally for traction when the fetus is dead; but the head and muzzle must be directed with the hand so that they will not become deviated. This technique is dangerous to a live fetus as it may cause injury to the spinal

cord and vertebrae in the occipital region. A loop of obstetrical chain is more commonly used around the poll, under the ears and through the mouth in the manner of a "war bridle" for applying traction to the head. This causes the mouth to gape when traction is applied; the operator should therefore watch for this and protect himself and the birth canal from injury by the sharp incisor teeth. Pinching the large link in the end of the obstetrical chain noose in a vise in such a manner that it catches on the chain, thus preventing the chain noose from tightening when traction is applied has been recommended.⁵⁴ A commercial head snare is available that also overcomes gaping of the mouth. By the use of blunt or knobbed Krey's hooks or short obstetrical hooks on a loop or cord in the orbits, traction may be applied to the head.^{3,4} This technique is safe unless excessive traction causes fracture of the facial bones. A technique in which an incision is made in the floor of the mouth anterior to the tongue, extending through the skin between the mandibles has been described. A loop of obstetrical chain is then passed over the lower jaw, behind this incision, and the opposite end of the chain is passed through the incision and tightened.⁵⁶ This provides a firm, solid hold on the lower jaw that will not slip and by means of which a large amount of traction may be applied. It is used most satisfactorily in dead fetuses, but even in live fetuses the wound heals quite rapidly after birth. The long or short blunt hook placed between the rami of the mandibles is not satisfactory because it frequently slips, or with moderate traction may cause a separation of the symphysis of the mandible. In a dead fetus the long blunt hook may be passed through the mouth into the pharynx, turned dorsally, and then traction may be applied fixing the hook in bones dorsal to the pharynx.

The long blunt hook may be used to advantage in the hiplock condition in anterior presentation. The hook is passed over the top of the fetal croup and turned ventrally to engage the posterior border of the ischium or sacrosclatic ligament. In this position much traction may be applied. By raising the fetal pelvis and pulling the fetal hips at an oblique angle through the maternal pelvis, the veterinarian can often relieve the dystocia.

In ewes, does and sows the obstetrical chains are too large to be of value. In anterior presentation snares or forceps are applied to the ovine or porcine fetal head, around the neck, or to the forelegs. In small sheep and swine, in which the hand cannot be passed through the pelvis into the uterus, forceps of various types, as well as obstetrical snares, may be used to advantage.³⁵ Whenever forceps, snares or chains are applied, the wall of the genital tract should be examined before traction is applied, to make sure it is not caught. In bitches and

queens forceps may be applied to the head of the fetus after the head is repelled out of the pelvis into the uterus; but great care should be used to prevent tearing an ear or lacerating the skin, fracturing the mandible, or crushing the skull. Excessive traction or twisting of the head should be avoided, since injury or dislocation of the vertebrae may occur in the occipital region in these small species. Forced extraction in multipara is limited to those fetuses which have entered the uterine body or pelvis. Snares of gauze may be used on the limbs of canine fetuses. The use of forceps in dystocia in dogs has been described.^{14,25}

In posterior presentation in large animals traction may be applied to the fetal pastern or above the hock by the use of obstetrical chains. The same danger exists as in the anterior presentation whereby excessive traction with chains fastened above the fetlocks or that slide down over the coronary band of the hoof, may cause fracture above the fetlock or removal of the hoof. In ewes and sows, snares may be fastened around the hind legs of the fetus. In bitches and queens snares or gauze around the hind legs or grasping the hocks with sponge forceps will assist traction. If forceps are used in multipara they should be fastened securely around or across the fetal pelvis, after the fetal hips have been repelled out of the maternal pelvis. In bitches, forceps are generally preferred to applying excessive traction to the hind legs with the accompanying possible danger of dislocating the fetal hips. Excessive twisting of the fetal pelvis by the means of forceps may injure the lumbo-sacral articulation; or if the fetus is emphysematous excessive traction may pull it apart. Dislocation of the first cervical joint may occur in posterior presentation in the bitch when the occiput becomes impacted in the pelvis and traction is continued. In this instance abdominal pressure by the operator's hand will raise the chin of the fetus and help force the fetal head through the pelvis.

Technique of Withdrawing Fetus Through the Maternal Birth Canal—In anterior presentation of the fetus in uniparous animals, traction should be applied at three points, the two legs and the head. After the limbs followed by the head have passed through the vulva, traction may be applied to the legs only. At the beginning of labor the main portion of the fetus is below the level of the brim of the pelvis. Traction when applied in either anterior or posterior presentation should be dorsally and caudally to lift the fetus up and over the brim of the pelvis into the birth canal. At this stage, with the fetal extremities approaching the vulva, the direction of traction should at first be caudal and slightly dorsal; and as the fetal legs and head engage in the vulva the direction of traction should be obliquely ventral. After the

head in anterior presentation or the hips in posterior presentation pass through the vulva, the direction of traction should be more and more ventral until when the back of the fetus is passing through the vulva the direction of traction is perpendicular to the spinal axis of the dam or parallel to her hind legs. Thus the direction of traction and that of the fetus as it passes through the birth canal is in the form of an arc. The ventral structures of the fetus are relaxed and concave, and the dorsal structures of the fetus are stretched and convex. This arc-like application of traction results in the fetus assuming the physiologic curved shape that facilitates its removal through the birth canal; by producing the smallest possible diameters of the fetal body stalling of the fetal pelvis, or the hiplock condition, is prevented. By applying traction to the legs, head, and spine the abdominal wall of the fetus is relaxed and the fetal pelvis is forced backward and upward reducing its sacro-pubic diameter and causing it to pass through the greatest diameter of the maternal pelvis. If traction is applied in a straight caudal direction and not in the form of an arc, both the linea alba as well as the spine are stretched, and the fetal pelvis is pulled ventrally and cranially thus increasing its sacro-pubic diameter and predisposing to hiplock. As described previously the rotation of the fetus in the birth canal into the dorsoilial position to cause the fetal pelvis to enter the maternal pelvis at an oblique angle corresponding to the greatest diameter of the maternal pelvis combined with lateral traction often prevents the hiplock condition.^{3,39a} After the fetal hips have been withdrawn through the maternal inlet in an oblique or dorso-ilial position, the fetus should be rotated back to a dorso-sacral position before further traction is applied.

When the head enters the vulva, if traction is applied dorsally or caudally instead of ventrally the fetal head jams against the dorsal commissure of the vulva and may cause severe stretching or laceration. At this point it is important to place ventral traction on the head. When the vulva is small, especially in primiparous cattle, ventral traction on the head alone together with insertion of the hands over the top of the head; stretching of the vulva with the wrists, arms or hands; and ventral and caudal traction with the hands over the occiput or with the fingers in the medial canthus of the orbit helps to pass the head through the vulva and prevent lacerations. Often, if this process is prolonged, lubrication of the head and vulva is helpful. Pushing or pulling cranially on the vulva if the vulva is tight while traction is applied on the fetal head will further aid dilation.

When abdominal contractions in the dam occur during parturition the linea alba pulls the pubis forward, increasing the pelvic diameters. When strong traction is

applied to the fetus and the pelvic ligaments are relaxed the maternal pubis is pulled caudally and the pelvic diameters are lessened. A rope or breeching around the buttocks of the cow in lateral recumbency fastened securely to the manger so that when traction is applied to the fetus the maternal pubis is pulled forward by this rope or breeching was recommended.⁵⁶ The metal breech device used with fetal extractors provides this same advantage. Preventing the maternal pubis from extending caudally, and applying ventral traction on the fetus, will usually prevent impaction of the fetal hips in the maternal pelvis. Improper traction such as that produced by a block and tackle pulling directly caudally will in many instances cause severe impaction of the fetus in the maternal pelvis.

When traction is applied the operator should constantly watch, examine, and direct the progress of the fetus by instructing his assistants when to apply traction, when it should cease, and in what direction it should be applied. If the progress of the fetus through the birth canal should cease, traction should be discontinued and the fetus and the birth canal should be carefully examined to determine the cause of the obstruction. This should be overcome or corrected before exerting further traction. The operator should conserve his strength and direct the operation and not join his assistants in applying traction except when necessary. If the patient is straining, traction should be applied principally during expulsive efforts. This both aids the withdrawal of the fetus and to some extent prevents the fetus dragging portions of the uterus and vagina along with it, thereby causing possible rupture or prolapse of the uterus. Traction should be applied in a steady, even manner. Jerky, irregular efforts at traction are ineffectual, painful and dangerous to both the fetus and dam. In most instances traction should not be applied in a hasty manner. To avoid lacerations or ruptures of the soft structures of the birth canal time should be allowed for dilation of the birth canal as the fetus advances. This frequently requires 30 minutes or longer in heifers. The same general technique of removing fetuses by traction in ewes, sows, does, bitches and queens is followed with traction caudally and then downward as the fetus passes through the vulva. In the bitch and queen pressure of the operator's hand upward through the abdominal wall will help the passage of the fetus into the pelvis and through the birth canal.

In uniparous animals traction may be greatly facilitated by lubrication if the fetus and birth canal are dry. Traction on one extremity at a time in an alternate manner is also of assistance in withdrawing a fetus. This is especially true in posterior presentation, in which traction should be applied to one limb at a time so that the

fetal pelvis is pulled through the maternal pelvis in an oblique manner, thus reducing the possibility of hiplock. Even in anterior presentation, after the forelimbs and head have passed through the vulva, pulling the bovine fetus laterally and ventrally around the dam's hips first to one side and then to the other may aid in withdrawal of the fetus and produce an oblique angle to the fetal pelvis, so that one greater trochanter will slip through the maternal pelvic inlet and then the other will follow, preventing or reducing the chances of hiplock or impaction. As traction is applied, rotating of the fetal body from side to side may aid withdrawal of the fetus.

Indications for Forced Extraction of the Fetus—

Forced extraction is indicated when uterine inertia is present and the fetus does not engage in the birth canal and stimulate straining. It is indicated when epidural anesthesia has been administered and after mutation has corrected the cause for dystocia. Forced extraction is used most often when the fetus is relatively too large to be expelled through the birth canal without assistance, fetopelvic disproportion, and when traction offers greater prospect of success than a fetotomy or cesarean. It is used in many cases in primipara with a small birth canal, as a means of withdrawing the fetus and dilating the canal. It may also be used when the birth canal is compressed by tumors or fat or other pathological conditions. It may be indicated in posterior presentation of the fetus to hasten delivery and prevent the death of the fetus when the umbilical cord is compressed between the fetal abdominal wall and the brim of the pelvis. Within 5 to 10 minutes after the umbilical circulation is cut off the fetus may die if its cranial extremities remain in the uterus and it cannot breathe. Hasty application of forced extraction may occasionally be indicated in mares with dystocia in which the cause for the dystocia has been corrected and the fetus is still alive. Thus it may effect removal of the fetus before separation of the placenta and death of the fetus occur. Forced extraction may occasionally be used to save time or in order to avoid fetotomy or cesarean section where working conditions are extremely poor. It is indicated in dystocia due to emphysematous fetuses after thoroughly lubricating the birth canal and fetus to avoid fetotomy or a cesarean, which are more hazardous to the dam than is forced extraction under such conditions. In many fetotomy operations, forced extraction is used as an aid.

Forced extraction by forceps or snares in the multiparous animals, sow, bitch, and queen, should not be used when one is short of time or patience as it may require a number of hours of intermittent work to complete the delivery of all the fetuses. It is, however, indicated when the owner is not interested in saving the

fetuses; when only one or two fetuses are present and secondary uterine inertia has set in; when the fetuses are dead and emphysematous; and when in the opinion of the operator the delivery of one fetus will result in the unaided delivery of the rest of the litter. The veterinarian may even decide to use forceps and forced extraction in cases of primary inertia where the litter is small. Young primiparous bitches may force the fetal head through the pelvis and then rest. This pup becomes cyanotic and must be delivered immediately. Since the vulva is small and tight it is necessary to force the pup's head through by means of outside pressure on the vulvar lips. Then by applying manual traction on the head and placing a finger under the pup's chest, the pup can be eased through the vulva.²⁵ To prevent the fingers from slipping, a gauze pad may be used.

Forced extraction should be limited strictly to cases in which the presentation, position and posture of the fetus are normal and in which, in the opinion of the operator, forced extraction is in the best interests of the fetus, the dam and the owner. Forced extraction is contraindicated or should only be undertaken with great care when abnormal presentation, position or postures are present, when the fetus is excessively large or defective, when the birth canal is obviously small, when the animal is affected with obturator paralysis, when the birth canal has been severely lacerated, when secondary uterine inertia is present with the uterine walls strongly contracted around the fetus, and when the cervix is stenotic or has failed to dilate. In these latter conditions uterine relaxants and spasmolytic drugs might be recommended.² However, these products for use in dystocia in animals in the U.S.A. are not currently available.

The Amount of Traction to Apply in Forced Extraction of the Fetus will vary greatly with the species of animal and the condition causing the dystocia. Although forced extraction appears simple and quick it is potentially dangerous to the fetus and to the dam. In the dam, excessive traction or traction in an improper manner or with the fetus in an abnormal presentation, position, and posture may result in trauma, laceration, rupture to the soft structures of the birth canal or uterus or wedging of the fetus in the dam's pelvis. It may predispose to prolapse of the uterus, or result in trauma to the obturator or gluteal nerves. However it is remarkable how seldom paralysis occurs even when excessive traction has been applied.

In the mare, abdominal contractions are so violent that if the fetus is in the proper presentation, position and posture, forced extraction is seldom necessary. Aid with obstetrical chains by one or two men may help dilate the birth canal and vulva gradually in old or young primi-

parous mares. Care should be exercised to avoid lacerating the vulva or the perineal region. If the mare is recumbent and much traction is applied, she will usually get to her feet. If the cow is standing and strong traction is applied to the fetus, the cow will usually fall and may injure itself or the attendants. In the cow, as in the mare, traction under certain circumstances should be moderate and intermittent; for example, if the fetus is alive and the cow already exhibits some obturator paralysis due to a hiplock condition. In normal circumstances the force of 2 to 3 men apparently causes no harm and may be indicated. The introduction of the fetal extractor with which one can exert great force in the proper manner, if necessary, has been received enthusiastically by many veterinarians because often sufficient manpower is not available and the block and tackle or wire stretchers previously used applied traction in only one direction and in an improper manner, that is, directly caudally. Since excessive power can easily be applied by the fetal extractor, judgment, caution, and care must be exercised in its use. Where great amounts of traction are used, epidural analgesia is strongly recommended to avoid excessive pain in the dam. The amount of traction to be applied will vary from case to case and with the judgment of the veterinarian. Following forced extraction of large fetuses of beef cattle including Charolais, Charolais-cross and Simmental-cross calves, both hard and soft tissue injuries have been reported.^{17a,30} The hard tissue injuries include; fractures of the proximal end of the femur and slipped capital femoral epiphysis,^{17a} fractures of the ribs, costo-chondral junctions, lumbar vertebrae and metacarpal or metatarsal bones. The soft tissue injuries include: femoral nerve paralysis and quadriceps femoris muscle damage and atrophy due to hyperextension of the femur.⁴³ The author has observed that the above injuries to the newborn are much more common with the recent increased breeding of the exotic beef crossbreds and the introduction of the fetal extractor often employed by farmers or ranchers to relieve dystocia. Traction if properly applied seldom results in injury to the fetus or to the genital tract of the mare and cow. However, to quote Williams,⁵⁶ "Application of great force in improper position, presentation or posture of the fetus is constantly to be condemned." The use of a tractor or horses to apply traction to the fetus, or tying the fetus to a tree and driving the parturient mare away, are definite examples of malpractice if performed by a veterinarian.

In the ewe, doe and sow the same principles in regard to the degree of traction may be applied. In all cases, however, the force exerted by one man is sufficient for the relief of dystocia in these species. In the ewe and doe, before applying traction one should make certain

the snare is attached to one, not two, fetuses. In bitches and queens traction should be applied carefully and never excessively. Twisting of the fetus should be avoided. Occasionally in emphysematous fetuses traction may pull the fetus apart. In these small species traction should be used with care, especially if secondary uterine inertia has set in, to avoid laceration of the uterus or birth canal at the pelvic brim. This will result in herniation of the viscera through the birth canal or discharge of the fetuses into the abdominal cavity.

Fetotomy

Fetotomy is defined as those operations performed on the fetus for the purpose of reducing its size by either its division or the removal of certain of its parts. In most cases these operations are performed within the uterus of the dam. Partial fetotomy is most commonly performed. Total fetotomy is performed infrequently. In fetotomy the life of the fetus is sacrificed if it is not already dead as is usually the case. In Germany attention has been paid to humane methods of killing the fetus, before fetotomy is begun.⁴ These authors indicate the fetal reflexes and threshold for pain are of a very low order. For this reason incising the carotid artery or rupturing the umbilical cord before fetotomy is not necessary. The injection of a rapid-acting drug to produce euthanasia or an anesthetic state in the fetus has not been investigated but any such agent might well be transferred by the placenta to the dam.

If the fetus is dead and the birth canal is not reduced in size, fetotomy should be given primary consideration.⁵⁹ The **advantages of fetotomy** are: It reduces the size of the fetus. It avoids a cesarean operation. It requires little assistance. It will prevent possible trauma or injury to the dam through the use of excessive traction.^{2,5,7,59}

The **disadvantages of fetotomy** are: It may be dangerous, causing injuries or lacerations to the uterus or birth canal by instruments or sharp edges of bone. It may take a long time, exhausting both the dam and the operator and is conducive to trauma and pressure necrosis of the birth canal. It offers certain dangers to the veterinarian by wounds from instruments, and if the fetus is emphysematous there is a possibility of infection of the skin of the operator's arms.

The advantages outweigh the disadvantages, however, and fetotomy in large animals is a practical and successful way of relieving dystocia. It is used, and rightly so, many more times than is cesarean section, which is more costly and time consuming, and requires more help

and more aftercare than do most fetotomy operations. Cesarean section is indicated over fetotomy only if the fetus is alive and the owner desires that it be saved; or when total fetotomy under difficult conditions, such as a small narrow birth canal, would probably cause greater trauma to the dam, take longer, and be more fatiguing to both the dam and veterinarian than would cesarean section. If there is little prospect of a successful fetotomy operation and forced extraction is impossible, the owner should be advised to have a cesarean operation performed or to slaughter the dam.

Since cesarean section is more difficult to perform successfully in the mare than in the other domestic animals, fetotomy or forced extraction are methods of choice in this species. Because the genital tract of the mare is more easily traumatized, and with more serious consequences than that of the cow, fetotomy should be performed carefully and gently. For more than a simply fetotomy in the mare, a general anesthesia should probably be administered. The mare should be restrained in a suitable location large enough for the operation to be performed with the mare lying on her side.

Simple fetotomy techniques using a guarded obstetrical wire² may be performed in the ewe and doe if the hand can be passed through the pelvis into the uterus. By threading a loop of the obstetrical wire through a pipe of small diameter, portions of the fetus, such as the head and forelimbs, may be removed with safety to the dam. Fetotomies are not performed in the sow, bitch, and queen because cesarean section is easier and safer. In rare cases in the bitch the skull of the fetus may be crushed intentionally by means of forceps in order to permit removal by traction.

Vandeplassche and his associates^{48,49,50} compared the results of 239 fetotomies and 150 cesarean operations in cattle and came to the conclusion that fetotomy was still the more important and practical of the two methods in bovine veterinary practice. In summarizing the data on these 239 cases it was found that in 3 to 5 percent of them fetotomy was impossible. Six percent of the cows died, 6 of them from septic metritis, 2 from malignant edema, 3 from necrotic vaginitis, 1 from a ruptured uterus, and 1 from hemorrhage. Thirteen percent of the cows had retained fetal membranes and 82 percent conceived within 10 months after the fetotomy operation. A more recent review of the literature reported on many hundreds of fetotomy and laparohysterotomy (Cesarean) operations and indicated that both procedures have their place in veterinary obstetrics.⁵⁹

The fetotomy operation may involve any portion of the fetal body and presents many variations and possibilities. It may be performed in any normal or abnormal

presentation, position, or posture of the fetus. In many cases it is employed in relieving dystocia due to fetal monsters in which the usual anatomical arrangement of parts may not exist. The operational procedure must be decided upon for each case. Fetotomy operations should be planned and carried out carefully, so that there will be no wasted effort. Generally, by careful planning and by using mutation or forced extraction, only one fetotomy operation, instead of two, may be necessary. It should be borne in mind that the aim of fetotomy is to reduce the size of the fetus so it may be removed from the birth canal. The veterinarian therefore should, depending upon the particular conditions and circumstances, plan the operation and procedures using one or more of the standard fetotomy operations or their variations. At the present time the fetatome is standard equipment for the practitioner working with large animals; therefore many of the older techniques⁵⁶ using instruments such as the knife, chisel, and blunt-pointed cutting hook are not often used. These older techniques, using simple instruments, involved some operations which were difficult to perform, requiring patience, strength, and extreme effort, placing a severe strain on both the operator and the animal. Veterinarians who have become adept through practice may perform many obstetrical operations with the knife, chisel, and hook and seldom use the fetatome. The author has for many years been a staunch advocate of the fetatome primarily because it is easier and safer to use. Except for minor simple obstetrical operations, he prefers it to the older instruments and their accompanying techniques. Some of the simpler older techniques are still practical, however, and will be described.

In dairy cattle practice in New York State 90 percent of the fetotomy operations performed include: bisecting the pelvis in anterior presentation, (hiplock) or in posterior presentation, (breech presentation), amputation of the head and neck, and decapitation. In some cases evisceration is used prior to bisecting the pelvis in anterior presentation.

Presently many of the subcutaneous fetotomy techniques advocated by Williams and others⁵⁶ are rapidly declining in popularity. The newer percutaneous techniques pioneered by the Utrecht clinicians with their modification of the fetatome are being rapidly accepted and utilized because of their ease and safety of application.^{5,4,59}

Fetotomy Operations in the Anterior Presentation

Decapitation, or Amputation of the Protruding Head is indicated when one or both forelimbs are retained and

the head has passed through the vulva and become swollen, edematous, or emphysematous so that it cannot be repelled or can be repelled only with great difficulty. In such cases the fetus is usually dead, and amputation of its head allows the fetus to be repelled, so that the abnormal posture of the forelimbs may readily be corrected by mutation, without the interference of the head.

Decapitation is easily accomplished by fixing a snare on the lower jaw, or eye hooks in the orbits, and exerting traction in any direction desired by the operator. With a scalpel or sharp knife a transverse incision is made behind the jaw through the skin, muscles, pharynx, larynx and esophagus to the cervical vertebra. This incision is continued through the skin ventral to the ears and across the frontal bones. The skin over the head, including the ears, is separated from the underlying muscle and bone to the occipital region, where another transverse incision is made ventrally through the ligamentum nuchae and muscles to the cervical vertebra. The head is grasped firmly and twisted, rupturing the articular ligaments. The remaining soft tissues are cut and the head removed from the neck at the occipital atlod articulation. The flap of skin, including the ears, should be firmly secured by an obstetrical chain or snare which pulls the skin over the exposed cervical vertebra. A small incision in this flap of skin distal to the loop of obstetrical chain and through which the free end of the chain is drawn will secure the chain so it cannot slip off even if strong traction is applied. The fetus is then repelled, and the abnormal posture of the limbs corrected by mutation. Traction on the neck and two front legs usually results in relief of the dystocia. In making the incisions the operator must guard against the knife accidentally slipping and cutting the vulva. The fetatome could also be used in this operation, but the technique just described saves time as well as aftercare of equipment.

Cephalotomy or craniotomy is indicated only rarely when fetal hydrocephalus or other cranial deformity is the cause for dystocia.

Cephalotomy is accomplished by fixing the head with a snare around the lower jaw or chain attached to Krey's tongs inserted in the orbits. In hydrocephalus sometimes simply incising the distended cranium causes a sufficient reduction in size to permit delivery. In most cases, however, it is necessary to separate the enlarged cranium from the rest of the head by passing the wire of the fetatome around its base. With the fetal head fastened under tension to the chain fixation plate on the handle of the Utrecht fetatome and its head against the base of the enlarged cranium it is readily severed. Then the collapsed cranial bones and skin may be removed. The rest of the fetus can be withdrawn unless this is prevented by ankylosis

of the joints, a common characteristic of the hydrocephalic fetus.

Amputation of the Head and Neck is indicated when the head and neck are retained alongside, beneath, or above the body of the fetus or when performing a complete fetotomy.² Correction of this abnormal posture by mutation may be impossible or extremely difficult or dangerous, due to such conditions as wry neck, a uterus contracted tightly around the fetus, or to a dry, emphysematous fetus. Amputation may possibly be indicated when, due to a juvenile or hypoplastic pelvis or to a large fetal head, there is not room in the birth canal for the simultaneous presence of the head and neck and the two limbs. If this condition is present, one should determine accurately the relative size of the fetus and the birth canal because, if after removal of the head and neck further operations such as a total fetotomy are necessary, cesarean section might be preferable.

Amputation of the head and neck may be performed by the wire saw or fetatome. The latter is preferred because if the operation is performed properly the neck is amputated close enough to the body so that traction of the forelimbs will pull the scapulas and shoulder joints over the exposed stump of the neck vertebrae. Occasionally in a large mare it may be necessary to remove the forelimb opposite the side to which the head and neck are flexed, and to apply traction to the fetus in order to enable the operator to reach the neck and pass the fetatome wire around it. With the aid of the fetatome wire guide or obstetrical chain the fetatome wire is threaded over the base of the flexed neck and drawn around it. The head of the fetatome is held forcibly between the shoulder joint and neck of the fetus and the neck is severed as close to the body as possible. The neck and head are then withdrawn by means of the hand, a snare, or Krey's hooks. Traction on the forelegs of the fetus will deliver the fetal body unless further operations must be performed. If the cervical stump is long, it must be guided with Krey's tongs and guarded with the hand to prevent possible laceration of the birth canal as the fetus is withdrawn.

Amputation of the Forelimb is indicated to provide space so that amputation of the head and neck may be possible or easier. If the foreleg is retained or extended beneath the body and mutation is not possible due to fetal emphysema or contraction of the uterine wall, amputation of the foreleg is necessary. It is indicated in large or emphysematous fetuses to reduce their size and expose the ribs for evisceration. In rare cases it may be indicated in transverse ventral presentation in the mare in which after amputation of the two hind legs at the tarsus, and the underneath foreleg at the humeroradial

joint, the upper front leg may be removed in the manner described below and evisceration performed, if necessary, before the fetus is corrected by version into a posterior presentation.

Amputation of the forelimb is initiated by means of constant traction applied to the leg with a snare or obstetrical chain. By making a crescent-shaped incision through the skin of the fetus and its trapezius and rhomboideus muscles dorsal to the scapula with a hoe-bladed castrating knife or other knife, the dorsal end of the scapula is separated from the body. A loop of fetatome wire is placed around the limb and moved up the limb as the head of the fetatome is placed in the pectoral region. The wire loop is then moved upward and placed in the incision under the cartilage of the scapula, and the limb removed. This technique is particularly adapted to the cow; it is more difficult to perform in the mare due to the longer limbs of the equine fetus.

Another technique is that of placing the loop of fetatome wire around the limb to be removed while the head of the fetatome is placed just dorsal and caudal to the top of the fetal scapula. The limb is extended tautly, by traction by a chain to the chain plate on the handle of the Utrecht fetatome. By means of acute-angled sawing the limb is removed. The wire usually passes through the dorsal part of the scapula. On occasion one forelimb as well as the head and neck can be removed in a like manner by proper placing of the wire to include the head and neck. The removal of the forelimb extended beneath the body is easily performed by passing the fetatome wire behind the elbow and beneath the arm. By placing the head of the fetatome on the withers of the fetus, the entire limb can be removed rapidly.

The above two methods of amputation of the forelimb removes the skin over the chest wall, so that if evisceration is performed the broken ends of the ribs are not covered. The older techniques of **subcutaneous amputation** of the forelimb with a knife and chisel are relatively simple and rapid, especially when the fetus is emphysematous.^{2,37a,56} They are seldom performed however because the use of the fetatome is more rapid and less stressful to the dam and operator. In fetal emphysema the muscles are greatly weakened. In many such amputations the fetal extractor is useful. For example one may girdle the skin above the knee, apply the extractor and rapidly remove the entire limb.

Amputation of the Anterior Limb at the Humero-Radial Articulation is indicated in the removal of the forelimbs in rare transverse ventral presentations in the mare prior to version of the fetus into a posterior presentation. Amputation of the entire forelimb is difficult or impossible in this presentation. Amputation at the hu-

mero-radial articulation is accomplished by exerting traction on the limb. A loop of fetatome wire is placed around the leg and the head of the fetatome is pushed ahead of the wire loop to the pectoral region and held there firmly while the wire loop is passed up the leg and over the olecranon and tightened around the leg. The handle of the fetatome may be fastened by a chain or held securely to the extended leg in the metacarpal region, preventing the head of the fetatome from slipping downward as the leg is amputated through the distal end of the humerus. The other limb is removed in a similar manner.

Evisceration in Anterior Presentation is indicated to reduce the size of a large or emphysematous fetus and make it less inflexible, or to release ascitic fluid in fetal ascites. It may be indicated to assist the operator in putting his arm through the birth canal to thread the fetatome wire around the pelvis in hiplock in anterior presentation. It is also helpful in rare cases if the ribs are to be broken down for further reduction of the size of the thoracic or pectoral girdle.

When the fetus is within the birth canal or uterus, evisceration in anterior presentation may be performed by amputation of the forelimb including the scapula with a fetatome which exposes the ribs. The intercostal muscles between the first, second, third, fourth, and fifth ribs are separated by the finger or knife from the spine to the sternum. In order to gain free access to the thoracic and abdominal cavities, the second, third, and sometimes the fourth ribs are removed by cutting the costal cartilage just above the sternum with a knife, chisel, or cutting hook and bending the rib dorsally to break it off next to the spinal column, or with a cutting hook or chisel cutting the rib loose as near the spine as possible. If the cutting hook and chisel are used they should be carefully guided and guarded by one hand of the operator while controlled traction or thrusting motions are provided by the other arm, so that the uterus or birth canal are not injured by slipping of the instrument. The ribs should not be broken in the middle as it is difficult to remove both ends, especially the ventral part, and the broken ends are likely to lacerate the operator's hand or arm. The heart and lungs are removed by manual traction after grasping the heart at its base and clasping the fingers firmly around the large vessels. By grasping the lungs in the region of the bifurcation of the trachea first one and then the other or both lungs can be removed. After the thoracic viscera have been removed the fingers are thrust through the diaphragm in the region of the large vessels and the opening enlarged. The stomach and intestines are easily removed by wrapping them around the hand. The liver, the largest organ to be removed, is pulled

loose from the diaphragm and withdrawn, usually in several pieces. The kidneys are small and therefore need not be removed.

Destruction of the Rib Cage—On uncommon occasions, to further reduce the size of the thorax, the remainder of the ribs may be broken down with the cutting hook or the chisel. If the blunt-pointed cutting hook is used, the hook is pushed caudally between the skin and ribs about midway between the spine and the sternum until the end of the hook passes beyond the last rib. The point of the hook is turned medially through the abdominal wall and by short, firm pulls the hook is drawn through one to two ribs at a time until only one rib remains to be broken. To avoid cutting this rib suddenly and having the hook tear out of the fetus and possibly injure the uterus or the operator's hand, this last rib may be broken by twisting the hook instead of applying traction. If necessary the ribs on the other side of the thorax may be broken down by introducing the cutting hook through the body cavity to the last rib turning the point outward through the abdominal muscles and pulling the hook back through the ribs in the manner described above. Since the point of the hook is under the skin and might catch it or cut through a fold of skin, the operator's hand outside the skin should guard and follow the progress of the hook. Another technique is to make a 3- to 4-inch vertical incision through the skin cranial to the opposite shoulder and push the cutting hook along the outside of the ribs beneath the shoulder and skin to the last rib and, turning the point of the hook medially, cut through the ribs as was done on the first side after the foreleg had been removed and the fetus eviscerated. A chisel instead of the blunt cutting hook may be used for breaking the ribs in a fetus fixed in the birth canal by traction.

Complete percutaneous Fetotomy in the Anterior Presentation—Since evisceration and breaking down the fetal ribs is difficult especially in a cow with definite fetopelvic disproportion, a complete percutaneous fetotomy in anterior presentation as described by Bierschwal and de Bois and others using the Utrecht model fetatome may be easier.^{5,4,59} This technique requires amputation of the head; amputation of both forelimbs, including the scapulas; transverse division of the anterior chest or trunk; transverse diversion of the posterior portion of chest through the abdominal wall caudal to the last rib; and bisection of the fetal pelvis through the sacrum and pubis. If the posterior portion of the chest or rib cage is of too great diameter to be withdrawn easily, the ribs are severed longitudinally by the fetatome near their vertebral attachment.

Detruncation in Anterior Presentation is indicated in rare instances when the fetus is in a "dog sitting" pos-

ture with the hind limbs extended alongside or beneath the body and wedged into or against the maternal pelvis. If repulsion and mutation are impossible due to protracted dystocia, or if the head and forelegs are outside the vulva, fetotomy is usually necessary.

To perform detruncation by means of the fetatome, a loop of fetatome wire is passed around the body of the fetus and the head of the fetatome is inserted into the birth canal over the lumbar region of the fetus. After the wire is manipulated back of the last ribs, detruncation is rapidly accomplished. On occasions two cuts through the trunk of a large fetus may be necessary. Using Krey's tongs on the exposed vertebrae for traction further reduction of the fetal body is facilitated. Evisceration would make this operation safer and easier if the fetus is large or emphysematous, or if the birth canal is swollen, small, or dry. Lubrication to prevent trauma to the birth canal is essential. Following detruncation, chains are applied to the two hind limbs and by traction on the limbs and repulsion on the spine the hind quarters of the fetus may be turned to a posterior presentation dorso-pubic position. After the hind quarters have been rotated to a dorso-sacral position they are removed by traction. If the pelvis of the fetus is large, its bisection with the fetatome should be considered without attempting mutation.

Bisection of the Pelvis in Anterior Presentation is commonly indicated when the fetal pelvis becomes wedged in the maternal pelvis. In these cases the bisiliac diameter of the maternal pelvis is smaller than the distance between the greater trochanters of the fetal hips thus causing hiplock. When this has existed for a number of hours as a cause of dystocia one should examine the cow carefully, since symptoms of obturator paralysis are present in many such cases. If symptoms of obturator paralysis are present, bisection of the fetal pelvis is indicated in preference to forced extraction to prevent further trauma to the obturator nerve. When the hiplock condition cannot be relieved by lubrication, mutation and traction, fetotomy is necessary.

This may be performed with the fetatome. In using the fetatome, the wire is passed over the top of the fetal pelvis and as far down as possible behind the ischial arch. By passing the hand under the fetus and fetal pelvis the introducer, threader or obstetrical chain which is attached to the wire is pulled between the hind legs. After placing this end of the wire through the fetatome, the head of the fetatome is placed alongside the body of the fetus opposite the ribs. If the loop of the wire is on the right side of the tail the head of the fetatome should be on the left side of the fetus so the fetatome wire passes through the middle of the pelvis and not through the head of the femur. After the pelvis is bisected, the fetus minus

one hind leg can be removed; then if the operator grasps the exposed pelvic bones the other hind leg can be withdrawn. This operation is made easier by evisceration, which allows the operator more room in the pelvic cavity for placing the wire and the fetatome in position.

A simple procedure combining forced extraction, evisceration, and bisection of the pelvis is frequently used by the author to relieve dystocia in heifers with fetopelvic disproportion. By means of forced extraction with the fetal extractor, the well-lubricated fetus is pulled through the birth canal until the hips approach the maternal pelvis. In rare instances it may be necessary to amputate the head and neck or the head, neck and one forelimb in order to accomplish this. The forequarters outside the vulva are pulled dorsally, exposing the umbilical region of the fetus. The abdominal wall is cut transversely and evisceration is easily completed through this wide incision. In many cases this incision extends dorsally through the intercostal muscles of one of the last 2 to 4 ribs, but these are short and cause no problem. If the difference between the size of the maternal and fetal pelvis is not relatively great, traction is once more attempted. The long blunt hook is passed over the top of the pelvis and hooked on the ischial arch or into the caudal border of the sacro-sciatic ligament, providing a firm hold for traction and for elevation of the fetal pelvis. This also causes the fetal pelvis to be turned obliquely, thereby facilitating delivery. Since the abdominal wall has already been cut, and evisceration has greatly reduced resistance in the birth canal and all the traction is on the fetal spine, correction of the dystocia in many such cases can be accomplished without bisecting the pelvis. Mutating the fetus into a dorso-iliac position before applying traction may assist in the removal of the fetus by traction without bisecting the pelvis with the fetatome.

Fetotomy Operations in the Posterior Presentation

Fetotomy in Normal Posterior Presentation is indicated when the diameter of the fetal pelvis is relatively larger than the diameter of the pelvic inlet and wedging or hiplock occurs. This condition is seen usually in immature or stunted heifers and may be complicated by an emphysematous fetus. Under these conditions cesarean section or slaughter may occasionally be advisable.

Fetotomy consisting of the amputation of one leg, or preferably one leg and part of the pelvis, may be accomplished by means of the fetatome. A transverse incision just cranial to the external wing of the ilium is made in the fetus through the skin and muscle. A loop

of fetatome wire is carried up the hind leg and placed in this incision. The head of the fetatome is placed between the hind legs. One hind leg and a portion of the pelvis are removed. A variation in this technique consists of passing the loop of fetatome wire around both legs and over the hips to the lumbar region of the fetus. With the head of the fetatome on one hip a cut is made with the wire halfway through the lumbar region just cranial to the fetal pelvis. The head of the fetatome is pulled outside the cow and reinserted to rest between the two legs of the fetus and the rest of the cutting is completed, bisecting the fetal pelvis longitudinally. Another technique is that of acute angle sawing with the fetatome.^{3,5} The loop of wire is placed around one leg and the head of the fetatome is placed dorsal to the wings of the ilium or even in the caudal lumbar region. The leg is tautly extended and fastened to the handle of the fetatome outside the dam to insure a portion of the fetal pelvis being included with the amputated limb. Often, the leg is amputated through the hip joint because it is difficult to hold the head of the fetatome in place.

Bisection of the Pelvis in Breech Presentation is indicated in posterior presentation in uniparous animals with the hind limbs of the fetus extended or retained beneath the body, when dystocia has been present for some time, the uterus is contracted, the fetus emphysematous, and the uterus and birth passages are dry and swollen, so that mutation is difficult or impossible.

The fetatome may be used in this operation. The heavy metal guide, introducer, or obstetrical chain is securely fastened to the fetatome wire and then introduced through the birth canal and over the thigh of the fetus between the leg and abdomen. It is pushed as far as possible ventrally and caudally. The hand is then passed beneath the fetal pelvis and between the legs and the wire is drawn out through the vulva. The threaded fetatome is placed on the hip opposite the leg to be removed; that is, if the wire loop is around the right leg of the fetus the head of the fetatome should be on or just behind the greater trochanter of the left leg to insure a large portion of the pelvis being removed with the leg. If the head of the fetatome is not firmly held in place it will pull directly caudal to the perineal region and the leg will be removed at the hip joint or proximal end of the femur. After the leg and portion of the pelvis is removed the rest of the fetus can usually be withdrawn by traction on the pelvic bones with the long blunt hook or Krey's hooks, with the opposite leg still extended alongside the body. If this is not possible, the operation may have provided enough room to correct the posture of the remaining limb by mutation. In rare cases evisceration may be performed to assist in the removal of the fetus.

