HEMORRHAGIC BOWEL SYNDROME

BASICS

OVERVIEW
• Hemorrhagic bowel syndrome (HBS) is a disease condition thought to be caused by *Clostridium perfringens* type A (or possibly other agents) and which leads to a necrohemorrhagic enteritis of one or more intestinal segments (usually jejunum).
• This condition can cause passage of very bloody diarrhea with blood clots in the feces or can cause an obstructive-type syndrome with production of scant or no manure and signs of colic.

INCIDENCE/PREVALENCE
• Sporadic, but occasionally occurs as an outbreak affecting up to 10% of a herd.
• Higher-producing herds have higher prevalence.
• Herds with higher rolling herd averages have higher prevalence.

GEOGRAPHIC DISTRIBUTION
• Worldwide
• Western states in the United States have a higher prevalence

SYSTEMS AFFECTED
• Digestive
• Cardiovascular
• Hemolymphatic

PATHOPHYSIOLOGY
The exact pathogenesis has not been established and attempts to replicate the disease in studies using specific pathogenic agents have not been successful. Postulated pathophysiologic mechanisms include the following:
• *C. perfringens* type A organisms are ubiquitous in environment but proliferate rapidly in the intestines under conditions of high carbohydrate or protein digestion, and liberate exotoxins that potentially play a pivotal role in disease.
• Hemorrhage occurs into the intestinal wall and lumen. Blood acts as a substrate for further proliferation of clostridial organisms.
• The fungus *A. fumigatus* has been proposed to incite tissue damage and releases immunosuppressive mycotoxins which can promote more rapid proliferation.
• Segmental intestinal necrosis develops in affected locations. Devitalized bowel provides a good environment for further proliferation of anaerobic bacteria and provokes the onset of peritonitis and shock.
• Intraluminal blood clots can act as an intraluminal foreign body, causing obstruction; hemorrhage can be severe enough to cause anemia and shock.
• Associated ileus also contributes to physiologic GI obstruction; fluid and gas distension of the bowel creates colic and potentially hypochloremic metabolic alkalosis.

HISTORICAL FINDINGS
Sudden decline in milk production with anorexia and diarrhea with clotted blood, progressing to scant or absent fecal passage in early lactation dairy cattle is a common complaint.

PHYSICAL EXAMINATION FINDINGS
• Thick, viscous, dark, tarry feces.
• Decreased to absent ruminations.
• Signs of hypovolemic and/or septic shock:
  ◦ Tachycardia
  ◦ Weak pulse
  ◦ Dehydration
  ◦ Pale/congested mucus membranes
  ◦ Cold extremities
• Right abdominal distension ("papple" shaped).
• Succussable fluid in the right ventral abdomen.
• Colic.
• Intestinal distension on per rectum palpation. Per rectum examination may rarely identify an intestinal mass.
• Clinical signs generally worsen with duration of disease. Sudden death is also possible.

SIGNALMENT
• Usually affects dairy cows in second or higher lactation and within the first 100 days in milk.
• Brown Swiss cattle may be predisposed.
• Occasionally affects beef cows and bulls.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Likely a multifactorial disorder arising from a combination of management factors (nutrition) and pathogen interaction.
• *Clostridium perfringens* type A is most commonly implicated, and the β2 toxin of this organism has been implicated. However, *C. perfringens* type A can be isolated from unaffected cows, and studies inoculating healthy cows with *C. perfringens* type A have failed to reproduce the syndrome.
• *Aspergillus fumigatus* has been hypothesized to play a role in some studies.
• A more recently proposed hypothesis is the combination of mycotoxic fungi in association with Shiga toxin–producing *E. coli.*
• Risk factors:
  ◦ Brown Swiss cows were predisposed, in one study
  ◦ High milk production
  ◦ Early lactation: first 100 days in milk
  ◦ Larger dairy herds (>100 cows)
  ◦ Older cows (median parity = third lactation)
  ◦ Dairies with higher rolling herd averages
  ◦ Dietary risk factors are significant and include high energy and low fiber diets and feeding a total mixed ration.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Intussusception
• Intestinal incarceration
• Intestinal volvulus
• Salmonellosis
• Coccidiosis
• Winter dysentery
• Abomasal ulceration
• Vagal indigestion

CBC/BIOCHEMSTRY/URINALYSIS
• Mild inflammatory leukogram is common.
• Hematocrit can be normal early in the course of the disease or anemia can be apparent due to blood loss. As disease progresses the hematocrit may normalize as a result of combined anemia and hypovolemia.
• Hypochloremic, hyopokalemic, metabolic alkalosis can occur with proximal intestinal obstruction.