Another method of reduction of the pelvis in breech presentation is to place a loop of fetatome wire in a fetatome around the presenting buttocks. The head of the fetatome is placed in the region of the fetal lumbar vertebrae and held in place by an obstetrical chain tightly fastened to the handle of the fetatome and by Krey's tongs to the fetal sacrosciatic ligament or sacrum. By acute angle sawing, this removes most of the pelvic bones and tail and may permit withdrawal of the fetus with both limbs alongside the body.

Amputation of the Rear Limbs at the Tarsus may be indicated in rare instances in the mare in order to obtain additional room for removal of the forelegs in transverse ventral presentation, in cases in which the metatarsal bone is wedged into or across the pelvis, or when mutation of a hock-flexed posture in a mare is impossible. It may occasionally be necessary in monsters with ankylosed hind limbs, such as *Perosomus elumbis*.

The operation is easily performed by slipping a loop of fetatome wire around the leg. The head of the fetatome is placed on the lower row of tarsal bones or the head of the metatarsal bone, and the leg is cut off in this region. Thus the lower portion of the limb is removed and the os calcis is left attached. The obstetrical chain will find secure lodging above this point when traction is applied.

Evisceration and Breakdown of the Ribs in Posterior Presentation is indicated when further reduction in the size of the trunk is desired in order to effect removal of the fetus.

After removal of one or both of the posterior limbs the opening into the abdominal cavity may be enlarged and the viscera removed as described under evisceration in anterior presentation but in a reverse manner, removing first the abdominal and then the thoracic viscera. The ribs may be broken down in the manner described previously, using the blunt-pointed cutting hook or chisel, but in the reverse order. In certain cases in which it is necessary to break down the thoracic cage after evisceration, the fetatome wire might be passed cranial to the shoulder and between the front legs, thus bisecting the thorax.

Other Fetotomy Operations

There are many other fetotomy operations that may occasionally be used to relieve dystocia. Some are variations of those just described. In fetal monsters causing dystocia, fetotomy operations must be designed to fit the individual case, using the basic operations and principles as a guide. In these cases fetotomies should be planned

carefully and in a manner to reduce the number of cuts to a minimum. Double monsters or those single monsters that are sharply bent, such as *Schistosomus*¹⁸ and *Cam-pylorrhachis*, should be divided as nearly as possible into two equal sections so that removal may be prompt and easy. One should not attempt to start a fetotomy operation without being quite certain that the dystocia can be relieved by the planned operation. In many cases consultation may be advisable. It should be borne in mind that a prolonged unsuccessful fetotomy will make the prognosis more grave if the operator finally attempts to perform a cesarean section.

Ischio-pubic Symphysiotomy—A simple, rapid, technique for splitting of the maternal pelvis at the symphysis pubis in immature or stunted beef heifers under 24 months of age suffering from dystocia due to a small pelvic inlet has been described.^{6,10,16,19} To facilitate securing a live calf, one could induce parturition within the last 2 weeks of gestation with dexamethasone (30 to 60 mg). It is interesting that a brief notation of this symphysiotomy technique was described in a French book in the nineteenth century.⁶ This operation is preferably done on a standing heifer. Epidural anesthesia is administered. One authority recommends passing a metal catheter into the bladder to monitor the location of the bladder before, during and after the symphysiotomy and using a small hypodermic needle to punch through the vaginal floor to ascertain before the operation that there are no areas of ossification in the symphysis.⁷ The area beneath the vulva is washed, shaved, and disinfected. In as aseptic a manner as possible a 4 cm incision is made through the skin and down the exact midline to the ischial arch avoiding the perineal vessels which can bleed profusely if incised. A small, guarded obstetrical chisel* is driven slowly into the symphysis, guided by the operator's hand in the vagina, and the pelvis is carefully split. The chisel should be pushed back and forth through the symphysis several times to separate any fibrous attachments. Traction is applied to the fetus. Because at the time of parturition the ligamentous structures are relaxed, the pelvis spreads 2 to 3 inches and allows the fetus to be withdrawn by manual traction or by the fetal extractor. Aftercare consists of keeping the heifer quiet, isolated and confined for several days or longer. Although the heifer may show some stiffness and slowness of gait it is able to get up and walk. Mounting by other cattle should be avoided. If symptoms of obturator paralysis are present it is advisable to tie a bowline around each hind fetlock with about 18 to 20 inches of rope between them. This

is removed in about 1 to 3 days if the animal can handle itself well. Parenteral antibiotics are given to control possible infection at the operative site. By this technique fetotomy and cesarean section are avoided. Although this practice may be acceptable for beef cattle in some of the range sections of the West, eastern dairymen and veterinarians would be reluctant to accept it for dairy heifers. This operation should not be performed on fat heifers or older cows. This technique of symphysiotomy has also been used successfully in yearling ewes to avoid a cesarean section.¹⁶ Occasionally in heifers a large calcified callus will form if the pubis bone is damaged. This might interfere with subsequent calvings.

Aftercare and Examination of the Dam after Mutation, Forced Extraction, or Fetotomy

Following a dystocia operation the genital tract should always be examined for the presence of another fetus in the uterus or abdominal cavity. This can readily be determined in the mare, cow, doe and ewe if the hand and arm can enter the uterus. It can be very embarrassing to a veterinarian to apparently relieve a dystocia only to be called back again in 2 to 4 hours or later for another dystocia in the same cow. Occasionally the second fetus may not be found until 2 to 3 days later when the cow develops anorexia, tenesmus, or attempts are made to remove a retained placenta. In the sow the farrowing of the last fetus is usually followed by the sow becoming quiet and content, nursing her pigs, urinating, eating, and drinking. If the sow remains restless, uneasy, shows anorexia and intermittent tenesmus, the birth canal should be examined for the presence of another fetus. Similar symptoms are exhibited by the bitch and queen. In rare instances, in large breeds of dogs, such as the Great Dane, St. Bernard and Newfoundland, the bitch may exhibit every outward sign of having finished whelping. Several days later the bitch may develop anorexia, depression, elevated body temperature, pulse and respiration, and a green, possibly fetid vaginal discharge due to a decomposing fetus. Careful palpation, or preferably a radiograph, of the abdomen after whelping would have avoided leaving a fetus in the atonic uterus.

After every dystocia operation the genital canal, including the uterus, should be examined for the presence of an invaginated uterine horn, lacerations, or ruptures. Small superficial tears of the cervix, vagina, or vulva are of little importance or significance unless retention of the placenta favors infection. In the region of the vulvo-vaginal border these lacerations may lead to infection

*Holmes Symphysiotomy Chisel, Holmes Serum Co., Inc., 1301 Knotts Ave., Springfield, Ill. 62703.

and necrosis with secondary swelling, pain, and tenesmus. Parenteral antibiotic therapy and local treatment with healing protective ointments are indicated. Lacerations of the cervix if extensive may lead to cervical induration and chronic cervicitis. Any tears in, or ruptures of, the uterus should be noted, inasmuch as the prognosis in these latter cases is poor. In large tears in the vulva, vagina, cervix, or uterus, suturing might be attempted by working through the birth canal. Pulling the cervix and uterus back to or outside the vulva, if possible, would make suturing easier. A small uterine rupture especially of the dorsal wall of the uterus may heal spontaneously; but the uterus should be stimulated to contract by the use of oxytocin. Antibiotic therapy and letting the genital tract strictly alone may save a few cases. In extensive ruptures of the uterus, especially where infection exists, slaughter is advised. In less severe cases laparotomy and hysterectomy or suturing of the uterine tear may be indicated.

The placenta and placentomes should be examined in cows and mares. If the placentomes are firm and hard, retention of the membranes generally follows. If uterine infection is obviously present, preventive steps may be taken to control infection by parenteral antibiotic therapy, local treatment of the uterus with antiseptics or tetracycline or other antibiotic compounds and possibly oxytocin to stimulate uterine involution and prevent uterine sepsis. In the bitch if placentas are still present in the uterus they may be withdrawn by the use of a gauze sponge on a forcep. Twisting the instrument in the uterus may catch and hold the placenta to be withdrawn. If retained placenta is suspected the owner should be instructed about subsequent aftercare of the case.

In most obstetrical cases involving forced extraction or fetotomy a dose of 3 to 5 ml., 30 to 50 units, of oxytocin in large animals; 1 to 3 ml., 10 to 30 units, in ewes, does and sows; and 1/2 to 1 ml., 5 to 10 units, in bitches and queens is indicated to prevent possible prolapse of the uterus and aid involution of the uterus and dropping away of the fetal membranes.

If the animal is unable to rise, further examination should be made to determine whether obturator paralysis, dislocation of the hips, pelvic, or spinal injuries are present, and if so the degree of severity. Hypocalcemia in the cow may be masked by the dystocia. Occasionally the administration of oxytocin without a concurrent injection of a calcium product may precipitate milk fever or hypocalcemia in a dairy cow. The cow's udder should be examined to make certain no pathology is present, or that teat wounds and lacerations did not occur during the dystocia.

If the operator has been working with his bare arms in an infected uterus he should wash his arms and hands

very carefully and thoroughly with soap and water and apply an antiseptic in order to prevent skin infections. If any infectious material has adhered to his clothes they should be changed before he goes to another farm. Boots and equipment should be washed and disinfected.

Cesarean Section

Cesarean section is the delivery of the fetus, usually at parturition, by laparohysterotomy. This operation is performed when mutation, forced extraction, and fetotomy are deemed inadequate or too difficult to be employed to relieve the impending or present dystocia or when it is desired that the fetus be delivered alive. The word cesarean is said to derive either from an edict by Julius Caesar that women about to die in advanced childbirth should have this operation performed to save the child, or from the Latin *caeso matris utera*, cutting of the mother's uterus. It is a misconception that Julius Caesar was born in this fashion, as his mother survived his birth in an era when this was impossible.²¹

John Field in 1839 was the first to report this operation in the English literature.⁵⁷ He operated on two bitches. The next year J. B. Carlisle reported on a cesarean section in a sow. Cesarean operations on cows, mares, sows, and bitches were reported soon after. Later, with the advent of anesthesia, suturing techniques, aseptic techniques, and antibiotic therapy, this operation became increasingly common. Cesarean section in the domestic animals has been well-described.^{1,2,7,9,38,47-52,53}

Cesarean section in the Mare may be indicated in pelvic fractures with exostosis, transverse dorsal or transverse rotated bicornual pregnancies, anterior longitudinal presentation with the rear limbs extended beneath the body (dog-sitting posture), torsion of the uterus, fetal monsters such as hydrocephalus, and possibly emphysematous fetuses. In rare dystocia cases in mares where mutation, forced extraction or fetotomy procedures do not offer promise of successful delivery, cesarean section should be considered. In one large clinic 15 fetotomies were performed for each cesarean section.⁴⁸⁻⁵⁰ In many instances the equine fetus is dead because the severity of the parturient problem is not recognized early enough, preferably before parturition, and the time from the onset of labor to the death of the fetus from placental separation or other causes is only 30 minutes to a few hours. The prognosis for a successful equine cesarean operation is poor if prolonged attempts at forced extraction or fetotomy precede the decision to operate. With modern surgical techniques, asepsis, anesthetics and antibiotics successful terminations of this operation on mares

are being reported with increasing frequency. It is no longer necessary to sacrifice the life of the dam to save the fetus. A number of cases have been reported in which the mare conceived following the operation.

The first successful equine cesarean was performed in Hungary in 1908.²⁰ Since then many reports and reviews on equine cesarean section have appeared.^{47b} In 1972 one study made a comparison between 129 equine fetotomy and 63 cesarean operations.^{47a} In the fetotomy cases there was a 10 percent mortality rate, 28 percent retention of the placenta and of those mares rebred a pregnancy rate of 42 percent with an abortion rate of 10 percent. In the cesarean cases there was a mortality rate of 20 percent of mares and 70 percent of foals, 50 percent retention of the placenta and of those mares rebred a pregnancy rate of 50 percent with an abortion rate of 30 percent. In 71 equine cesarean operations 82 percent of the mares survived but only 28 percent of the foals as 64 percent were stillborn. Of 27 mares bred after cesarean section, 50 percent became pregnant but 6 of 14 aborted at 7 to 10 months of gestation.^{47b} Thus, if at all feasible, vaginal delivery in mares is preferable to cesarean section.

General anesthesia is indicated when the fetus is dead. This usually consists of epidural anesthesia and tranquilizers prior to induction by a 5 to 10 percent glycerylguaiacolate in a 5 percent glucose solution to which an ultra-short acting barbiturate such as thiamyl sodium may be added. This is given intravenously to effect. In modern clinics halothane inhalation anesthesia may be used. These general anesthetics may have an adverse affect on the fetus if it is alive. Tranquilizers and local anesthetics in the form of epidural analgesia and local blocks of the abdominal area, or infiltration of the incision sites have been used when the fetus is alive. One clinic recommends using epidural anesthesia, glyceryl guaiacolate and local infiltration anesthesia.⁴⁷ The mare should be restrained in a recumbent position on the left or right side or back depending on the site of the incision.

Various incision sites have been successfully used in the mare and the site should be determined on the basis of the nature of the dystocia, and the presentation or position of the fetus particularly the location of the head of the fetus. The most popular incision site is the Marcenac approach in the left flank starting at the middle of the last rib and extending caudal and ventrally toward the stifle. The incision is usually 25 to 40 cm. in length.⁴⁷ Other reported incision sites have been in the upper left flank or the left paramedian or midline abdominal areas.^{2,53} Herniation is less common with the flank incision sites. Operations in the right flank area are complicated by the large cecum and its dorsal attachments. When incising

the peritoneum care should be taken not to injure the viscera.

The equine uterus is more difficult to bring to the incision than is the uterus in cattle, but if the proper incision site, the Marcenac site in the lower left flank is probably the best, has been selected this can probably be done. Excessive manipulation of the viscera or contents of the abdominal cavity should be avoided as this may precipitate shock symptoms and death. If the uterus is infected great care should be used to avoid contamination of the abdominal cavity. The incision of the uterus should be on its greater curvature over a fetal prominence. Because of the long fetal extremities, mutation, forced extraction and even partial fetotomy may be necessary to remove the fetus. If the foal is alive when delivered the umbilical cord should be left intact for a few minutes until respirations have been established. If the placenta comes away easily it should be removed, otherwise the uterus should be promptly sutured.

A complication of the equine cesarean operation is the rather diffuse bleeding that occurs from the submucosal area of the uterus after it is incised. To prevent severe intrauterine bleeding a continuous lock stitch suture of catgut should be placed through the endometrium, submucosa and serosa completely around the uterine incision for a depth of 1 cm being careful not to include the placenta. This suture was inverted into the uterine cavity by a double row of Lembert or Cushing sutures used to close the uterus after the fetus had been removed.^{47,53} The peritoneum, muscle and fascial layers of the abdominal wall should be sutured separately with #2 Dexon or strong #4 chromic catgut to obliterate dead space and subsequent seroma development. The modified Mayo or overlapping mattress suture for closure of the wound on the ventral abdomen was recommended.²⁸ The skin incision was closed with a nonabsorbable nylon suture. They also recommended the use of quill sutures. The use of a tightfitting canvas or elastic support bandage may be indicated.⁴⁰ Severe edema of the incision area with occasional rupture and gaping of the skin wound are not unusual following surgery in the horse.

Aftercare should include stall confinement, feeding limited amounts of laxative feed, administering tetanus antitoxin, oxytocin and broad range antibiotics both locally and systemically. The latter should be continued for 7 to 10 days. Retained placenta was a common problem in equine cesarean operations.^{46,47} To correct this condition 40 units of oxytocin in 1/2 to 1 liter of saline was administered by a slow intravenous drip method over a period of 1 to 2 hours to produce more normal physiologic contraction of the uterus. Colic was avoided, and the afterbirth dropped away promptly in about 80 percent

of the cases. Complications occurring in the postoperative period are shock that occurs within a few hours after the operation due to manipulation of the uterus and viscera, peritonitis that may cause illness and death 2 to 5 days later, and fatal colic due to strangulation of the gut that may develop one to three weeks or more after the operation due to fibrinous adhesive peritoneal bands secondary to a non-fatal peritonitis.²² Four to 5 days after the operation a rectal examination may be performed to break down any adhesions forming around the involuting uterus.⁴⁷ Hysterectomy, as in the cow, is extremely difficult to perform.²⁸

Cesarean Section in the Cow has been performed in increasing numbers by practitioners in the United States since 1940. Prior to that period it was performed only sporadically. Since 1942 the clinic at Kansas State College has performed between 50 to 100 cesareans each year.^{12,13,31,32} Many more cesareans are performed in the western range states, where immature beef heifers are bred on pasture, than in the northeastern dairy states, where bulls are closely confined and artificial insemination is widely used.

Indications for cesarean section in the cow are as follows.^{2,7,30,42} In the United States immaturity and growth retardation or stunting of heifers resulting in fetopelvic disproportion are by far the most common causes. It is seen particularly in beef cattle when the bull runs on pasture with heifer calves. Some young cattle come into estrum and conceive at 4 to 15 months of age with pregnancy resulting in a severe dystocia due to a very small pelvis and genital tract. In these cases the difference between the size of the fetus and the birth canal is marked. Performing fetotomy operations through such a narrow birth canal is very difficult and the fetus is always lost.

Incomplete dilation or relaxation of the cervix may be associated with secondary uterine inertia with advanced involution of the cervix and uterus secondary to torsion of the uterus, or fetal dystocia and emphysema in which the onset of parturition was not observed, or the cow was neglected for 36 to 48 hours. In other cases it may be observed, without a known predisposing cause, due to a primary uterine inertia, or it may be caused by sclerosis of the cervix. In such cases the fetus may still be alive; oxytocin might be given, and the condition of the cervix observed in 3 to 4 hours or more to make certain that parturition was not in its initial stages.

An abnormally large living fetus may be a cause for cesarean section. Apparently normal healthy fetuses may occasionally be too large for birth without total fetotomy excessive traction or cesarean section. If the forefeet but not the head can enter the pelvic inlet or in posterior presentation if the hips are much too large to enter the

pelvis, cesarean section should be considered, as it is frequently easier, safer, and faster than total fetotomy and in many such cases the delivery of a live calf is possible. These large-sized fetuses are most frequently seen in the large breeds, such as Holstein, Charolais, Simmental, Brown Swiss, Shorthorn, and Herefords. They are usually male. The cause of the dystocia may appear to be a large normal fetus; actually, however, the cause may be an abnormal or relatively small pelvis; or both conditions may be present. In breeds of cattle with muscle hypertrophy or double muscling, affected calves frequently require cesarean section for delivery. In other cases the oversized condition of the fetus may be due to emphysema or to anasarca. In rare cases an excessively large fetal giant may be caused by a greatly prolonged gestation period exceeding 300 days. The prognosis in these latter pathologically oversized fetuses is grave because of the overdistention of the uterus, the uterine inertia, and the high incidence of septic metritis and retained afterbirth following the relief of the dystocia. Other causes for oversized fetuses include fetal monsters such as *Schistosomus reflexus*, general ankyloses, and double monsters. At times, certain of these may be more safely and easily removed by cesarean section than by fetotomy.

Other cases where cesarean section is indicated include: a torsion of the uterus that is difficult or impossible to correct by other means; a juvenile hypoplastic genital tract due to poor growth and development; hydrops amnii and allantois when the life of the dam is imperiled by great distention of the uterus and other methods have failed to relieve the condition; marked stenosis of the vagina in prolonged dystocia in heifers due to perivaginal hemorrhage compressing the genital tract; fetal mummification when ordinary treatments fail, or in heifers or young cows with a 6- to 8-month fetal mummy too large to be expelled through the undilated birth canal; when the dam is unable to rise, is exhausted, debilitated, diseased, or near death; and stenosis of the birth canal due to tumors or extensive scar tissue in the pelvic birth canal. In rare cases in cattle with prolonged dystocia the uterine wall contracts tightly around the emphysematous fetus, producing a contraction or retraction ring dystocia. Since forced extraction may cause rupture of the uterus and fetotomy would be difficult, cesarean section may be indicated. Fracture of the maternal pelvis in cattle is rare and therefore cesarean section due to this cause for dystocia is only seldom indicated.

Prognosis—A review of cesarean operations,^{2,31,34,37b,49,57,58,59} indicates that in cattle that are good surgical risks, and are operated on within 6 to 18 hours after the onset of labor, in cases where the fetus is still

alive or very recently dead and the cow is in good condition physically and has not been damaged by excessive manipulation, injury, or infection of the birth canal or uterus, the mortality rate should be less than 10 percent, and possibly only 5 percent. Under field and actual practice conditions the mortality rate might reach 15 percent.

The mortality rate is about 10 to 30 percent in cases where the cesarean section is performed from 18 to 36 hours after the onset of the second stage of parturition. The fetuses are generally dead and occasionally slightly emphysematous; the cow is in poorer condition for the operation, and the genital tract is usually injured or traumatized. In cases in which dystocia has existed for 36 hours or more, the fetus is emphysematous, the cow is usually in poor physical condition, and the uterus is atonic and infected, the mortality rate may reach 30 to 50 percent or more. In 103 cesarean operations where emphysematous fetuses were removed, the recovery rate was over 80 percent in a college clinic.⁵¹ In 121 bovine cesarean operations, mainly in primipara, 93 percent of the dams survived, 60 to 70 percent of the calves survived but the subsequent pregnancy rate was 52 percent compared to the herd average of 80 percent.³⁴ In 340 cesarean and 80 fetotomy operations; the maternal mortality rate for each series was 5 and 9 percent, retained placenta was 33 and 20 percent and conception rates in cows rebred after the operation were 80 and 73 percent, respectively.⁸ In field cases on ranches the death rate after 117 bovine cesarean sections was 17.9 percent but it was 38.4 percent in cows with purulent decomposition of the fetus while in 412 cases of fetotomy the mortality rate was only 8.4 percent.⁴² In this latter study of nearly 2500 dystocias, 2.6 percent of all dystocias terminated in maternal deaths and of these 44.5 percent were slaughtered after the initial diagnosis was made or after unsuccessful treatment was attempted. The decision therefore as to which procedure to use should be based on a careful evaluation of each case.

The more common causes of maternal death are: shock, secondary to exhaustion; toxemia; excessive manipulation of the abdominal viscera as in torsion of the uterus, or when abdominal pressure is released rapidly, as in removal of a large fetus or excessive amounts of fluids as in hydrops; septicemia, pyemia, and toxemia secondary to septic metritis; uterine inertia in prolonged dystocia; retained placenta; peritonitis; or severe necrotic vaginitis due to excessive manipulation and injury prior to the cesarean section. Hemorrhage and ventral hernia are occasional causes of death. In rare cases hemorrhage, especially from the stalk of a torn or lacerated caruncle, may occur in atonic uteri. Ventral hernia may be prevented by proper suturing technique and suture

material. Most maternal deaths occur 1 to 8 days after the operation. In recent years improved surgical techniques, asepsis, antibiotics and supportive therapy have greatly improved the prognosis for recovery even in cases offering great surgical risks.

It is generally stated that from 60 to 80 percent of cows having cesarean section should be fertile and conceive subsequently. Failure to conceive may be due to peritoneal adhesions or to severe endometrial damage secondary to septic metritis. Of 48 cows without adhesions after cesarean section 81 percent conceived, while in 47 cows with adhesions only 51 percent conceived.⁸ The incidence of retained placenta following cesarean section is high, between 20 and 35 percent, and the incidence of metritis may vary from 20 to 50 percent. Fifty to 80 percent of recovered cows conceived after the cesarean operation.^{2,7,52} About 80 percent of the cattle operated upon had an abnormal puerperium due to retained placenta, uterine infection and delayed involution of the uterus. Uterine infections should be expected and preventive treatment given. The reason for this high rate of placental retention after cesarean section is not known.

According to the authors cited above, the incidence of live calves produced by cesarean section is from 30 to 60 percent. This varies with the promptness with which dystocia is observed, the veterinarian summoned, and the operation performed. Fetotomy in cattle with dead fetuses should be carefully considered before performing cesarean section, since cesarean section requires more trained assistance, is more costly, and results in a higher percentage of subsequent sterility. If it appears that a fetotomy is going to be difficult, prolonged, or dangerous to the dam or operator especially in cases in which the birth canal is small or the birth canal is swollen, compressed, or dry making it difficult to perform a fetotomy; or in cases in which the fetus is emphysematous cesarean section should be considered. It should give promise of being a safer, easier means for relieving the dystocia than does fetotomy or forced extraction. Fewer than 1 percent of the dystocias cannot be relieved by cesarean, while 3 to 5 percent will end in failure if fetotomy is employed.⁴⁹

Selection of the Operative Site, Means of Restraint, and Anesthesia—These will and should vary depending upon the case. The operation has been performed in the upper left and right flank, with the animal standing. This site makes the operation easier for the veterinarian as he can perform it standing; the incision can be smaller because the muscle tissues can stretch into a circular shape when the fetus is removed; subsequent herniation is less likely, and many veterinarians are experienced in operating in the flank site because of frequently having per-

formed rumenotomies. The upper right flank approach may be desired when torsion of the uterus is present, as the standing position is of assistance in correcting the torsion. The disadvantages of the right flank incision are that the cow may be more difficult to restrain and control. It is difficult to bring the uterus to the incision, and abdominal contamination with the uterine contents is nearly unavoidable. This is of no consequence when the fetus is alive and little or no infection is present in the uterus; but it is a major disadvantage with a dead fetus and an infected uterus. If during the operation the incision is extended too far ventrally it is difficult to hold the small intestines within the abdomen. If the cow strains, coughs, or struggles intestines may be expelled through the laparotomy incision.

The operation may be performed in the left flank, at which site intestines usually are not present to offer a problem. The operation can be performed more ventrally on this side if it is desired, but the same advantages and disadvantages apply as for the right flank incision. A large full rumen may make it quite difficult to bring the uterus from the right side of the abdominal cavity to the left. Since these upper flank operations are performed with the cow standing, anesthesia consists of a small dose of epidural anesthesia to control straining; a tranquilizer to quiet the animal; local infiltration, an inverted L-block or paravertebral nerve block anesthesia of the flank region.

Some veterinarians prefer to perform the cesarean operation on a recumbent animal by an oblique abdominal incision in the lower left or possibly right flank region below the fold of skin in the flank and above the attachment of the udder on a line between the stifle and the umbilicus, parallel the ventral borders of the ribs. This site allows easy access to the gravid uterine horn. The muscles in this region stretch easily. It is easier to prevent contamination of the abdominal cavity by uterine fluids. There is less possibility that hernia will develop than when the incision is on the ventral aspect of the abdomen. The disadvantage of this site on the right side is that it is necessary to control the small intestines during the operation so that they do not prolapse. In most cases intestinal prolapse may be prevented by making the cow lie on her left side, a position necessary for performing the operation. The lower-left flank as a site for the incision requires the cow to be laid on her right side. On the left side the incision is more caudal than on the right side, and the apex of the uterus can be brought to the incision behind the rumen. Control of the intestines is only occasionally necessary when the incision is on the left side. In these lower-flank incisions the cow is restrained or stretched in lateral recumbency by tying the

two rear legs together and the two front legs together. Anesthesia may consist of an epidural of 40 to 60 cc. of 2 percent procaine or lidocaine solution, which will produce sensory and motor paralysis of the perineum and rear limbs. This will cause the standing animal to stop straining and to go down. If the cow is laying on her side when epidural anesthesia is administered, sensory loss may be incomplete because the uppermost nerves may not be properly blocked. Paravertebral nerve block or local infiltration of the operative site is usually necessary. In some cases a tranquilizer may be desirable.

Other clinicians prefer the ventral median or paramedian approach, with an incision through the abdominal floor. The site between the linea alba and the right subcutaneous abdominal vein has been recommended.^{12,13,31} Others^{6,46,57} preferred to operate 4 to 10 cm. lateral but parallel to the left subcutaneous abdominal vein. In all ventral abdominal incisions the cow is placed on her back and the incision starts at or slightly lateral to the fore udder and extends forward as far as necessary, usually 24 to 32 cm. In this region the apex or ventral portion of the gravid horn can be brought to and outside of the incision, thereby preventing uterine contents being released into the abdominal cavity. This is a great advantage in cases in which the uterus is infected. The abdominal wall is not as thick in this area as in the flank. There is less muscle tissue and fewer blood vessels, especially in heifers, and the abdominal wall is composed mainly of fibrous connective tissue, the abdominal tunic. The presence of the uterus in the abdominal incision usually keeps the intestines within the abdominal cavity. The main disadvantages to this approach is that the abdominal wall at this site is composed of largely fibrous tissue tunics and will not stretch as does muscle tissue. Thus the incision must be longer than in the flank. If the proper suture material and technique are not employed herniation is more common.

The choice of operative site and mode of anesthesia should fit the amount of help available, the nature of the dystocia requiring cesarean section, the type of cow, the nature of surroundings, the location of the fetus and uterus, and the preference of the operator.^{2,7,30,53} It is desirable to have one skilled assistant to aid the operator, and two lay assistants to control the cow, especially if the cow is in lateral recumbency.

To perform the operation in lateral recumbency the operator should place the animal down by using the rope squeeze method after heavy tranquilization or should administer a large dose of epidural anesthesia, 40 to 60 cc. of 2 percent procaine or lidocaine solution. The cow should not be dropped suddenly, as there may be danger of uterine rupture. Local anesthesia may be used on the

incision site, or if the incision is lateral to the mammary veins an L-block or paravertebral anesthesia is satisfactory. The innervation of the abdominal wall in cattle has been described.² In operations on the ventral abdominal floor the hind limbs should be tied together and the front limbs tied together. They should be stretched apart and sufficient help should be available to roll the cow on her back at certain times during the operation. The cow should not be left on her back for a protracted length of time.

The Operation should conform to all other surgical operations on the abdomen with regard to preparation and draping of the operative site. An approach to asepsis should be attempted. Hemorrhage from the incision should be controlled but in the ventral approach hemorrhage, especially in heifers, is slight. The upper flank operation is performed like the laparotomy incision in a rumenotomy, except that the incision is about 30 cm. long. The author believes that the ventral paramedian approach¹³ and the oblique lower left flank or ventrolateral abdominal approach^{6,1,27,33} are most satisfactory for the majority of cases. The former technique will be described in detail. After the skin is incised the cow should be rolled on her back and the rest of the incision completed. After incising the abdominal tunic the fascia of the transverse abdominal muscle and peritoneum is opened and the incision completed with scissors. In about 7 out of 8 cows the omentum is observed covering the uterus and abdominal viscera. This can be incised, but it is better to pull the omentum cranially as it helps to hold the intestines from the incision. One or both arms are inserted into the abdominal cavity and the fetus is grasped through the uterine wall, and the apex of the uterine horn containing the fetus is pulled into or through the abdominal incision as the cow is returned to lateral recumbency. The gravid uterine horn fills the incision and prevents the escape of the viscera. The uterine horn and fetal membranes are incised longitudinally over the greater curvature, avoiding the cotyledons. Incising of the caruncular stalk may result in persistent hemorrhaging. Chains are applied to the limbs of the fetus and by exerting traction in a ventral and caudal direction the fetus is removed. If necessary the incision in the abdominal wall and uterus should be enlarged to prevent tearing. If the fetus is in posterior presentation the head should be fastened by a snare and the two forefeet secured before the fetus is withdrawn. In rare cases fetotomy may be required on the fetus to assist removal. If uterine torsion is present the direction of torsion should be accurately ascertained before the cow is forced down. This is not so important when the standing cow is operated upon. The torsion should be corrected, if possible, by grasping the fetus through the uterine wall and rotating the uterus.

If this is not easily accomplished, the fetus may be removed before the torsion of the uterus is corrected. In cases in which the uterus is greatly distended due to an emphysematous fetus or hydrops it may be difficult or impossible to draw the apex of the uterus through the incision. If the uterine contents are infected the uterus should be pulled tightly against the abdominal incision and the lips of the incision and the abdominal cavity carefully packed off to avoid contamination when the uterine contents are released. The normal noninfected allantoic and amniotic fluids cause no trouble in the abdominal cavity.

After a live fetus has been removed the fetal membranes are left in the uterus. If the fetus is dead the fetal membranes are removed manually if they drop away readily. Otherwise, they are left within the uterus. Some of the excess fetal membranes may be trimmed away with scissors so that they do not interfere with the suturing of the uterus. Because of the high incidence of uterine infections and retained afterbirths following cesarean section it is advisable to place 1 to 2 grams of tetracycline in the uterine cavity whether or not the fetal membranes are removed. The uterine incision is closed with a double row of Lembert or Cushing sutures of No. 1 or 2 chromic catgut. A long straight intestinal needle should be used. The assistant can greatly facilitate the suturing by holding the edges of the uterine incision together. The cow is then rolled on her back, the uterus replaced, and the omentum pulled caudally over the uterus so that when the abdominal incision is sutured the omentum will lie against it. If torsion was not corrected before the fetus was removed it should be corrected after the uterine closure is completed. The uterus should always be examined for the presence of twins, although these are rarely encountered in conditions requiring a cesarean section.

The ventral abdominal incision may be closed in several ways. Good success using a continuous overlapping mattress suture of heavy nylon (Vetafil), #2 Dexon, or umbilical tape through the abdominal tunic, muscle, and peritoneum was reported.^{2,13,53} This is left in place to prevent eventration or herniation. Interrupted double mattress sutures of No. 4 to 5 chromic catgut with a supplementary continuous suture of doubled catgut along the muscle incision after the peritoneum had been securely closed was recommended.^{46,50} Until this second suture line was used occasional cases of herniation occurred. After its use no cases of herniation developed in 48 consecutive cesareans. In the ventral incisions just described, the tough abdominal tunic provides a firm anchorage for the sutures. The superficial muscles and fascia may be pulled together with catgut. Mattress, inter-

rupted, figure 8, or lock stitches of nylon, silk, linen, or umbilical tape are placed in the skin and underlying fascia or muscle.

The peritoneal and muscle layers in the upper flank incisions are sewn with catgut or if preferred the stronger figure-eight sutures of umbilical tape or nylon through all layers including the skin. The skin sutures are usually removed in 7 to 10 days. This operation generally takes from 30 to 60 minutes to perform if complications are not encountered. Three to 5 ml., 30 to 50 U.S.P. units of posterior pituitary extract or oxytocin is given to stimulate uterine contraction and involution. This should not be given until after the operation, because if given earlier, it may complicate the suturing by contracting the uterus and pulling it away from the abdominal incision.

Postoperative Care—Most cases should receive 3 to 6 million units of penicillin or 1 to 2 grams of the tetracycline compounds parenterally after the operation. This should be repeated daily for 3 to 7 days. The cow should be observed closely for the first 24 hours for evidence of shock especially if large amounts of fluid or a large fetus were removed or if there was much manipulation of the uterus or abdominal contents. If shock develops it should be combatted immediately with intravenous injections of blood, saline, and glucose. In rare cases hypocalcemia, and straining due to vulvar irritation or other causes, may occur, requiring prompt attention. If the calf survives it should receive some colostrum soon after birth. If the afterbirth is retained and metritis develops the condition should be handled conservatively by allowing the afterbirth to drop away by itself. It is dangerous to remove the placenta manually, since little can be gained by the attempt, and much lost by injury to the uterus. The cow should be kept quiet and away from contact with other animals after the operation, in order to avoid possible injury to the operative site. The skin sutures may be removed in 7 to 14 days.

Cesarean Section in the Ewe and Doe—This operation has been performed successfully by many veterinarians in recent years but it requires a careful, aseptic technique oftentimes difficult to achieve under farm conditions.^{2,2} Sixty nine ovine cesarean operations to relieve dystocia with a 77 percent recovery were reported.¹¹ Most deaths were due to infection. For this reason the operation is best performed in a veterinary hospital to which the ewe can be transported easily. The operation is indicated in the ewe when the cervix fails to dilate, "ring-womb," or when the ewe is bred too young or is poorly grown and the birth canal is too small to permit the operator to relieve the dystocia by forced extraction. In rare instances monster fetuses, fetal emphysema, fetuses with a large head, torsion of the uterus, and other conditions

similar to those in the cow may necessitate cesarean section. Prolapse of the vagina is a common cause for the cesarean operation in ewes.⁹ However, this may be treated by the induction of parturition with the corticosteroids.² Another indication for a cesarean is in pregnancy toxemia or ketosis in ewes, in which dead twin fetuses are usually present. Under usual circumstances the severely affected ewe would die before the dead fetuses were aborted despite glucose and cortisone therapy and other supportive treatments. The valuable ewe may be saved by cesarean section. The prognosis should be more guarded than in the cow.

The operation is similar to that in the cow and is performed through the flank, through the ventrolateral abdominal wall, through the ventral abdominal wall between the linea alba and the subcutaneous abdominal vein, or through the midline.¹¹ Tranquilizers and epidural, local, inverted L block, or paravertebral anesthesia can be used. If bicornual twins are present in the uterus an incision should be made in each horn. No. 4 chromic catgut is satisfactory for suturing the abdominal wall.

Aftercare of the ewe is similar to that of the cow. If pregnancy ketosis is present glucose injections, propylene glycol orally and cortisone may help promote appetite and recovery in the convalescent ewe.

Cesarean Section in the Sow—has been performed successfully for many years. The sow is more resistant to infection and peritonitis than is the ewe and cow. Cesarean is indicated in the sow when because of being bred too young or of being poorly grown, the resulting small pelvis and genital canal prevent normal farrowing. The canal is usually too small to permit the introduction of the hand in order to apply traction. Cesarean may be indicated in primary uterine inertia that fails to respond to oxytocin or in secondary uterine inertia in which the second stage of labor has been prolonged and lay or veterinary assistance failed to correct the dystocia. In this latter type of dystocia the genital tract is usually swollen and may occasionally be severely traumatized. Cesarean may be indicated occasionally due to monster fetuses or to pelvic fractures with exostoses or other abnormalities.^{2,9,38}

Cesarean section in the sow is 85 to 90 percent successful when performed soon after the onset of the second stage of parturition, when the fetuses are still alive and the sow or gilt is still strong and vigorous. Mortality in the sow rises when the operation is not performed until 18 to 24 hours after the onset of straining. By this time the pigs are usually dead and the sow is in poorer shape for the operation. If the operation is delayed more than 24 hours the fetuses are usually emphysematous, the uterus infected, and the sow exhausted and toxic.

Although some sows may survive surgery at this stage the prognosis is guarded to poor depending upon the condition of the genital tract.

As in the ewe, the operation should be performed in a veterinary hospital if possible inasmuch as the average hog farm is rather unsanitary and inconvenient for surgery. If it must be performed on the farm the sow's legs and body may be strapped to a panel and the panel placed across two supports, to form a satisfactory operating table set up in a clean, dust-free location. Many veterinarians prefer to use heavy tranquilization and to supplement it with local anesthesia along the incision line. Epidural anesthesia with 2 to 4 percent procaine or 2 percent lidocaine solution injected in 8 to 10 ml amounts into the epidural space at the lumbo-sacral articulation has been recommended.^{13,15,38} The operator should make sure that the sow's foreparts are kept elevated or level, so that the anesthetic solution does not gravitate forward. Surgical preparation and procedures similar to those in the cow and ewe should be carried out in preparing the operative area and maintaining near asepsis during the operation on the sow. For this purpose a large sterile rubber or plastic shroud to drape over the sow's body is very helpful.

A vertical incision, 17 to 20 cm., in length in the upper flank region^{13,38} or a horizontal flank incision parallel to but 1 to 3 inches above the mammae have been recommended.²⁶ A midline abdominal incision site is not recommended for obvious reasons. The large amount of fat between the peritoneum and the body wall may cause some confusion unless it is recognized. One entire horn may be drawn through the incision to the outside before incising and removing the fetuses; or one fetus can be brought to the outside and removed, then the next fetus brought out and removed through the previously-made incision; and so forth until all the fetuses in the one horn have been removed and the horn is completely outside the abdomen. The fetuses may be pulled from the inside of the horn or forced toward the incision by pressure on the outside of the horn or a combination of both in order to facilitate their rapid removal. The pelvic portion of the canal should be examined to be certain a fetus is not left there. If the fetal membranes are expelled with the fetus they are removed. If not expelled with the fetuses they are left in the uterus to be expelled later—usually within 12 hours. The incision is sutured with a single or double row of Lembert or Cushing sutures of No. 1 chronic catgut and that horn replaced. The same technique is followed on the other horn. In exceptional cases, if the uterus is well-involved it may be necessary to incise the horn in several sites. If the uterus is severely infected, introduction of antibiotics—especially the tet-

racycline derivatives—is indicated prior to closure of the uterine incisions. The peritoneum and muscle layers are sutured separately with chromic catgut or Dexon by continuous sutures; and the skin with silk, nylon, Vetafil, or umbilical tape.

For aftercare of the sow administration of oxytocin and antibiotics are indicated, as in the cow. The sow should be confined in a clean, quiet place for 8 to 10 days, at which time the skin sutures may be removed.

Cesarean Section in the Bitch and Queen is very common and useful in the correction of dystocia in these species. It is performed most commonly in primary uterine inertia that fails to respond to "feathering," or vaginal stimulation of uterine contractions, or to the injection of oxytocin. This condition is seen most commonly in certain toy breeds such as the Dachshund. It is frequently required to relieve dystocia in the brachycephalic breeds of dogs with large heads and small pelves, such as the Boston and other bulldogs, Pekinese, Boxers, Pugs, and even the Scotch Terriers and Sealyhams. There is no doubt that cesarean section has been a great boon to these breeds of dogs. The discussion that centers around the fact that this operation has been conducive to the perpetuation of such abnormal breeds is a subject of importance, but is not discussed here because it is not appropriate to this text. Cesarean section may be indicated in Cocker, in which for apparently psychotic reasons whelping does not progress normally. It is indicated when pelvic fractures, tumors, rickets, or the rearing of a young dog under unfavorable conditions has resulted in dystocia due to a small pelvic canal. It is indicated in secondary uterine inertia in which more fetuses are still in the uterus and dystocia has been prolonged so that even if 1 or 2 fetuses could be removed by traction, the rest would not be expelled, because of uterine atony and fatigue. It may be indicated with 1 or 2 excessively large fetuses, or when a fetus is transversely located in the uterine body and cannot be removed manually. In rare instances it may be indicated for uterine torsion and for retention of one fetus in the uterus following apparently normal parturition, as is seen occasionally in the large breeds, such as the Great Dane and St. Bernard. The cesarean operation may also be used to remove mummified fetuses from the uterus and in cases of inguinal hernias containing a portion of the pregnant uterus.² It may be indicated when general debility and inanition make normal parturition impossible. When a greenish-black discharge appears at the vulva it is an indication that the placentas are disengaging, and cesarean might be indicated even though probably one fetus or more are dead.

The same general indications for this operation apply to the queen. In the queen the most common cause for

dystocia is deviation of the fetal head and neck, and if mutation per vaginam is not successful a cesarean operation is indicated.

Many veterinarians perform cesarean operations when possibly mutation or forced extraction could be used because they are surer of their results with this operation. They are better acquainted with it than with the other techniques in which fetuses might be injured by improper or unskilled use of instruments per vaginam. The operation is frequently employed because it requires much less time and patience of the busy practitioner. Otherwise the veterinarian might have to observe and assist the bitch at intervals for 4 to 6 hours or more. Besides this inconvenience to the veterinarian, it would be more costly to the owner. Lastly, many owners, expecting the bitch to be in dystocia because of its breed or past history, request and expect the veterinarian to perform a cesarean operation.

Prognosis—Cesarean section in the bitch when performed during the first stage of labor or within 12 hours after the onset of the second stage of parturition when the fetuses are still alive, should result in less than a 2 to 3 percent mortality rate. In many hospitals this may be less than 1 percent. If the operation is not performed until 12 to 24 hours after the onset of labor some of the fetuses may be dead, but the results nevertheless are usually quite good. If the operation is delayed beyond 24 hours after the onset of labor the maternal mortality rate may be 50 percent or more due to shock, toxemia, septic metritis, and exhaustion. In these neglected cases the fetuses are usually dead, the uterus diseased and atonic, and hysterectomy may be indicated.

In general, bitches should be examined if they have labored for 3 to 4 hours without delivering a fetus. The cause of the dystocia should be determined and if cesarean is decided upon it should not be delayed too long by efforts to remove fetuses by other means. Fetotomy is rarely possible in the bitch or cat due to the small birth canal. In cases in which dystocia, relievable only by cesarean, is expected on the basis of the previous breeding history or examination, the bitch should be observed closely for signs of beginning parturition. Body temperature readings may be made 2 or 3 times daily and when the temperature drops 1 degree or more below normal or goes below 100° F. the bitch is either in the first stage of labor or beginning the second, and a cesarean operation should be performed immediately. Cesarean section apparently has little effect on the subsequent fertility of the bitch; many bitches have had from 4 to 8 cesarean operations performed without becoming sterile, even though slight to severe adhesions may form at the operative site. After 3 cesarean operations adhesions are

common and the number of pups per litter decrease and operations are more difficult to perform.¹

The Operation should be performed in a skillful, aseptic manner under hospital or clinic conditions. Complications should be anticipated and prevented or handled. Extra aid should be present for receiving the pups as they are delivered. An incubator that provides warmth, 85 to 90° F, and oxygen may save many pups.²³ Pre-medication for the canine cesarean operation consists of a small dose of atropine. After the operative site has been prepared an ultra short acting barbiturate is administered followed by a light plane of halothane or methoxyflurane or ether anesthesia. **Innovar**, a neuroleptanalgesic has been used and followed by naloxone to reverse its action in the bitch and pups after the operation. Local anesthesia may be used in the bitch in either of the above procedures to reduce exposure to the anesthetic. **Doxapram**, a respiratory stimulant, may aid recover of the pups. In the queen the above anesthetics may be used with the exception of **Innovar**. If local anesthesia is used in the queen diluting 2 percent lidocaine to 0.5 percent is indicated to avoid overdosing.⁴¹ In the queen a combination of zylazine and **Ketamine** have also been used but since these drugs also affect the intrauterine live fetuses, delayed recovery after birth is to be expected. Epidural analgesia is the method preferred in the bitch by some veterinarians.²⁴

The incision may be made through the flank at an oblique angle parallel the last ribs. This site reduces the possibility of eventration but may leave a noticeable scar in shorthaired dogs. The approach takes more time, the horns are harder to reach, and an incision must be made in each horn. A left-flank incision 7 to 12 cm long parallel to the spine and beginning 3 cm. behind the costal arch and 3 cm above the mammary glands provided better access to the uterus, and the scar is less noticeable.⁴ Many other veterinarians prefer the midline, or linea alba, as an incision site. The greatest disadvantages to this site, which are not serious, are possible eventration or injury to the wound by the pups. It has the advantage of easy access to the uterus. Because the withdrawal of the gravid uterus through the incision might predispose to shock, pressure should be applied to the abdomen after removal of the gravid uterus, and then gradually released. To prevent shock some veterinarians bring the uterus and a fetus to the incision, pack the incision with towels and incise each horn, removing the fetuses by pressure and traction, and keeping the uterus within the abdominal cavity. Because this procedure might result in peritonitis from uterine fluids, it is not desirable unless the fetuses are alive and the uterus not infected. This technique is also more time-consuming. Most veterinarians remove

one horn of the uterus at a time through the abdominal incision. The horn is incised near the bifurcation. The fetuses may be removed from one or even both horns through the same hysterotomy incision. The uterus is incised longitudinally on the side opposite the attachment of the broad ligament, care being exercised not to incise through a placental area. After the fetus is removed the placenta will come away by pressure on the outside of the uterine horn over the placental area of attachment. This can be aided by tension on the umbilical cord. As the fetuses are removed the umbilical cord is clamped with forceps which should not be allowed to dangle as this might predispose to hernia. The placenta is cut or torn away.

The pups are rubbed with a towel to stimulate respirations. The pup's head is held down, to facilitate drainage of mucus from the nostrils and throat. If respirations are delayed, the pup should be dipped alternately into hot and cold water, or its umbilical vein injected with a respiratory stimulant like **Doxapram**. This may also be placed under the tongue and absorbed there.^{41,55} The pups should be kept warm, 80° F. or higher, until placed with the bitch for nursing. Each horn should be carefully checked to be sure all fetuses are removed. If a fetus should be in the birth canal it should be removed by traction through the vagina or drawn cranially through the incision in the uterine body.

The uterine incision is closed by a single or double row of Lembert sutures of catgut. The flank incisions are sutured with several rows of catgut or Dexon with nylon or silk in the skin. The peritoneum on the midline incision is sutured with continuous catgut, the fascia of the linea alba with nylon, and the skin with interrupted nylon or silk sutures. The skin wounds are covered with adhesive if surgery was aseptic. If the wound is likely to be infected it should be left open for daily dressing and bandaging. Gauze or other dressing may be wrapped around the body between the breasts, but not so tightly as to cause discomfort. This is difficult to hold in place. After the operation all pups, especially those of the brachycephalic breeds, should be checked for abnormalities such as cleft palate, hydrocephalus, and so forth, and deformed pups destroyed.

Aftercare of Bitch and Pups—After the bitch has recovered from the anesthesia the pups are placed with her. If she does not encourage their suckling or ignores them she should be restrained or tranquilized while they suckle for the first several days until she “adopts” them. If the bitch should succumb, orphan pups may be raised on rich cow's milk or goat's milk, 1 to 5 parts of evaporated milk and water, or “Esbilac” (Borden's). A formula for feeding pups of 8 ounces of homogenized milk

containing 2 egg yolks may also be used. About 1/2 to 3/4 oz. is given every 8 hours for the first week or two and by the third and fourth week about one ounce, 80 to 100 calories per lb. of body weight, is given every 8 hours.^{2b,39} Pups should be dried after they are fed. Defecation in the pups will be stimulated after they have eaten by their being rubbed beneath the tail with cotton dipped in olive oil. In a week or so some pabulum may be given. Later they can be fed milk from a dish or pan. Ground meat, cereal and ordinary cow's milk can be given when they are 3 weeks of age. Pups can be completely weaned at 4 to 5 weeks after birth.

The aftercare of the bitch following cesarean operation is similar to that given the cow, in that a small dose of oxytocin 1/2 to 1 cc., 5 to 20 units, or ergonamine is given to aid contraction of the uterus. The bitch should be placed on parenteral antibiotics for several days or more and observed closely for symptoms of shock, peritonitis or sepsis the first 6 to 48 hours. If this is suspected or occurs, prompt administration of blood and saline is indicated, along with keeping the bitch warm. The abdominal wound should be observed for any evidence of infection or breakdown or evidence that the incision has been licked or chewed. If it has, muzzling or other restraint of the bitch may be necessary. If the fetuses are dead, the size and congestion of the mammary glands may be reduced by massaging them with camphorated oil. It is advisable to send the bitch home, where she will be in a familiar environment, as soon as possible after the operation. The stitches may be removed about the seventh day after the operation.

Hysterectomy

Occasionally hysterectomy may be indicated due to prolonged dystocia, in which much trauma, injury, and even rupture of the uterus has been produced by unsuccessful fetotomy, mutation, or forced extraction operations, or the fetus is emphysematous and the uterus is atonic, severely infected and diseased.² In severe uterine torsion in which the uterine circulation is obviously compromised hysterectomy is indicated. The dam is usually toxic and exhausted, with a subnormal temperature, anorexia, and a rapid, weak pulse. It may be obvious before the operation or at least at the time of the laparotomy that cesarean section alone, without hysterectomy, will not save the life of the dam. In cases where there is a severely diseased uterus, hysterectomy offers the only hope of saving the dam. The prognosis is always very guarded to poor, since shock and peritonitis generally cause death in these already poor operative risks. In cases

such as severe rupture or laceration of the uterus during fetotomy or forced extraction, hysterectomy might occasionally be considered.

In mares, cows, ewes and sows hysterectomy is usually of questionable value as the economic value of the animal does not generally warrant the expense and effort of surgery and aftercare because the mortality is high. Because of the large size of the uterus and fetus or fetuses it may be necessary to remove the fetuses first in order to remove the uterus. Contamination of the abdominal cavity is difficult to avoid when tying the uterine and ovarian arteries and removing the uterus. After removal of the uterus, eversion of the cervix or uterine or vaginal stump offers further severe difficulties. Shock frequently develops. Successful hysterectomy has been reported only occasionally in cows and sows and rarely in mares.²⁸

In bitches and queens hysterectomy is more often successfully employed because working conditions are good and the animals and their uterus and fetuses are relatively small.² Hysterectomy is often considered in bitches and queens with a prolonged dystocia of 24 to 36 hours or more.² In 52 cesareans and 52 hysterectomies the recovery rate was 82 percent and 67 percent, respectively. The recovery rate was only 50 percent when the fetuses were putrid.²⁹ The prognosis in cases in which hysterectomy is necessary in bitches and queens is therefore guarded. Prior to and during surgery, proper attention should be paid to preventing shock and the contamination of the abdominal cavity. A plentiful supply of instruments should be available. Because the animal is a poor surgical risk anesthesia should be selected and used carefully. A relatively small dose of a tranquilizer with local anesthesia of the incision site is often used in these cases. A midline incision is favored in a hysterectomy operation. If possible the fetuses should be removed within the intact uterus to avoid contamination of the abdominal cavity or incision. Care must be used in exteriorizing the uterus so that tearing of a vessel and subsequent hemorrhage does not occur. Double ligatures should be fastened securely around the utero-ovarian, uterine and caudal uterine arteries. At times excessive fat complicates the placing of tight ligatures around the large vessels in the broad ligament. Forceps are placed across the body and cervix of the uterus after the broad ligament has been incised and the ovaries and uterus are free. The uterus, fetuses, and ovaries may be removed by incising the body of the uterus between the forceps. The serosa of the stump of the uterus should be inverted by a Parker-Kerr stitch as the forceps are removed. After surgery the bitch should be kept warm and given blood and fluids to prevent the shock that sometimes follows the removal of such a large

organ. Antibiotics and corticosteroids should be administered to control possible abdominal contamination and necrosis of the liver associated with shock. Careful continuous aftercare and nursing of these cases should be given.

Chapter X

DIAGNOSIS AND TREATMENT OF VARIOUS TYPES OF DYSTOCIA

In previous chapters the causes, equipment, and operations for the handling of dystocia were outlined. In this chapter the various conditions which produce dystocia and the practical handling of these problems will be discussed under the headings of: dystocia due to pathological presentation, position, and posture of the fetus; abnormal size of the fetus; postmortem changes in the fetus; uterine displacements; stenosis of the birth canal; and uterine inertia.

Dystocia Due to Pathological Presentation, Position, and Posture of the Fetus

Pathological presentations, positions, and postures are apparently due to a combination of uterine inertia and a reduced viability and activity in the fetus especially during the first and second stages of parturition. Uterine inertia may be caused by hormonal or disease factors causing a lack of, weak or irregular contractions of the uterine wall. If the fetus is diseased, deformed, lacks vigor, or is dead, its movements and righting reflexes are weak or absent, and postural abnormalities in such cases are common. In the mare, bitch, and sow these factors when combined with a normal dorso-ilial or dorso-pubic position prior to parturition may result in the failure of the fetus to rotate into a normal dorso-sacral position at parturition. As the fetus is forced through the birth canal the catching or impinging of an extremity at the pelvic inlet causes a progressive flexing of that extremity as the remainder of the fetus passes beyond it. Transverse pregnancies caused by uterine disease, abnormal attachment and development of the fetus and its membranes, or in the case of multipara a single fetus developing in both horns transversely across the body, usually result in dystocia. (See Figures 86, 89, 90.)

Dystocia in Anterior Presentation may result from the following types of abnormalities:

Dorso-ilial or Dorso-pubic Positions are observed in all species as a cause of dystocia, especially in unipara, particularly when the fetus is of normal or large size. In rare cases small or premature fetuses are expelled in these abnormal positions. In these dystocias the fetus should

be rotated into a normal dorso-sacral position before being removed. (See Figure 90.) Before doing this, one should carefully observe and examine the uterus and genital canal to make certain that torsion of the uterus is not the cause of the abnormal fetal position. If torsion is present the fetus should be rotated in the direction which will reduce the torsion. Many of the fetuses found in this position are weak or dead. Lubrication of a dry birth canal prior to rotation of the fetus is of great assistance.

Deviations of the Head and Neck are common types of abnormal posture in anterior presentation causing dystocia in all species. In swine, because the neck is so short, this type of dystocia is very rare. The deviation of the head and neck may be in any direction. Lateral deviation of the head is seen most often in unipara. The deviation may be directly lateral, with the head alongside the thorax in the bovine fetus, or alongside the flank of the equine fetus. This lateral deviation may also be obliquely upward or downward, and occasionally the head may be rotated 45 to 90 degrees on the neck. Diagnosis in the cow is easily made by finding the two forelimbs in the birth canal, but not the head. By passing the hand and arm as far alongside the fetal body as possible and then carrying it around the body, the head and neck are found and the direction of the deviation noted. In the mare this may be more difficult because the head is usually out of reach of the hand. By locating the withers and mane or the trachea of the equine fetus these may be followed to the left, right, downward or upward and the direction of the deviation determined. If the bovine fetus is alive and labor has not been in progress more than 4 to 12 hours the deviation may be corrected with the least amount of difficulty by means of mutation. This is best performed under epidural anesthesia with the animal standing. If the animal is down it should be placed in lateral recumbency with the rear parts higher than the foreparts and with the fetal head in the upper flank of the dam, above the fetal body. Repulsion on the fetal chest in an oblique manner is performed. The body of the fetus is pushed away from the fetal head and neck so that room is produced to allow correction by traction on the fetal head. The incisor teeth should be guarded to prevent laceration of the uterus. If the dam is recum-

bent it is helpful, particularly in the mare under general anesthesia, to have an assistant exert caudal pressure on the fetal head through the mare's flank, helping to force it back toward the operator's hand. In the mare caudal traction on a loop of chain passed around the neck or the use of a detorsion rod to push the chain loop toward the head before applying traction may aid in bringing the fetal head near enough the pelvis to grasp with the hand, hook or snare and thus correct the deviated posture. If the neck and head are twisted this is corrected in the uterus by grasping the muzzle or the orbits with fingers and rotating the head in the proper direction as traction is applied to the jaw, drawing the head and the forelimbs into the birth canal. In the bitch and queen lateral deviation is corrected by vaginal manipulation with the finger, and pressure applied through the abdominal wall. Forced extraction should never be applied to these cases

of deviation of the fetal head and neck without first correcting the abnormal posture. If mutation fails because the fetus is emphysematous or because the uterine wall is contracted tightly around the fetus, fetotomy and amputation of the head and neck with the fetotome is indicated. Occasionally it may be necessary to amputate the opposite forelimb at the elbow joint or to remove the entire limb in order to move the fetus nearer the vulva so that the wire can be placed around its neck. In the bitch and queen cesarean section or in exceptional cases hysterectomy may be indicated.

Wry-neck is seen occasionally in equine and bovine fetuses. It usually occurs in transverse bicornual pregnancy in the mare in which movement of the fetal head and neck is restricted or prevented during most of the gestation period. It may occur in a longitudinal pregnancy with the fetus in one horn and the body. The outer bones of the face become convex while the facial bones lying against the fetus are concave, due to the pressure applied by the uterine wall. The cervical vertebrae are curved and the articulations and atrophied muscles produce a sharply-bent "muscle contracture" condition of the neck resembling torticollis that cannot be straightened, even outside the dam, without fracturing the cervical vertebrae. A bicornual or transverse pregnancy with a wry-necked fetus may rarely at the time of parturition undergo spontaneous version into an anterior or posterior presentation.⁴² In posterior presentation dystocia seldom if ever occurs. The extreme bend in the neck, the stiff, firm neck, and the fact that the head and neck move with the fetal body and cannot be straightened, aids in confirming the diagnosis. Fetotomy is indicated and amputation of the head and neck is simple and practical

Figure 90. Normal dorso-pubic position of an equine fetus late in gestation. The fetus must rotate into a dorso-sacral position during the early stages of parturition or a dystocia will result.

with the fetotome. Removal could also be effected by the removal of the opposite forelimb and evisceration. With forced extraction the fetus could then be withdrawn with the head occupying the space of the removed viscera.

Downward deviation of the head between the forelimbs is occasionally seen in all species except swine. In mild cases, only the nose of the fetus is caught on the brim of the pelvis with the forehead entering the pelvic inlet, "vertex presentation." In more severe flexing of the head and neck the ears and the top of the head are presenting, "poll presentation." This is usually corrected by mutation by repelling the fetus and grasping the muzzle of the fetus and raising it into the pelvic cavity. In the more severe cases the neck extends between the forelimbs, "nape presentation," and the head is against the fetal sternum or abdomen. This latter condition is more difficult to diagnose but by means of careful palpation the operator will notice that the forelimbs do not come together, and that in the mare the mane of the fetus may be felt between the legs, and the head found beneath the fetal body. In cases which are diagnosed early, mutation may correct the deviation. As an aid in relieving this type of dystocia, after the fetus is repelled a forelimb may be flexed alongside the body and the abnormal posture of the head and neck corrected by moving them laterally beneath this leg. The abnormal position of the limb is then corrected and the fetus removed by traction. In the mare, or in bovine cases diagnosed after prolonged dystocia, fetotomy is necessary. Removal of one forelimb and then correction of the deviation by mutation has been recommended.⁴² It may be advisable to amputate the head and neck and one forelimb by a single cut with the fetotome when the fetus is emphysematous or the uterus strongly contracted. In some cases cesarean section may be indicated in the bitch and queen. Upward deviation of the head is rare in the cow and mare but occasionally it is found as a cause for dystocia in bitches and queens. The handling is the same as in lateral deviation of the head and neck.

Deviations of the Forelimbs are relatively common causes for dystocia in uniparous animals. They are rarely a cause for dystocia in multipara because their forelimbs are short and flexible. In unipara, especially the cow and mare, normal birth cannot occur, unless the fetus is very small or premature, with one forelimb extended or retained alongside the body. Forced extraction should not be attempted. In ewes normal birth can occur with one forelimb retained. If dystocia is present with this posture and the ovine fetus is not too large, dystocia may be relieved by forced extraction without mutation. During birth the shoulder and large shoulder joint are displaced

forward alongside the neck when the forelimb is extended in the normal manner. This is made possible by a lack of a clavicle in these species. Pathologically when a portion of the forelimb is caught at the pelvic inlet or in the birth canal the leg is forced backwards toward the body, flexing the shoulder and the elbow joints. Dystocia results from the shoulder being pushed back over the chest, and thereby increasing the pectoral diameter of the fetus. In mild, early dystocia the toe may be caught on the pelvic brim or by a fold in the genital tract, and the fetlock then becomes flexed. The head is present in the birth canal or at the vulva, with one or no forefeet. Mutation by repulsion of the fetus and traction on the retained limb corrects the dystocia. The fetal toe or claw should be cupped in the operator's hand or handled carefully so that a fold of uterus or birth canal is not caught, causing a laceration or rupture of the genital tract. A more severe dystocia is present when the knees are flexed, knee-flexed posture, or the forelimbs are extended beneath the fetal body. In these cases if the fetal head is not extending through the birth canal the condition may be corrected by mutation. The fetus is repelled under epidural anesthesia. The knees are grasped and repelled cranially and laterally into the cow's flank as the feet are extended medially and caudally into the birth canal. If possible the body of the fetus should be repelled into the flank of the dam opposite the side where the abnormal posture of the forelimb is being corrected.

In dystocia cases when the head is outside the vulva repulsion is very difficult or impossible unless the fetus is small, because the head rapidly becomes very edematous. Decapitation should be performed especially if the fetus is dead or emphysematous. Following decapitation the fetus is repelled and the abnormal posture of the forelimbs corrected. If the forelimb is extended beneath the body traction on the forearm and repulsion of the body cranially and dorsally will bring the leg to a knee-flexed posture. In a very few cases it may be necessary when the fetus is emphysematous and the uterine wall closely invests the fetus to remove the forelimb extended beneath the body by a fetotomy operation. Once the legs have been brought into the birth canal they should be extended by traction and the fetus removed by traction on them and on the head or stump of the neck vertebrae if decapitation has been performed. In rare cases to avoid fetotomy a small bovine fetus may be withdrawn with one leg retained, when the head is outside the vulva and the thorax is in the pelvic cavity.

Dystocia due to the one or both forelegs being crossed over the neck is rare except in the mare. This abnormal posture increases the chest diameters as the elbows are forced against the pubis. It may also result in the dor-

sally-directed hooves engaging the roof of the vagina and causing rupture of the vagina, rectum, or perineum. This condition is readily diagnosed. Traction by the operator's hand or with a snare or chain by an assistant should be placed on the uppermost pastern or foot, if both legs are crossed over the neck, and this leg should be pulled upward and then laterally and downward and medially so the leg is brought beneath the neck and head and fully extended. Elevation of the head helps in placing the legs beneath the head. Repulsion and epidural anesthesia usually are not necessary unless the foot is engaged in the dorsal vaginal wall.

Flexion of the anterior limbs at the elbow is a relatively common cause for dystocia particularly in young cattle. It is caused by the olecranon catching on the brim of the pelvis with the leg not fully extended as the fetus passes into the birth canal. In many instances both elbows are impacted. The elbow and shoulder joints are flexed, greatly increasing the pectoral diameters of the fetus. This condition is diagnosed by the fact that the nose of the fetus is resting on or below the fetlock joints while in the normal extended position the nose rests on the middle of the metacarpal bone. By feeling along the fetal leg the operator finds the olecranon firmly wedged against the pelvic brim. This condition is easily corrected by traction first on one limb and then on the other; or the operator can place his hand under the olecranon and raise it as traction is applied to the limb extending it into its proper posture.

Interlocking of the Maternal and Fetal Pelves or "Hip lock" in Anterior Presentation is commonly observed as a cause for dystocia in heifers. The major trochanters of the fetal femurs are the structures that fail to pass through the bony pelvis of the dam. The tuber coxae in calves are small and rarely if ever are the cause of dystocia. Dystocia due to hip lock may be caused by an improper direction of traction putting tension on the linea alba and increasing the pelvic diameter of the fetus and by traction causing the maternal pelvis to tip caudally and dorsally, thereby reducing the diameter of the pelvic inlet of the dam. In most of the naturally occurring longstanding cases of interlocking of the maternal and fetal pelves, obturator paralysis is observed and always should be looked for before relieving the dystocia. This type of dystocia is easily diagnosed by the fact that the head, forelimbs, and a portion of the thorax extend through the vulva. In dystocia due to fetal ascites, or the hind limbs extending alongside the body or against the pelvis as in the *Perosomus elumbis* monster, the thorax seldom extends through the vulva. There should be a careful examination of the relative sizes of the maternal and fetal pelves. If traction is decided upon, the fetus

and birth canal should be well-lubricated. Traction should be applied by assistants or by the fetal extractor, pulling the fetus in an arc-like curve, first backward and then downward and if the dam is down even exerting leverage with the handle of the extractor between the rear legs. In other cases lateral traction around the dam's hips may aid by pulling the fetal pelvis through the maternal pelvis at an oblique angle or in a dorso-ilial position. Some veterinarians rotate the fetus by placing the arms between the fetal legs and over the neck as gradual traction is applied to rotate the fetal pelvis so it can pass through the greatest diameter of the maternal pelvis in an oblique manner. Others tie the forelimbs of the dead fetus together and by placing a long handle between them will rotate or twist the fetus as a traction is applied. The use of the long blunt hook placed over the fetal ischial arch or into the caudal border of the sacro-sciatic ligament aids in placing traction on the pelvis, lifts the fetal pelvis in the maternal pelvis, and pulls the fetal pelvis in an oblique manner aiding in the relief of the dystocia. If the fetus is dead an extensive transverse incision in the abdomen of the fetus caudal to the xiphoid region followed by evisceration, insures traction being applied not to the linea alba or fetal pubis but only on the spinal column. This produces extension of the fetal pelvis on the spinal column and facilitates withdrawal of the fetus. If judicial traction fails to relieve the dystocia, fetotomy should be performed by bisection of the fetal pelvis with a fetotome. This is made less difficult by evisceration after transversely incising the abdomen.

Forward Extension of the Hind Limbs beneath the Fetal Body or the "Dog Sitting" Posture is observed uncommonly in the mare and cow. The reason for the dystocia may not at first be obvious. The cranial extremities are usually presented normally and pass into the birth canal before dystocia results. Passing the hand forward along the fetus, the operator can feel the hind feet and limbs entering the pelvic cavity alongside the fetal abdomen. This examination will serve to differentiate the condition from twins, fetal ascites, or a fetal monster such as a *Perosomus elumbis*. This condition is seen most commonly in the mare because it is possibly a vertical form of the transverse ventral presentation in which the anterior portion of the fetus became dislodged and entered the pelvis. The prognosis in the mare should be guarded to poor. Traction by laymen or veterinarians not recognizing this condition may cause severe damage especially if the hind feet are caught beneath the brim of the pelvis instead of extending into the pelvic cavity. This operation may be handled by mutation only in large mares with a small fetus, or in the cow by repelling the hind limbs into the uterine cavity as the fetus is pulled

from the vulva. Forced extraction should never be used. Fetotomy is often the method of choice and consists of detruncating the fetus with the fetatome through the posterior thoracic or anterior lumbar region. Sometimes evisceration is helpful if performed before detruncation. Often it is necessary to make two cuts through the trunk in order to remove enough of it so that the rear quarters can be manipulated. Krey's tongs placed into the exposed vertebrae assist greatly in drawing the lumbar portion of the trunk toward the vulva, in placing the fetatome wire and in removing more of the trunk of the fetus. After detruncating, chains are placed on the hind pasterns, the rear quarters are repelled into the uterus as the hind feet are drawn into the birth canal and the hind quarters are rotated from a dorso-pubic to a dorso-sacral position and then removed by traction. If necessary the pelvis may be bisected with a fetatome. In some instances cesarean section may be preferred for the correction of this serious type of dystocia.

Dystocia in Posterior Presentation is relatively much more common than dystocia in anterior presentation. Posterior presentation is considered pathological in all except the multiparous animals. The frequency of physiological birth in posterior presentation in the mare and cow is quite low. The fetal mortality in posterior presentation is high. Most authorities advise rather prompt removal of the live fetus in posterior presentation to prevent asphyxiation following pressure on or rupture of the umbilical cord. Most fetuses are usually dead at the time of the examination.

Dystocia due to Dorso-ilial or Dorso-pubic Positions in Posterior Presentation is similar in nature to, and handled by rotation in the same manner as pathological positions in anterior presentation. They are usually less difficult to correct, because the head and neck are not present to offer obstruction to rotation as in anterior presentation; and, because the rump is more rounded than the withers, rotation is easier. Occasionally, in the mare in posterior presentation, the hind feet may engage the roof of the vagina and cause lacerations of the vagina, vulva, and rectum. Lifting the fetal buttocks upward and to one side or the other aids rotation of the fetus by opposite traction on the two rear limbs. Prior to correcting the abnormal position, the operator should determine if the birth canal requires lubrication and whether torsion is present.

Deviations of the Hind Limbs in Posterior Presentation are common in uniparous animals. They are uncommon as a cause for dystocia in multiparous animals because of the latter's small, flexible limbs. These are caused by failure of the hind limbs to extend into the pelvic cavity or by the foot or fetlock catching on the

birth canal or pelvic brim, causing the hind limb or limbs to become flexed. When one joint becomes flexed all joints in the hind limb flex except when the hind leg is extended beneath the body.

The flexion of the limbs at the tarsus or "hock-flexed posture" causes the flexing of the rest of the articulations, followed by dystocia. It may be diagnosed by palpation of the perineal region and tail and then below these the point of the flexed hock either in or just below and cranial to the pelvic cavity. This condition should be differentiated from ankylosed rear limbs seen in **Perosomus elumbis**. Correction of this dystocia is easily accomplished by mutation when dystocia has not existed too long. After epidural anesthesia is administered the fetal buttocks are repelled cranially and to one side. The flexed hock is grasped and repelled forward and laterally into the opposite flank while the foot is drawn caudally and medially and extended through the birth canal (see Figure 88). The hoof or claw should be guarded or cupped in the hand as it is brought back over the pelvic brim so that it does not catch and lacerate the soft structures of the uterus or birth canal. If the dam is recumbent the rear parts should be elevated above the fore parts and the flexed fetal limb should be in the upper flank of the dam so that room is available for mutation and so that the weight of the fetus does not rest upon the flexed limb. In cases of a very large or an emphysematous fetus, or a contracted uterus that will not allow repulsion and room for mutation, or in recumbent cases in which mutation is very difficult, fetotomy with amputation of the rear limb at the tarsus may be necessary and is simple to perform with the fetatome. Rarely in the mare the flexed rear limb may become wedged in the pelvis with the hock impacted against the sacrum and the fetlock against the floor of the pelvis. Amputation of the tarsus is the safest procedure to follow as it prevents further laceration or contusion of the birth canal. Occasionally the rear limbs will have the stifles flexed with the tibias impacted against the pelvic brim. Repulsion of the fetus, lifting the femorotibial joint upward with the hand, as traction is exerted on the pastern, will remove this cause for dystocia.

Complete Retention or Extension of the Rear Limbs beneath the Body, or Breech Presentation is observed frequently as a cause for dystocia in animals. This is a more advanced case of retention of the rear limbs than the hock-flexed posture. The rear limbs are usually completely extended beneath the fetus. The buttocks and tail are in the pelvic cavity and occasionally the tip of the tail is hanging from the vulva. In many cases no part of the limb can be reached until the fetal buttocks are repelled cranially out of the pelvic inlet. Epidural or gen-

eral anesthesia is very helpful or necessary. By grasping the cranial aspect of the tibia with the hand or passing a chain around the tibia the operator can pull the fetal leg back into a hock-flexed posture as the fetal hind quarters are repelled forward and upward. If this is possible the procedure is the same as outlined previously (see Figure 88). If, however, the fetus is dead, emphysematous, or large, and the uterine wall has contracted around the fetus so that room for mutation is not available, fetotomy is indicated. Forced extraction is seldom indicated, warranted, or necessary. Bisecting the fetal pelvis in breech presentation in posterior presentation is easily performed with the fetatome by passing the fetatome wire around one hind leg, placing the head of the fetatome on the opposite hip and making a diagonal cut through the fetal pelvis. In multipara forceps may be applied across the fetal hips after lubrication and the fetus removed by traction; or the hind limbs may be extended into the birth canal and traction applied by a snare, or manually with gauze wrapped around the rear legs of the fetus. Excessive traction in multipara is to be avoided. In severe or prolonged dystocia in multipara, cesarean section or hysterectomy may be indicated.

Hip Lock in Normal Posterior Presentation is occasionally a cause for dystocia, especially in heifers. In posterior presentations, uterine inertia or delay in the second stage of labor are commonly observed. For this reason, in many cases traction is applied successfully by laymen, or the veterinarian may be called to effect a simple delivery with the fetus in posterior presentation, and its hind limbs lying in the birth canal. This should not be termed, or confused with, true hip lock, where, as in anterior presentation, the width of the fetal pelvis at the level of the greater trochanters is greater than the bisiliac diameter of the maternal pelvis. In hip lock in the posterior presentation, the fetus should be repelled and lubricated, if necessary. Traction should be applied to only one rear limb at a time. Some veterinarians will tie the two rear limbs together, place a long handle or their arms between them and rotate and twist the hips as traction is applied. This causes the fetal pelvis to pass through the maternal pelvis at an oblique angle or in a dorso-iliac position necessary to effect a correction of the condition. If this fails, because of the large size of the fetus or the small size of the maternal pelvis, or both, then cesarean section or fetotomy should be considered. If the fetal hips can pass through the pelvis, little difficulty will be encountered with the chest and pectoral girdle. In rare cases fetal ascites may cause dystocia in posterior presentation, simulating a hip lock condition. In dystocia due to severe hip lock, if the fetus is alive and the birth canal small, cesarean section should be given serious

consideration. If the birth canal is relatively large and the fetal size not excessive, fetotomy may be the procedure of choice. This is accomplished by amputation of the rear limb at the hip joint or preferably by bisecting the pelvis with the fetatome, as previously described under fetotomy.

Dystocia due to Bicornual Pregnancy or Transverse Presentation is rare and is seen most commonly in the mare. In rare instances it may occur in all species except swine, in which it has never been reported. The incidence of this type of pregnancy was reported as 1 in 1000 equine births.³⁵ This author believes it may be even more rare. Some bicornual pregnancies might possibly undergo spontaneous version at the time of parturition into an anterior or posterior presentation,^{41,42} but this is questioned. For a transverse presentation to occur it is essential that either a bicornual pregnancy be present or that a fetus in a normal longitudinal pregnancy become deflected at parturition across the pelvic inlet into the opposite horn. The former condition, a primary bicornual pregnancy, has been described most commonly in mares, bitches, and cows (see Figures 86 and 89). It is possible for it to occur also in ewes and queens. Secondary bicornual pregnancy may occur occasionally in multiple or bicornual pregnancy in ewes, does and cows or in bitches and queens. When a fetus is wedged in the birth canal, the next fetus may be forced across the uterine body into the opposite horn; when both horns are large one fetus may fail to enter the birth canal in a proper manner and be forced into the opposite horn. In bitches bicornual or transverse pregnancy is seen most commonly in conceptions with a single fetus that develops across the body of the uterus with the fore quarters in one horn and the rear quarters in the other horn and the dorsum toward the pelvic canal. It is suggested that this is a natural attempt of physiological forces to equalize the load of pregnancy between the two horns. Usually this single canine fetus is large. Transverse pregnancy has not been reported in swine because of the very acute angle at which the horns meet the body and the short compact body of the porcine fetus, making transverse pregnancy a near impossibility. In the cow the transversely developing fetus must assume a U-shape, with portions of the fetus in both horns. It is necessary that the dorsum of the fetus becomes convex and lies against the cervix. In cattle this condition is extremely rare. In sheep it has been observed occasionally in cases where triplets or quadruplets cause a great distention of the uterine horns, and a transverse presentation of one fetus may develop at the time of parturition. In rare cases an equine body pregnancy may occur with the fetus in transverse presentation, with only a small portion of the

cranial and caudal parts of the fetus in each horn.