OTHER LABORATORY TESTS
N/A

IMAGING
Abdominal ultrasound (transabdominal or transrectal) can reveal small intestinal distension with hypomotility. Intraluminal blood clots may be apparent. The intestinal wall of devitalized segments can appear thickened and hyperechoic.

OTHER DIAGNOSTIC PROCEDURES
• Abdominocentesis—increased total nucleated cell count, total protein and lactate concentration combined with low glucose concentration of the peritoneal fluid suggests devitalization and secondary septic peritonitis.
• Exploratory laparotomy.

PATHOLOGIC FINDINGS
• Segmental necrohemorrhagic enteritis is apparent. The jejunum is most commonly affected but the ileum and duodenum can also be affected.
• Intramural hematomas and intraluminal blood clots.
• Mucosal ulceration and necrosis.
• Submucosal hemorrhage and edema.
• Neutrophilic infiltration.
• Fibrinous covering on serosal surfaces.
• Peritoneal effusion.

TREATMENT

THERAPEUTIC APPROACH
• Affected cows require supportive medical care with appropriate fluid treatment (preferably IV) to restore circulating volume and to reverse electrolyte and acid-base imbalances.

(CONTINUED) HEMORRHAGIC BOWEL SYNDROME

• A combination of surgical and medical therapy is generally regarded as optimal; however, the prognosis is typically poor, regardless (<50% survival expected).

SURGICAL CONSIDERATIONS AND TECHNIQUES

• Right flank exploratory laparotomy is indicated.
  ◦ The lesion can usually be palpated but may be difficult to exteriorize.
  ◦ Affected bowel loops feel distended and turgid. If visualized, they may appear dark, congested, and necrotic.
• Extraluminal massage of affected segments allows fragmentation of intraluminal blood clots and is preferred if possible.
• Enterotomy can be performed to remove intraluminal hematomas, and resection and anastomosis of necrotic bowel segments might be necessary; both are associated with worse prognosis compared to extraluminal massage.

MEDICATIONS

DRUGS OF CHOICE

• Antimicrobial drugs are indicated, such as procaine penicillin G.
• NSAIDs, such as flunixin and ketoprofen, provide analgesia and anti-inflammatory effects.
• Prokinetic agents such as metoclopramide may help restore GI motility after surgery.
• Laxatives.
• Whole blood transfusion is indicated for cattle with severe anemia or signs of hemorrhagic shock.

CONTRAINDICATIONS

Prokinetic agents should not be given to animals with suspected GI obstruction.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• The prognosis is guarded to poor with reported mortality rates varying from 55% to 100%.
• Recurrence is possible in cows that recover from clinical disease.
• Cows that undergo enterotomy or enterectomy have a worse prognosis than cows undergoing extraluminal massage of affected bowel segments.
• Cows undergoing surgical intervention may need to be reoperated if they fail to improve postoperatively.

POSSIBLE COMPLICATIONS

• Peritonitis
• Hemorrhagic or septic shock

CLIENT EDUCATION

Educate clients to closely monitor the most vulnerable group (high-producing mature cows in second or higher lactation and the first 100 days of milk).

PATIENT CARE

Transfaunation or supplemental nutrition may be required for cows with prolonged anorexia.

PREVENTION

• Improve feed management
• Increase fiber content in feed
• Administer *C. perfringens* type A toxoid (vaccine) to adult cows
• Addition of mycotoxin binding agents or probiotics to the ration

MISCELLANEOUS

ASSOCIATED CONDITIONS

Peritonitis

AGE-RELATED FACTORS

Older cows are predisposed: median parity of affected cows is third lactation.

ZOONOTIC POTENTIAL

None

PREGNANCY

N/A

BIOSECURITY

Not usually regarded as a contagious disorder

PRODUCTION MANAGEMENT

Although this is usually a sporadic disorder, economic losses can be severe due to reduced milk production, treatment and surgical expenses, and mortality.

SYNONYMS

• Jejunal hemorrhage syndrome
• Bloody gut
• Dead gut
• Hemorrhagic enteritis

ABBREVIATIONS

• GI = gastrointestinal
• HBS = hemorrhagic bowel syndrome
• NSAIDs = nonsteroidal anti-inflammatory drugs

HEMOTROPIC MYCOPLASMAS (FORMERLY EPERYTHROZOONOSIS)

BASICS

OVERVIEW

• Epierythrocytic parasites (*Candidatus Mycoplasma* spp.) are often considered to be a subclinical disease of cattle, small ruminants, and camelids. However, it can be a significant cause of hemolytic anemia in immunologically naïve, immunosuppressed, or debilitated individuals.
• Current nomenclature recommendations are as follows: *Mycoplasma* (formerly *Eperythrozoon*) *wenyonii* in cattle, *Mycoplasma* (formerly *Eperythrozoon*) *ovis* in sheep, and *Mycoplasma haemolamae* in camelids. Collectively, these are often referred to as the hemoplasmas.

INCIDENCE/PREVALENCE

The disease is often subclinical, and widely used diagnostic methods (examination of blood smears or serology) are not sensitive enough to detect latent infection. Thus, it is difficult to actually determine the prevalence of the disease. The use of a recently developed and highly sensitive PCR assay has thus far detected latent infection in approximately 20% of New World camelids in the United States, Canada, and Australia. Recently, *Mycoplasma wenyonii* was found in 89% of cattle in Japan and was associated with lower milk yield.

GEOGRAPHIC DISTRIBUTION

Cases have been reported worldwide

SYSTEMS AFFECTED

• Cardiovascular
• Hemolymphatic
• Integument
• Reproductive

PATHOPHYSIOLOGY

• Hemoplasmas are contractible via inoculation of infected blood. Biting insects are considered vectors, though a specific insect has not been identified as the principal vector. *Mycoplasma wenyonii* has been detected by PCR in lice, flies, and mosquitoes. Transmission may also occur vertically and via blood-contaminated needles or instruments.
• Parasitemia develops within days of inoculation, but the rapid onset of an effective immune response curtails proliferation, halting further progression. Thus, latent infection can be common in endemic herds and the organism often coexists symbiotically within the host without causing clinical signs of anemia.
• The recent development of highly sensitive PCR assays have detected the organism in the blood of otherwise apparently healthy individuals.
• Debilitated, immunosuppressed, or immunologically naïve individuals are susceptible to uncontrolled parasitemia and clinical signs of disease develop. The organism is found on the surface of erythrocytes, which are primarily removed from the circulation by the mononuclear phagocytes in the spleen and liver.
• Icterus without hemoglobinemia or hemoglobinuria is a cardinal clinical sign. In sheep, intravascular hemolysis may also occur. Anemia develops and, in severe cases, death from hypoxemia may ensue.

SIGNALMENT

• Cattle, small ruminants, camelids, mule deer, elk. Sheep and camelids appear to be most susceptible.
• Any age may be affected but younger immunosuppressed or immunologically naïve ruminants may be more susceptible.

HISTORICAL FINDINGS

Concurrent illness, progressive depression, weakness and lethargy, poor growth or chronic weight loss, poor coat quality, anorexia, and icterus.

PHYSICAL EXAMINATION FINDINGS

• Hemoplasmas rarely cause clinical signs of disease and their presence may be a coincidental finding. Severely debilitated or immunosuppressed individuals are more susceptible to clinical hemoplasmosis.
• The signs of the primary disease process that are responsible for immunosuppression often overshadow the clinical signs of hemoplasmosis.
• Clinical signs of disease infrequently occur in cattle and the presence of hemoplasma species may be a coincidental finding in some individuals.
• Immunosuppression from concurrent systemic disease may predispose individuals to hemoplasmosis; however, the primary disease process may conceal the signs of hemoplasmosis.
• Fever, weakness, and recumbency are expected if the condition progresses. In severe cases, tachycardia, tachypnea, pallor of the mucus membranes, lack of episcleral vessels, and icterus develop.
• Although hemolysis is primarily extravascular, intravascular hemolysis can occur in sheep and thus hemoglobinuria may be present.
• In chronic infection, signs of anemia or chronic ill thrift may be present without signs of active hemolysis (e.g., icterus). In cattle, mammary gland or scrotal and/or hindlimb edema, reduced fertility, reduced milk production, and lymphadenopathy may be the predominant signs.