Transverse Ventral Presentation is the transverse presentation most commonly observed in the mare. The limbs are extended into the uterine body. The occurrence of wry neck is common in equine fetuses developing transversely. Thus at parturition the four limbs are wedged across each other in the pelvis. The head is usually out of reach alongside the fetal body. Expulsive efforts by the mare or traction by laymen result in failure to relieve the dystocia. Due to the nature of the transverse presentation little or no damage of the birth canal or uterus usually results from these efforts. It is necessary to carefully examine the limbs to differentiate the fore and hind legs, so tightly are they impacted and wedged across each other. In certain cases the feet may protrude from the vulva. The prognosis in transverse ventral dystocia in the mare is fair to good depending upon the condition of the mare and her genital tract. Occasionally the transverse ventral presentation is somewhat oblique in presentation, with no portion of the fetus extending into the pelvis. Possibly these are partially rotated bicornual pregnancies. In these cases it is difficult or almost impossible to relieve the dystocia and save the mare without resorting to cesarean section. To correct the usual transverse ventral pregnancy, mutation alone—by repelling the fore parts and applying traction on the rear limbs as the forelegs are flexed and repelled along with the fore parts—can be accomplished only when the fetus is small and the uterus and birth canal are relaxed and large. Epidural analgesia or general anesthesia is usually necessary. The generally accepted manner of relieving this type of dystocia is to remove the forelimbs by amputation at the humero-radial joint with the fetatome. It may be necessary or advisable to amputate the rear limbs at the tarsus in order to provide room for amputating the forelimbs. By applying traction with rotation of the rear limbs and repulsion on the fore quarters or sternum, the fetus is turned by version and rotated into a posterior dorso-sacral position. With the fetus in a posterior presentation the fetal head and usually wry neck do not cause difficulty for the operator. Aftercare of these bicornual pregnancies in the mare is important, as metritis and vaginitis are likely to develop.

The Compound or Rotated Bicornual Pregnancy is of rare occurrence in the mare. It is basically a bicornual pregnancy, usually ventral, that during the latter stages of gestation rotates so that the fetus comes to rest beneath the elongated vagina and uterine body. The dorsum of the uterine horns is ventral and the ventral portions of the horns lie dorsal to the fetus, with the legs of the fetus pointing cranially and dorsally. This rotation of the two horns may be nearly a complete 180 degrees.

At the time of parturition the birth canal is very long and the elbow may be the only portion of the fetus that can be reached by the operator. The rest of the fetus may be palpated through the long narrow birth canal, below the hand and arm. For this reason it may occasionally be confused with an extrauterine fetus. Occasionally the rotation may not be through 180 degrees, and the fetus may be resting on its back, as the uterine horns have rotated only 90 degrees; but here too the birth canal is long and narrow, offering a serious obstacle to birth. In the author's limited experience on only 6 to 10 of these rotated bicornual pregnancies, the mare in most instances had a history of dystocia or retained placenta the previous year. Another report did not confirm this association.³⁵ The symptoms of dystocia in these rotated bicornual transverse presentations are mild, resembling the first stage of labor. Tenesmus or straining is absent or slight because the fetus does not enter the pelvic canal and stimulate labor. In this respect it resembles torsion of the uterus. By the time the veterinarian is summoned to examine the mare, in many instances 24 to 48 hours after the onset of parturition, the uterus is well-contracted and the fetus is often emphysematous. A cesarean operation offers the only hope for saving the mare with this type of dystocia. The prognosis is usually guarded. In many cases consultation may be desirable whether the mare is destroyed or a cesarean operation performed. Fetotomy is impossible because of the stretched narrow, long birth canal.

Transverse Dorsal Presentation is very rarely observed in the mare but usually occurs in the rare transverse pregnancies in ruminants and carnivora because of the sharp angle at which the two horns leave the body. In cases which have had an early diagnosis, mutation may be performed by repelling one end of the fetus—preferably the cephalic portion—and by putting traction on the opposite, or caudal extremities of the fetus by means of chains, Krey's hooks, or a blunt hook inserted through an incision in the skin. If version of the fetus into a posterior presentation cannot be brought about then version into an anterior presentation should be attempted. When mutation fails fetotomy is often successful in the large animals and is accomplished by passing a fetatome wire around the fetus in the lumbar region and bisecting the fetus so each half may be removed separately. If this cannot be done with the fetatome then the skin over the lumbar region should be incised transversely, the back bone broken with a chisel, and the fetus eviscerated. The fetatome wire may then be passed around the collapsed body of the fetus and the body divided and removed. In the bitch mutation is usually impossible and cesarean section is the method of choice.

This may also be decided upon the the cow and mare.

Dystocia Due to the Umbilical Cord and Placenta—Dystocia caused by the cord being wrapped around a portion or extremity of the fetus does not occur in domestic animals. Occasionally the umbilical cord may be found around a leg, especially a rear leg, of the fetus. In this position it will usually rupture before causing dystocia. Thus it may be the cause for the death of the fetus by asphyxia. The belief that amputation of the fetal limbs can be caused by the umbilical cord being looped around them is erroneous. A bovine dystocia due to a very thick amnion that required incising to deliver a normal live calf has been described.²¹ This appeared to be a vascular lesion involving the entire amnion as little edema was present.

Dystocia Due to Abnormal Size of the Fetus

Dystocia may occur as a result of fetal giantism, excessive volume of parts of the fetus, excessive volume of the fetal fluids (hydrops), fetal monsters, and multiple births in uniparous animals.

Fetal Giantism is observed only in rare instances in domestic animals. True fetal giantism is seen most commonly in the cow and occurs only as a result of a prolonged gestation period of over 300 to 310 days. True fetal giantism with prolonged gestation has been reported only very rarely in other domestic animals. In mares that carry foals 365 days the foals are not excessively large. An inbred herd of Holsteins and an Ayrshire herd have been described,^{18,23,43} in which fetal giantism was due to a simple recessive hereditary factor. This condition has been described in other breeds of cattle.^{16,17} The cows carried their fetuses over 310 days. The fetuses were excessively large and the cows showed no signs of pelvic relaxation and little or no mammary development prior to parturition or at the time that normal parturition was expected. All the calves died shortly after birth even when a cesarean operation had been performed. These calves had possible anterior pituitary gland abnormalities, hypoplastic adrenals and an abnormal glucose metabolism.²² Most fetal giants have long hair, long hoofs, and the incisor teeth are well-erupted. In many cases hairballs may be found in the amniotic cavity. Fetal giants are poorly viable and often male. When a bovine fetus weighs over 130 lbs. it may be termed a fetal giant. Prolonged gestation does not necessarily indicate the presence of fetal giantism. In cases of excessively prolonged gestation in Guernsey cattle¹⁹ (See Duration of Gestation and Initiation of Parturition) most fetuses are small,

immature and pathological and in some cases mild hydrops of the amnion and allantois may occur. Dystocia in these cases is uncommon and not severe.

Prolonged gestation may also rarely occur in cattle and other species associated with congenital defects of the head such as hydrocephalus,¹⁷ with cerebral hernia, or a Catlin mark, with a reduced size of the cranial cavity and in ewes grazing on *Veratrum californicum* resulting in fetal cyclopia and often associated giantism. These animals have an abnormal or hypoplastic pituitary gland and hypoplastic adrenals. As mentioned previously normal or increased amounts of glucocorticoids are necessary in these species to initiate parturition. When this does not occur gestation is prolonged and the fetus continues to grow in size. Oversized lambs weighing more than 20 pounds are occasionally described.¹⁵ Prolonged gestation and oversized lambs were reported in Karakul sheep in Southwest Africa.⁸ In these cases of prolonged gestation and fetal giantism in sheep and those in cattle the fetus in many cases dies after a variable period and then a number of days later the dam attempts to expel it. In many cases the pelvic cavity and genital tract is not properly relaxed, there is a lack of fetal fluids, udder development is often lacking and severe dystocia occurs. In a few cases beginning mummification of the large fetus may begin before the fetus is expelled. In cows and ewes the mortality is high due the severe dystocia, uterine inertia, septic metritis, and retained placenta.

The condition of fetal giantism should be carefully differentiated from a large fetus, especially in the large breeds of cattle, causing dystocia due to fetopelvic disproportion at the end of a normal gestation period when the relatively small size of the birth canal makes the large fetus seem a "giant." This latter condition, resulting in dystocia, may occasionally be handled in a mature cow by forced extraction. Percutaneous total fetotomy might be considered in selected cases.^{6,44} If the birth canal is small and underdeveloped or not relaxed, and the fetus emphysematous, fetotomy is extremely difficult or impossible to perform. Cesarean section should be considered. Under certain conditions slaughter might be recommended.

If fetal giantism is discovered or suspected at 280 to 300 days of gestation, and parturition does not seem imminent, a daily dose of 15 to 20 mg. estradiol alone or together with 20 to 40 mg. of dexamethasone or 5 to 10 mg. of flumethasone repeated daily or every third day and possibly combined with 25 to 40 mg of prostaglandin F_{2a} might be indicated to induce parturition or abortion. Large repeated doses of estrogen, such as 60 to 240 mg. of stilbestrol every 24 hours, resulted in 13 to 16 cows calving within 2 to 5 days.³⁷ These were cases of

prolonged gestation, where the fetuses had been carried 9-1/2 to 12 months. Lactation was not affected in most of these cattle so treated. (See Artificial Induction of Abortion.) When parturition is artificially produced the cow should be observed carefully so that aid may be given if necessary. Cesarean section might be used to terminate the prolonged pregnancy; however, metritis and retained placenta invariably complicate the treatment. Slaughter should be seriously considered in dairy cattle since milk production is greatly reduced.

Dystocia Caused by Excessive Size of Parts of the Fetus may be due to rare instances of hypertrophy of any gland; a tumor such as a melanoma, sarcoma or others (see Tumors of the Newborn); a pathological enlargement or cystic dilation of any hollow or secreting organ or structure due to an anomaly in development causing a stenosis or an obstruction to the release of fluid. Reports show that dystocia may be due to an enlarged fetal thyroid, thymus or kidney, polycystic kidney, cystic dilation of the ureter,³⁰ hydrocephalus, distention of the rumen in a *Schistosomus reflexus* monster or fetal ascites. If forced extraction is not successful, incision of the abnormal glands or cystic enlargements to allow the escape of the soft parenchyma or fluid will usually relieve dystocia due to these causes. Except in cases of hydrocephalus and ascites further fetotomy is seldom required. In a few unusual cases cesarean section might be indicated.

Dystocia caused by a Disparity between the Size of the Normal Fetus and the Maternal Pelvis, Fetopelvic Disproportion. These dystocias occur usually in primipara in which the fetus may be slightly larger than normal or the pelvis may be slightly smaller than normal, or both causes may be present. Male calves are carried slightly longer and weigh 5 to 10 pounds more than female calves. Thus male fetuses are frequently present in these dystocias. As discussed under the basic causes for dystocia, crossbreeding of certain breeds and breeding heifers to certain bulls may predispose to dystocia. If primiparous animals are not grown well by proper feeding and management practices or are bred too young, the size of the pelvis at parturition may not be adequate.

In these mild to moderate disparities between fetal size and maternal pelvic diameters, application of moderate forced extraction is indicated when the fetus is in a normal presentation, position and posture for birth and the genital tract, especially the cervix, has dilated to its fullest extent. Delaying assistance by traction for too long may result in a dead fetus or an exhausted dam. In some cases added lubrication may be desirable. Traction should be in the proper direction. Alternate traction as well as lateral traction should be used. Twisting or rotation of

the fetus may be helpful. If excessive traction is to be used epidural anesthesia should be given. If traction is not successful, early consideration of cesarean section should be given in order to save a living fetus. Fetotomy is less commonly indicated in animals with a narrow birth canal and a large fetus. But percutaneous total fetotomy might be considered if the birth canal is not too small.^{6,44}

Dystocia may be caused by Dropsical Conditions, such as Fetal Ascites, Fetal Anasarca, Edema of the Allantois Chorion, and Hydrops of the Amnion or Allantois or both. Fetal ascites is seen as an occasional cause for dystocia in any species but occurs most often in the cow. It is occasionally associated with a dropsical condition of the uterus, mesotheliomas of the fetal abdomen, and has been observed associated with brucellosis. The fetus is usually fairly small but the distended abdomen causes it to become wedged in the pelvic inlet. (See Figure 91.) It might be confused, therefore, with the hip lock condition. Close examination of the fetus in the birth canal will readily reveal the cause for the dys-

Figure 91. Ascites and mild anasarca of a 6-month bovine fetus that caused dystocia.

Figure 92. An anasarous bovine fetus that caused dystocia at the time of abortion.

tocia. To release the fluid from the abdomen the fetus must be sacrificed but this is no great loss as these fetuses are usually dead or weak or would fail to survive if delivered alive. The easiest method is to reach in alongside the fetus and with a castrating knife make a liberal incision through the abdominal wall. In anterior presentation a foreleg could be removed and evisceration would release the ascitic fluid.

The other dropsical conditions of fetal anasarca (see Figure 92), edema of the allantois chorion, hydrops amnii and allantois, and hydrops allantois were discussed in Chapter 5. In removing large anasarous fetuses, forced extraction is usually successful. If the fetus is too large, fetotomy including amputation of the forelimb and evisceration may occasionally be necessary. This is easily performed because of the soft, friable, edematous fetal tissues. Rarely cesarean section might be indicated. In these dropsical uterine conditions uterine inertia and a weak or dead fetus frequently occur and favor abnormal postures, emphysema and dystocia that can usually be relieved by mutation and forced extraction.

Twining in Uniparous Animals is a Common Cause of Dystocia. This is produced by portions of bicornual fetuses becoming wedged in the maternal pelvis. Dystocia is predisposed in unicornual twins because of the inertia of the long, distended uterine horn bent at a 180-degree angle at the diaphragm. Uteri containing multiple fetuses in unipara are prone to develop uterine inertia and uterine disease. The fetuses are less viable. These latter factors usually produce abnormal postures. In many cases one fetus presents anteriorly and the other posteriorly, the latter often in breech presentation. Dystocia due to twins is most common in dairy cows, and less common in beef cattle. Twin dystocia is uncommon in the mare inasmuch as twins almost always are aborted. Sheep have adapted themselves to two fetuses and twin dystocia is uncommon by comparison with the incidence of twins in that species. Twin dystocia usually may be diagnosed readily on examination of the birth canal by

finding three or more limbs attached to two separate fetuses. Diagnosis should differentiate between this condition and double monsters, *Schistosomus reflexus*, campylorrhachis, or dystocia in anterior presentation with the hind limbs extended alongside the body. If twins are wedged in the birth canal usually traction is placed on the twin nearer the vulva. The other fetus is repelled at the same time. Since twin fetuses are small, mutation is invariably successful. Conditions of twin pregnancy and dystocia may be followed by metritis and retained placenta. In cases of unicornual twin dystocia it occasionally happens that one twin is removed and the other overlooked. The same may happen in triplet pregnancies. Thus following all dystocias the uterus should always be examined carefully to be certain no fetus is left in the uterus.

Dystocia due to Fetal Monsters. The relative incidence of fetal monstrosities by species is reported as follows:

Table 15. Relative incidence of fetal monstrosities.

	Craig (citing Gurlt)	Williams	Roberts
Cow	239	15	92
Ewe	179	1	2
Sow	87	1	2
Bitch	78		
Cat	71		
Mare	56		3
Goat	24		2
Total	734	17	101

According to other authors, out of 2340 foals in one stud, only 9 were monstrosities; in cattle about 0.5 per cent; and in sheep 1 in 768 lambs were anomalous.⁷

Not all anomalous fetuses or monsters cause dystocia. The monsters that are characterized by an increased size of the fetus include: hydrocephalic, anasarous, or ascitic monsters; monsters with marked skeletal defects such as *Schistosomus reflexus*, *Campylorrhachis scoliosa*, *Perosomus elumbis*; monsters due to conjoined twins or double monsters; monsters due to pseudo-ankylosis of the limbs or neck; achondroplastic fetuses with short, broad bodies; and mummified fetuses that died late in gestation. Other anomalous fetuses that are weak or dead at birth may cause dystocia due to abnormal positions and postures because of their lack of movement and muscle tonus. If these latter defective, malformed, non-viable fetuses cause dystocia they can usually be removed by mutation and forced extraction unless emphy-

sema or marked contraction of the uterine wall has resulted.

Among the author's cases the incidence of dystocia in cattle due to excessive size of the fetus was as follows, in order of frequency: **Schistosomus reflexus**, 14 cases; **Perosomus horridus** (Gurlt) with ankyloses of the limbs and a short S-curved spine 13 cases; **Perosomus elumbis**, 5 cases, double monsters, 3 cases (two Thoraco-abdomino-pagus, one Dicephalus); fetal anasarca, 2 cases; **Achondroplasia**, 2 cases; and **Hydrocephalus**, 2 cases. Hydrocephalus is occasionally seen also in equine, porcine, canine and feline fetuses. Most single fetal monsters weigh less than normal fetuses, so they are easily handled.

In a dystocia case a careful examination of the fetus should be made for signs of a monster such as: deformed limbs, ankylosed thin limbs with prominent joints, improper placement or location of extremities, atrophied muscles and small fetal size. This examination is particularly important in differentiating between twins and double monsters. When traction or repulsion is placed on one portion of the fetus and the opposite part also moves, either a double monster or a sharply-bent single monster is present. In other cases of dystocia when proper and normal progress toward the correction of the dystocia ceases the fetus should be carefully reexamined for the possible presence of a monster or an anomalous condition.

In the handling of dystocia due to monsters each case is an individual problem. The operator must rely on a careful examination of the fetus and birth canal and on his own ingenuity and ability to plan a procedure that assures a satisfactory outcome. If the condition is severe and complicated extra assistance and even consultation should be obtained. Double monsters occur most commonly in the cow, sow, bitch, and queen, and only very rarely in the mare. Fetotomy, including evisceration, is usually indicated to reduce the size of the monster to the point where the fetatome wire may be placed around conjoined twins at the point of attachment and separate them for removal. A cesarean section to relieve dystocia due to excessive size of the fetus requires a large abdominal incision that may complicate the operation and aftercare.

Hydrocephalus is seen most often in the cow, bitch, queen and mare and when it is severe enough to result in a dystocia that cannot be relieved by mutation and forced extraction the soft portion of the distended cranium should be reduced in size by an incision to release the fluid. An excessive bony enlargement of the cranium may require that a cephalotomy be performed with the fetatome, by placing the wire around the base of the en-

larged skull, amputating and withdrawing the collapsed cranial bones and tissues.

An achondroplastic calf generally can be removed by traction with a chain looped around its neck. Lubrication is of vital importance in severe cases. The limbs are quite short and small and cause little trouble. In cases associated with fetal emphysema, removal of the foreleg and evisceration of the fetus may be indicated. This applies also to anasarca calves (see Figure 92). The latter are usually aborted prematurely and their tissues are soft and easily mutilated for the purpose of releasing fluid in order to reduce the size of the fetus. Fetal ascites often is associated with this condition.

Schistosomus reflexus (see Figure 43) is seen in cattle and occasionally the sheep, goat, and pig but never in the other species. It may be presented in the birth canal in a ventral manner, with the viscera easily palpable. When examining these monsters in this presentation, the operator may be startled to feel viscera and even a beating heart. The fetal viscera might be mistaken for the dam's viscera, and a diagnosis of a ruptured uterus may follow. This mistake will be avoided by a careful examination of the fetus. The dorsal presentation of the *Schistosomus* monster consists of the head and the four feet extending into the pelvic cavity. Since many of these monsters are small they may be removed by careful traction especially from adult dairy cows with a large pelvis. In the ventral presentation hooks or Krey's tongs may be used for traction. In dorsal presentation alternate traction on the legs is sometimes successful in relieving dystocia. In many cases, however, fetotomy is indicated. It is desirable to cut the body in half at the point of the greatest ventral curvature of the spine. Every effort should be made to place the fetatome wire around the middle of the fetus and between the front and hind limbs before the actual cutting operation. In some large fetuses after removing the head, forelimbs, and part of the thorax, it may be necessary to bisect the pelvis before the dystocia can be relieved. In rare cases a sac of skin may completely enclose the limbs and must be incised and the enclosed fluid released before starting the fetotomy (see Figure 43). Cases of dystocia in this type of monster associated with a greatly distended rumen have been observed by the author and others.^{14,41,42}

Campylorachis scoliosa is rarely observed but is handled similarly by cutting the body into two halves with the fetatome. **Perosomus elumbis** if in posterior presentation may be mistaken for a breech presentation. This abnormality is seen most often in cattle and pigs. In anterior presentation the rigid ankylosed hind limbs may obstruct the passage of the caudal portion of the fetus through the maternal pelvis. Since the fetus, es-

pecially the rear quarters, are small, atrophied, and loosely attached to the trunk, correction of the dystocia by mutation and careful traction can be accomplished in many instances. Occasionally amputation of the rear limbs at the tarsus or hip with the fetatome may be necessary in order to remove the fetus without endangering the dam.

Perosomus horridus with general ankylosis or muscle contractures of the fetus is an occasionally observed anomaly in cattle in New York State. The monster, usually a Holstein, is small and very short due to an S-shaped multiple bending of the spine from the occiput to the sacrum. The vertebrae are definitely abnormal, shortened, and ankylosed. The limbs, neck, and tail are ankylosed and deformed. Due to the small size of the fetus, however, the dystocia is usually relieved by traction.

In any of the above types of dystocia due to monsters with the exception of the achondroplastic or anasarctic calves, pseudo-ankylosis of one or more joints or limbs is common. If fetotomy does not give promise of success, cesarean section would be indicated; but the abdominal incision will necessarily be large unless fetotomy can be performed on the fetus *in utero* before its removal through the abdominal incision. Most of these animals will conceive on subsequent breeding and produce normal young unless complications following the dystocia cause pathological conditions that delay or prevent conception. In the sow, bitch, and queen cesarean section is the method of choice and often is necessary in order to relieve dystocia due to a fetal monster.

Dystocia Due to Uterine Displacements

Dystocia may be caused by uterine displacements such as uterine torsion, displacement of the uterus in inguinal or ventral hernias, rupture of the prepubic tendon, folding of the uterus cranial to the pelvis in older deep bodied sows and possibly vagino-cervical prolapse.

Uterine torsion as a cause of dystocia is uncommon in the mare, however one report indicated that 5 to 10 percent of all serious dystocias in mares were due to torsion of the uterus.³⁶

Dystocia due to Uterine Torsion is frequently observed in cattle, especially dairy cattle confined for long periods in the stable. It is occasionally observed as a cause for dystocia in ewes, does, mares, bitches and queens and in rare instances in the sow (See Figure 93). As noted in Chapter 5, in which the etiology, symptoms, and diagnosis of torsion of the uterus in the preparturient animal were discussed, about 90 percent of torsions of the uterus in cattle are observed at parturition and cause dystocia. Whereas in the other species, except possibly

the occasional ewe or doe, most uterine torsion occurs with symptoms during the latter third of the gestation period prior to parturition.^{3,25} Torsion of the uterus as a cause of dystocia was present in 7.3 and 7.0 percent of 1555 and 998 cases of bovine dystocia observed in the Ambulatory Clinic of the New York State Veterinary College from 1943 to 1953 and 1963 to 1968, respectively. Records from the same clinic from 1925 to 1945 showed that of 1703 cases of bovine dystocia, 225, or 13.2 percent, were due to uterine torsion.⁴² In other countries the incidence varies from 1 to 12 percent.³⁴ About 70 percent of torsions occur in cows and 30 percent in heifers. This is probably a reflection of the numbers of pregnant cows at risk. Uterine torsion is apparently rare in **Bos indicus** type cattle due to the anatomical attachment of the uterine ligament.³⁴ The condition is observed most frequently in stabled cattle during the spring months. Apparently most cases of torsion occur during the first stages of labor. Torsions to the right are usually associated with fetuses in the left horn and viceversa.^{3,34} Most twisted uteri are outside the omentum that usually encloses the uterus. The degree of torsion varied from 90° to more than 720° with 80 percent of the cases between 180° and 270°^{33,34} or more. Uterine torsion is rare in twin pregnancies.

The symptoms of uterine torsion of the cow occurring at the time of parturition and resulting in dystocia are frequently so mild that the owner thinks the cow is still in the first stage of labor. The cow is uneasy, restless, may show colic by treading, kicking at its abdomen, and switching its tail. Moderate anorexia is present. Tenesmus, or abdominal straining characteristic of the second stage of labor, is either absent or mild and intermittent because the twisted birth canal prevents the entrance of the fetus into the pelvis—a necessary prerequisite to the initiation of normal abdominal straining. The history given by the owner is usually that the cow had acted as if calving was imminent for the past 8 to 18 hours or more, but true labor or straining has not occurred. This history of a prolonged first stage of parturition is usually observed in uterine torsion causing dystocia and is significant when an owner observes his parturient cows closely.

Examination of the cow reveals increased respirations, and the heart rate is usually elevated to 80 to 100 per minute. In advanced cases with complications of uterine gangrene, uterine rupture, or fetal emphysema, the animal may be toxic, with a very rapid, weak pulse, severe depression, weakness, prostration, low body temperature, cold extremities, and possibly a fetid diarrhea. Hemorrhage from ruptured uterine vessels, occasionally occurs in uterine torsion and causes the cow to exhibit symptoms of anemia, weakness, rapid breathing, rapid

pulse rate, and prostration. In some severe 270° to 360° torsions in cattle it may be noticed that the dorsal commissure of the vulva is pulled forward and to the left or right, depending upon which direction the uterus rotated. An accurate diagnosis of uterine torsion may be made by vaginal and rectal examination of the uterus, broad ligaments, vagina, and fetus, as described in Chapter 5 (see Figure 93). Whenever the birth canal is narrow and stenosed in the region of the cephalic portion of the vagina or the cervix at the time of parturition, torsion should be suspected. If the torsion is greater than 180° to 240° it is usually impossible to pass the hand through the twisted portion of the birth canal. This twisted portion usually includes the cephalic portion of the vagina, the cervix, and occasionally the body of the uterus. Frequently in the mare, but rarely in the cow, the torsion may be entirely cranial to the cervix so a vaginal examination is not as highly diagnostic in the mare as it is in the cow.^{25,36} Epidural anesthesia is usually necessary, as oftentimes this examination initiates severe straining. The fetus is usually in a dorso-ilial or dorso-pubic position as most torsions in cattle are 180° to 240°. The fetal membranes may have ruptured. The fetus is likely to be dead, and long-standing neglected cases of dystocia may show evidence of emphysema or maceration. In all cases of dorso-ilial or dorso-pubic positions of fetuses in unipara the birth canal should be carefully examined for the presence of a torsion. The incidence of uterine rupture is fairly high in cases of uterine torsion and therefore an examination for this should be made prior to treatment. The direction of the torsion should be carefully ascertained. Torsions in the mare and cow of 180° or less during the gestation period may recover spontaneously.

The symptoms in the mare and ewe are similar to those in the cow. In the mare the foal is usually dead and often the symptoms are mistaken for colic or indigestion. Torsions of the uterus greater than 180° are fairly common in the mare. In the ewe the fetus cannot be directly palpated, due to the twisted narrow birth canal. In multipara, such as the bitch, parturition progresses with the fetuses being expelled from the normal horn and in some cases from the caudal or patent portion of the horn in which torsion may have occurred. Unless the abdomen is palpated fetuses in the twisted or rotated horn or portion of a horn that may be still attached to the rest of the uterus or rarely separated from it will not be noted. Transverse rupture of this uterine segment may release the fetuses into the abdominal cavity. In 24 to 48 hours, the bitch will show depression, anorexia, elevated temperature, and rapid pulse, with symptoms of abdominal involvement by a tense, firm abdomen, arched back, and a slow, painful gait and attitude. The extrauterine fetuses

may be diagnosed by radiographs or palpated through the abdominal wall. In rare instances, especially in the queen, the twisted segment of the uterus containing one or two fetuses, isolated or separated from the rest of the uterus due to torsion of the uterus, may be walled off in the abdominal cavity by connective tissue causing the fetuses to macerate or mummify.

The prognosis of uterine torsion causing dystocia is usually fair to good when the condition is diagnosed early, before the occurrence of fetal emphysema, secondary contraction of the cervix, uterine ischemia, necrosis, rupture and peritonitis. In the 113 cases of bovine uterine torsion occurring in the Ambulatory Clinic from 1943 to 1953 there was an 11 percent mortality of the dams. In 70 cases of uterine torsion treated from 1963 through 1968 in the same clinic there was only a 4.3 percent mortality. A series of 225 cases of uterine torsion were reported⁴² from 1925 to 1945, in which an 18 percent mortality resulted.

In 42 cases of equine uterine torsion, 5 to 10 percent were associated with serious dystocias but more than 50 percent occurred before the end of gestation.³⁶ Most equine cases of torsion were 360° or more, usually to the left. Thus the prognosis is guarded for the dam and fetus with 40 percent mortality in the dams and 70 percent in the foals. Correction was best accomplished in the standing mare by rotation of the fetus and uterus through the genital tract. If this was not possible, correction through a laparotomy rather than rolling was preferred.³⁶ In very serious cases cesarean section was the method of last resort. In an excellent recent review of 26 cases of equine uterine torsion, the mean duration of gestation at the time of diagnosis was 9.6 months with a range of 8 months to term.²⁵ Torsions were clockwise in 59 percent of cases and 23 percent had torsions of 360° or more. Uterine rupture was diagnosed in 4 cases. Correction was by left or right flank laparotomy in the standing mare. Of the foals alive at surgery 70 percent were born alive. Of the 26 mares operated on 73 percent survived, 7 died from peritonitis, shock, or hemorrhage.

The prognosis in the other smaller species is guarded to poor because an early diagnosis is difficult or impossible to make without an exploratory laparotomy operation. The prognosis in respect to the life of the fetuses is poor, since in most cases veterinary aid is not summoned until too late and the fetuses, having a reduced oxygen supply, are less viable and die due to asphyxia. In torsion of the uterus with an extensive rupture of the uterus, hemorrhage from the uterine vessels or severe uterine edema and gangrene secondary to thrombi in the large uterine vessels, the prognosis is poor, especially when the latter condition is present in large animals. In

Figure 93b. The Schaffer method for the correction of right uterine torsion. A. The cow is cast on the right side corresponding to the direction of the 180° right uterine torsion, note the position of the right mesometrium. A plank and weight of 75 to 100 kg (black arrows) are applied over the abdomen. B. The cow is rolled slowly to the right in the direction of the uterine torsion. C. Rolling is completed, with the correction of the uterine torsion.³¹ Courtesy of the Cornell Veterinarian.

the bitch and queen hysterectomy may be successful if shock and peritonitis can be controlled. Most cases of unrelieved uterine torsion of greater than 180° result in the death of the dam. In rare cases the fetus remains in the uterus and macerates, with extensive adhesions developing around the uterus; and the condition may not be diagnosed for several months. Uterine torsion in cattle is likely to be followed by retained placenta, metritis, perimetritis, and delayed conception. Only rarely does torsion recur at the following parturition.

The handling or treatment of dystocia caused by uterine torsion in large animals includes several techniques, such as cesarean section, rolling the dam, and rotation of the fetus and uterus through the birth canal or through a laparotomy incision. These treatments and the modifications thereof are designed to correct the torsion of the uterus and to remove the fetus. The techniques of laparotomy, cesarean, and rolling are indicated when the birth canal is so twisted usually more than 240° and the hand cannot be passed through it to grasp the fetus, or when the cervix is not dilated, as may occur in torsion during the gestation period.

Rolling the dam is one of the oldest and simplest of the various methods used to relieve torsion of the uterus. Its principal drawback is that it requires the assistance of 2 to 4 men depending on the size of the cow or mare. If possible, rolling should be done out-of-doors, on a grassy, gentle slope with the cow's head lower than the rear quarters. In the winter months the barn floor, litter alley, or large box stall that are well-bedded or covered deeply with straw or hay may be used. The cow, especially if large and vigorous, should be given a large dose of tranquilizer intravenously or intramuscularly, or 0.5 to 1.0 ounce of chloral hydrate intravenously or 1.5 to 3.0 ounces orally, as a sedative 20 minutes prior to rolling. After the direction of the torsion has been determined accurately, the cow is laid down in lateral recumbency on the same side as the direction of the torsion. The squeeze method, with half hitches around the thorax and abdomen; or the Alabama technique, with ropes crossed over the back and between the hind legs, is used to force the cow to lie down. The hind leg on the side on which the cow is to be cast is pulled cranially and underneath it by a rope attached to the pastern and passed to the other side at the same time the body ropes are tightened. Occasionally this procedure of dropping the cow suddenly on the same side as the direction of the torsion relieves, or partially relieves, the condition. The hind legs of the cow are fastened together and the front legs are tied together, leaving an 8- to 10-foot end on each rope. The cow's head is held extended by a halter and rope and if necessary a nose lead. The front and hind

feet should not be tied together, because this compresses the abdominal cavity and tends to make the gravid uterus rotate with the cow. It is better not to tie the front legs in a flexed position to the body, as the cow will throw her knees apart and brace herself, thus making it difficult to roll her. The object in rolling the cow when relieving torsion is to rotate the body of the cow in the same direction as the torsion of the uterus, rapidly enough to rotate the body around, or faster than, the inert uterus and fetus. The rapidly rotating body of the cow thereby overtakes the more slowly rotating inert gravid uterus. The cow should be rapidly rotated in the same direction as the torsion, by strong coordinated pulling on the ropes attached to the forelegs and hind legs. If because of a lack of assistance, rolling cannot be done rapidly, some other method should be selected to relieve the torsion. Since this is often the case, the rolling technique of Schaffer may be utilized. After the cow has been rapidly rolled 180 degrees her body must then be either rolled back slowly to the original position or be pushed, usually slowly, over her legs and sternum so that she is once more in lateral recumbency on the same side as the direction of the torsion, ready to be rapidly turned over again. Although some authors advise the operator to keep the hand in the vagina or even to grasp the fetus, in order to hold the gravid uterus in place, this is very awkward position to assume or maintain as the animal is being rolled, and is unnecessary unless the operator is uncertain as to the direction in which the uterus is rotated. Placing the hand in the cranial portion of the vagina as rolling is performed will reveal at once, by the tightening of the spiral folds in the vagina, if the rolling is in the wrong direction. After each two or three rapid rotations of the cow's body the birth canal should be examined to determine if the torsion is corrected. If so, the spiral folds and stenosis of the birth canal have disappeared and if the cervix is dilated the fetus may be palpated with ease. Occasionally there may be a rush of fetal fluids from the uterus as the torsion is relieved. If the torsion is not relieved, this procedure should be repeated 4 to 5 more times before failure is admitted and another technique attempted. Rolling mares with torsion of the uterus often results in correction of the torsion as in cattle.^{12b} Rolling might result in rupture of the uterus or cause a rupture of a uterine vessel especially if the uterus was edematous.^{10,36}

A modification of this rolling technique, called **Schaffer's method** has been described^{3,31} (See Figure 93b). This method requires less assistance because the cow or mare with torsion is rolled slowly instead of rapidly. The mare should be anesthetized with a short-acting narcotic. The cow is cast on the same side as the

direction of the torsion and tied in a manner similar to that described for the previous rolling technique. A plank 9 to 12 feet long and 8 to 12 inches wide is placed on the cow's abdomen with the lower end of the plank on the ground. An assistant stands on the plank and the cow is slowly rolled in the same direction as the torsion by pulling on the ropes around the front and hind feet. This creates pressure first on the upper abdominal wall, then the floor and finally the opposite side of the abdomen resulting in a correction of the torsion that can be determined by examining the genital tract. If there is any question concerning the direction of the torsion, the operator, by placing his hand in the genital canal, can readily determine whether the torsion is being relieved or not as the cow or mare is slowly rolled. As in the initial rolling technique if the torsion is not relieved the first time the animal is rolled, the procedure may be repeated several times. In most cases the torsion is corrected on the first rolling. In the Schaffer method the uterus and its contents are held in place by the plank and the weight of the man or a similar weight placed on it while the animal is rolled.

Laparotomy for the intra-abdominal correction of torsion is especially valuable during the gestation period or when the cervix is closed. It is usually performed on the standing cow or mare through the left or right paralumbar fossa. This technique has the advantage of requiring less assistance than does rolling. In most cases tranquilizers or a small dose of chloral hydrate, 0.5 to 1.0 ounce intravenously and light epidural anesthesia are given to control tenesmus at the time of the operation. The right flank in the cow is anesthetized by paravertebral, inverted L block, or local anesthesia and a 6- to 8-inch vertical laparotomy incision is made. The omentum is pulled cranially if it is over the uterus. If torsion of the uterus is to the right the hand and arm are passed downward between the uterus and abdominal wall until the bottom or ventral surface of the uterus can be felt. A portion of the fetus, usually the leg, is grasped through the uterine wall and by alternately lifting and lowering the uterus it is made to rock up and down in an arc of 10 to 12 inches and finally by strongly lifting the uterus and pushing it toward the midline and downward, correction of the torsion is accomplished. If torsion is to the left the hand and arm are passed over the top of the uterus and down between the rumen and uterus. The same procedure of rocking and then rotating to the right or laterally and downward is carried out to correct the left torsion. A left flank incision is preferred in mares. The laparotomy incision then is closed securely. In rare cases in which laparotomy alone is unsuccessful because of chronic adhesions or a very large distended uterus or ru-

men, making correction impossible, cesarean section may be indicated. If at the time of parturition the cervix is not dilated sufficiently and the operator does not wish to lose a living fetus by delay, a cesarean may be performed. This may be done by enlarging the laparotomy incision. Although the torsion may be corrected before or after the fetus is removed, it is easier to relieve torsion after cesarean section. If a cesarean section in a cow is decided upon before making the right flank incision, another laparotomy site may be chosen since correction of the torsion is usually easily accomplished, even in the recumbent cow after the fetus has been removed. Torsion in the ewe and goat may be relieved by laparotomy if elevation of the animal by hanging it by the rear legs or by rolling it is not successful. The relief of uterine torsion in two sows after a laparotomy operation has been described.⁴⁰ One sow died due to hemorrhage from a vessel in the broad ligament; the other recovered following correction of the torsion and removal of the pigs.