CAUSES AND RISK FACTORS

• Hemoplasmosis is caused by a small (0.5 μm) coccoid prokaryotic organism that lacks a cell wall, is Gram-negative in staining, and cannot be cultivated. Although historically classified as a rickettsial organism, recent studies suggest that it is more closely related to mycoplasma.
• Current nomenclature recommendations are as follows: *Mycoplasma* (formerly *Eperythrozoon*) *wenyonii* in cattle, *Mycoplasma* (formerly *Eperythrozoon*) *ovis* in sheep, and *Mycoplasma haemolamae* in camelids.
• Hemoplasmosis is most commonly considered to be an opportunistic infection that infrequently results in clinical disease, unless an individual is severely immunosuppressed or systemically compromised.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Any cause of extravascular hemolysis in cattle would cause similar signs including anaplasmosis and autoimmune hemolytic anemia.
• The absence of hemoglobinemia and hemoglobinuria distinguishes hemoplasmosis from causes of intravascular hemolysis in cattle.
• With the occasional occurrence of intravascular hemolysis, leptospirosis and copper toxicity should be considered as differential diagnoses in sheep.

CBC/BIOCHEMISTRY/URINALYSIS

• Anemia: Regenerative anemia 5–7 days after onset (signs of regeneration include an increased MCV, anisocytosis, polychromasia, basophilic stippling, reticulocytes, Howell Jolly bodies, nucleated red blood cells); nonregenerative anemia may occur in chronic cases.
• Hemoglobinemia (pink plasma, MCH, and MCHC increased) and/or hemoglobinuria may occur in sheep.
• Hyperbilirubinemia (unconjugated) rarely occurs.
• Hypoglycemia.
• Acidosis.

OTHER LABORATORY TESTS

• Hemoplasma species may be seen in a routine Wright-stained peripheral blood smear on the surface of erythrocytes as a coccoid, rod, or ring-shaped organism. Smears should be made as soon as possible after blood is drawn as the organisms may detach from the red blood cells in vitro.
• Giemsa, Romanowsky, and acridine orange stains are particularly helpful to highlight the organisms. Parasitemia is often low, or affected cells are removed from the circulation by the mononuclear phagocytic system, therefore absence of visible hemoplasma species does not preclude the diagnosis.
• Complement fixation and indirect fluorescent antibody tests are positive within a few days of onset of clinical disease but, in some cases, may remain positive for only a short period of time. Unless paired serology is used, a single positive titer cannot distinguish

between recent infection and previous exposure.
• A PCR test has been developed to detect the organism in camelids and cattle and is more sensitive in detecting the organism than examination of blood smears.
• The evolution of an immune attack directed at the organism on the surface of red blood cells may lead to a positive Coomb's test.

PATHOLOGIC FINDINGS
Splenomegaly, edema, body cavity effusion, and widespread icterus

TREATMENT

THERAPEUTIC APPROACH
• Tetracyclines (see "Medications").
• If anemia is severe and clinical or laboratory evidence of hypoxemia is evident (intense lethargy or weakness, profound tachycardia or tachypnea, severe anemia, acidosis, increased anion gap), a whole blood transfusion is indicated.
• The normal total blood volume is approximately 8% of the body weight (i.e., 0.08 × body weight in kilograms equals the total blood volume in liters). Typically, transfusing one-fourth to one-third of the total blood volume is adequate.

MEDICATIONS

DRUGS OF CHOICE
Tetracycline (10 mg/kg IV q12–24h for 3–5 days in cattle or long-acting oxytetracycline 20 mg/kg SQ q72h for 2–5 treatments in camelids) is effective in controlling acute parasitemia, but it may be less effective in eliminating latency. Tylosin (5 mg/kg IM for 3 days) has also been reported to be effective in cattle.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
The prognosis is good with treatment.

POSSIBLE COMPLICATIONS
Death from hypoxemia, poor wool quality, reduced fertility, chronic weight loss

PATIENT CARE
• Monitor heart rate, respiratory rate, attitude, appetite, PCV
• Limit activity by confining animal

PREVENTION
• Single use needles in infected herds to minimize transmission.
• Disinfect instruments between animals.
• Currently, there is no vaccine for hemoplasmosis.

MISCELLANEOUS

ZOONOTIC POTENTIAL
N/A

BIOSECURITY
In infected herds, since transmission may occur vertically and via blood-contaminated needles or instruments, use single use needles and disinfect instruments between animals.

SYNONYM
Eperythrozoonosis

ABBREVIATIONS

HEREDITARY CHONDRODYSPLASIA: OVINE

BASICS

Ovine hereditary chondrodysplasia (HC), also known as spider lamb syndrome (SLS).
• *Heritable* congenital defect that produces multiple, severe skeletal deformities in young lambs. "Spider" relates to severe valgus limb deformities that create a "spider-legged" appearance.
• *Genetic defect* disrupts normal ossification processes involving transformation of cartilage to bone resulting in skeletal overgrowth phenotype.
  ◦ Semilethal—affected lambs seldom survive past 6 months of age.
  ◦ Most common in black-faced breeds of sheep.
  ◦ First described in United States in 1980s in popular lines of Suffolk and Hampshire sheep.
  ◦ Documented in Suffolk, Hampshire, Shropshire, Oxford, Southdown, and associated crossbred sheep.
  ◦ Entered non-black-faced breeds (*ex*: *Southdown*) through crossbreeding programs.
  ◦ Prior to availability of DNA testing, *white* and *gray* pedigrees used to define carriers. *Gray* individuals—pedigrees linked to suspected carriers. *White* individuals—pedigrees with no apparent incidence of carriers. Pedigrees often inaccurate—now DNA testing a better option.
  ◦ Inheritance pattern—simple autosomal recessive. NN = normal; NS = carrier; SS = clinically affected lamb. Some researchers suggest codominant rather than simple autosomal recessive, with a single mutant (A) allele sufficient for long-bone growth enhancement.
• Inherited chondrodysplasia in crossbred Texel sheep
  ◦ Skeletal disease in Texel sheep characterized by disproportionate dwarfism, limb deformity, tracheal collapse.
  ◦ Inheritance pattern—recessive mode of inheritance in Texel sheep.

INCIDENCE/PREVALENCE

• In a German Suffolk mutation frequency study, 125 healthy, unrelated Suffolk rams were analyzed; 11 HC carriers were observed, indicating an FGFR3 allele mutation frequency of 4%.
• Another study found 97 of 336 (28.9%) carriers of A allele (HC-associated).
• During 5-year study of Texel sheep, 20 of 1,500 (1.3%) lambs per year were affected.

GEOGRAPHIC DISTRIBUTION

• United States and Canada as well as other countries where carrier sheep have been imported (Australia, New Zealand, Germany).
• Regions where black-faced breeds are common (Midwestern US).

SYSTEMS AFFECTED

• Musculoskeletal
• Respiratory (Texel sheep)

PATHOPHYSIOLOGY

Genetic defect linked to fibroblast growth factor receptor 3 (FGFR3) on sheep chromosome 6.
• Single-base change in tyrosine kinase II domain of the ovine FGFR3.
• FGFR3 normally downregulates chondrocyte growth in bone development process.
• Homozygous SS disrupts downregulation of process resulting in excessive and disorderly proliferation and transformation of chondrocytes to bone.
• Newly-recognized in the Texel breed.
• Recessively-inherited genetic disease with a defect in synthesis of glycosaminoglycans in cartilage matrix.

HISTORICAL FINDINGS

Two distinct clinical entities can confuse practitioners:
• *Affected lambs that appear grossly normal at birth*. While subtle deformities are present at birth, typical limb deformities and muscle atrophy associated with HC may not be readily apparent until the lamb is 4–6 weeks old.
• *Affected lambs with visible deformities at birth*. Severe skeletal deformities obvious at birth, may affect neonatal survival.