Rotation of the fetus and uterus through the birth canal is probably the most common way of relieving dystocia due to torsion of the uterus in the cow and may be used in the mare. Since most bovine torsions, about 90 percent, are discovered at the time of parturition when the cervix is relaxed and dilated, and since most torsions are less than 240 degrees, the hand may be passed through the twisted portion of the birth canal and the fetus grasped and rotated in the standing cow. Manual rotation of the fetus and uterus through the birth canal is very difficult to perform with the cow lying down. In the mare with a 180° torsion of the uterus the cervix may be dilated and the fetus grasped. It is advisable, and in many cases necessary, to have the cow on its feet or its rear parts elevated, and enough epidural anesthetic injected to prevent straining. If the birth canal is dry, lubrication is necessary. If the fetal membranes have not ruptured and released the fluids this should be done to reduce the size and weight of the uterus. Depending on the position and posture of the fetus and the direction of the torsion, the left or right arm is used for manually rotating the fetus. The leg of the fetus is grasped in the metacarpal or metatarsal region and the knee or hock joint flexed. By repelling the fetus and twisting the leg in rotating manner at regular intervals the fetus and uterus are rocked back and forth through an arc of 10 to 12 inches; and then with a sudden strong twist they are lifted and then pushed downward to the side opposite to the direction of the torsion, thereby in many cases relieving the torsion. Some veterinarians pass the hand alongside the body of the fetus, start it rocking and then lift it upward, over, and downward, in a like manner, opposite to the direction of the torsion. This manual technique is easier in the smaller

breeds of cattle with the smaller and lighter calves. It is also easier for the stronger, taller operators.

In the larger breeds of cows when correction of the torsion is not possible by manual rotation of the fetus and uterus the detorsion rod described by DeMott and Roberts,⁹ or a similar instrument such as Erickson's detorsion rod or Cammerer's fork is of great value. Modification of these detorsion rods to permit the tight attachment of obstetrical chains to the handle is desirable. The DeMott detorsion rod is made of 3/8-inch steel rod, 30 inches long, has an eye at either end with 1-1/4 inch inside diameter. After making an 8- or 9-inch loop in a 60-inch obstetrical chain the end of the loop is passed through one eye of the detorsion rod and the rod and loop of chain are carried into the uterus. The free end of the loop is passed around one leg of the fetus and the rod is pushed up to that leg. The other end of the loop, on the opposite side of the eye of the rod, is passed around the other leg. Both ends of the loop around the legs should be placed around the pasterns or just above fetlocks and the free end of the chain drawn tight. If the loops of chain are passed up the leg to the knees or above the knees of the fetus, the hoofs and feet may be forced into or through the uterine wall as the detorsion rod is rotated unless they are carefully held by the operator. A short piece of broom handle or Gibbon's obstetrical handle is then inserted into the eye of the rod and the tightly drawn chain wrapped several times around the handle.

There is another method of applying this instrument, but it is not as safe inasmuch as it may injure the fetal limbs. If, however, the fetus is dead this aspect is unimportant. A loop is made in the long obstetrical chain. It is carried into the uterus and placed around one or preferably both legs of the fetus. The free end of the chain is placed through one eye of the rod and the rod is pushed into the uterus so that the eye fits tightly on the loop around the leg or legs. The chain is drawn tight and the free end of the chain wrapped around the handle.

Before and during rotation of the fetus and uterus, the hand should be inserted into the vagina and uterus to make certain that no portion of the mucous membrane is being pinched by the chain and that the claws of the feet do not engage or rupture the uterine wall. Vaginal examination during the reduction operation is helpful in making certain that the fetus and uterus are being rotated in the proper direction and in determining when the torsion is corrected. When rotating the fetus, repulsion by means of the rod is definitely helpful. In most cases, rocking the fetus and uterus back and forth a few times before starting reduction of the torsion makes the operation easier. Then the handle is rotated slowly in the direction opposite to that of the torsion, and the torsion is

relieved. Rotating a fetus in anterior presentation a quarter of a turn beyond the normal position and then returning the fetus to the normal position will bring the head into the proper posture. If the torsion and stenosis of the birth canal are not severe and both fetal limbs are lying in the vagina, rotation of the fetus and uterus is simplified; but the torsion should not be overlooked.

Other techniques may possibly be used to correct torsion or to assist in the previous procedures. Abdominal ballotment is recommended⁵ and may be of use in aiding manual correction of the torsion through the birth canal, or in rolling the cow. In right torsion an assistant on the right side pushes downwards and inwards in the upper right flank while an assistant on the left side pushes upwards and inwards on the lower left flank. In left torsion the upper left flank and the lower right flank are pushed strongly with the fists. These two assistants push alternately, at intervals of about one second. This causes the uterus to roll back and forth, aiding the operator who is working on the fetus and uterus through the birth canal. When the cow is on her back during the rolling, alternate pressure through the relaxed abdominal walls may aid in reducing the torsion. If the fetus cannot be palpated per vaginam it is very doubtful that rectal palpation and manipulation would be of much value in aiding correction of the torsion. The stimulation of vigorous fetal movement is an aid to correction of early cases of torsion.⁵ If the hand can be passed into the uterus, the eyeballs of the fetus should be pressed firmly. This results in strong reflex movements of the fetus that may aid manual correction of the torsion. A technique that may be useful in correction of torsion when manual correction of the torsion is to be accomplished by rotation of the fetus and uterus through the birth canal or through a laparotomy incision was illustrated.²⁹ One end of a wide board about 8 feet long is placed on the ground under the abdomen and at a right angle to the body of the standing cow. An assistant pushes upward on the other end of the board into the right flank if right torsion is present or into the left flank if left torsion is present. The operator can lift the twisted gravid uterus and fetus from 4 to 6 inches; the board is pushed into the flank and the uterus rests on the board until the operator can get another hold on the uterus or fetus and lift it higher, where pressure upwards and inward on the board again holds it until the process can be repeated. The gravid uterus is thus "walked up" the board until it is in a position to be pushed over and downward, and the torsion corrected. Another old technique, rather crude and not recommended for cows but useful in ewes is that of suspending a ewe's body by her hocks, until only the ewe's shoulders remain on the ground. The gravid uterus rotates more easily into

its normal position when the viscera fall forward. Abdominal ballotment or manual rotation of the fetus through the vagina or rectum, or both, may be necessary to effect correction.

Cesarean section may be indicated in uterine torsion when correction by laparotomy or other means fails; when the cervix is not dilated or only slightly so and it is desired to save the live fetus; when the cervix has undergone a secondary constriction after prolonged dystocia and an emphysematous fetus is present; when uterine rupture has occurred and the fetus is partially in the abdominal cavity; or when torsion of the uterus is suspected in multiparous animals such as the bitch, queen and sow. In these latter species cesarean section should not be delayed. In the ewe and doe as in the cow, cesarean section may be used whenever ordinary means of handling fail or are not indicated. Before performing cesarean section under these complicated conditions the prognosis should be discussed with the owner, as slaughter may be preferable. In the mare, rolling usually results in correction of this condition, although some veterinarians indicate that rolling may be more hazardous for the mare than reduction by a laparotomy incision in the left flank. Manual or instrumental rotation of the fetus might be attempted but is more difficult and dangerous than rolling. The rotation of the uterine horns in the mare in rotated bicornual pregnancy has been discussed under transverse presentations. In severe uterine torsion, especially in the bitch and queen, in which the uterus is severely damaged and necrotic, hysterectomy is indicated and is usually successful if shock or peritonitis do not present severe complications. When hysterectomy is indicated in the cow, the prognosis is very grave. In rare cases in which torsion has become chronic with many adhesions between the involved horn and uterus and the rest of the abdominal viscera, the cow should be slaughtered. In bitches and queens this encapsulated mass containing macerated or mummified fetuses may be removed if necessary.

After the torsion has been corrected by the above methods, with the exception of cesarean section, the fetus may usually be removed by traction after correction has been made of any abnormal posture of its head, neck, or limbs. Before the fetus is removed the uterus should be examined carefully to make certain a rupture, which is usually located transversely in the uterus just cranial to the cervix, has not occurred. In some cases the cervix is not completely dilated. If the fetus is alive, this may be because the stage of parturition has not progressed sufficiently. The treatment indicated in these cases is to administer 20 to 50 units of oxytocin and wait 2 to 4 hours for further dilation or normal parturition to occur.

A slow intravenous drip of the same amount of oxytocin over a period of several hours may produce a more physiological dilation of the cervix. In most cases, however, the cervix is only partially dilated due to an atony or inertia of the cervix and uterus caused by the torsion of the uterus and interference with normal circulation and the fetus is dead. Due to unrelieved dystocia during the period corresponding to the first and second stages of parturition the cervix may partially contract with the fetus still in the uterus. This latter condition is usually observed with a dead fetus and occasionally fetal emphysema is present. The condition of the fetus is an important factor in the decision whether to wait for the cervix to dilate more or to exert moderate, continuous traction with lubrication at once and gradually dilate or, if necessary, even slightly lacerate or incise the cervix, cervicotomy,³⁴ in order to remove the fetus. When the cervix is poorly dilated great traction is not indicated, since it may cause severe cervical laceration or rupture of the uterus especially when the fetus is dead, or dry and emphysematous. Under these circumstances cesarean section, using one of the ventral abdominal laparotomy sites, is indicated.

After the fetus has been removed, the uterus, birth canal, and the cow should be carefully inspected. Rupture of the uterus with peritonitis, internal bleeding due to rupture of the large uterine vessels, retained placenta, septic metritis, and perimetritis are common sequelae to torsion of the uterus. There should be proper treatment or preventive treatment of these complications.

Dystocia due to Abdominal Hernias, such as inguinal hernias in the bitch and rarely in the queen; large ventral hernias in the mare, cow and ewe; and extensive ventral hernias due to rupture of the prepubic tendon in the mare (see Figure 80) and cow, were described in Chapter 5. Dystocia might be possible but would be of great rarity, due to diaphragmatic, umbilical, or perineal hernias. Inguinal hernias causing dystocia must be relieved by a cesarean section; in some neglected cases hysterectomy might be necessary.³ In rupture of the prepubic tendon in the mare, traction should be provided as soon as the first stage of labor is completed. Induction of parturition might be considered. Cows and ewes may give birth normally even with large ventral hernias but aid should be available if it is needed.

Dystocia due to Vagino-Cervical Prolapse is rarely observed in domestic animals. In most cattle affected with vagino-cervical prolapse that carry their fetuses to term, parturition is usually uneventful. Occasionally abortion with a secondary dystocia may be associated with vagino-cervical prolapse. The vagina or cervix might be severely diseased, atonic, edematous, and traumatized

and cause dystocia that might have to be relieved by lubrication and gentle traction. In rare instances vaginocervical prolapse might be severe enough to indicate cesarean section as an aid to relieving the condition. A cesarean might be necessary if cervical stenosis is present, associated with cervical prolapse (see Chapter 5).

Dystocia Due to Stenosis or Obstruction in the Birth Canal

The immediate causes for dystocia due to stenosis or obstruction of the birth canal may be divided into several groups according to the structures affected—the pelvis, the cervix, the vagina, or the vulva.

Dystocia due to Abnormalities or Injuries of the Pelvic Bones resulting in a stenosis or narrowing of the pelvic inlet is seen commonly in domestic animals. In all animals, especially in the cow and sow, the females may be bred too young and the pelvis at the time of parturition be too small and juvenile to allow passage of the fetus. Primiparous animals, especially the cow and sow, may also commonly have dystocia due to a disparity in the size of the maternal pelvis and the size of the fetus even though bred at the proper age, when they have been grown poorly or stunted, usually due to a lack of the necessary nutrients for normal growth, or have suffered chronic disease processes that prevented or retarded normal growth and development. (See Chapters VII and IX.) Dystocia is common in achondroplastic dwarf cattle. In certain breeds of dogs especially the brachycephalic breeds, with a large broad head, dystocia is common due to the relatively small, narrow flattened pelvis. Pelvic fractures and exostoses as a cause for dystocia are uncommon in the large domestic animals but are occasionally seen in bitches and queens that are struck or injured by moving vehicles. Fortunately most females with fractures and exostoses of the pelvis are not bred. Occasionally in the cow, rarely in the mare, a large or sharp bony prominence may be found on the cranial portion of the symphysis pubis. This prominence may project into the pelvic canal and cause lacerations or contusions of the vagina or cervix when traction is applied to the fetus. It is unlikely that an owner would breed any animal affected severely enough to have pelvic deformities.

Correction of this type of dystocia may be overcome in most cases with steady, moderate traction in the proper direction or directions on a well-lubricated fetus. When there is a bony prominence on the cranial part of the symphysis pubis care should be taken not to rupture or lacerate the vagina, cervix, or uterus. In most cases of

severe dystocia due to pelvic stenosis, in which there is a great difference between the size of the fetus and the pelvic diameters cesarean section is indicated. Fetotomy may be indicated only in selected cases. If the head of the fetus cannot enter the pelvic cavity at the same time as the forelimbs in anterior presentation, or if the fetal pelvis is much larger than the maternal pelvic inlet in posterior presentation, cesarean section is indicated. Especially if the dystocia is severe, the fetus is alive, and mutation and forced extraction offer little hope of success, cesarean section is the method most often selected. If in anterior presentation the fetal extractor can with moderate traction draw the thorax through the birth canal, sometimes after amputation of the head and neck, evisceration through a transverse abdominal incision is performed and the impacted fetal pelvis is bisected with a fetatome. This procedure may be simpler and safer than a cesarean operation. Fetotomy through a narrow birth canal is often difficult, prolonged, and usually must be total rather than partial. The newer percutaneous total fetotomy techniques in selected cases may be indicated.^{6,44} The possibility of severe trauma to the birth canal by prolonged fetotomy operations through a small pelvic inlet is great. In severe cases, even those complicated with fetal emphysema, cesarean section may be more desirable and easier for the operator and the cow than a prolonged, difficult fetotomy operation. Pelvic symphysiotomy might be indicated in certain cases in heifers in range areas. In the bitch, queen, sow, and probably the ewe, cesarean section should be resorted to immediately as soon as dystocia develops. With the exception of young animals which have been on a low nutritive plane, or been bred at too young an age, or possibly brachycephalic dogs, these females should not be rebred after dystocia.

Dystocia due to Failure of the Cervix to Dilate is seen occasionally in the cow and the ewe and very rarely in other domestic animals. In England and Australia this condition is spoken of as “ring-womb,” especially in ewes. Failure of cervical dilation is due to a number of causes—cervical induration, primary uterine and cervical inertia, secondary uterine inertia with cervical involution—and in the early stages of normal parturition this condition might be diagnosed erroneously. In ewes this condition has been associated with prepartum prolapse of the vagina lending further credence to the hypothesis that “ring-womb” is of an endocrine etiology.³

The cervix may fail to dilate because of severe fibrous induration or sclerosis of the cervix. This is observed most often in older cows with a history of cervical lacerations and uterine and cervical infections. The incidence of true cervical induration or sclerosis producing

dystocia is rare and this diagnosis should only be made after a careful clinical examination.

In other cases the diagnosis of stenosis or atresia of the cervix may be erroneous, because the animal may not yet have entered the first or second stage of labor. If the animal is left alone for a number of hours cervical dilation will often take place physiologically. In these animals the uterine tone is good, the fetus is alive, the uterine artery is very large and has the typical whirring feeling, the tenacious cervical seal is loosening and the fetal membranes are intact. There have been rare cases in which for some undiagnosed reason the animal began to strain intermittently a day or more prior to parturition. Rabies in cattle, because of the frequent occurrence of tenesmus in this disease, may resemble approaching parturition in a cow in advanced pregnancy.

Stenosis or atresia of the cervix may be associated with dystocia when, in abortion or at term, the cervix does not dilate completely, or relaxation of the cervix fails to take place. This condition is probably caused by hormonal factors that fail to produce a normal relaxation and dilation of the cervix. It is often associated with uterine inertia. This may be due to a failure of the usual or necessary hormones to be secreted or their receptors to develop or possibly more frequently due to disease of the cervix and uterus that renders the cervical and uterine muscles incapable of responding normally to the hormonal stimulus that relaxes the cervix and produces dilation by contraction of the uterine muscles forcing the fetal membranes and fluids, and the fetus into the cervix. The estrogenic hormone, relaxin, and prostaglandins are considered to play important roles in this process by releasing collagenase causing a breakdown of collagen in the cervix and its relaxation (See Chapter VI, Parturition). The exact mechanism requires further study. Failure of the cervix to dilate properly at the time of parturition is associated with or observed in: uterine inertia, uterine torsion, metritis, placentitis, death of the fetus, septic metritis of pregnancy, diffuse peritonitis due to traumatic gastritis, hydrops of the fetal membranes, a terminal condition in severe septic or toxic diseases, mummified fetus, in certain abortions, preparturient paresis, ketosis in ewes, and twin pregnancies in unipara. The history, evidence of uterine inertia, lack of uterine tone, evidence of a diseased fetal membrane or fetus, possible rupture of the fetal membranes and results of attempted treatment will aid in making a diagnosis.

A further condition resulting in a cervical stenosis is involution of the genital tract. In neglected cases of abortion or dystocia, characterized by a dead and usually emphysematous fetus, ruptured membranes, loss of fluid, and a dry birth canal, a stenosis of the cervix may be

observed. It is seen after correction of uterine torsion, a breech presentation or other prolonged type of dystocia, especially one in which no part of the fetus enters the birth canal. As a result there is a contraction or involution of the cervix with the dead fetus still in the uterus. It may be difficult to differentiate this type from failure of the cervix to dilate when uterine disease results in uterine atony and death of the fetus.

The handling of these cases will depend on the cause of the cervical stenosis, the condition of the fetus and uterine contents, and the uterus. In rare cases due to cervical induration and sclerosis the prognosis is guarded and cesarean section is probably indicated if cervical dilation is slight. Dilation of the cervix by mechanical means such as the operator's hands and arms, instruments, a heavy rubber balloon inserted into the cervix and then inflated, or steady, moderate traction on the fetus, will often result in success in selected cases but the cervix may be severely traumatized. Incision of the cervix, vaginal hysterotomy or cervicotomy^{3,34} might be tried through the dorsal and dorso-lateral portions of the cervix. Such an operation is of questionable value and is dangerous and not recommended for valuable breeding animals. In cases in which normal parturition is approaching or the animal is in the first stage of labor no treatment is indicated; often however, veterinarians will give estrogens and oxytocin and wait for normal birth to occur. As described previously in Chapter VI, parturition in mares may be induced more physiologically by 30 to 50 units of oxytocin in saline given by an intravenous drip technique over a period of several hours.

In the type of case in which the cervix fails to dilate due to uterine inertia, diseased uteri, metabolic diseases, and others, the prognosis is guarded and a careful diagnosis should be made if possible. If sufficient time is available a large dose of estradiol, 20 to 30 mg. and/or 20 mg. of dexamethasone administered intramuscularly possibly with prostaglandin F_{2a} , and repeated every other day if necessary, may aid relaxation of the cervix and initiation of parturition. Injections of oxytocin and calcium gluconate may improve the tonus of the uterus and aid or hasten cervical dilation. Uterine relaxants and spasmolytics have been used in other countries.³⁴ Gradual traction on the fetus along with lubrication massage and stretching of the cervix of the cow may relax the partially dilated cervix sufficiently after one-half to one hour to remove the fetus. Strong, forced traction on the fetus is to be avoided, since it pulls the stenosed cervix caudally toward the vulva, narrowing its lumen. Strong traction may cause a transverse rupture of the uterine wall just cranial to the cervix. Occasionally, however, forced extraction, even though it produces a slight to

moderate laceration of the cervix, is indicated over fetotomy or cesarean.

Good lubrication is essential. Fetotomy is very difficult because of the small diameter of the cervix. Cesarean section may be indicated especially if the fetus is alive and the uterus free of infection. In cases of parturient paresis occurring during parturition, an intravenous injection of 250 to 750 cc. of a 20 percent solution of calcium gluconate usually results in parturition within 4 to 6 hours. In ketosis in ewes the fetuses are usually dead and the ewe will die unless the fetuses are aborted and removed promptly; cesarean section therefore may be necessary.

In neglected dystocia cases with cervical stenosis due to involution of the cervix, the prognosis is poor because the fetus is usually emphysematous. The uterus may already be ruptured or may easily be ruptured if forced extraction is applied. Fetotomy, moderate careful forced extraction with much lubrication, or cesarean section, may be attempted depending upon the conditions and the judgment of the operator. Following the correction of the dystocia, the aftercare of the animal is important, as septic metritis, retained placenta, perimetritis, necrotic vaginitis, metritis, and cervicitis are common. In the bitch and queen cesarean section or hysterectomy are usually performed in cases where there are conditions associated with uterine inertia.

Dystocia due to Stenosis or Obstruction of the Vagina may be found in all species. It may be due to tumors such as fibromas or leiomyomas. In rare instances in the mare, ewe, sow or cow dystocia may be due to compression of the vagina by a massive intrapelvic hematoma often following rough intervention by laymen. This may develop during forced extraction or a fetotomy operation. In rare cases a pelvic abscess, excessive fat around the vagina, or possibly a perineal hernia may cause dystocia because of compression of the vagina. A high incidence of fat necrosis was reported in beef cattle grazing on heavily fertilized fescue pastures in northern Georgia.³⁹ In some cattle the fat necrosis was extensive enough to cause a stenosis of the birth canal. In occasional instances a severe necrotic vaginitis may heal and the resulting scar tissue cause a marked stenosis of the vagina and dystocia at the next parturition. A persistent hymenal band may cause stenosis of the birth canal. A persistent median wall of the Mullerian duct, usually found as a fibrous band from 0.5 to 2 inches in diameter just caudal to the cervix, may cause dystocia if the limbs of the fetus straddle this band. This condition is seen most commonly in the cow but may rarely occur in other species.¹³ Either rearing the heifer under unfavorable conditions, or breeding the heifer at too young an age, may cause dystocia due to vaginal infantilism. Occasionally,

however, in abortions or premature births in heifers, the normal relaxation of the birth canal does not occur and dystocia results, due in many instances to lack of normal dilation of the cervix and vulva rather than to underdevelopment of the vagina.

The handling of vaginal stenosis will vary with the cause. If a tumor is present it often can be repelled cranial and lateral to the pelvic inlet as the fetus is withdrawn. In dystocia due to a persistent wall of the Mullerian duct, the fibrous band can be located and cut with a knife or scissors. In mild cases of vaginal stenosis steady moderate traction on the fetus, together with good lubrication, will usually dilate the vagina and allow the fetus to be removed. Occasionally if excessive traction is applied, rupture of the vagina may occur with prolapse of fat or the bladder. In most severe cases of vaginal stenosis, obstruction, or compression, especially in multipara, cesarean section is the method of choice for relief of dystocia. Fetotomy is of very limited or no value because the small size of the vagina makes manipulations and operations very difficult and conducive to postpartum necrotic vaginitis.

Dystocia due to Stenosis or Constriction of the Vulva and Vestibule is occasionally seen in the heifer or mare and less commonly in the other animals. It is usually observed in heifers with genital hypoplasia due to improper growth of the heifer because of chronic disease or poor nutrition or due to a genetic recessive such as anovestibular stenosis or rectovaginal constriction (RVC) in Jerseys.²⁰ Dystocia due to a small vulva may be observed sometimes in heifers that abort or calve prematurely before the vulva is properly relaxed. About 55 percent of dystocias in two-year-old Angus heifers was due to stenosis of the vulva or vestibule.²⁸ This incidence seems too high unless mild stenosis predominated or the heifers were too fat. In exceptional instances it may be hereditary in nature or be secondary to extensive scarring from lacerations following previous parturitions or dystocias. In anterior presentation the nose and head, and in posterior presentation the thighs or stifles stall at the vulva or vestibule. This condition will also occur when large mummified fetuses are expelled by injections of prostaglandins because the genital tracts are not relaxed by estrogens or relaxin.

The treatment or handling of stenosis of the vulva is best performed by gradual, steady, moderate traction over a period of 1/4 to 2 hours, in order to dilate the vulva slowly. The use of lubrication is essential. Prolonged attempts to dilate the vulva, especially if care and lubrication are not used, may result in an extensive necrosis and cellulitis of the vulvar and vestibular tissues. Stretching the vulva by pulling it over the fetal head and pushing outward on the vulva from the inside with the

hands and wrists, helps to dilate it. Moderate traction on the fetal head alone, with the feet released, will help draw the head through the vestibule and aid dilation because of the triangular- or wedge-shape of the fetal head. Patience is essential, since excessive or too-rapid traction will rupture the vulva, vestibule or perineum, causing laceration, severe hemorrhage or contusions. Excessive traction on the fetal jaw may fracture it. Excessive rotation of the fetal head should be avoided. Placing the hand over the poll and pulling the head ventrally and caudally and the vulva cranially and dorsally helps slide the dorsal commissure of the vulva over the top of the fetal head. Severe laceration of the vestibule and vulva rarely occurs, even in the mare, when parturition proceeds unassisted; but if traction is applied, even by one man, laceration may be severe because normal, gradual dilation was not permitted.

If the vulva and vestibule fail to dilate within a reasonable length of time, if haste is imperative or if it is obvious that vulval dilation will not occur, an episiotomy may be performed under epidural anesthesia or local infiltration of the incision sites.^{12,34} With the vulva under tension an incision should be made on either side of the dorsal commissure in a dorso-lateral direction. This is done to prevent a recto-vaginal laceration or a "gill flirter" in the larger domestic animals, in which the dorsal commissure of the vulva is near the rectum. In multipara the vulva is a greater distance from the rectum and an episiotomy is made in a dorsal direction toward the rectum. After removal of the fetus the episiotomy incisions should be sutured together immediately with interrupted deep vertical mattress sutures of catgut and/or nylon and the animal treated with antibiotics for several days.

Fetotomy is not indicated in these cases for the same reasons as in vaginal or pelvic stenoses. In rare cases cesarean section may be the method of choice particularly in multiparous animals or if the live fetus is to be saved. Gradual, moderate traction is the most satisfactory method, inasmuch as dilation of the vulva is necessary or advisable in order that the dam may give birth without assistance at subsequent pregnancies.⁴²

In mares and cows in which the vulva has been sutured to prevent pneumovagina, this band of tissue should be cut just before parturition in order to prevent uneven or irregular tearing of the scar between the two vulvar lips. This thin band of tissue will not cause dystocia.

Dystocia Due to Uterine Inertia

For convenience in discussing this problem it will be divided into two parts: primary inertia and secondary in-

ertia. Both are characterized by a weakness or absence of uterine contractions during the first or second stage of labor that usually persists into the third and involution stage after parturition.

Dystocia due to Primary Uterine Inertia is observed most frequently in the bitch, cow—especially the older dairy cow—and sow. It is uncommon in the other species. It is produced by a lack of tone or failure of the uterine muscles to contract. The failure of the uterine muscles to contract normally at parturition may be due to a primary failure of the muscles to respond to hormonal stimuli due to disease of the muscle; or it may be due to an actual lack or failure of release of hormones or the development of receptors such as estrogen, oxytocin and possibly prostaglandins that initiate uterine contractions in normal muscles (See Chapter VI, Parturition). In bitches it is observed more frequently in certain small breeds such as the Dachshund. In a few Cocker spaniels it may be associated with psychotic abnormalities and nervous voluntary inhibition of parturition due to pain. Primary uterine inertia was common in infertile dogs with 3 or fewer fetuses.^{3,11} Lack of exercise, excessive fatness, debility, and senility are all causes of weakness of uterine contractions at parturition. Overdistension of the uterus in fetal giantism, hydrops of the fetal membranes, fetal anasarca, twins in unipara—especially unicornual twins—and an excessive number of fetuses in small bitches are other conditions conducive to primary uterine inertia. Undoubtedly uterine disease, or pathology associated with uterine infections and placentitis during gestation, also play a role in the production of uterine inertia. Apparent bovine uterine inertia is observed in parturient paresis due to a hypocalcemia. A type of primary uterine inertia in dogs, especially Chows, Retrievers, Bull Terriers and Spaniels, associated with a small litter, with slight or absent mammary development, and with no signs of parturition at the proper time has been described.⁵ The fetuses apparently succumb and by 70 to 80 days after service a dark green viscid fluid escapes from the vulva. This was probably due to a hormone disfunction.

The animals affected with primary uterine inertia are usually and obviously parturient and in the first stages of labor, as shown by relaxation of the soft structures of the pelvis, marked mammary development, and discharge of mucous from the vulva. The animals show no distress and eat and drink nearly normally but the second stage of labor does not occur for 6 to 36 hours or more, if at all. On examination, the cervix is usually relaxed and dilatable but the fetus and fetal membranes are not being forced into the cervix or birth passage. In some cases in cattle the cervix fails to dilate normally due to a lack of hormones or to a failure of the uterus to con-

tract. What may be diagnosed as a failure of the cervix to dilate may in reality be a manifestation of a primary uterine inertia. One or both membranes may have ruptured. There is usually no abnormality in presentation, position, or posture of the fetus. The uterus apparently fails to contract normally, and consequently does not force its contents through the cervix and into the birth canal. Usually in 24 to 48 hours the second stage of labor may set in but in many cases by then the fetus is dead and occasionally infection of the fetal membranes and fetus is apparent. The prognosis is favorable in most cases that are diagnosed early.

In the cow or ewe this condition is rather easily handled if the cervix is relaxed and open by rupturing the membranes, correcting any abnormal posture, and removing the fetus by moderate or slight traction. In certain cases in the cow as well as in multiparous animals in which the condition is diagnosed early, intramuscular injections of oxytocin, 2 to 10 ml (20 to 80 units) for large animals, or 1 to 2 ml (10 to 20 units) for small animals, may stimulate uterine contractions and normal birth of the young. Giving this injection in saline by an intravenous drip technique over a period of several hours may be a more physiologic procedure. Others state that the intravenous injection of calcium gluconate, 500 ml of a 20 percent solution in cattle and 10 ml of a 10 percent solution in bitches, is of value in these cases, especially if calcium levels of the blood are low or if parturient paresis is present. In the bitch as well as other species "feathering" the vagina by inserting a finger, and stroking the dorsal wall of the vagina, or in other similar ways stimulating the production of oxytocin by the animal's own pituitary may be helpful. If this treatment does not result in the initiation of normal parturition in 1 to 2 hours the treatment might be repeated. After 3 to 4 hours with no response, cesarean section is indicated and should be performed at once in the multiparous animals. If according to the history primary uterine inertia has existed for 4 to 6 hours before the veterinarian examines the case, cesarean section may be indicated at once rather than the use of the above techniques and waiting for uterine contractions to begin. Hysterectomy may be preferred if evidence of infection is present in the uterus of the bitch or queen. Morphine, 1/8 to 1/2 grain or tranquilizers may quiet nervous, psychotic Cockeris sufficiently to permit normal parturition.

Since this inertia extends into the third stage of parturition and beyond, retained placenta, metritis, and delayed involution of the uterus are common. Administration of several injections of oxytocin or ergonovine accompanied by intrauterine and parental antibiotic therapy, may help prevent septic metritis and other compli-

cations due to delayed involution of the uterus.

Secondary Uterine Inertia usually follows a prolonged dystocia and is characterized by exhaustion of the uterine muscle. This condition is seen in all species and is more common in large animals than is primary uterine inertia. In multiparous animals when prolonged labor or dystocia is relieved by removing the fetus causing the dystocia, it is quite common to find that secondary uterine inertia has occurred and consequently the rest of the fetuses are not expelled. This type of inertia can be prevented by correcting dystocias early. In certain breeds of dogs such as the Scotch Terrier or Dachshund secondary uterine inertia may occur spontaneously early in the second stage of parturition. Usually one or two fetuses are expelled normally and then labor ceases even though more fetuses are present in the uterus.

In cattle examined after prolonged dystocia the uterus is often contracted tightly around the fetus. In some cases this condition closely resembles the condition called retraction, Bandl's, or contraction ring dystocia, described in humans following prolonged dystocia.²⁷ In retraction ring dystocia the uterine muscle just cranial to the cervix contracts tightly, so that normal expulsion of the fetus into the birth canal can not take place. A contraction ring may occur any place in the uterus and if it occurs around the fetus it can interfere with birth. These abnormal contractions of the uterine muscle are strong sustained tetanic contractions caused by exhaustion spasms of the muscle which are a fatigue phenomena. Diagnosis of this condition may be based on the history of prolonged dystocia; in multipara on the birth of one or two fetuses with a cessation of labor, or the removal of the fetus causing the dystocia, not followed by the normal resumption of parturition. In large animals intrauterine examination reveals the nature of the condition causing the dystocia—usually an abnormal position, posture, or presentation, and the contraction of the uterine walls upon the fetus. In some uteri in which contraction bands or rings are very strong and broad especially around or caudal to the fetus, this condition will complicate the primary cause for the dystocia. The prognosis in secondary uterine inertia is more guarded than in primary uterine inertia because the fetuses may be weak, dead, or emphysematous, and rupture of the uterus is more common. Retained placenta and metritis are usual sequelae.

In the handling or correction of this type of dystocia in large animals the condition causing the original dystocia should be corrected by mutation if possible and the fetus then removed by moderate, careful traction. Lubrication of the fetus and birth canal is usually necessary. Excessive traction should be avoided if strong contraction or retraction rings are present in the uterus and

definitely retard removal of the fetus, since transverse rupture of the uterus may occur. This is a highly important reason for examining the uterus carefully in prolonged dystocia cases as occasionally ruptures occur spontaneously or due to previously applied traction. If contraction rings are not too strong, careful, slow, cautious mutation and traction may be successful in relieving the dystocia. If they are severe and markedly reduce the lumen or diameter of the uterus it may be necessary to resort to fetotomy or cesarean section to relieve the condition. In other countries uterine relaxants or spasmolytic or tocolytic drugs, such as isoxsuprine lactate, are recommended in this condition.^{3,25,34} Since infection of the uterus is often present, the ventral abdominal approach for the cesarean operation is indicated. In humans these contraction or retraction rings may be relaxed by intravenous administration of adrenalin or modern relaxants and by general anesthesia; if this fails, a cesarean is necessary. The author in a limited number of bovine cases has had little success using adrenalin. Epidural anesthesia is not effective in relaxing the uterine muscle. In bitches, mild narcosis or anesthesia with morphine may be helpful. This marked contraction of the uterine wall in prolonged gestation is another reason for being very careful not to rupture the uterus by repelling the fetus in an attempt to gain room for mutation operations.

In the sow it is common practice, when several pigs have been expelled before dystocia occurred, to remove by traction the one causing dystocia, lubricate the birth canal, and give 1 to 2 ml. of oxytocin, or 2 to 3 ml. of **Lentin**. If the rest of the litter is not expelled in 2 to 3 hours, another pig may be removed by traction and the injection repeated; or cesarean section may be decided upon as the method of choice. This decision should not be delayed too long. In bitches the situation is similar to that in sows, in that the handling of the case will depend upon the duration of labor, the number and condition of the fetuses, and the degree of uterine infection. Early cases in bitches may be handled in the same manner as in sows except that **Lentin** should not be used. If the dog appears exhausted but the fetuses are in good condition, 1/4 grain of morphine will relax the bitch and possibly the uterus and after one or two hours rest strong uterine contractions will commence again and whelping continue. In this condition of secondary uterine inertia, helping the bitch with forceps may be indicated if only one or two fetuses remain in the uterus. If, however, there are 3 or more fetuses and dystocia has been prolonged, cesarean section is indicated. If the fetuses are dead and infected, hysterectomy may be desirable. Cats are quite resistant to infection. Oxytocin usually will reinitiate labor even after dystocia of 48 hours' dura-

tion.³² As in primary inertia, retained placenta, septic metritis, delayed involution, and pyometra are common following secondary uterine inertia.

Dystocia Due to Postmortum Changes in the Fetus

These dystocias may be caused by mummification of the fetus in cattle, and by fetal emphysema and fetal maceration in all species.

Dystocia due to Fetal Mummification in cattle was described in Chapter 5. In some instances mummified fetuses may macerate. This is probably secondary to a relaxation of the cervix at the time of an unobserved, spontaneous, but incomplete abortion. Organisms entered the previously sterile uterus and start the maceration process. Hematogenous uterine infection may possibly occur.

Dystocia due to Fetal Emphysema is observed in all species and is usually associated with a prolonged dystocia of 24 to 48 hours' duration. The fetus dies and organisms from the vagina pass through the open cervix, invade the uterus and cause rapid fetal emphysema. Fetal emphysema may complicate dystocia in incomplete abortions after the fourth month of pregnancy when the dead fetus is retained in the uterus (see Chapter 5). Although fetal emphysema usually occurs with the cervix open it may occur with a closed cervix in rare conditions such as a septic metritis of pregnancy in which the fetus dies, becomes emphysematous, and may even macerate before the cervix opens. Such a condition occurring late in pregnancy especially in a heifer with a small, underdeveloped, or unrelaxed genital tract may result in a serious and often fatal termination. Fetal emphysema is also observed in cases of neglected torsion of the uterus in which the fetus dies. It is commonly seen in rotated bicornual pregnancies in mares. In any type of condition causing uterine inertia, fetal death and emphysema may result if treatment is not given promptly. In bovine twin pregnancy one twin may be expelled and the other remain in the uterus and become emphysematous or macerate. This is more commonly seen in unicornual twins. Dystocia due to any condition causing the death of the fetus may result in fetal emphysema if the fetus is not removed promptly. In bitches and sows fetal emphysema may occur in prolonged dystocia in a manner similar to that in other animals. It is also observed in the large breeds of dogs such as Great Danes, Afghans, Boxers, Newfoundlands, and St. Bernards. In these dogs birth proceeds normally until the last fetus.⁵ This remains in the uterus and goes undetected for one or two days; by

at this time the bitch shows a fever of 103°, there is a green, black, fetid discharge from the vulva, the bitch manifests no interest in the live pups, and exhibits symptoms of depression and toxemia. In these breeds a careful examination should be made for the last fetus, if necessary by radiographs of the bitch, since usually this last fetus cannot be palpated through the abdominal wall or felt by forceps through the birth canal.

Fetal emphysema can usually be suspected if dystocia has existed 24 hours or more. The animal is usually depressed, toxic, and shows anorexia. Labor is usually weak and intermittent. The temperature is frequently elevated early but may be normal or subnormal late in the condition or at the time the veterinarian is summoned. This is especially true in the cow. The heart and respiratory rates are elevated. The extremities are cold and the feces may be loose and fetid. Often a fetid, watery, reddish vaginal discharge is observed. The mucous membranes of the genital tract are dry, swollen, and inflamed. In some cases the cervix may be partly involuted or contracted. The uterine walls are contracted closely about the fetus. The fetus is dead and swollen because of gas, that can be felt as it crepitates beneath the skin. In early cases of fetal emphysema only that portion of the fetus nearest the vulva may be emphysematous, but in prolonged dystocia cases the entire fetus is involved. In some cases of twins, the twin nearer the cervix may be emphysematous and the deeper twin may be normal. The fetal hair may be beginning to shed. Fetal meconium is often present on the fetus. The corneas of the eyes are grey; and the teeth usually loose. Rupture of the uterus may be present or be easily produced by traction due to the dry fetus and the tense, contracted uterine walls. Examination is likely to result in violent straining. The prognosis is always guarded to poor as uterine disease, septic metritis, and retained placenta usually follow this condition. The future breeding life of the dam is in doubt. Complications such as rupture of the uterus are likely to arise in the handling of dystocia due to fetal emphysema, making the prognosis guarded to grave.