SIGNALMENT

• Ovine, primarily US black-faced Suffolk and Hampshire sheep, of both sexes.
• Larger-framed.
• Young (between 3 weeks and 9 months of age) or congenital disorder.
• Clinical signs as early as 1 week and as late as 2 years in Texel sheep.

PHYSICAL EXAMINATION FINDINGS

Clinical description of skeletal deformities observed in both groups include:
• Abnormally long, thin-boned legs with a long, fine neck (extreme type for breed).
• Small, rounded head (Roman nose) with occasional lateral deviation of the nose.
• Moderate-to-severe muscle atrophy—progresses with age.
• Scoliosis (usually) and/or kyphosis (less common) of the spine.
• Wide, flattened-appearing sternum with small palpable "dimple."
• Moderate-to-severe valgus deformities distal to the hock and/or carpus; severity increases with age and growth.

GENETICS

See "Pathophysiology"

CAUSES AND RISK FACTORS

• Breeds commonly associated with the problem
• Mating carrier sheep: NN × NN = 100% NN; (NS × NS = 25% SS + 50% NS + 25% NN

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Inherited ovine arthrogryposis (IOA)
• AGH syndrome (arthrogryposis-hydranencephaly syndrome) and/or limb deformities
• Cache Valley Virus—joints feel "frozen," lack of articulation; die at birth
• Plant toxicities—*Veratrum californicum*, locoweed (*Astragalus or Oxytropis* spp.)
• Maternal manganese deficiency

CBC/BIOCHEMISTRY/URINALYSIS

Nondiagnostic: Slightly increased alkaline phosphatase activity associated with bone lesions

OTHER LABORATORY TESTS

• Blood or semen can be submitted for DNA testing to confirm genotype.
• Genetic test based on A > T polymorphism in exon 17 of ovine FGFR3.
• DNA isolated from blood or semen can identify NN, NS, or SS status.

IMAGING

• Radiographic findings—abnormal areas of ossification observed throughout skeleton.
• Live animal or postmortem: Flexed lateral of the elbow reveals multiple irregular "islands" of ossification in the olecranon.
• Postmortem: VD or DV view of the sternum (disarticulated from ribs) reveals multiple irregular islands of ossification instead of normal symmetrical bipartite pattern.

OTHER DIAGNOSTIC PROCEDURES

Clinical signs (suggestive), radiologic and necropsy findings (supportive)

PATHOLOGIC FINDINGS

• *Skull*: Rounding of dorsal silhouette (Roman nose appearance) with elongation and erosion of cartilage on the occipital condyles.
• *Sternum*: Sternebrae irregular shape and size, failure to fuse, malalignment and dorsal deviation of second-to-sixth sternebrae.
• *Vertebrae*: Consistent scoliosis, misshapen, excessive amounts and abnormal configuration to vertebral body cartilage.
• *Appendicular skeleton*: Excessive cartilage in olecranon and scapula, lateral "bowing" of distal radius and ulna, hindlimbs usually less severely affected, erosion of articular cartilage in most joints.

Texel Sheep

• Erosions of articular cartilage (femoral head).
• Exaggerated convex curvature of the ribs and costal cartilages, creating a "barrel-chested" appearance and a wide-based stance.

• Gross and microscopic lesions in tracheal, articular, epiphyseal, and physeal cartilage.
• Affected sheep that survive to breeding age: prematurely developed DJD, especially in major weight-bearing joints (shoulder, hip, and stifle).

TREATMENT

None. Euthanasia suggested once diagnosis confirmed.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Semilethal in US black-faced Suffolk and Hampshire
• Lethal chondrodysplasia in Texel sheep

POSSIBLE COMPLICATIONS

N/A

CLIENT EDUCATION

Breeders should be informed about the DNA-based test for the detection of HC carriers.

PATIENT CARE

• Due to the ALD, may need to help lambs to stand so they can nurse.
• Avoid excessive exercise/stress (exercise intolerance) in Texel sheep (i.e., movement with sheepdogs).
• Euthanasia is justified upon diagnosis or with lameness/reluctance to walk.

PREVENTION

Where appropriate, DNA test and utilize only NN rams in the breeding program.

MISCELLANEOUS

AGE-RELATED FACTORS

Clinical signs noted upon birth, some noted at 1 week and some as late as 2 years.