The least difficult and the best method of correction of fetal emphysema in large animals is forced extraction after mutation, if the latter is necessary. Care should be used in repelling the fetus and in exerting traction of the fetus, so that rupture of the uterus or cervix does not occur. Lubrication of the birth canal and fetus is essential. In bitches forced extraction is probably not indicated unless only the one fetus is present or is wedged in the birth canal so that it would have to be removed by traction before a hysterotomy or hysterectomy is performed. In some cases such a fetus may be pulled apart and a portion may drop back into the uterus and become

difficult to remove by forceps. Occasionally in large animals fetotomy may be necessary. Extensive mutilation of the fetus and its evisceration greatly reduce the size of the fetus by releasing the gases present. The fetal tissues are soft and friable due to the emphysema and operations are performed with greater ease and speed than in normal fetuses if the birth canal is dilated. Frequent lubrication is essential to prevent trauma to the birth canal. Necrotic vaginitis or vulvitis or even metritis are likely to follow removal of an emphysematous fetus. In large animals cesarean section is indicated when the birth canal is involuting and is small, swollen, and dry, and when the uterine wall closely invests a greatly swollen and emphysematous fetus. If the cow's life is to be saved a cesarean may be a last resort if fetotomy is not feasible or possible. A total fetotomy of an emphysematous fetus may be more exhausting and dangerous for the cow and operator than is a cesarean section. The prognosis should be guarded and the operation performed on the ventral abdominal wall so that contamination of the abdominal cavity can be avoided. In removing emphysematous fetuses in uniparous animals care should be taken not to leave a hoof in the uterus that might remain and act as a chronic foreign body, producing chronic pyometra.

Another possible technique for relief of dystocia due to bovine emphysematous fetus is to make a long laparotomy incision in the left flank, suture the uterus to the peritoneal and fascial tissues around the periphery of the incision. The uterine wall is incised and sutured with non-absorbable material to the musculature and skin. The fetus and membranes are then removed, by fetotomy if necessary, thus preventing contamination of the peritoneal cavity. The vaginal and uterine cavities are well irrigated and parenteral antibiotics administered. The cow may be slaughtered for beef several months later.³⁸

In the bitch and other multiparous animals cesarean section may be indicated. Many veterinarians prefer to perform a hysterectomy in dogs and cats in order to prevent possible contamination of the abdominal cavity. In multipara with emphysematous fetuses, secondary uterine inertia, or associated uterine torsion, administration of oxytocin might result in uterine rupture and death due to peritonitis and shock. In these cases care should be taken to prevent shock and hemorrhage and to be certain a fetus is not left in the birth canal.

The aftercare of cases of dystocia due to fetal emphysema should consist of antibiotics parenterally and into the uterus, and injections of oxytocin and ergonovine to stimulate uterine contractions, an increased blood supply to the uterus, and to hasten the overcoming of infection. Other supportive therapy such as blood, saline, and glucose may be given, inasmuch as septic metritis and re-

tained placenta are common sequelae to the removal of an emphysematous fetus.

Fetal Maceration as a Cause of Dystocia in incomplete abortions was discussed in Chapter 5. It may develop in all species during pregnancy, as a sequela to abortion or mummified fetuses that were not expelled when the cervix dilated. In rare cases this condition may be observed following undiagnosed and untreated torsions of the uterus during pregnancy or at term. In all animals the uterus or a twisted segment of it containing the macerating fetuses may be walled off in the abdominal cavity; or if the uterus ruptures and the fetuses escape into the abdomen, they may become walled off there and macerate. In rare cases some fetuses may slough to the outside or into the alimentary tract. In uniparous animals uterine torsion can cause fetal death and maceration with adhesions between the uterus and the other abdominal viscera. Fetal maceration is often observed in animals at term when a dystocia or a twin fetus has been overlooked or neglected for 3 to 10 days.

The symptoms are usually limited to a persistent, fetid, vaginal or vulvar discharge often containing hair, hooves, or bones. The cervix is usually partially dilated and the fetus is in an advanced stage of emphysema, maceration and decomposition and pulls apart when handled. In chronic cases the cervix is only slightly open, and the animal fails to show estrus. On rectal examination fetal bones can be felt to crepitate within the uterus. In some cases a perimetritis may be present. In undiagnosed or untreated dystocias a history of constant but intermittent straining, generally considered by the owner as due to retention of the placenta, is noted, as is also a fetid, purulent discharge. The lack of general symptoms shown in some of these cases is amazing. The author observed a 7-year-old cow with macerating twins in the uterus. The owner believed the cow had calved 7 days before on pasture, although he had found no calf. The cow was eating normally and milking 30 lbs. a day. The fetuses were pulled apart in removal through the cervix, which was about 12 cm. in diameter. The uterine wall was about 3 to 5 cm. thick. Recovery was uneventful. A number of similar cases have been described in mares that subsequently conceived following the removal of the macerating fetus.²⁴ The fact that other veterinarians have similar experiences suggests that in extremely difficult dystocia cases it might possibly be advisable in certain cases to try only supportive treatment and antibiotics, for 4 to 6 days, until the fetus has macerated sufficiently to be removed easily. During this same period the uterine wall builds up its natural defenses against infection. The dangers might be uterine rupture due to fetal emphysema before the inception of

maceration or further closure of the cervix which might be prevented by injections of estrogens. In certain cases exploratory laparotomy may be advisable. The prognosis in these cases, occurring more than three days to a week following dystocia, is guarded. In the more chronic cases, with the cervix nearly completely closed the prognosis is very poor.

When these cases in large animals occur, they are handled in a manner similar to that of treating emphysematous fetuses. In the more chronic bovine cases the cervix cannot be dilated manually. Estrogens are usually ineffective in evacuating the uterus, as the bones are more or less imbedded or caught in the endometrium. Laparohysterotomy or hysterectomy in the cow is very difficult in chronic cases with only fetal bones and pus in the uterus because the uterus is so small it is difficult to bring to the abdominal incision even if no adhesions were present. The prognosis as far as the future breeding life is concerned is very poor. Since most of these animals are in fair to good health, slaughter is usually advised. In multipara, especially bitches, hysterectomy is advised in most cases.

After handling cases of fetal emphysema or maceration in large animals, especially if fetotomy was performed, the operator should be careful to cleanse and disinfect his arms and instruments carefully, and then boil the instruments. This is done to avoid a severe infection on the arms or the introduction of infection into the next cow through the use of the contaminated instruments. Aftercare of cases of fetal maceration in which the fetuses were removed is similar to that following fetal emphysema.

Chapter XI

INJURIES AND DISEASES OF THE PUERPERAL PERIOD

The injuries and diseases of the puerperal period discussed in this chapter include puerperal infections and metabolic diseases as well as hemorrhages, lacerations, contusions, ruptures, and prolapses of various organs, especially the genital organs that may occur during or following parturition. A summary of the causes of post-parturient paraplegia is included. In a study of 2,480 cases of dystocia⁴³ in six dairy and four beef breeds reported by veterinarians in Australia in 13 country practices, a total of 528 dams, 21.3 percent, suffered parturient or post-parturient conditions with about one-quarter of the dams being affected with two or more complications. A partial list of the complications and their incidence were: paraplegia other than hypocalcemia 9.1 percent; retained placenta, 4.9 percent; septicemia and toxemia, 2.7 percent; injury to vagina and cervix, 2.2 percent; uterine rupture 1.0 percent; metritis, 1.1 percent; peritonitis, 1.0 percent; lameness and paresis, 0.9 percent; shock, 0.8 percent; prolapse of portions of birth canal, 0.6 percent and hemorrhage 0.3 percent. Maternal death was usually associated with a prior existing disease state or developed as a result of it and aggravated the dam's condition.⁴³

Postpartum Hemorrhages

Hemorrhage or bleeding into the uterus or birth canal may occur postpartum due to trauma, lacerations, or rupture of the genital organs. Hemorrhage into the uterus may be due to bleeding from an incised or torn caruncle or caruncular stalk in the cow or ewe, from the incised or lacerated endometrium in the mare, or from premature removal of the fetal membranes or placenta. This accident may occur at the time of parturition, during a cesarean section or fetotomy, or may take place later due to improper or too early removal of a retained placenta in any uniparous animal. Severe intrauterine hemorrhage in rare cases occurring from several hours to a day or so after calving and dropping of the placenta, that resulted in a massive blood clot filling the gravid horn of the uterus was described.^{59,60} Rarely death may occur. Slight bleeding may be observed, from the rup-

tured end of the umbilical cord or from slight lacerations of the uterus, cervix, vagina, or vulva. A hemorrhagic discharge from the vulva in a bitch was due to an invagination of a portion of one horn not visible externally.³⁰ In severe lacerations or rupture—particularly of the cervix, vagina, and in rare instances, the vulva—hemorrhage may be profuse due to a rupture of a large vessel. Blood may flow in a stream from the vulva as soon as the fetus is removed. Most of these lacerations and injuries follow forced extraction. Intraperitoneal or extravaginal hemorrhage may occur. If severe enough the former may produce acute symptoms of anemia and rarely death, especially in the mare. This is ordinarily seen in cases of dystocia, rupture of the uterus and uterine vessels before, during, or after correction of torsion of the uterus, in prolapse of the uterus, and in trauma especially in fetotomy operations or forced extraction in young heifers. These hemorrhagic conditions would be greatly aggravated in cattle fed moldy sweet clover hay.

In the treatment or handling of these conditions the usual surgical procedures to control the hemorrhage and supportive treatment are indicated. Most cases of slight bleeding from the genital tract at parturition are not serious and require no treatment. In more severe bleeding from the uterus of large animals oxytocin, 20 to 50 I.U., may help control hemorrhage by contracting the uterus and its vessels. Injecting 500 ml. of saline to which 10 cc. of formalin has been added, or 500 ml. of calcium gluconate may also aid in hastening the clotting of blood, and thus control the hemorrhage. If bleeding occurs from a large vessel through a laceration in the vaginal wall, the vessel may be clamped by forceps. These should be left in place for 24 to 48 hours, or the vessel should be ligated. If this cannot be accomplished, packing the vagina to provide intravaginal pressure should be done promptly. In severe intrauterine hemorrhage the clot should not be disturbed. In several weeks or months the large clot will be reduced and absorbed by natural processes. Intrapelvic or perivaginal bleeding may cause a stenosis of the vagina during or after forced extraction or fetotomy but neither it nor the intrauterine hemorrhage is usually fatal. In 12- to 21-year-old mares rupture of the uterine vessels and sudden death due to hem-

orrhagic shock may occur before, during or after an apparently normal gestation and parturition. The middle uterine artery was most commonly involved but the iliac or utero-ovarian arteries occasionally were affected. Prepartum rupture occurred most often in the latter vessel.⁴¹ Most fatal hemorrhages occur intraperitoneally due to rupture of the large vessels in the broad ligament caused by degenerative changes in the vessel wall, especially in mares or by torsion of the uterus or prolapse of the uterus. Definite symptoms of severe hemorrhage may be observed, indicated by weakness, depression, very rapid pulse and respiration rates, and pale mucous membranes and death within a few hours.³⁴ If the operator promptly enters the peritoneal cavity through the abdominal wall in the flank region or through the uterine wall in prolapse, he may be able to control bleeding by ligating the ruptured vessels. The prognosis is very poor in these cases as severe hemorrhage, shock, and death may occur in rapid succession. In mares early signs of colic, sweating, pain, rapid pulse rate and moderate anemia may occur due to rupture of a uterine vessel with relatively slow loss of blood between the two layers of the broad ligament causing a large hematoma. If this ruptures intraperitoneally within the next few weeks then severe acute signs of shock, rapid weak pulse, anemia, prostration and death follow. If hemorrhage is severe enough to cause clinical symptoms, blood transfusions of 2,000 to 8,000 ml. or more in large animals, saline injections, gelatin or other types of solutions designed to maintain blood pressure should be given, and repeated as often as necessary. The mare should be sedated with a large dose of a tranquilizer and closely confined.

In lacerations or ruptures of the genital tract preventive treatments to control infection should be used, such as the administration of sulfonamides, antibiotics, or local mild antiseptics. Thrombosis of the larger uterine arteries and veins is occasionally observed or described in animals. Thrombi are seen most often in the veins following prolapse of the uterus or uterine torsion when circulation has been restricted. Occasionally an aneurism of the middle uterine artery may be palpated on rectal examination after parturition in the cow, or a hematoma in the broad ligament of the mare. Adhesions between the genital tract and ovaries and other pelvic and abdominal organs and tissues may occur following postpartum hemorrhage.

Subinvolution of the placental sites formerly called "persistent decidual reaction" and occasionally mistakenly called uterine chorioepithelioma is observed infrequently in bitches and is characterized by a persistent discharge of blood from the vulva for 30 to 60 or more days after whelping.^{2,6,31} Subinvolution of the placental

sites should be differentiated from cystitis, uterine tumors, acute or chronic metritis, and cystic endometrial hyperplasia. This condition has been reported¹¹ in Alaskan Malamutes and in some cases causes a decline in the hematocrit. The bloody discharge was nonfetid and it ceased about two weeks before true estrus. Conception occurred normally.

Normal involution of the canine uterus requires about 12 weeks. In a study of 95 postpartum bitches' uteri 20 had subinvolution of one or more placental sites indicating that hormonal influences or infection were probably not causative factors.² The lesions of subinvolution of certain placental sites include sites that are twice normal size and hemorrhagic and on microscopic section several large collagen masses, dilated endometrial glands, and numerous "trophoblast-like (decidual) cells," are usually seen.^{2,6,31} In the normal bitch these latter cells regress and disappear spontaneously within a month postpartum. The pathogenesis of subinvolution is unknown. Further studies are indicated. The discharge of blood in affected bitches is most noticeable about the time of weaning. Most bitches recover spontaneously without or despite various treatments including progesterone.^{4,31} Occasionally a few bitches become anemic and ovariectomy and blood transfusions may be necessary.^{2,29} Most recovered bitches subsequently breed and whelp normally.

Lacerations and Contusions of the Birth Canal and Adjacent Structures

After each dystocia operation the operator should carefully examine the uterus and genital canal for evidence of contusions and lacerations. Minor lacerations and trauma are common especially to the vulva, vestibule and cervix in uniparous animals after forced extraction or fetotomy. Since the vagina is freely dilatable it is less often injured. Minor lacerations are of little importance and usually heal promptly without treatment. Although the more severe lacerations of the cervix in cows seldom result in rupture, a few veterinarians recommended that these be immediately sutured through the vagina to prevent the healed cervix from gaping or being ectopic, and to prevent the formation of excessive connective tissue in the cervix. Mild lacerations of the endometrium heal promptly. These may be aided to heal by the injection of oxytocin which favors uterine contraction. Vaginal lacerations generally occur near the vulvovaginal border. Lacerations of the vulva are usually mild when parturition is normal. Occasionally the mare, especially if sutured by the Caslick operation, will

tear the vulva in a normal parturition. In the mare and cow vulvar and vestibular lacerations are quite common when strong traction is applied too rapidly to permit normal dilation of the vulva. Mild lacerations need not be sutured. Deep lacerations or episiotomy incisions should be promptly sutured after parturition with deep vertical mattress nylon or catgut sutures to prevent gaping and scarring of the vulva and thereby predisposing to vulvitis and vaginitis. Parenteral antibiotics should be administered. Certain mares and cows with relaxed, flaccid, tipped or horizontal vulvas should have the dorsal half or two-thirds of the commissure sutured as described under the Caslick or vulva-suturing operation to control postpartum infection. Lacerations, if not sutured, commonly become infected especially if the tissue is traumatized or devitalized or if metritis and retention of the fetal membranes are present. Infected lacerations of the vulva and vestibule result in pain, swelling, and persistent straining or "wind sucking"—conditions which are particularly undesirable in the postpartum cow or mare. Recommended treatment consists of parenteral antibiotics and local treatment of lacerations by suturing early, or application of protective mild antibiotic dressings. Tetanus antitoxin or a booster injection of toxoid should be administered in the mare.

Hematomas and Contusions of the Vagina or the Vulva are occasionally noted in all animals but most commonly in the mare and sow. They may be confused with or mistaken for tumors or prolapse of the vagina or bladder. Hematomas involving the vaginal wall are found on examination of the genital tract. In rare instances they may be observed protruding between the vulvar lips. A temporary Caslick's operation closing the dorsal portion of the vulva will prevent the protrusion, contamination and irritation of the vaginal hematoma. Hematomas of the vulva are readily noted. If left alone they are usually absorbed within 1 to 3 weeks. In some cases they may rupture through the mucous membrane or the owner of the animal may request that they be removed; this can be done by incising, removing the clot and carefully suturing to control further bleeding and to obliterate the area that contained the large blood clot. This should not be performed until after 3 to 4 days following parturition. In occasional cases diagnosed early, ice packs or cold water spray might be indicated. Contusions of the vulva, vagina, and cervix resulting in swelling and edema, occur most frequently due to trauma during fetotomy operations or from external injuries.

Occasionally in the sow hematoma of the vulva may rupture and cause serious or fatal hemorrhage. To control or prevent such hemorrhage the labial branch of the internal pudendal artery should be ligated by inserting a

heavy Vetafil or umbilical tape suture at the junction of the vulva and the semimembranosus muscle in the dorso-lateral quadrant of the vulva, at about 2 to 3 o'clock (9 to 10 o'clock) into lumen of vulva and out again through the dorsal mucosa and skin at about 12 to 1 or 11 to 12 o'clock. This ligature can be removed in 5 to 7 days. Mechanical protection of the vulva can be provided by placing a piece of plywood behind the sow at a 60 to 70 degree angle to the floor of the farrowing stall with the uppermost end nearest the sow.^{12a,27}

Occasionally a blow or a kick in the region of the clitoris will result in marked edema of the clitoris and vulva in the mare. In most cases these swellings subside fairly promptly and should not be confused with edema from the udder that may extend upward and involve the vulva in cattle. If edema is severe, alternate cold and hot applications, massage, and in certain cases small punctures or incisions through the mucous membrane may release the fluid or reduce the edematous swelling of the vulva.

Contusions of the Maternal Pelvic Structures by the fetus or by instruments used during fetotomy may result in intrapelvic hematomas and hemorrhages, or may cause obturator or gluteal paralysis by injury to those nerves at parturition. **Gluteal paralysis** is rare and is described only in the mare; it is brought about by contusions caused by a bony prominence on the fetus pressing on the gluteal nerve as it passes over the bony portion of the lumbosacral articulation or ilium. This may be a bilateral or unilateral injury and usually occurs in mares that apparently give birth without difficulty. In this condition the mare will show some difficulty in rising and may require assistance in rising if the injury is bilateral. The gait is characterized by a definite lameness and weakness of the affected limb. After a few days to a week, a marked atrophy of the gluteal muscles on the affected side is very noticeable. After a few weeks the lameness or paralysis of the limb becomes less observable but it may take 6 to 18 months for complete recovery. The prognosis is favorable. Treatment consists of good nursing and possibly nonsteroidal antiinflammatory drugs such as phenylbutazone. The mare should be in a large, well-bedded box stall with good footing. In some cases slings or assistance in rising may be necessary for several days or a week. Affected mares should not be allowed to struggle or exert themselves in rising. External applications, massage, or other treatments are of no value.

Calving Paralysis or Obturator Paralysis may occur in the mare or cow but is most common in the latter. It is much more prevalent in heifers than in cows. Injury to the obturator nerve and lumbar (L6) roots of the sciatic (ischiatric) nerves¹⁴ is observed so often in hip lock in the anterior presentation that before this type of dystocia is

relieved calving paralysis should always be suspected. An examination is done to inform the owner of the paralysis before the obstetrical operation so that later the veterinarian will not be blamed for the injury. The condition may affect one or both rear limbs. If the cow is down and laboring with a hip lock condition, the underneath leg and nerves is the one most commonly and severely affected. This contusion is usually caused by the bony tuberosities of the fetal hips, especially the greater trochanters, contusing the obturator and sciatic nerves as the nerves either pass over the bony prominence of the lumbo-sacral articulation, or as it passes down the shaft of the ilium before it enters the obturator foramen. Calving paralysis in heifers is very common in the hip lock condition that has existed for several hours. Yet when strong forced extraction has to be applied manually or with the fetal extractor to draw a large fetus through a heifer's pelvis, calving paralysis seldom occurs. Injury to the obturator and sciatic nerves causes a paralysis of the medial and caudal adductor muscles of the thigh and partial loss of tibial and peroneal nerve function. This seriously effects the total support of the pelvic limb.¹⁴ If the condition is unilateral the cow can stand on the unaffected limb and as it walks the affected limb is moved stiffly forward and is abducted so the foot is placed on the ground 8 to 24 cm. lateral from the normal position. The cow is unsteady and is likely to slip and fall. If both nerves are bilaterally contused and injured, both limbs are stiffly extended and abducted and the cow usually is unable to rise. If assisted to its feet and the hind limbs held together, the animal can stand but when it takes a step the affected limb is extended cranially and abducted and the cow falls to the ground.

If paralysis is severe and bilateral the prognosis should be guarded. If the paralysis is mild and the animal can walk, even though with difficulty, the prognosis is good. In most cases the condition improves rapidly and in 2 to 7 days the animal is able to walk quite well. Other cases may take longer for recovery, even up to 4 to 8 weeks. In rare cases the damage to the obturator and L6 roots of the sciatic nerves may be severe and permanent. The chances for recovery after 2 to 3 weeks are poor, and slaughter may be recommended. The only treatments of any value are good nursing and tying the animal's rear legs together in order to prevent excessive abduction, over 35 to 45 cm., and possible complications of a dislocated hip or fractured pelvis. The use of straps such as hame straps around the pasterns tied with a length of rope or chain aids in preventing abduction of the limbs and helps the animal to rise. Some veterinarians strap or tie the hocks together but it is difficult to fasten straps or ropes above the hocks tightly enough so that they do

not slide down, and yet loosely enough to allow movement of the gastrocnemius tendon. In the mare and occasionally in the cow the use of slings may be of value in assisting the animal to rise to its feet and supporting it for a short period. The animal should be kept in a well-bedded large box stall or pen, preferably with a dirt floor. Under such conditions dairy cattle should be milked by rolling the cow first to one side and then to the other. Possibly treatment with the anterior inflammatory non-steroidal drugs such as phenylbutazone may be helpful.

Peroneal paralysis due to injury or trauma to the peroneal nerve as it passes over the dorsolateral condyle of the tibia and fibula is observed in cattle confined in stanchions with their rear parts over the edge of the gutter. It occurs most often in cows with dystocia and hypocalcemia that struggle to rise (See Figure 94). Injury to the peroneal or fibular nerve results in anesthesia of the cranial surface of the fetlock and metatarsus and paralysis of the muscles that extend the digit and flex the hock, namely the long and lateral digital extensors, the peroneus tertius and the anterior tibial muscles. This results in knuckling of the fetlock and dropping of the hock and difficulty in rising, standing and walking.²⁵ As with injury to the obturator nerve good nursing care and close confinement are essential. A rigid supporting bandage to the lower leg may prevent knuckling of the fetlock. Peroneal paralysis should be differentiated from rupture of the gastrocnemius muscle and posterior paresis due to

Figure 94. Bilateral peroneal nerve injury and paralysis in a cow.

lesions in the spinal cord. Rarely other paralyses may be observed following dystocia or injury at the time of parturition including brachial or radial nerve paralysis in stanchioned cattle in which the forelimb was caught in the manger and forcefully extended. These miscellaneous nerve paralyses have been well-demonstrated.⁶²

Rupture of the gastrocnemius muscle is apparently secondary to Zenker's degeneration of the muscle and usually follows considerable struggling or efforts to rise during dystocia, hypocalcemia or after epidural anesthesia (See Figure 95). Zenker's degeneration may be due to excessive muscular activity especially in cows that have been confined for long periods and provided very limited exercise. Furthermore it is seen more often in states where selenium is known to be deficient.⁴² Eleven cases of rupture of the gastrocnemius muscle were reported,³⁶ in 3 high-producing Holstein herds in one year in south-central New York State where selenium is deficient. The condition may be diagnosed by the inability to support weight on the affected leg, the flaccid gastrocnemius tendon and the hard swelling due to edema, hemorrhage and Zenkers' degeneration in the gastrocnemius muscle. Mild cases that can stand may recover in several weeks if they are confined and possibly a support such as a metal brace or Thomas splint provided. In most advanced cases slaughter is indicated. Prophylactic injections of selenium or selenium provided as a trace mineral may be indicated in selenium deficient areas.

Rupture of the Uterus, Cervix, Vagina, and Perineum

Uterine or Vaginal Rupture may occur in any species.^{3,22,33,35,43,46,48,55} It may be due to prolonged dystocia

Figure 95. Unilateral rupture of the gastrocnemius muscle in a cow during postparturient paresis.

with fetal emphysema; torsion of the uterus, in which transverse rupture may occur in prolonged cases; to improper manipulations and traction on the fetus; to fatigue of the operators, or to an accident in fetotomy operations in large animals or to forceps removal of a fetus in bitches; to protruding bones of the fetus after fetotomy; or due to inexperienced manipulations of the fetus by laymen. The author has observed a ewe with maternal intestines in the vagina due to a ruptured uterus caused by an owner with large hands attempting to relieve a dystocia. For this latter reason and others associated with prolonged dystocia, the uterus and vagina should be carefully examined prior to any obstetrical operation to be certain that a rupture of the uterus, cervix, or vagina is not present. Rupture produced by the operating veterinarian even if due to his fatigue is extremely embarrassing and should be avoided. In 26 cases of uterine rupture in cows out of 1004 referred obstetric cases to a college clinic, 7 cows had uterine torsion, 7 had oversized fetuses, 4 had emphysematous fetuses, 3 had fetal monsters and 2 had an immature pelvis. Nineteen of the 26 cows recovered after surgery.³⁵ In the birth of fetuses with long extremities, such as the foal, vaginal rupture may be due to improper presentations, positions, and postures, especially dorso-pubic positions, anterior longitudinal presentations with the hind limbs extended beneath the body, transverse ventral presentations, and when the forefoot or feet are crossed over the neck. This latter presentation may result in rupture of the vagina, rectum and perineum (See Figure 96). Rupture of the uterus is common in the mare in rotated bicornual pregnancy if traction is applied to the fetus. Forced extraction of a bovine fetus in a normal presentation may cause rupture of the uterus, cervix, or vagina by forcing these structures against a sharp bony prominence occasionally found on the cranial portion of the pubic symphysis. Transverse rupture of the uterus may be caused by retraction or contraction rings of the uterine wall; or rupture of the cervix if the cervix is poorly dilated; rupture of the vagina may occur if perivaginal fat is pushed caudally as the fetus is forcibly drawn toward the vulva. In this latter instance the vaginal wall near the hymenal ring or vestibular-vaginal border ruptures to allow the escape of the fat. A similar tear or rupture of the vagina occasionally results in a prolapse of the bladder. Forced extraction with the fetus in abnormal posture or position or in torsion of the uterus may cause a portion of the uterine or vaginal wall to be caught by a deviated extremity and folded upon itself to produce a rupture. A dry, emphysematous fetus and a swollen, dry birth canal are conducive to rupture of the vaginal, cervical, or uterine walls when strong traction or repulsion is applied. In one cow rupture of the uterus occurred

Figure 96. Rupture of the rectum, vagina and perineum of a mare caused by dystocia. This picture was taken 8 weeks after the accident.

apparently due to extensive severe adhesions of the uterus to the adjacent viscera. Administration of oxytocin to dogs or other animals with dystocia and/or uterine torsion may cause uterine rupture.²⁶ (See Figure 97.) In a few cases spontaneous uterine rupture may occur due to unknown causes. After each dystocia case the veterinarian should carefully examine the uterus and birth canal for the presence of a rupture of the uterus or birth canal in order that it may be treated promptly or in hopeless cases the cow may be slaughtered and some value thereby salvaged.

The symptoms and prognosis of rupture of the genital tract vary with the animal and the portion of the genital tract involved; the size of the rupture; the character of the rupture, whether regular or irregular, horizontal or vertical; the nature of the uterine contents; the amount of uterine contents that have escaped into the abdominal cavity; and whether or not intestines or bladder have prolapsed through the rent in the wall of the genital tract. In a mare unless the uterine rupture is small and no infection was present in the uterus, a fatal peritonitis usually develops rapidly. In the cow or other domestic an-

imal rupture of the uterus due to an emphysematous fetus rapidly produces a fatal peritonitis. A similar termination can be expected in a uterine rupture in any animal in which the uterine contents are severely infected. In rare cases in cows, a rupture of the uterus may occur which releases a live or recently dead fetus into the abdominal cavity. Occasionally the symptoms of uterine rupture in the cow may be slight, but usually anorexia, lack of ruminations and rumen contractions, restlessness, rapid pulse and respiration rates, and cold extremities are present. The body temperature is usually normal or subnormal but may occasionally be elevated. If infected fetuses and material are released into the abdominal cavity, acute, severe septicemia or shock symptoms develop rapidly. Prostration, and death usually occur in 1 to 2 days. In less severe cases peritonitis is less marked and the animal may survive with the fetus becoming walled off, or death may occur in 3 to 7 days. The fetus may be removed through a laparotomy incision and the uterus sutured. With proper technique and aftercare some of these cases will survive. In small ruptures of the uterus after parturition or dystocia when no infection is present and the rent is in the dorsal half of the uterus some cows have survived after repeated doses of oxytocin and with parenteral antibiotic therapy. In these cases penicillin (three to six million units), and streptomycin (4 to 5 gms.), or **Aureomycin** or **Terramycin** or tetracycline in 2- to 4- gm. doses or similar antibiotic therapy is given daily to the average 800- to 1000-lb. cow or mare. One to two grams of the latter broad-range antibiotics should be placed in the uterus to control intrauterine infection. The administration of antibiotics and of sodium sulfonamides in concentrations of 5 to 10 percent, through the abdom-

Figure 97. Transverse rupture at parturition of the isolated uterine horn containing canine fetuses—this condition apparently followed trauma or torsion of the horn at about midgestation resulting in the separation of the horn from the rest of the uterus, note the scarring.

inal wall into the peritoneal cavity might be indicated in some cases. Occasionally the uterine rupture is large enough to require suturing. This is difficult in cows, but may be performed by working through the birth canal, using continuous or mattress sutures to bring the serous surfaces of the uterus on either side of the rupture into apposition. Some veterinarians have recommended prolapsing the uterus or vagina by pulling it to the outside through the birth canal and then suturing the rent and replacing the organs. A few veterinarians have successfully prolapsed the severely lacerated uterus through the birth canal and amputated it.¹³ In large animals suturing the uterus through a laparotomy incision may be successful or it may be sutured in this manner with assistance through the birth canal. The presence of a retained placenta, septic metritis, an atonic uterine wall, or prolapsed intestines results in a poor prognosis. In most severe cases of uterine rupture in the cow, ewe, or sow the prognosis is poor and slaughter is usually advised if the animal is in an otherwise satisfactory condition. Even if recovery takes place, the future breeding life of that animal is very questionable, as chronic perimetritis and peritonitis are the probable results. In the bitch uterine rupture, as in the larger animals, is usually characterized by anorexia, depression, weakness; in the early stages an elevated and in late stages a depressed body temperature; rapid pulse and respirations; cold extremities; constipation, or fetid diarrhea; pale mucous membranes especially if there is internal hemorrhage or shock; followed by prostration and death in 1 to 3 days. In the bitch laparotomy and hysterectomy, if performed early, together with flushing of the abdominal cavity with warm saline solution and antibiotics, and treatment to prevent shock and infection, occasionally results in recovery of the bitch. In all species except the mare extrauterine fetuses may be walled off or encapsulated as described previously. Under no circumstances should fluids be injected into the ruptured uteri nor should manipulations of retained placentas take place. The latter should be allowed to drop from the uterus without assistance. Complete rupture of the cervix in large animals is similar to rupture of the uterus but because proper suturing of this structure is so difficult, the prognosis is poor if the rupture is extensive.

Rupture of the vagina is usually not as serious as uterine rupture and the prognosis is much better unless the rupture extends into the peritoneal cavity. Simple ruptures of the vagina especially of the lateral or dorsal wall need not be sutured unless the operator desires to do so. In most cases there is no need to suture small ruptures even on the floor of the vagina, but some veterinarians prefer to do so in order to prevent a possible perivaginal abscess if a retained placenta or metritis occurs. In rare cases these perivaginal abscesses, which may also occur

secondary to an infected perivaginal hematoma, become large and finally after 2 to 6 weeks or more break out between the vulvar lips and the tuber ischii. Mild wounds of the vagina heal rapidly. Recto-vaginal fistulas due to rupture of the dorsal wall of the vagina and ventral wall of the rectum are occasionally observed, especially in mares in which parturition is violent. If these are noted promptly they should be sutured immediately, care being taken that the rectal wall is tightly sutured in a transverse manner. Suturing of the vaginal wall is not as essential. If 24 to 48 hours pass before this condition is noticed it usually is impossible to correct at that time and one must wait until the edema, swelling, granulation tissue, and wound edges have completely healed before surgical intervention is undertaken to correct the fistula.^{57b} In these chronic cases some feces and a mucopurulent discharge are expelled from the vulva. If the fistula is small, the rectum may be packed with cotton and the vagina douched with saline before breeding. If pregnancy occurs the fistula may then be sutured without the loss of a breeding season.

Due to straining, rupture of the uterus may be followed by prolapse of the intestines into the uterus or birth canal or through the vulva. If rupture of the vagina or cervix extends into the peritoneal cavity it may also result in prolapse of the intestines. The bladder or fat may prolapse through a rupture in the ventral or lateral wall of the vagina. These conditions will be discussed later.

Rupture of the Perineum and Vulva is observed chiefly in the mare but may occasionally be observed in cows and possibly ewes when excessive traction is applied to rapidly remove the fetus. Thus the vulva and perineal region may be ruptured before it has time to dilate gradually. This condition has been rarely observed in dairy heifers; hemorrhage may be severe and in some cases fatal.^{59,60} More often it is observed in the mare in which the forelegs and even the nose in anterior presentation or in the dorsopubic position the long limbs of the equine fetus may be pushed dorsally into the vaginal roof and rectal floor. This sacculated portion, due to the violence of parturition, is forced into the dilated anus. (See Figure 96.) The vagina and rectal floor rupture, the feet protrude from the anus, and as the fetus is expelled the vulva and anus are torn longitudinally. In rare cases the vulva and vestibule remain intact and the fetus is expelled through the ruptured rectum, anus and perineal tissues. The presence of the ruptured perineum or "gill flirter" condition causing the rectum and vestibule to become a continuous cavity or "cloaca" is readily noted. As in recto-vaginal fistula it is advisable to correct and suture the rupture immediately, paying particular attention to suturing the rectal wall and anal sphincter. If the operation is not performed at once it must be postponed

about 6 weeks until the swelling and granulation tissue has subsided and the wound has completely healed.^{57b} If these mares are not operated upon the feces drop into the vagina, the vulva and vaginal mucous membranes are irritated, and the animal sucks air, pneumovagina, and there is a profuse discharge of mucus and feces that soil the rear parts. This condition is seldom observed in the cow but mild vulvo-anal lacerations and ruptures are seen especially in beef heifers and rarely in ewes. Proper use of episiotomy operations in cattle would prevent this condition. The prognosis for the life of the patient is good if hemorrhage or shock is not immediately fatal. If the condition is not corrected, the future breeding life of the animal is poor. Very rarely "gill-flirter" mares may conceive. The prognosis for this operation is usually guarded. For a discussion of this operation and that of the recto-vaginal fistula the author recommends the standard veterinary surgical texts the detailed anatomy of the perineal region of the mare,²³ and a description of the operation in the mare and cow.^{1,5,8,50,57b} The author particularly commends the technique of a two-phase operation for the surgical repair of third degree perineal lacerations and rectal vaginal fistulas.¹ The first operation produces a firm shelf of tissue between the rectum and vagina by suturing the scarified tissues between the rectum and vagina and the vaginal mucous membrane but not placing sutures through the rectal mucosa. In about 2 weeks the second operation is performed that closes and reforms the perineal area, the anus and vulva.

Rupture of the pelvic and abdominal organs other than the genital tract during birth or dystocia have been described rarely in the cow and mare. A rupture of the rectum in cows has been described.^{16,56} Four cases were reported²⁰ where the free end of the cecum ruptured through the rectal wall. In all these cases the fetus was in posterior presentation. Rupture of the intestine of cows has been described.^{47,48} Rupture of the cecum and ventral colon have been reported during parturition in the mare.^{17,28,57a} Death always occurred in mares after rupture of the intestine and usually occurred in cattle. A few cows operated on immediately after the rupture survived. Rupture of the bladder may occur occasionally in the mare and cow.^{7,45,58b} In very rare instances rupture of the diaphragm in a mare may result from violent straining.

Prolapse of the Abdominal or Pelvic Viscera

Prolapse of the Intestines may occur through a rupture or laceration in the uterus, cervix, or cranial portion of the vagina at the time of parturition. The intestines

may only enter the uterus or may pass into the vagina and out the vulva. This condition should be differentiated from a **Schistosomus reflexus** or a ruptured umbilical hernia of the fetus. The prognosis is invariably poor, since the dystocia causing the rupture usually is severe, contamination and infection of the intestines and abdominal cavity is probable, and it is difficult to control the intestines to prevent their injury during removal of the fetus. Slaughter of the animal is usually recommended. In occasional cases in which infection or trauma to the intestines is minimal, replacing the intestines, suturing the rupture and removing the fetus might be possible. Closure of the rupture wound in the uterus may be accomplished through the birth canal, or probably a better approach would be through the laparotomy incision after a cesarean operation. If the intestine is traumatized or severely contaminated resection of a portion of it may be necessary. Perforating lacerations or ruptures of the cervix and anterior vagina are sutured through the birth canal.^{21,58} Aftercare consists of carefully suturing the rupture, and administering local and parenteral antibiotic treatment to control peritonitis, as recommended for the handling of uterine rupture. **Left displacement of the abomasum** is a fairly common occurrence after parturition in the cow.

Prolapse of the rectum may occasionally occur in any animal in dystocia or other causes associated with persistent violent straining and a relaxed anal sphincter. Slight eversion of the rectum at parturition is common, but severe prolapse is rare. In the mare prolapse of 2 to 3 feet of rectum is usually fatal since rupture of the rectum or small colon often occurs secondarily. If prolapse of the rectum begins in the mare it should be controlled by holding the rectum in place forcibly with a towel over the anus until the fetus is expelled or withdrawn. In other species prolapse is neither as serious nor as extensive. It should be prevented if possible or replaced promptly before or after the fetus is removed. A purse-string suture of heavy nylon material around the anus is often indicated after replacement. If unnoticed until trauma and edema are present, surgery, including either the sub-mucosal resection reefing operation or amputation, together with retaining sutures may be necessary to replace and maintain it in position. The different types of equine rectal prolapses and their correction was reviewed.⁵²

Prolapse of the Bladder may occur in all species but it is seen most commonly in the larger domestic animals before or after parturition. Prolapse of the bladder usually takes place through a rupture or tear in the floor of the vagina and the bladder is noticed hanging from the vulvar orifice after parturition. Due to the sharp bend in the urethra the prolapsed organ fills with urine. This con-

dition must be differentiated from eversion of the bladder through the urethra, vaginal or vulvar tumors, cysts, a mass of fat protruding through a rupture in the floor of the vagina, or vaginal or vulvar hematomas.⁵¹ If the bladder is distended with urine it may be replaced and the urine forced out or it may be drained with a needle before replacing. The external surface of the bladder should be carefully cleaned, covered with an antibiotic solution, and the organ replaced. The rupture in the vaginal floor permitting the prolapse should be sutured and the animal placed on parenteral antibiotics.

Eversion of the Bladder has been described mainly in the mare, in which the urethra is large and parturition violent. It has only very rarely been seen in the other animals such as the cow or sow.^{17b} In rare and serious cases in the mare intestines may prolapse into the everted bladder and prevent reduction.^{24,55} Eversion of the bladder may occur before or during parturition. It seldom if ever obstructs the passage of the fetus but occasionally the everted bladder and urethra may be severely traumatized when the fetus passes through the vestibule. Eversion of the bladder is easily recognized, as this organ is attached to the area of the ventral floor of the vulva where the urethra orifice is normally located. The everted bladder is pear-shaped. The openings of the two ureters drip urine and the mucous lining of the bladder may be noted and felt. If the everted bladder is small it may not become exposed through the vulvar lips until the animal lies down. In handling eversion of the bladder, the bladder should be thoroughly cleansed. If a tear or rupture is present it should be sutured or if a portion is damaged severely that portion might be removed and the edges of the incision sutured. Following the injection of epidural anesthesia, the operator should use both hands to compress the bladder and force it back through the urethra. The bladder should be massaged and pressed through the vagina floor until it is in its proper position. Aftercare consists of irrigating the bladder with saline solution and antibiotics and administering antibiotics parenterally so that the urine will contain a high concentration of the antibiotic for a number of days. It is seldom necessary to place a stitch in the external urinary meatus to prevent another eversion once the fetus has been removed and labor has ceased.

Prolapse of Perivaginal Fat may occur through a small rupture of the caudal portion of the vagina during forced extraction of the fetus especially in fat dairy or beef heifers. These masses of fat should be differentiated from prolapse or eversion of the bladder, as they are likely to resemble those structures. On examination, the vaginal rupture, which is usually quite small, may be found at the base of the prolapsed mass of fat. This fat may be

cut off with a knife or scissors, as there will be little bleeding. The vaginal rupture may be sutured or left to heal without suturing. Sulfonamide powder or antibiotics are customarily placed in the wound before suturing. The prognosis is good as a perivaginal abscess seldom develops.

Prolapse or Eversion of the Uterus may be called casting of the "wethers" or casting of the "calf bed." It is observed most commonly in the cow and ewe, occasionally in sows,^{12a} and rarely in the bitch, queen and mare. It occurs most often immediately after parturition and occasionally up to several hours afterward. In rare cases it may occur 48 to 72 hours after parturition. In bitches there may be rare cases of prolapse of one horn while fetuses are still in the other horn.¹⁰ Prolapse of the uterus is predisposed by long mesometrial attachments; violent or strong tenesmus; a relaxed, atonic, flaccid uterus; retention of the placenta especially at the ovarian pole of the gravid horn in cows and of the nongravid horn in mares; and by excessive relaxation of the pelvic and perineal region. In dairy cows it is commonly seen in confined or stabled cattle during the winter months that calve in a stallion with their rear parts sloping downwards and hanging over the gutter. The use of great force in forced extraction of the fetus predisposes to tenesmus after relief of the dystocia. If the uterus is not contracting it frequently prolapses immediately after relief of the dystocia. Prolapse of the relatively flaccid uterus in older cows is frequently associated with hypocalcemia at parturition.^{5,32} Dystocia associated with a mild hypocalcemia was present in 42 percent of 26 beef cows with uterine prolapse compared with only 6.7 percent of the control animals.³⁸ In dystocia when the uterus is contracted tightly around a dry fetus, forced extraction is likely to result in prolapse of the uterus. Prolapse of the uterus is seen most commonly in pluriparous dairy cows but is not infrequent in poorly grown, thin, debilitated dairy heifers. Prolapse of the uterus was frequently observed in sheep in Australia due to a hyperestrogenism from eating clovers high in estrogenic hormones. Prolapse of the uterus is apparently not hereditary although occasionally it may be seen in dam and daughter. There was a probable hereditary basis for prolapse of the uterus and vagina in Hereford cattle.⁶¹ A low plane of nutrition may also be a factor. Prolapse of the uterus very rarely occurs following prolapse of the vagina prior to parturition despite the common belief among owners that if the cow prolapses the vagina prepartum it is apt to suffer prolapse of the uterus postpartum. Prolapse of the uterus rarely recurs at a subsequent parturition.

In a Norwegian study³² of 955 cows treated by 171 veterinarians for prolapsed uterus, 27 percent occurred

within 1 hour, 48 percent within 3 hours, 65 percent within 6 hours and 90 percent within 15 hours after calving. Numerically uterine prolapse was most common in primipara but the highest incidences, 3 times higher than first and second calvings, occurred in cows at their fifth or greater calving where it was related to hypocalcemia. Of 506 cows that prolapsed, only 18 had prolapsed at 1736 prior calvings, an incidence of about 1 percent. About 1 percent of cows with vaginal prolapse prior to calving developed uterine prolapse after calving. At the time of uterine prolapse 56.6 percent of the fetal membranes were still attached. Of 955 cases 83 percent recovered. Of those not surviving 35 percent died before or during treatment, 24 percent were slaughtered because of uterine injury or irreplaceable prolapse, 16 percent died shortly after treatment and 24 percent died or were slaughtered later in the course of the illness. Deaths were highest in cows with both a prolapsed uterus and hypocalcemia. Of 407 cows with prolapse that were rebred 78.4 percent conceived. Breeding after 90 days postpartum resulted in normal conception rates. In only 6 cows did the prolapse reoccur within a few days. Thus suturing the vulva to prevent subsequent prolapse is not necessary.³²

The symptoms of prolapse of the uterus are obvious. (See Figure 98.) The animal is usually recumbent but may be standing, with the uterus hanging to the hocks. Retention of the placenta is likely. The fetal membranes and/or mucous membrane of the uterus is exposed and usually covered with feces, straw, dirt, or blood clots unless of very recent occurrence. The uterus is usually enlarged and edematous especially if the condition has existed for 4 to 6 hours or longer. Excellent illustrations of the condition in various species of animals have been made.¹⁰ In the cow the gravid horn prolapses or everts sufficiently so that the cervix is usually present at the vulva. The nongravid horn is inside the peritoneal surfaces of the prolapsed gravid horn and does not evert because of the strong intercornual ligament. The opening of the nongravid horn may be observed as an oval or slit-like orifice near the vulva on the ventral or lateral side of the prolapsed gravid horn. Prolapse of the uterus in the ewe is similar to this condition in the cow. In the other species, horses and multipara, usually one horn—or rarely both horns—may be prolapsed or everted. Ninety percent of the uterine prolapses in sows were bicornual with the initial invagination occurring in the uterine body.⁵⁴ In cows the initial invagination also occurred at this site. Prolapse or invagination also occurred at this site. Prolapse or invagination of the uterine horn should be differentiated from a prolapse of the vagina. In the bitch and queen palpation of the abdomen may reveal the

Figure 98. Uterine prolapse in a Hereford cow.

thickened invaginated uterine horn and abdominal pain. In the mare the uterine body may compose the major portion of the exposed everted uterus. In most animals prolapse of the uterus results in mild to moderate symptoms of tenesmus, restlessness, pain, anxiety, anorexia, and an increase in pulse and respiration rate. In cases with complicating factors of internal hemorrhage due to rupture of one of the uterine vessels, shock, incarceration and ischemia of intestines present in the peritoneal sac of the prolapsed uterus due to pressure obstructing the circulation of the intestines, or other diseases such as hypocalcemia may cause the animal to be recumbent. A very rapid, weak pulse, irregular, rapid respiration rates, pale mucous membranes, expiratory grunt, and prostration with severe depression and inability to rise indicate serious complications. When intestines or excessive hemorrhage with a large blood clot are present in the peritoneal sac formed by the prolapsed uterus, the bovine uterus may be 30 to 45 cm. or more in diameter. In ewes, intestines frequently are present in the prolapsed uterine horn.

The prognosis in uterine prolapse varies greatly. In

most cases in which the condition is observed early, the veterinarian called promptly, the cow able to stand and the uterus not severely injured, the prognosis for the life of the cow is good. In 158 cases of prolapse of the uterus in dairy cattle seen from 1943 to 1953 in the Ambulatory Clinic of New York State Veterinary College, the mortality rate was 18 percent. If cases obviously complicated by other conditions were eliminated the mortality rate in cows in good physical condition at the time of the operation would probably be 5 percent or lower. The prognosis is poorer in beef cattle on pasture, where the condition may not be observed as early and aid secured promptly.⁶¹ The animals' future breeding history may be good or poor depending upon the severity of the uterine lesions, the promptness of treatment and the rate of involution. If the uterus is grossly contaminated, or dried due to exposure to the sun, or if lacerations are present, the prognosis is more guarded due to the possibility of a septic metritis, perimetritis or peritonitis developing, and the prognosis for the future breeding life of the animal is questionable. It is surprising how much trauma, irritation, and contamination the uterus can withstand. Upon replacement of the organ this infection is overcome, the traumatic lesions heal, and the animal recovers. In other cases, with the animal prostrate, unable to rise and conditions complicated by shock, internal hemorrhage, or incarceration of the intestines, the prognosis is usually very poor to hopeless. In the author's experience, mainly with dairy cattle, the percentage of cases of uterine prolapse that terminated fatally due to internal hemorrhage, shock, or incarceration of the intestines was high when the cows were in stanchions and the prolapsed uterus had dropped into the gutter. This is further reason for having box stalls for calving cows or having them calve on pasture. If other diseases are present, such as hypocalcemia or obturator paralysis, the prognosis is based on the severity of those conditions as well. In cattle in which the uterus is so badly damaged or diseased that replacement cannot be considered and amputation of the uterus is the only recourse, the prognosis is poor although some of these cases may survive.

In the ewe the prognosis for prolapse or eversion of the uterus is similar to that of the cow. In the mare the condition is more serious, but if the animals are treated promptly most will survive. Amputation of the uterus in the mare should seldom if ever be attempted since it is indicated only when the uterus is severely traumatized and lacerated, and then the prognosis is extremely grave. In the sow the prognosis is poor as extensive prolapse usually results in internal hemorrhages and shock. The author has observed 5 or 6 cases of prolapse of the uterus in the sow and all were either dead on his arrival at the

farm or died with 15 to 30 minutes. A few cases of prolapse of the uterus in sows have recovered following a laparotomy or replacement.^{5,37} In the bitch and queen the prognosis is fair to good even though the condition is rather difficult to handle because of the length of the uterine horns and the inability of the operator to aid replacement with his hand and arm as in the larger domestic animals. Laparotomy and replacement of the uterus in the abdomen may be necessary in the bitch, queen and sow. Ovario-hysterectomy is more frequently and successfully performed in the bitch and queen than in the larger animals.¹⁸ Following proper replacement of the prolapsed uterus very few cases recur in any species.

The treatment or handling of prolapse of the uterus in the cow can be made much easier if the owner is instructed to wrap the cow's uterus in a wet towel or sheet or to place it in a plastic bag to keep it moist and clean until replaced. If the cow is standing the uterus should be raised and supported level with the vulva until assistance arrives. If the cow is recumbent in a stanchion the gutter should be built up to support the uterus and keep it from hanging. This prevents the uterus from becoming edematous and may possibly prevent rupture of the uterine vessels. If possible the cow should be in or near the barn, in a clean paddock or well-bedded stall to make the operation cleaner, more convenient, and less difficult. Good light is essential. Proper restraint of the animal aids in prompt and easy replacement of the everted uterus. Epidural anesthesia should be used routinely in sufficient dosage to provide good anesthesia but at the same time to keep the animal standing. In fact some cows and mares that are down and refuse to stand may get up promptly after epidural anesthesia is given. Epidural anesthesia controls and prevents defecation during replacement of the uterus. Elevation of the rear parts greatly facilitates replacement of the uterus. The ordinary standing posture of the cow usually gives sufficient elevation of the rear parts. If replacement is to be made even easier the fore feet may be lowered or the rear parts elevated by making the animal stand on a slope. If the animal is recumbent and refuses to rise and cannot be stimulated to do so by prodding with a sharp object or an electric prod, by rolling her tail beneath the foot, or the intravenous injection of calcium gluconate, benzydrene stimulants, or 20 to 40 ml or more of Pyribenzamine, even after giving epidural anesthesia, and since it is very difficult or harmful to elevate the rear quarters of a cow that is unable to stand either manually or mechanically, a practical effective procedure is to place ropes on the rear pasterns and draw both legs out behind the cow. This tips the pelvis ventrally and greatly facilitates replacement of the uterus. Epidural anesthesia is not nec-

essary in ewes because with the aid of one or two men grasping each hind leg the rear parts can be elevated high enough so that the uterus almost falls into place. In multiparous animals, and possibly the mare, general anesthesia may be indicated.

The uterus of the cow should be carefully prepared for replacement. It should be held level with the ischial arch or vulva during these operations. The purpose of this is to relieve pressure on the broad ligament and uterine veins as they pass over the ischial arch, and to restore normal circulation in the prolapsed uterus. This avoids further edema of the uterine wall and aids in absorption and disappearance of the edema already present. This position of the uterus permits the bladder to resume its normal position and if intestines are present in the uterus they return to the abdominal cavity. The danger of possible rupture of the vessels in the broad ligament is greatly reduced and the cow is more comfortable when the uterus is held level with the vulva. This can be done by supporting the uterus in a towel or sheet held by a man on either side of the rear quarters of the cow, or it may be supported on a wooden or metal tray, or held in the arms of the veterinarian if he is suitably attired in a rubber apron, gown, or coveralls. The afterbirth, if present, should be gently removed. Only rarely is the afterbirth attached so securely it cannot be removed. If the removal of the placenta is impossible without severe trauma and hemorrhage resulting, it may be left in place. Following replacement of the uterus, the placenta is handled in the same manner as retained placenta in a cow not affected with prolapse of the uterus.

The uterus should be cleansed thoroughly with a warm physiological saline solution, or with water to which a small amount of mild antiseptic such as chlorine or quaternary ammonium compound has been added. To cleanse the uterus thoroughly may require 5 to 10 gallons of water. Usually if the farmer is warned at the time of the call to have plenty of hot water available, it will be ready, but if it is not available, the veterinarian should be equipped to take some with him. In some cases it may be necessary to use cotton to help clean and wipe the uterus. The adjacent vulva and perineal region should be carefully washed and cleansed at the same time, particular attention being given to folds and creases in the skin. If the uterus is lacerated, torn, or perforated, it should be carefully sutured bringing the serosal surfaces in apposition. If hemorrhage from the surface of the uterus is severe the vessel should be ligated. If prolapse of the uterus has been present for some time and edema is severe, the massage of washing the uterus and the holding of the uterus level with the vulva may not be sufficient to readily reduce its size so that it can be replaced. Vig-

orous massage of the uterus with the palm of the hand, with the fingers extended but held tightly together, may be accomplished by wrapping a towel or piece of sheeting tightly around the uterus and applying pressure through the towel without the danger or possibility of forcing a finger through the uterine wall or edematous mucosa. The author believes that the practice of applying sugar to the edematous uterus on the theory that it removes fluid through the endometrium is crude, unscientific, and not necessary. Probably most of the edematous fluid removed when sugar is massaged into the swollen uterus is forced out through small fissures produced in the endometrium by the sharp granules. It may be well to palpate the bladder before replacing the uterus, since in rare instances it may be distended and require catheterizing so that it will not interfere with the operation.

Some veterinarians advise giving 30 to 50 units of oxytocin or pituitrin to contract the bovine uterus when it is ready for replacement. The author does not advise this, inasmuch as it makes the uterine wall tense, contracted, and difficult to return to its normal position without a portion of the horn remaining invaginated. On several occasions when the prolapse occurred 36 to 72 hours after parturition and oxytocin was administered before replacement, the contracted, tense uterus could not be replaced through the contracted cervix until the uterine walls had relaxed. Many veterinarians advise coating the prolapsed uterus with oil or ointment containing a mild antiseptic or antibiotic. In replacing the uterus it should be held above the level of the floor of the pelvis; the vulvar lips should be pulled apart, and first the ventral portion and then the dorsum of the prolapsed portion of the uterus should be replaced, starting at the cervical end of the uterus nearest the vulva. Since the uterus is still more or less in the form of an arc, replacing 3 or 4 inches of the ventral or concave portion of the prolapsed horn is accompanied by replacement of 6 to 8 inches of the dorsal or convex portion of the horn. In replacing the uterus, pressure should be exerted with the palm of the hand, with the fingers extended but held tightly together, to avoid perforating the uterus. Finally the ovarian pole of the uterus is pushed by the fist through the vulva, vagina, and cervix, into the uterine cavity. If the cervical rings are contracted, pulling them gently backward with one hand and working the uterus through with the other is helpful. The ovarian pole is pushed through the vagina, cervix, and uterus with the clenched fist and arm by a piston-like or shaking motion on various parts of its perimeter until the horn is completely straightened out and no invagination is present. This is of great importance to prevent possible necrosis of the invaginated pole of the uterine horn. One should use care

not to tear or remove a caruncle and thus cause bleeding. If the uterus has been sutured no douching should follow replacement. If complete replacement of the ovarian pole is difficult the introduction of 2 to 3 gallons of very warm water or physiological saline solution into the uterine cavity is often of assistance, since it stimulates uterine contractions and helps to wash out uterine debris. This fluid should be siphoned out. Most cases do not require douching.

After the uterus is replaced properly and completely, 30 to 50 units of oxytocin should be given intramuscularly or intravenously. If it is given by the latter method the uterine wall will contract tightly on the operator's arm within 30 to 60 seconds. Following replacement, most veterinarians use a uterine antiseptic or antibiotic such as those described in treating retained placenta. Probably one to two gms. of a tetracycline or similar antibiotic is most efficient in controlling infection. In treating valuable cows another dose of oxytocin might be administered in 2 to 4 hours. If the cow is standing and not straining, a recurrence of the prolapse is very rare. Temporary suturing of the vulva with a figure of eight or mattress suture of umbilical tape into the hair line, or some other type of vulvar suture described under vaginal prolapse, or the application of a truss for 1 to 3 days is a placebo for the farmer. Very rarely does a prolapse recur if the uterus is properly replaced in a cow. If the owner has the cow under close observation for the next 3 days, as he should, a rare recurrence of the prolapse can be treated promptly. This is much better than having, as the author did in one cow, the prolapse recur into the vagina, and because of the vulvar sutures it went unnoticed for 3 days. It was impossible to replace at that time and the cow was slaughtered. A cow that failed to conceive following a prolapse of the uterus was examined and on finding no evidence of the uterus on rectal examination, a small involuted uterus was present in the vagina protruding through the cervix.¹⁹ If vulvar sutures are used they should be removed in 24 hours. Pessaries are not recommended, as they tend to cause straining. If the cow continues straining following replacement of the uterus it may be due to invagination of the ovarian pole of the uterine horn or an irritation or inflammation of the vulva. The former should be corrected, and oily protectants or anesthetic ointments may be used for the latter condition, together with a long-lasting epidural anesthetic. If the cow is recumbent the rear parts should be kept slightly higher than the fore parts for several days. If the cow can stand this is not necessary. In uncomplicated cases it is generally found that within 24 hours the cervix is closed tightly enough so that recurrence is unlikely.⁵ Parenteral antibiotics are often indicated to help

control uterine infection after replacement. In rare cases a severe or even fatal infection with metritis or peritonitis may follow prolapse of the uterus.

In the ewe the same general replacement technique is applied as in the cow but it is less difficult, since the rear quarters can be easily elevated. Recurrence is possible but vulvar sutures are also of questionable value. In these cases epidural anesthesia is valuable. Close confinement of the ewe with her rear parts elevated may be indicated. In the mare replacement is similar to the cow except that general anesthesia may occasionally be necessary. In the mare the body of the uterus is the only visible portion of the prolapsed organ.^{5,12} Tetanus antitoxin, oxytocin, antibiotics, and other supportive treatments are indicated to prevent secondary tetanus, metritis, and laminitis in the mare. In multiparous animals replacement of the uterus in the manner described in the cow is difficult, but may occasionally be possible if the rear parts of the animal are well-elevated. A laparotomy is usually necessary to accomplish the return of the uterus to its normal position. Some authors advise suturing the apex of the uterine horns to the body wall to prevent a recurrence. Occasionally in the sow and bitch one horn of the uterus prolapses and a few fetuses may still be in the other horn. Therefore in most cases in multipara a laparotomy is probably advisable. If the uterus is badly traumatized, amputation of the horn or hysterectomy is indicated in the bitch and queen and possibly rarely in the larger animals.

Hysterectomy or amputation of the prolapsed uterus is undertaken only when replacement is impossible or when it is quite certain that replacement of a badly torn, lacerated, necrotic, infected uterus possibly would result in death. In some cases where the cow is unable to rise, chickens or hogs severely mutilate a prolapsed uterus. The prognosis is always guarded to poor because of the severity of the operation and the conditions preceding it. It is contraindicated in the mare, but is often the method of choice in the bitch and queen. Although the prognosis is poor there are many recorded cases of successful amputations or hysterectomies. In the cow and ewe amputation of the uterus may be accomplished by making a long longitudinal incision in the prolapsed uterus and cervix on the dorsal and caudal surface between the rows of caruncles starting at the vulvar lips (See Figures 99 and 100). Through this extensive incision the uterine arteries and veins can be seen in the tense mesometrium. These vessels are carefully ligated in 2 or 3 places and the broad ligament is severed from the uterus between the ligatures. The cranial portion of the vagina anterior to the prolapsed cervix is easily drawn out of the vulva and is carefully ligated with fixation ligatures. The uterus

and part or all of the cervix is removed and the stump is replaced in the vaginal cavity. This technique precludes the occurrence of hemorrhage from the uterine vessels, and insures the vagina and peritoneal cavity being closed tightly.⁴⁰ In the bitch, queen and sow a similar technique can be used, but the incision is circular and the uterine stump can be closed by a Connell suture followed by a Lembert stitch. In the bitch a dorsal episiotomy may be necessary in order to make the operation less difficult. In the bitch, queen and sow a laparotomy can be done, the prolapsed horn returned to the abdominal cavity, and an ovario-hysterectomy performed.

In the cow or ewe the most common technique recommended for amputation of the prolapsed uterus consists of making certain that neither the bladder nor any intestine is present in the prolapsed portion and then ligating that portion close to the vulva, using a strong ligature or preferably a soaped or oiled cord or fine rope tightened by two men pulling on opposite ends of the cord or rope. Three or 4 separate ligatures are firmly tied around the neck of the prolapsed portion of the uterus allowing 15 to 20 minutes to elapse between the application of each ligature. This is necessary as edema is always present in such cases, and the enclosing ligatures

must be tight enough so that when the uterus is removed 3 or 4 inches caudal to the ligatures the uterine vessels in the mesovarium will not withdraw into the abdominal cavity and cause fatal hemorrhage. Some veterinarians have successfully used a heavy elastic ligature made of long 2-inch-wide strips of rubber inner tube wrapped a number of times very tightly around the neck of the prolapsed portion in a manner similar to the cord method just described. After a lapse of 20 to 30 minutes to permit the edema to be forced from beneath the ligature, the uterus is amputated, leaving a fairly large stump to be replaced in the vagina. The ligatures or elastic tubing should be held in place by transfixing sutures through the enclosed vaginal wall. Following this operation the cow should be observed closely for evidence of shock, and saline solution, blood, glucocorticoids, and other stimulants should be administered at once. This is very important if the patient is to survive, as shock or hemorrhage may be fatal. The stump replaced in the vagina will slough in several weeks. It is usually advisable to administer parenteral antibiotics for 4 to 6 days.

Invagination of the Uterine Horn is occasionally noted in the cow and mare, but occurs only rarely in other species. In this condition the ovarian pole of the gravid

horn in the cow and usually the nongravid horn in the mare is everted but not far enough to be observed at the vulva. Ordinarily the invagination is completely within the uterus and is like an intestinal intussusception. It is more likely to occur during or after parturition and after replacement of a prolapsed uterus. It may be due to the pull or weight of the attached placenta on the ovarian pole of the uterus. Not infrequently it may be produced by traction on the fetal membranes at the time their removal is attempted. In a few cases the ovarian pole of the uterus may become incarcerated and necrotic with the cow showing symptoms of a septic metritis and peritonitis followed by death. In some mild cases the condition may correct itself spontaneously, while in others the invagination may progress until complete prolapse of the uterus occurs. This is another reason for careful examination of the uterus after relieving a dystocia.

The symptoms of an invaginated horn may be lacking, or there may be evidences of uneasiness, straining, or pain. In an occasional advanced case the invaginated portion of the horn may become necrotic; there may be symptoms of toxemia and septicemia; and a fetid, reddish-black vulvar discharge similar to that in a septic metritis may appear. On rectal palpation the enlarged uterine mass may feel like a large intussusception, and the mesovarium will be tense and tight. On vaginal examination if the hand can enter the uterus the invaginated horn is recognized as a dome-shaped, tumor-like mass projecting upward into the lumen of the uterus. This is noted most often in removal of an afterbirth in the cow when strong traction is placed on the placenta and the ovarian pole invaginates toward the cervix. In the mare this may also occur and in most cases involves the nongravid horn.

The prognosis is usually good unless the invaginated ovarian pole has been incarcerated by the contracting uterine muscle and becomes necrotic, in which case death usually occurs unless a hysterectomy is performed. The treatment of the condition in large animals consists of kneading the invaginated pole back into place with the fist, with piston-like shaking movements around the edge of the uterine lumen. Douching with 2 to 4 gallons of water may aid in replacing the invaginated pole. If one hand inserted in the rectum puts traction on the cranial portion of the broad ligament and the mesovarium attached to the invaginated pole, and the other hand pushes on the "tumor," this bimanual action may reduce the invagination. Ordinarily when the uterus is contracting strongly this condition cannot be relieved at that time. In cases where the invaginated horn cannot be replaced, when the animal's uterus is examined again in 3 to 6 hours it will be found that the condition often was cor-

rected spontaneously after the uterus relaxed. The attending veterinarian should closely follow and treat such cases of an invaginated uterine horn until the condition is corrected.

METABOLIC DISEASES OF THE PUERPERAL PERIOD

Milk Fever, Parturient Paresis or Hypocalcemia is a metabolic nonfebrile disease of dairy cows usually four years of age or older, characterized by hypocalcemia occurring just before, during, or most often within 72 hours after parturition and the onset of lactation.¹⁹ Parturient hypocalcemia is an adaptation disease.¹¹ Although difficult to quantitate parturient hypocalcemia costs the dairy industry many millions of dollars each year.¹⁹ At the beginning of lactation when there is an increased demand for calcium, 2 to 5 times that of the gestation period, the cow is forced into a hypocalcemic state and parturient paresis ensues.^{11,16,19,20,21,23} With the onset of lactation an adequate increase in dietary calcium intake and

absorption to meet the body demands is essential. Inappetence frequently associated with parturition, together with the "lag period" of several days before bone tissue is activated to supply sufficient calcium retard the normal adaptation of the cow from the loss of calcium at the onset of parturition and lactation and results in a high incidence of parturient hypocalcemia and relapses following therapy.¹⁹

The blood serum calcium level drops from a normal of 8 to 12 mg. per 100 ml. to 3 to 7 mg., with symptoms of parturient paresis becoming progressively more pronounced as the calcium level declines. Hypocalcemic paresis is due to a depression of neuromuscular transmission of motor stimuli.⁶ Subclinical hypocalcemia, with calcium levels below 8 mg. per 100 ml. of serum may last for 11 to 32 hours in many parturient cows without paresis developing. Paralysis was usually associated with calcium levels below 5 mg. per 100 ml. serum.²⁰ Hypophosphatemia, hyper- or hypomagnesemia and hyperglycemia are other changes associated with parturient hypocalcemia.¹⁹ Parturient paresis is observed in all dairy breeds but most commonly in Jerseys. Recurrent attacks of milk fever may occur at subsequent parturitions.

The symptoms of parturient paresis are anorexia, cold extremities, lowering of the body temperature, stiff gait, staggering, incoordination, inability to rise, an S-curve in the neck, failure of the pupil to contract on stimulation by light, suppression of urination and defecation, constipation, slight tympany of the rumen, cessation of parturition if it develops during that period, coma, and finally death usually occurring in 6 to 24 hours if treatment is not instituted. Only rarely does spontaneous recovery occur in the paretic cow. With proper care and prompt handling the prognosis is good, and the mortality should be less than 2 to 3 percent in uncomplicated cases that do not injure themselves in attempting to rise. Prolonged recumbency in parturient hypocalcemia frequently results in pressure damage of ischemic necrosis of muscles and inflammation of sciatic and peroneal nerves leading to the downer cow syndrome and death.⁷ Early and prompt treatment of milk fever is necessary to avoid the latter syndrome especially in the larger heavier, often obese, cows of the Holstein breed. It has been demonstrated that 50 percent of normal healthy cows confined in recumbency for 6 to 12 hours developed extensive lesions leading to the downer cow syndrome and death or euthanasia.⁷

Treatment consists of administering 500 to 1000 ml. (depending on the size of the cow) of 20 percent calcium gluconate, one half of the amount injected intravenously and one half subcutaneously. In 100 cows recumbent with parturient hypocalcemia the overall relapse rate was 22

percent after treatment with calcium preparations either intravenously or intravenously and subcutaneously. The incidence of relapse was about 38 percent in the cows treated only intravenously while it was about 4 to 8 percent in the cows treated both intravenously and subcutaneously.⁸ In these latter cows the serum calcium levels 12 hours after treatment were significantly higher than the cows only treated intravenously. Reduced amounts of milk should be removed from the udder for 2 to 3 days. Complete emptying of the udder should be avoided if possible.

Udder insufflation to raise the plasma calcium concentration by reducing milk secretion and transferring calcium in the udder back into the circulation was reported upon.²¹ This technique did not induce hypercalcemia and was seldom followed by a relapse. Cotton-filtered compressed air from a cylinder introduced into the barrel of a syringe filled with an antibiotic udder infusion preparation to firmly distend the cow's udder and teats was used. Following treatment the teats were tied with a tape for several hours to hold in the compressed air. Since 1930 many attempts have been made to prevent parturient hypocalcemia by administering large amounts of vitamin D either orally or by injection. These studies have been recently reviewed.^{19b} Although various forms of vitamin D and D₃ will produce a temporary hypercalcemia, their toxicity and the timing of the administration of these products with parturition have created serious drawbacks to their practical widespread acceptance and use.^{19a} Recent preliminary studies on administering a large dose of a readily absorbed proprietary calcium product containing other trace minerals and vitamins immediately after calving has shown some promise in reducing the incidence of parturient hypocalcemia and retained placenta in dairy cows.⁹ Milk fever or hypocalcemia has been described in the ewe, doe and sow mainly in Europe. The symptoms are similar to those in cows.³

To prevent the occurrence of parturient paresis which may reach an incidence of 80 percent or more in the pluriparous cows in certain dairy herds, the total dietary calcium intake late in lactation and during the nonlactating period should be greatly reduced by removing legumes such as clover and alfalfa from the diet as well as common mineral supplements used for lactating cows which are usually high in calcium. This practice causes a slight hypocalcemia and increased secretion of parathyroid hormone. Timothy hay, straw and corn silage are low in calcium content and may be fed.^{13b,19} If too much of the corn silage is fed the cows may become overly fat resulting in the "fat cow syndrome" in which the cows are more susceptible to milk fever, ketosis, digestive dis-

orders as displaced abomasums, retained placentas and metritis, mastitis and foot problems. In certain areas and herds where some or all legume roughage must be fed, the addition of 2.5 to 5 percent monosodium phosphate to the grain ration, resulting in Ca:P ratio of 1:1 instead of a 3 to 7:1 may reduce the incidence of milk fever.^{5,13b,19} However low calcium diets, regardless of dietary phosphorus intake, prevent milk fever by the prepartal activation of both bone and intestinal tract.^{13b}

Ketosis or Acetonemia is only rarely observed prior to parturition in cows.^{3,13} It may occur the first 7 to 10 days after parturition but by far the greatest number of cases occur from 10 to 60 days after parturition. Ketosis in dairy cows is a lactation disorder, with elevated levels of ketones in the blood, urine and milk, associated with high milk production and a negative energy balance.¹⁹ It is estimated that clinical and subclinical ketosis costs U.S. dairymen about 150 million dollars a year. Three types of ketosis in cattle may develop:²⁴ (1) primary spontaneous ketosis which may have an hereditary predisposition, (2) primary nutritional, which is the most common and (3) secondary ketosis which occurs with reduced TDN intake due to metritis, displacement of the abomasum, traumatic gastritis and other diseases. Ketosis is characterized by hypoglycemia, ketonemia and ketonuria. The normal bovine blood levels of 40 to 60 mg. per 100 ml. of glucose drop to 40 to 18 mg. of glucose and the blood ketone levels rise from a norm of 2 to 15 mg. to 15 to 75 mg. per 100 ml. This condition is due basically to a reduced intake of nutrients, especially carbohydrates, in relation to the loss of energy by heavy lactation. Secondary conditions such as fatty changes in the liver may occur. There is a marked loss in weight due to the use of body fat, carbohydrates and proteins for milk and energy. The condition may develop in dairy cows at any age.

The symptoms observed are of two types, digestive and nervous. In the more common digestive type, the symptoms are anorexia, constipation, gradual drop in milk flow and rapid loss of weight. In the less common nervous type the symptoms are more severe, and depression is marked; various nervous symptoms such as trembling, nervousness and licking may be present; paresis is not uncommon, and anorexia and drop in milk flow are also observed. At times it may be difficult to differentiate between acetonemia and metritis following parturition, and both may be present. By testing the urine or milk with Ross reagent, the development of a definite purple color is usually indicative of ketosis. Inasmuch as very few animals die of ketosis, the prognosis is good; but the loss in milk production and body weight can be of great economic importance to the dairy farmer. The av-

erage incidence of ketosis in the United States is about 4 percent but in some high producing herds it may reach 20 to 50 percent. The condition is more common in the winter stabling period.

The treatment of ketosis in cattle consists of raising the blood sugar level for a period, thereby restoring the cow's appetite. Following the increased intake of additional nutrients, especially carbohydrates, the cow will recover and a relapse is unlikely. The preparations used to raise blood glucose levels include glucose solutions of 500 ml. to 1000 ml. of 40 percent glucose injected intravenously, or continuous, slow intravenous drip of several thousand ml. of 25 percent glucose. Sodium propionate, 1/3 to 3/4 lb. fed daily in small doses or given as a drench or a similar but more palatable product, propylene glycol administered orally in 200 to 500 ml. amounts daily increase propionic acid in the rumen which is absorbed and used by the cow in place of glucose. This conserves and raises the blood glucose level. Glucocorticoids injected intramuscularly raise blood glucose levels rapidly and also improve appetite and lower milk production for several days. ACTH, 200 to 600 I.U. injected intramuscularly stimulates production of the glucocorticoids by the adrenal glands and thus raises the level of blood sugar. Ten to 30 gms. daily of chloral hydrate in divided doses given orally also raises blood sugar levels. If metritis, mastitis or other infectious process due to bacteria is present the glucocorticoids should not be given or they should be accompanied by parenteral antibiotics. They are contraindicated in viral diseases. Relapses are likely to recur if the level and amounts of nutrients, especially carbohydrates, TDN or energy in the ration are not increased so that the cow will consume 1 lb. of 12- to 14-percent protein grain for 2-1/2 to 4 lbs. of milk produced, depending upon the quality and quantity of roughage. The level of energy intake must equal the work of milk production so that the cow maintains a positive energy balance and does not relapse into ketosis. As nutrition and management of present dairy cows are improved to reduce ketosis, the genetic increase in future milk production of cows will ensure this disease remains a problem.

Ketosis or Pregnancy Disease in Ewes is seen the last 2 to 4 weeks of pregnancy. Usually the dam is carrying twin or triplet fetuses. It is caused by a hypoglycemia produced by the rapid growth of the fetuses and insufficient intake of nutrients, especially carbohydrates in the ration.³ Ketosis is not due to an insufficiency of ACTH as hydrocortisone levels are elevated.¹⁰ The affected ewes are usually thin but ketosis may be observed in ewes in good condition. It is also predisposed by a lack of exercise. The liver shows fatty changes and the

ketone levels in the blood and urine are greatly elevated. In ewes the symptoms of ketosis are dullness, anorexia, paresis, or inability to rise without assistance, and nervous symptoms of mental derangement such as walking in a circle, pressing the head against some object, drawing the head backward and to one side. The nervous signs exhibited might be due to inability of nerve cells to utilize sugar.¹⁰ Urine obtained by a small catheter or by stopping respirations by squeezing the nose and mouth firmly shut can be tested by the Ross test, as in cattle, for the presence of ketones. In more advanced cases the fetuses die and if they are aborted promptly the ewe may recover. Ketosis may be differentiated from listeriosis by a lack of paresis of the lips or ears. In listeriosis the limbs are flaccid while in ketosis the limbs will resist flexion if upward pressure is applied to the toe. The course of the disease is 2 to 6 days. The prognosis is usually poor unless cases are diagnosed and treated early or abortion occurs before the ewe is severely affected. Treatment consists of any one or a combination of the following: the injection of 200 ml. of 40 percent glucose intravenously; administration of glucocorticoids or 50 to 100 I.U. of ACTH intramuscularly which may initiate premature parturition; an increase in the carbohydrate intake of 1/2 to 1 lb. of grain, 1/4 to 1/2 lb. of molasses daily per ewe or 2 ounces of propylene glycol 2 to 3 times a day. Sometimes valuable ewes which are severely affected can be saved by cesarean section; the fetuses are often dead. The glucocorticoids and estrogens have been used to cause or hasten parturition or abortion in ewes with severe ketosis. The disease may usually be prevented in the rest of the flock by increasing the grain ration or by feeding molasses and increasing the amount of exercise. Ketosis in goats is similar to that in ewes but is observed less commonly.