PRODUCTION MANAGEMENT

The continued use of rams from the same breeder will, eventually, lead to carrier ewes in the commercial herd being bred to carrier rams.

SYNONYMS

• Congenital chondrodysplasia in sheep
• Ovine hereditary chondrodysplasia or hereditary chondrodysplasia
• Spider lamb syndrome
• Spider leg syndrome
• Spider syndrome

HISTOPHILUS SOMNI COMPLEX

BASICS

OVERVIEW

• *Histophilus somni* is a small, pleomorphic, Gram-negative bacterium.
• An infection with *Histophilus somni* is often referred to as "Histophilosis," implying that the infection is systemic even though the clinical manifestation may be specific to an organ system. It was first identified in 1960 as the cause of infectious thromboembolic meningoencephalitis (ITEME) in feedlot cattle. It was later modified to thrombotic meningoencephalitis (TME) when it was recognized that embolism was not part of the pathogenesis.
• Historically this encephalitic form of the infection was recognized to be the main manifestation.
• More recently it has been shown to be an important cause of sporadic "sudden death" in groups of weaned, confined cattle and associated with diverse pathologic processes.
• Investigators have isolated the organism from the reproductive tract of both male and female cattle, but descriptions of overt disease are not common.

INCIDENCE/PREVALENCE

• Culture of normal animals and serologic evidence suggests infection is widespread. Clinical disease is less common.
• While histophilosis is probably a common infection of cattle in North America and elsewhere, the disease is often undiagnosed or misdiagnosed.

GEOGRAPHIC DISTRIBUTION

• In Canada and the northern United States, *H. somni* infection is considered to be a significant cause of morbidity and mortality in feedlot cattle.
• Commonly isolated in Canada, western and midwestern US. Rarely isolated in northeastern and southeastern US.
• Identified in South America, Europe, Australia, New Zealand, Russia, Israel, and Japan in both beef and dairy cattle.

SYSTEMS AFFECTED

• Respiratory
• Nervous
• Cardiovascular
• Musculoskeletal
• Ophthalmic
• Reproductive

PATHOPHYSIOLOGY

• The organism can survive in biologic fluids for several weeks in the environment. It has been established that pathogenic strains can survive within macrophages and neutrophils. Additionally, the mechanism by which this organism manages to evade antimicrobial sensitivity in vivo is not well described and it has been suggested that the presence of biofilm formation, as well as the unique pathogenesis of the lesions, may explain the often reported nonresponse to treatment.
• *H. somni* can be isolated from respiratory and reproductive tracts of a healthy animal.
• Entry via the respiratory tract is the probable route of systemic exposure to the organism. *H. somni* initially colonizes mucus membranes and contributes to the etiology of routine undifferentiated respiratory disease in this fashion.
• The presence of the organism in the bloodstream or septicemia probably initiates all other manifestations of the disease, occasionally even causing an embolic pneumonia.
• Structurally the organism has the ability to adhere to the endothelium of vessels, especially veins, causing a thrombophlebitis. This adhesion initiates a pathologic cascade in the vessel wall and leads to a thrombus formation, which ultimately compromises the blood supply leading to that portion of the organ or organs.
• All subsequent pathologic processes associated with histophilosis can be attributed to destruction of viable tissue due to the interrupted blood supply (see Web Figures 1 and 2), referred to as an infarction.
• Clinical and pathologic observations have shown that some organ systems are more affected than others, indicating that different strains may have a varying predilection for specific organ tissues.
• Thus, historically, isolated strains were associated with encephalitic pathology; however, current isolates seem more predisposed to produce pathology in the myocardium, specifically, the papillary muscles of the left ventricle.
• The change in organ system preference of *H. somni* to produce the predominant pathology has been clinically but not microbiologically described.

SIGNALMENT

• Bovine—similar disease syndromes seen in sheep infected with *Haemophilus agni* and *Histophilus ovis.* These organisms are very similar to *H. somni* and the assigned nomenclature has and may change.
• Systemic disease is seen predominantly in beef cattle and only sporadically in dairy cattle.
• Reproductive disease can be seen in both beef and dairy cattle, predominantly in females although *H. somni* can easily be cultured from semen.
• Respiratory, neurologic, and cardiovascular disease are predominantly in feedlot cattle (6–12 months of age). *H. somni*-associated respiratory disease has also been anecdotally reported in beef calves as young as 2 months still sucking their dams on range.