Grass Tetany, Lactation Tetany, Transport Tetany, "Wheat Poisoning" or Hypocalcemia, or Hypomagnesemia is a metabolic disease of beef and dairy cattle, and sheep and goats in Europe, especially those which are in advanced pregnancy or lactating heavily, grazing on lush, heavily fertilized grass or early wheat pastures or are transported or stressed in the puerperal or early lactation period. This disease complex is well-described.^{3,19} It occurs more commonly on certain types of soils and in certain regions. It is seen most often during the spring or fall months and less often during the summer months. Grass tetany is characterized by a hypocalcemia, occasionally a concurrent hypomagnesemia, or hypomagnesemia alone. It is caused by the excessive consumption of young lush grass on well-fertilized pastures. Some^{9a,17} believe that the high potassium or transaconitate and citric acid content in grass causes a loss of

calcium and magnesium from the body, accentuated in advanced pregnancy or during heavy lactation, when there is an increased drain on body calcium and magnesium. Hypomagnesemia may occur in stabled animals fed rations low in magnesium. The symptoms of grass tetany are similar to those of milk fever when a simple hypocalcemia with hyper- or normo-magnesemia is present. If, however, a hypomagnesemia is present with hypo- or normo-calcemia trismus, hyperesthesia, tachycardia, nystagmus, erect ears, tetany of the hind limbs, tremors, twitching of muscles that may progress into general spasms or convulsions, may be exhibited.¹⁷ Paresis is a common symptom. Unknown extrinsic or intrinsic factors apparently play a role in precipitating signs of hypomagnesemia when the serum levels of magnesium are low. A recent study indicates there may be a relationship between age, renal function, magnesium antagonists and parathyroid hormone in the etiology of hypomagnesemic tetany.^{9a} Decreases in magnesium levels in the cerebrospinal fluid are more closely associated with clinical signs of grass tetany than are serum magnesium levels. Thus grass tetany may be due to alterations of central nervous system function possibly brought on by vascular lesions and hemorrhagic edema characteristic of pathologic lesions of grass tetany.¹⁹ Often during the early stages of grass tetany the animal is excitable and may be aggressive. Some hypomagnesemic cows may act normally until handled when signs of tetany suddenly develop. This disease is more gradual in onset than is milk fever. The prognosis is usually good but sudden deaths are not uncommon if the condition isn't treated early.

The treatment consists of injecting 500 to 1000 ml. of a calcium-magnesium solution intravenously and subcutaneously in a divided dose, removing the animal from the grass pasture, feeding good alfalfa hay, and supplying a mixture of bone meal or dicalcium phosphate, and magnesium oxide, sulphate or carbonate, up to 60 to 120 gms. daily, free choice, in a molasses block or preferably in the grain ration. Since magnesium can't be stored in large amounts in the body, a nearly daily intake is necessary. Magnesium may be combined with the calcium gluconate or 200 to 500 ml. of a 10 to 25 percent solution of magnesium sulphate may be given subcutaneously. An outbreak of transport tetany or hypocalcemia was described in which a flock of ewes kept on a stubble field low in calcium was driven 9 miles to a new pasture. The ewes near parturition or in early lactation showed depression, stiff gait, high pulse and respiration rate and excessive salivation. Giving 150 ml. of 20 percent calcium gluconate subcutaneously resulted in recovery.¹

Tetany or Eclampsia in the Mare is rare but has been

described.³ Usually it occurs within several weeks after parturition, in a mare that has a normal foal, is lactating heavily, and is on a good, lush pasture. An attack may be precipitated by unusual handling, transport, or by a change in surroundings. It is probably a hypocalcemia similar to grass tetany in the cow or eclampsia in the bitch. In the early stages, symptoms of restlessness, rapid breathing, staring eyes, twitching, trembling and clonic spasms, especially of the diaphragm, are common. In later stages clonic spasms are followed by more tonic spasms, with trismus, marked restlessness, labored breathing, profuse sweating, and injected cyanotic mucous membranes. In advanced cases the animal is unable to stand. Tetany of most muscles is present; the animal becomes prostrate; convulsions are nearly continuous; and death results in 12 to 48 hours. The condition should be differentiated from tetanus. If treated promptly the prognosis should be good but deaths are not uncommon in untreated mares. Spontaneous recoveries have occurred at any time during the course of the disease. The treatment consists of intravenous injections of calcium gluconate and possibly the administration of narcotics such as chloral hydrate, sodium pentobarbital or heavy tranquilization.

Puerperal Tetany or Eclampsia in the bitch and queen is a metabolic disease characterized by hypocalcemia.^{2,26} It is seen in heavily lactating bitches during the first 3 weeks after parturition, although it may occur prior to, during, or up to 6 weeks after parturition.^{4,18} The serum calcium level drops from a normal of 9 to 12 mg. to 5 to 7 mg. per 100 ml. It may occur in all breeds but is seen most commonly in small or medium-sized bitches. The disease is characterized by rapid breathing, a dry mouth and sclera, restlessness, nervousness, and whining, followed by staggering, incoordination, stiffness of limbs, and an elevated body temperature. Later there is the development of symptoms of inability to rise, extended legs, excessive salivation, champing movements, dilated pupils, clonic and tonic spasms and convulsions, congested mucous membranes, labored respirations and a rapid, hard pulse. The prognosis is good if treatment is instituted. Spontaneous recoveries may occur. Treatment consists of administering sodium pentobarbital or 5 to 10 ml. of a 10 percent calcium gluconate solution intravenously, intraperitoneally or subcutaneously. Recurrence of the condition is more common following the use of calcium gluconate than of sodium pentobarbital. If the pups are old enough they should be weaned. The bitch and queen should be fed added amounts of calcium lactate or gluconate in the ration. The administration of corticosteroid therapy, 5 mg. prednisolone or 25 mg. hydrocortisone, daily will help prevent a relapse. If given

for a week or more the steroid therapy should be withdrawn gradually.¹² If the bitch has metritis, antibiotics should be given with the corticosteroids. If affected bitches are rebred the condition frequently recurs in the subsequent lactation period.² The disease is rare in the queen but symptoms and treatment are the same as in the bitch.¹⁰

Postparturient hemoglobinuria is an uncommon disease of high-producing, older dairy cows occurring 2 to 4 weeks after calving and characterized by hemoglobinemia, hemoglobinuria, and anemia.³ It is associated with rations deficient in phosphorus or rations high in rape, turnips, kale, beet pulp or cabbage. The affected cows show anorexia, weakness, dehydration, pale mucous membranes, rapid pulse and respiration, constipation and in the later severe stages, prostration and death after a course of 3 to 5 days. In mild cases or treated cases recovery occurs after several weeks. In severe cases there is a hypophosphatemia as low as 0.5 to 1.5 mg./100 ml. of serum; normal values are 4 to 6 mg./100 ml. Postparturient hemoglobinuria should be differentiated from leptospirosis and pyelonephritis. Treatment consists of blood transfusions to effect; the intravenous injection of phosphorus containing compounds and oral supplementation of the ration with monosodium phosphate or possibly bone meal or dicalcium phosphate especially if cruciferous plants are in the diet.³

Puerperal Infections, Uterine Infections and Diseases

Retained Placenta or Retention of the Afterbirth or Fetal Membranes is one of the most common conditions occurring in animals following parturition. It is observed chiefly in the cow and less commonly in the other domestic species.

Retained placenta in the cow. In physiological parturition the afterbirth of the cow falls away within 3 to 8 hours following calving. If the placenta is retained longer than 8 to 12 hours the condition is considered pathological.

Etiology. Retention of the fetal membranes is basically due to failure of the villi of the fetal cotyledon to detach themselves from the maternal crypts of the caruncle. After the fetus is expelled and the umbilical cord ruptures no blood is pumped into the fetal villi and they shrink in size. In the dam, uterine contractions continue and the large amount of blood formerly going to the uterus is markedly reduced. The maternal caruncles become smaller in size, due to a reduced blood supply, and the maternal crypts dilate. Although there is no muscle in the caruncle, during contractions of the uterine wall following parturition the shape of the caruncles may change from oval to round.² Detachment of fetal cotyledons from the maternal caruncle was much easier during these contraction waves than between them. The weight of the fetal membranes assist in their normal dropping away from the caruncles and the uterus. Other workers^{17,24,60} have stated that stimulating uterine contractions by the injection of oxytocin immediately after calving apparently lowered the number of retained placentas, by comparison with control cows not thus injected. In a small trial oxytocin, 40 IU every 20 to 30 minutes for up to 6 treatments, was given to cows judged unlikely to pass their fetal membranes with a reduction of the incidence of retained placenta by 50 percent.¹⁷ Separation of buffalo calves from the dams immediately after birth so that suckling could not stimulate the release of oxytocin from the posterior pituitary gland, resulted in 22.7 percent retention of the afterbirth in 189 calvings as compared with 4.9 percent retained placentas in 122 calvings on the same farms when suckling was allowed.⁶⁸ Stress could also have been associated with this high incidence of retained placenta.

On histologic examination of fetal cotyledons and maternal caruncles taken an average time of 4.75 hours after normal calving, degeneration and necrosis of the fetal villi and necrosis and degeneration of the epithelium of the maternal crypts were present, and the latter were filled with debris.³⁵ These findings in normal cows were essentially similar to those in cows having a retained placenta. Incomplete data showed little or no histologic differences between normal cotyledons and caruncles and those in which retained placenta developed. There were morphologically three types of retained placentas; one type was associated with abortion and premature birth with immature placentomes; the second type was associated with hyperemia and were few in number; and the

third and most common type was associated with small portions of necrotic epithelium between the chorionic villi and the cryptal walls.⁹ In retained placenta normal separation and loosening of the villi from the maternal crypts is interfered with and adhesions form. In easily removed placentas the loosening process comes about by autolysis of the chorionic villi. After several days leucocytes and bacteria were in the placentomes. Therefore placentitis was a secondary phenomenon. The incidence of retained placenta is high in births occurring several days before the expected date because the placenta has not undergone the degeneration necessary for normal detachment.⁸ Although there is as yet no definite information about the exact manner in which the fetal membranes are expelled or fall away from the caruncles, it is rather apparent that it is a complex process involving a reduction of blood supply followed by shrinking of both maternal and fetal placental structures, degenerative changes, and strong uterine contractions.

There is evidence to show that infections of the uterus during gestation may be a cause for retained placenta. Infectious agents, such as *Brucella abortus*, tuberculosis, *C. fetus* and various mold infections cause a placentitis and cotyledonitis resulting in abortion or pathological parturition at term with retention of the placenta. Sound evidence to minimize the importance of this general cause of retained placenta has been provided.² This author agrees that in the past too much emphasis has been placed on intrauterine infections during gestation as a cause for retained placentas. About 20 to 25 percent of 282 cases of retained placenta in one study²⁴ were infected with *Brucella abortus*, but these were also associated with abortions and premature births. The occurrence of many placental retentions in herds affected with *C. fetus* were reported. It was stated⁸ that 30 percent of all retained placentas in cattle in Germany were due to *Brucella abortus*. The author has observed many mold infections, due to *Aspergillus* or mucor molds, causing a marked cotyledonitis and severe retention of the fetal membranes. Examination of 2027 placentas revealed 121 with mold.⁷ Of these latter 73 percent were *Aspergillus*. Many infected placentas were not retained. Other diseases and organisms causing abortion or premature birth might also produce endometritis, placentitis, and retention of the fetal membranes by inflammatory reactions of the cotyledon and caruncle similar to lesions described in brucellosis.²⁸ As noted in Chapter V, under uterine involution, during or following parturition, bacteria from the caudal portions of the genital tract or the environment invade all uteri. The degree of contamination or numbers of invading bacteria, the type and virulence of the organisms and the immunity or re-

sistance of the dam determine the seriousness of the infection which may vary from a mild infection with a rapid recovery within a few days or weeks to a severe metritis, septicemia, toxemia and death in the same period.⁷⁰

The highest incidence of retained placenta, 69 percent, occurred in an experimental group of cattle on low levels of carotene intake.⁵⁶ The incidence could be correlated with the various feeding levels of carotene. In hyperkeratosis, and P.B.B. toxicity, in which vitamin A levels are very low, the incidence of retained placenta, metritis, and abortion is high. Probably vitamin A is necessary for maintaining the health and resistance of the epithelium of the uterus and placenta. Low vitamin A levels lead to the development of infections. A deficiency of minerals such as iodine and selenium has been reported to be a cause of retained placenta, but this requires further substantiation.⁴⁴ Premature calvings and calves with enlarged thyroid glands together with an increased incidence of retained placentas may occur in iodine deficient herds.^{16b} Numerous recent studies have been performed in cows to prevent retained placenta by the injection of vitamin E and selenium about a month before parturition.^{32,48,61,62} In Ohio and Kentucky this therapy proved effective in reducing the incidence of retained placenta but in Maryland, Virginia, New York, North Carolina, Nebraska and South Dakota it was ineffective. There were great variations in results between herds. Thus this therapy cannot be recommended with assurance of its value.

Retained placenta in 1610 Holstein parturitions was 50 percent higher in both cows and heifers with dystocia than in normal births, and 50 percent higher in calvings in which milk fever occurred than in calvings where no milk fever was present.⁵² Heat stress during the summer months, May through September, in Georgia increased the incidence of retained placenta and metritis from 12.2 to 24.0 percent. This was apparently related to a reduction in the length of gestation by 5.25 days in the cows with retained placenta compared to the cows calving during the cooler seasons.²⁰

In the cow, many abortions occurring after the fifth month of pregnancy are accompanied by retained placenta. In cattle calving 1 to 2 weeks prematurely, especially in twin pregnancy, retained placenta occurs in 30 to 50 percent of the animals. The ratio of retained placenta to abortions at different times of gestation was 1:7 at 121 to 150 days, 1:6 at 151 to 180 days, 1:3 at 181 to 210 days, 1:2.2 at 211 to 240 days and 1:1.7 at 241 to 250 days of gestation.⁴⁶ Practically no retained placentas occurred after abortions prior to 120 days and the incidence dropped to 1.5 percent of calvings between

271 and 280 days of gestation. Progesterone deficiency may cause the retention of the fetal membranes or indirectly cause it by predisposing to early parturition.⁴² It may be possible that some abortions, premature calvings, or retained placentas are due to a progesterone deficiency or a cortisol excess late in gestation. Profiles of hormone levels in cows with and without retained fetal membranes 12 hours after calving were not conclusive. Further studies in the week prior to calving are indicated as low estradiol and high progesterone levels on day 6 prepartum were associated with retained placenta.¹⁵ Inducing parturition 2 to 10 days before expected calving usually resulted in a 50 to 75 percent incidence of retained placenta. (See Chapter VI.)

Diseases causing uterine inertia or atony result in a high incidence of retention of the fetal membranes. These are: dropsy of the fetal membranes, uterine torsion, twinning, fetal giantism, primary or secondary uterine inertia, dystocia, and other pathological conditions. Retained placenta was observed in about 70 percent of dystocia cases due to uterine torsion and failure of cervical dilation, and in about 25 percent of dystocia cases due to over-size of a living fetus.¹⁸ An incidence of 8 percent retained placenta in normal births but a 55 percent incidence in abnormal deliveries such as twins, cesareans, fetotomies, dystocias and abortions was reported.^{66b} Failure of normal uterine involution was frequently associated with retained placenta. The pathological conditions causing these diseases or abnormal conditions resulting in uterine inertia—whether they be infectious, hereditary, nutritional, circulatory, or hormonal—also predispose to retention of the placenta. In a study of 7,387 calvings in one Holstein herd for a period of 25 years, the incidence of retained placenta averaged 10.5 percent and affected 38.6 percent of the 2607 cows. Retained placenta rose from 5.4 percent in primipara to nearly 25 percent at the ninth calving.²³ Elimination of brucellosis from the herd did not lower the incidence of retained placentas. Twins and abortions were associated with 37.7 percent of all retained placentas. Significantly more daughters from dams having retained placentas had retained placentas than daughters from dams not retaining their afterbirth. Retained placentas were more common following the birth of single male calves, 56 percent vs. a 51.6 percent herd average. Twin births in which two males or one male was present also had a higher rate of retention. It was concluded²³ that retained placenta is not entirely caused by previous pathological conditions, a theory strongly supported by others.^{69b} Retained placentas were more common during February through April in the northern hemisphere.^{16a, 23}

Retention of the fetal membranes is less common in

beef breeds than in dairy breeds confined in stables for long periods. The incidence of retained placenta varies widely from herd to herd at various times. Retained placentas in 6.4 percent of 450 parturitions that included only brucellosis-free cows and births of living, single calves were reported.¹² An incidence of 8.3 percent in 431 calvings in British herds in which brucellosis was either absent or quiescent was recorded.³⁵ The incidence in Hannover, Germany, was 4 to 5 percent.² In over 24,000 calves in Israel, a 5.08 percent incidence of retained placenta in single births and a 99 percent incidence in twin births, for a total over all incidence of 8.4 percent was recorded.⁶ In New Zealand the incidence of retained placenta was 1.96 percent in over 36,000 dairy cattle kept at pasture the year around.⁴⁶ In comparison with stabled herds it may indicate that exercise, less stress, more vitamin A and a less contaminated environment is conducive to a low incidence of retained placenta. The incidence of retained placenta in herds infected with active brucellosis, in cows producing twins, or in cows aborting due to other causes is high, probably from 30 to 50 percent or more. Once retention of the afterbirth occurred in a cow, there was about a 20 percent chance of it recurring again.²³

It has been repeatedly observed by the author that in a certain year a high incidence of retained placentas 30 to 80 percent, would develop in a dairy herd that formerly had relatively few cases, 2 to 8 percent. Once retained placentas started nearly every cow calving thereafter would be affected and/or develop postpartum metritis. These herds were free of the common enzootic infections of reproduction that cause abortion such as brucellosis, vibriosis, leptospirosis, IBR-IPV and mold infections. The affected cows were calving in the same barn and in many instances in the same calving stalls in frequent succession. When there was an hiatus of several months or more when no cows calved or when cows were calving on pasture away from the barn, the incidence of retained placenta and metritis dropped dramatically to the low levels of former years even when calving was again resumed in the barn or calving stalls at a later date. This pattern of retained placentas and postpartum infection closely resembles that seen in calf scours and the metritis-mastitis-agalactia syndrome in sows. In fact the author has observed severe outbreaks of virulent scours in the newborn associated with a high incidence of retained placentas and metritis in the dams in the same herds. From these observations the author has hypothesized that these severe enzootic outbreaks of retained placentas and secondary metritis were due to certain highly virulent organisms of *Streptococcus dysgalactiae*, *E. coli*, *Staphylococcus*, *Pseudomonas aeruginosa*, *C. py-*

ogenes and/or other organisms which developed in these barns or calving stalls infecting the genital tract of the parturient cow at the time of calving and causing an acute metritis, uterine inertia, retained placenta and then secondary placentitis and metritis. As long as cows are calving in frequent succession in such an environment the infection continues from one cow to the next. When a period of several months or more elapses between cows calving in such an environment the infection dies out on the premises. Since it is difficult to thoroughly disinfect a barn or even most calving stalls a possible alternative is to remove the parturient cow from this environment to a clean noninfected one for calving. This is difficult on most farms and farmers are reluctant to go to this inconvenience even if suitable noninfected calving stalls or areas can be improvised. On affected farms where the author has secured the cooperation of the farmer to follow this regimen of removing the parturient cow from the infected environment for 5 to 10 days before and after calving whether by placing the cow in a noninfected or noncontaminated separate barn, lot, shed or stall or by putting the cow on pasture, the results have been very gratifying with a marked drop to normal in the incidence of retained placenta and postpartum metritis. Because of the adverse effects on reproduction and milk production the veterinarian should not hesitate to strongly recommend this often troublesome chore upon the farmer. With the increased size of many dairy herds and the trend toward "zero" pasture and the confinement of cows in barnyards and freestall housing, the author foresees the continuation of such serious problems unless management and housing designs develop so that calving stalls can be built isolated from each other and of such construction that lends itself to thorough disinfection as has been necessary for continuous farrowing operations to develop in the swine industry. There is evidence in England, Sweden and the U.S.A. that bedding cows on sawdust is more conducive to coliform mastitis, calf scours and retained placenta and post-partum metritis than bedding the animals on straw. For those of my readers who are reluctant to accept the hypothesis that acute uterine infections resulting in retained placentas and metritis can develop in the few hours between the onset of parturition and the normal time of expulsion of the placenta they should note the very short period needed for the development of acute bovine mastitis, calf septicemia and acute mastitis in sows.

The morbid anatomy of retained placenta may vary from slight evidence of disease to severe lesions. According to the location of the inflammatory reactions in the uterus, placentitis may be classified as apical, cervical or diffuse. The nongravid horn may or may not be

involved when the placenta in the gravid horn is retained. The degree of placentitis in the nongravid horn is usually not as severe as in the gravid horn since the placentomes are smaller and less complex. The degree of placentitis may vary from a mild peripheral type of necrosis involving only the villi to a severe necrosis involving the entire cotyledon and a part or all of the caruncle.

If the placentitis developed prior to calving or abortion, the allantois chorion may be edematous, necrotic or leathery, or hemorrhagic. Uterine "sand" and old or fresh clotted blood may be present. Often a reddish-brown to yellow exudate is found in the utero-chorionic space. Adventitious placentae may vary from a few small areas to nearly complete involvement of the entire endometrium of one or both horns. In mold infections the cotyledon is usually very large and swollen. Uterine and placental disease may occasionally cause fetal disease or anoxia that results in the presence of fetal meconium in the amniotic fluid, staining the fetus. In most cases of retained placenta the calf appears quite normal.

The symptoms of retained placenta are usually obvious, a portion of the fetal membranes hang from the vulva 12 hours or more following abortion, normal parturition, or dystocia. Occasionally the fetal membranes do not hang from the vulva but are entirely within the vagina or uterus. In the treatment of herds severely affected with genital disease close observation of the cow to observe when the fetal membranes were dropped is recommended.^{69b} Examination of the fetal membranes can be made to be certain they are completely expelled and no portion remains in the uterus. If they are not expelled normally the uterus should be examined manually per vaginam in 24 to 36 hours. After 48 hours it is usually difficult or impossible to insert the hand into the uterus if no fetal membranes are within the cervix. The presence of the membranes lying in the cervix tends to retard contraction of that organ. After a dystocia the placentomes may be felt; if they are very swollen, hard, firm, inflamed, or congested, the placenta will be retained. If the placentomes are soft and pliable the cow will often drop the afterbirth within a few hours.

About 75 to 80 percent of cows with retention of the fetal membranes show no marked illness. About 50 to 60 percent may exhibit slight to moderate illness by a temporary reduction in appetite or milk flow.² About 20 to 25 percent may exhibit moderate to severe symptoms of metritis and septic metritis as shown in some cases by anorexia, depression, elevation of body temperature, increase in pulse rate, decrease in milk flow, and loss of weight. These percentages may differ in herds depending upon the severity of the infections causing the

secondary metritis. In severely affected animals retained placenta may be associated with or complicated by other diseases such as: mastitis, septic metritis with perimetritis or peritonitis, severe straining, necrotic vaginitis, parturient paresis, and acetonemia. The bacteriological picture of the uterus in cases of retained placenta was similar to that of a uterus with delayed involution or atony without retained placenta.² First the *Streptococci dysgalactiae* and the staphylococci appear, and later the diptheroids, *Corynebacterium pyogenes*, coliform, and anaerobic bacteria may be found. In retained placenta the white blood cell picture showed a slight to marked shift to the left. In uncomplicated cases a lymphocytosis developed. In more severe metritis cases a definite leucopenia occurred.⁴³ The total number of white blood cells usually do not increase markedly. After 24 hours the placenta begins to macerate and a fetid, putrid odor develops. The afterbirth may fall away anytime within 24 hours to 14 days, depending upon the severity of the disease and possibly the type of treatment used. In most cows with retained placenta the cervix contracts after 48 to 72 hours, so that it may be difficult to insert the hand through the cervix. This contraction takes place sooner if no fetal membranes are present in the cervix.

Prognosis. The mortality rate in retention of the fetal membranes should not exceed 1 to 2 percent in uncomplicated cases.² In retained placenta cases a mortality rate of 4 percent: emaciation, infertility, or unprofitableness in 20 percent, a short duration of the disease with temporary irregularities of milk production and fertility in 50 to 60 percent, and nearly undisturbed puerperium in 15 to 25 percent was reported.² Another study²⁴ reviewed a substantial number of cases of retained placenta treated by various means in the Ambulatory Clinic of the New York State Veterinary College from 1920 to 1941. During the years 1920 to 1928, 755 cases were treated by early or late removal, and much douching, with a mortality rate of 4.2 percent. During 1928 to 1934, 1109 cases were treated by removal at 72 hours, with little or no douching, with a mortality rate of 2.8 percent. From 1934 to 1941, 1680 cases were treated with late removal, 72 hours or more, no douching and liberal use of sulfanilamide, with a mortality rate of 1.1 percent. In this same clinic, from 1943 to 1953, 3742 cases of retained placenta were treated by late removal, 72 hours or longer, no douching, and the use of sulfonamides and antibiotics, if necessary, with a mortality rate of 1.3 percent. This latter figure included cases in which septic metritis, mastitis, peritonitis, and other conditions were complications which undoubtedly contributed to or caused the fatalities. A very interesting study⁵¹ was conducted of 44 cases of retained placenta in 2 herds totaling 125

animals in which no manual removal of the placenta was attempted during a period of 3 years. These herds were free of brucellosis and tuberculosis. No treatment was given to any cows with the exception of 4 that became quite ill. In these 4 cows proflavine and saline solutions were introduced into the uterus but probably had no influence on the course of the disease. Of the 44 cows 81.8 percent had calved at term, 18.2 percent had aborted, and 16 percent had twins. The placentas were retained from 2 to 11 days, an average of 6.8 days before dropping away naturally. During the first two weeks after calving the appetite was good in 31.8 percent, fair in 54.5 percent, and poor in 13.6 percent. Body weight remained normal in 88.6 percent. Lactation was good in 29.5 percent, fair in 63.6 percent and poor in 6.8 percent. When the 44 cows that had untreated retained placentas were compared with 44 cows in the same herds calving normally without retained placenta there was no significant difference in the numbers of cows in the two groups having to be sold because of sterility, abortion, or delayed conception. In these two herds no cows were bred back until 90 to 150 days after calving.⁵¹

The effect of retained placentas on subsequent fertility is important to consider, as delayed involution and chronic endometritis following retention of the membranes is common. Apparently after 2 to 3 months and a number of estrous periods most cattle having a retained placenta eliminate the infection and the uterus becomes normal. In 71 abnormal calvings the postpartum interval from calving to complete uterine involution averaged 52 days or only 5 days longer than in 252 cows that calved normally.¹³ If the owner desired to breed the cow before 90 days after the abnormal calving, examination of the uterus to determine if it was completely involuted was recommended. About 20 percent of cows retaining their placenta at one calving had another retention at subsequent parturitions. Young cows having a retained placenta averaged one less calving than cows the same age not affected with retained placenta.²³ Cows not having genital disorders such as chronic metritis following retained placentas were nearly as fertile as normal cows but there was a 30 to 50 percent greater probability that genital disorders would occur in affected cows. The nonreturn rate to first service before 60 days postpartum was 28.2 percent in cows with retained placenta and 50.3 percent for cows without a retained placenta; after 60 days the comparable percentages were 52.2 percent and 64.0 percent. When "nonreturn" cows after service were checked to diagnose pregnancy they found 10.6 percent of 592 cows with retained placenta at their previous calving were not pregnant while only 5.4 percent of 19,173 cows with no retention were not pregnant.⁴⁶ Following

retained placenta in some cows, permanent sterility results, due to pyometra, perimetritis, salpingitis, ovaritis, severe damage to the endometrium, or other causes related to the retention. In most of the animals affected with retention of the fetal membranes the major loss is an economic one of a slight to moderate loss of milk and a slight to moderate delay in the involution of the uterus and subsequent conception.

In 100 dairy cows calving within a 4-month period,^{12b} 27 percent had retained fetal membranes of which only two-thirds were noted within 24 hours after parturition. Thirty-four percent of the cows had postpartum metritis of which 76.5 percent were secondary to other postpartum problems, mainly retained fetal membranes. Despite several types of local and systemic antibiotic therapy given within 24 hours of parturition to problem cows, 76 percent developed a secondary metritis compared to 12 percent of the untreated normal-calving cows. Delayed uterine involution at 30 days postpartum was more than twice as common in the cows with metritis than in the normal-calving cows. This recent study and review^{12b} confirms earlier reports on the lack of information on the incidence, causes and therapeutic procedures to prevent and treat herds and cows with postpartum uterine disease problems.

Treatment. After reviewing the literature on bovine retained placenta and listening to many veterinarians describe their methods of treatment, the author has been amazed and impressed by the infinite number and variety of techniques employed, the drugs and hormones recommended, and the time lapse between parturition and the attempted removal of the placenta. With so many varied techniques and products being used, one is forced to recognize the fact that probably no treatment would be necessary in handling most cases of retention of the fetal membranes. This has been demonstrated.⁵¹ In England and in Europe there is an increasing volume of opinion in favor of not making any manual attempt to detach the fetal placenta from the maternal caruncles.² No matter how carefully the operation is performed some injury to the endometrium may result, and the risk of toxemia and septicemia is thereby increased.

Presently the author conservatively recommends that all cows having a retained placenta 12 hours after calving be given a parenteral antibiotic injection that may be repeated. Since the colostrum milk is discarded this therapy causes no economic hardship and the cow is significantly protected against a serious uterine or systemic infection. It is optional with the owner and veterinarian whether the placenta is removed manually.

A clean, manual examination of the uterus can be made. The operator should wear a surgical rubber glove and

long sleeve on one arm and a surgical glove on the other to protect himself from brucellosis or an infection of the arm or hand. Disposable plastic gloves and sleeves of good quality are more sanitary and practical than rubber gloves and sleeves. He should wear rubber coveralls or an apron and boots that may be easily cleaned and disinfected after the operation. The perineal region of the cow should be carefully cleaned and washed with soap, water, and mild antiseptic, and kept clean during the operation. To keep the cow, especially one with loose feces, from either defecating frequently or straining, epidural anesthesia may be used. A plentiful supply of clean water is essential. The cow's tail should be held out of the way by an assistant or tied with a tail rope over the back to one of its fore legs. The free part of the fetal membranes should be drawn through the cervix, thereby reducing the amount of membranes in the uterus and aiding its drainage. If the fetal membranes fall away readily from the caruncles they should be removed. If much fluid is present in the uterus it should be siphoned off by a sterile soft rubber horse catheter or stomach tube held in the fist to keep the fetal membranes from plugging the end of the tube. The siphon may be started by filling the rubber tube with water and holding it pinched off as it is introduced. Douching the uterus is contraindicated when membranes are present as it is difficult to remove the fluid completely. Another method of removing this excess fluid is to use large swabs of absorbent cotton and gently wipe the uterus free of exudate.²⁴ Large amounts of fetid reddish watery fluid in the uterus is usually accompanied by signs of toxemia, depression, and anorexia.

Manual removal of a retained placenta in the dairy cow is practiced by most veterinarians because the diseased, macerating fetal membranes are serving no good purpose and the farmer desires and expects the veterinarian to remove this unsightly fetid mass from the genital tract. In most cases the fetal membranes have not macerated sufficiently for easy removal before 48 hours after parturition. Although in some cases enough autolysis has occurred so the villi separate readily from the crypts and removal may be accomplished easily as early as 12 to 24 hours after calving. The best time for removal of the placenta was reported to be 24 to 48 hours after parturition.^{6,64} These easily removed fetal membranes would probably have dropped away without aid within another 24 to 48 hours. It has been the practice of the author and many other veterinarians not to examine or treat retained placenta until 72 hours after parturition unless the cow develops anorexia, an elevated temperature or other symptoms of septicemia. At this time the uterus has contracted in most cases so the apex of the horn may be

reached. The cervix is usually still sufficiently open to allow passage of the hand and arm without resultant trauma. When removal is attempted at 72 hours after parturition the uterus has developed a protective barrier to the infection and there is less chance of a septicemia or toxemia occurring than there would be if removal is attempted earlier. At whatever time the placenta is removed this should be done gently and quickly within 5 to 20 minutes, in a clean manner, and with as few withdrawals and reintroductions of the arm as possible. The use of epidural anesthesia controls straining and defecation and makes possible a cleaner, more hygienic, and gentler operation. If the operation cannot be performed in a gentle manner, with as little interference as possible with nature's processes, the fetal membranes should be left alone even though the cervix may contract so that on subsequent visits by the veterinarian the hand cannot be inserted into the uterus. If this happens it is best not to attempt dilation of the cervix, as it is difficult or nearly impossible to do so without severe trauma. The membranes should be allowed to fall away naturally, or gentle traction on the fetal membranes will remove them after the maternal caruncles and fetal cotyledons have separated from the uterine wall by autolysis. Even if the membranes or a portion of them macerate and are absorbed in the uterus this is better than severely traumatizing the cervix in attempts to dilate it.

It has been observed by the author and others that if the placenta is allowed to drop away of its own accord, or if it is gently withdrawn from the uterus even 10 to 12 days after parturition, involution of the uterus occurs sooner, and cessation of uterine discharge ceases more quickly than when the placenta is removed in a rough manner and portions are left in the uterus. In a study of 632 cows with retained placenta a conservative systemic treatment with sulfonamides orally and intravenously resulted in higher subsequent fertility than a more "radical" treatment with manual removal and various local intrauterine treatments.²⁹ The uterus containing a retained placenta may be compared with a large abscess in which the necrotic core has not separated from the surrounding tissues. The surgical procedures governing the handling of an abscess should also govern the handling of the infected uterus. Conservative treatment is indicated and essential.

The veterinarian should have the courage of his convictions in handling these cases, inasmuch as traumatizing the uterus by attempting to remove the placenta when removal is difficult or impossible results in either immediate septicemia with a marked drop in milk and appetite, elevation of temperature, loss of weight and possible death, or else a prolonged period of convalescence

during which time shreds of placenta and exudate are expelled from the uterus, pyometra or chronic metritis develops, or protracted or even permanent infertility may result from a uterine abscess, perimetritis, salpingitis or severe endometritis. If in order to avoid traumatizing the uterus or leaving placental shreds and fragments in the uterus a veterinarian refuses to remove a placenta that is not ready to be separated from the maternal caruncles, and explains to the owner his reasons for the decision, this may prevent criticism by a client who formerly has been accustomed to having the placenta "taken" on the first and only call in all cases of retained placenta.

Manual removal of the placenta is contraindicated in cows with an elevated body temperature, above 103° F. and in cows or heifers suffering from severe necrotic vaginitis. In the former a septicemia and toxemia are already present and would be aggravated by manual manipulation of the placentomes. Administration of antibiotics parenterally and locally, or sulfonamides orally or intravenously in cows showing toxic symptoms is indicated for a period of several days before removal is attempted. Removal of the placenta particularly in heifers having necrotic vaginitis and vulvitis with a small, dry, swollen genital canal may make the vaginitis and vulvitis worse and may increase straining that is probably already present. Since it has been proved that most cows suffering from retained placenta need no treatment, and the others only parenteral treatment with antibiotics or parenteral and oral treatment with sulfonamides to control septicemia, the removal of the placenta from a cow with an elevated temperature, vaginitis, septic metritis or possibly other diseases, such as acute mastitis and traumatic gastritis, is contraindicated. Removing the placenta in an incomplete, rough, insanitary manner is always inadvisable.

Occasionally when the union between the cotyledons and caruncles is very firm and most of the caruncle becomes necrotic and sloughs, it may be 10 to 15 days before the macerating placenta and cotyledons can be removed. If the fetal membranes are removed prematurely by traction or improper manual removal, thereby leaving the fetal cotyledon on the necrotic maternal caruncle, these necrotic caruncles and cotyledons may become dry and inspissated and remain as a foreign body in the uterus for 3 to 8 weeks or longer. When found several weeks after parturition, they may be removed by injections of estrogens to relax and dilate the cervix and contract the uterus together with gentle massage of the uterus per rectum. A rubber douche tube may be used as a siphon and by suction on the caruncles by the siphon tube they may be coaxed and withdrawn through the cervix. If left in the uterus these may eventually macerate,

but recovery is prolonged and chronic metritis, pyometra and sterility usually occur.

In removing the placenta manually the third or fourth days after parturition, or earlier if the placenta can be removed easily, the hand is inserted between the endometrium and chorion in the intercotyledonary space and the individual fetal cotyledon and its caruncle are grasped gently, squeezed, and with the thumb and forefinger the two structures are gently separated by a rolling, pushing, squeezing motion. This may be aided by traction with the other hand on the adjacent portions of the fetal membranes as the separation is completed. The cotyledons in the cervical area of the uterus are removed from the caruncles first and then by traction with the outside hand the placenta is pulled out and tension maintained as the cotyledons in the middle portion of the horn and the non-gravid horn are removed. The ovarian pole may be difficult to reach. Sometimes traction on the placenta will pull the apex of the horn nearer the cervix and thus aid removal. It is highly desirable to remove all of the fetal membranes and not leave remnants in the uterus to act as foci of infection as these must be expelled or macerate before recovery can take place.^{69b} The blood vessels of the placenta are among the last portions of the placenta to macerate. If the entire placenta cannot be removed, it is better to insert a few capsules, tablets, or a solution of antibiotic and revisit the cow in one to three days, or let the placenta fall away naturally.

The layman's practices of tying a weight on the placenta or of cutting the placenta off close to the vulva are not desirable. First, the weight frequently causes the cow to strain and causes premature and incomplete breaking away of the afterbirth, leaving a part of it still in the uterus. In rare cases this weight may cause invagination of the uterine horn. Removing the placenta close to the vulva in order to prevent the cow from swinging it against the milker is likely to result in the placenta dropping back into the uterus followed by early closure of the cervix. The afterbirth may remain in the uterus long after it has separated from the caruncles, because the weight of the placenta hanging from the vulva is not present to draw it out. If the placenta is dragging on the ground it should be cut off at the level of the hocks to prevent its being stepped on and torn away from the uterus.

Hormones have been widely used in the treatment of retained placenta. The use of oxytocin has been mentioned as being of possible value in preventing retained placenta when given shortly after the expulsion of the fetus or after dystocia operations. In dystocia, besides aiding in the expulsion of the fetal membranes, oxytocin may prevent prolapse of the uterus. It is advisable to inject 3 to 5 ml., 30 to 50 units, immediately after calving. One to

3 further subcutaneous injections of 2 to 3 ml. of oxytocin at 1- to 2-hour intervals may be given. Occasionally injections of oxytocin precipitate milk fever in cows with subclinical hypocalcemia. The oral administration of a proprietary calcium product containing trace minerals and vitamins within a few hours after calving reduced the incidence of milk fever and also reduced the incidence of retained placenta by about 50 percent.¹⁹ Further studies on the administration of oxytocin and calcium to cows failing to drop their fetal membranes soon after calving is indicated as there is a close association between milk fever and retained placenta. Oxytocin is of questionable value after 24 to 48 hours after calving.

The estrogens have been widely used in the past in the treatment of retained placenta. Stilbestrol or estradiol has little or no effect on the rate of separation of the fetal cotyledons and maternal caruncles. Estrogens do, however, exert a definite action on the uterus by increasing its tone and muscular activity, stimulating the flow of mucus, increasing the circulation, and relaxing the cervix. These facts, together with the reports^{10,57} that the uterus is better able to control or overcome infection during estrus or when treated with estrogens, show the logic of using this hormone in the treatment of retained placenta. Presently estrogens are rarely used to treat retained placenta or metritis in dairy cows because of the ban on their use in dairy cows in the U.S. to prevent their presence in milk. Some cases of uterine atony associated with retained placenta may greatly benefit from the injection of calcium gluconate especially if a subclinical hypocalcemia is the cause of the uterine atony.²⁴ Following the injection of calcium during the first day after calving the afterbirth is often expelled within several hours. If the uterus is severely diseased and atonic the uterine wall may be incapable of responding to the injections of hormones. In recent years many veterinarians have used 1 to 3 mg of ergonovine or a similar product developed from ergot that produce a more prolonged rate of uterine contraction than doses of oxytocin. The results are equivocal.