PHYSICAL EXAMINATION FINDINGS

Septicemia/ Systemic Disease

• Sudden death is commonly the presentation in this form of the disease.
• Depression, reluctance to move (it may be difficult to differentiate between joint pain and depression) (see Web Figure 3).
• Febrile (e.g., >104.9°F, >40.5°C).

Meningoencephalitis

• Usually found "down." If not "down," affected animals usually become recumbent quite quickly, e.g., within 8–12 hours (see Web Figure 4). Occasionally cases will demonstrate signs of hyperesthesia, opisthotonus, nystagmus, and strabismus. Convulsions can occur, rarely.
• The animal acutely affected is febrile (often high).
• Extremely depressed.
• If treatment is initiated early, thereby sparing the progression of the disease, "head-pressing" may be reported by the stock attendants (see Web Figure 5).
• Blindness is often present but may be difficult to determine when depression is so profound.
• Hemorrhagic and/or fibrinous lesions may be visible in the fundus of the eyeball if an ocular examination is possible (see Web Figure 6).

Pleuritis

The thoracic space may fill with fluid and fibrin (see Web Figure 7) so rapidly that animals die without showing clinical signs.

Pneumonia

• Pneumonia caused by *H. somni* alone is impossible to differentiate clinically from pneumonia caused by other microorganisms, especially *Pasteurella multocida*.
• The acutely affected animal is febrile (often high).
• *H. somni* most often is part of the disease complex referred to as bovine respiratory disease complex (BDRC).

Myocarditis

• Animals affected with the myocardial form of histophilosis may also be found "down" and with no treatment history.
• If not, they will usually show exercise intolerance and when movement is initiated, extreme dyspnea may develop. They too, may collapse and die "in transit."
• The hypoxemia of cardiovascular malfunction or a thoracic space lesion may mean the animal presents with signs of ataxia or apparent lameness that may confuse the attending diagnostician.

Arthritis/Synovitis

• Currently, it is uncommon to make a diagnosis of arthritis or polyarthritis caused by *H. somni* alone, because the other manifestations of the infection predominate

clinically and quickly overwhelm what is usually a mild disease.
• The *infarctive* pathologic process, so typical of this disease, may also develop in the skeletal muscles, especially in the semimembranosus and semitendinosus muscles of the hindlimbs. Animals with these lesions will usually present with "knuckling over" from the fetlock of the affected limb, ataxia, stilted gait, or even recumbency.

Reproductive Disease

• Sporadic abortion with little or no clinical signs in the dam has been reported to occur. Additionally, the organism often can be cultured from the female reproductive tract in suspect cases of infertility.
• Reproductive disease is spread via respiratory or urinary tract routes, although venereal spread remains highly probable.

CAUSES AND RISK FACTORS

• *H. somni* is a Gram-negative, nonmotile, non spore-forming, nonencapsulated, pleomorphic coccobacillus. The original name of *Haemophilus* given to the genus derived from the fact that hemolysis occurred when cultured on blood agar within 24 hours.
• Recently weaned calves are at a higher risk of infection and disease. In western Canada a possible seasonal effect (historically demonstrated by increased diagnostic laboratory submissions during November, December, and January) occurs because 80% of calves are spring-born and therefore weaned and placed in the fall.
• Confined "high risk" (e.g., multiple-source, sorted and commingled via the sale barn) calves are exposed early in the feeding period.
• Method of transmission in confinement is assumed via respiratory secretions or urine.
• Titers to *H. somni* peak within first 3 weeks of confinement, suggesting early transmission of the organism, but immunologically naïve cattle experience higher morbidity and mortality following feedlot entry.
• *H. somni*-caused mortality commonly occurs 20–60 DOF, but pathologic sequelae to a previous infection may cause death sporadically at any time during the entire feeding period.
• *H. somni*-associated reproductive tract disorders such as mastitis, abortions, vaginitis, and metritis have been reported but were not duplicated in an infectious disease model.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Sudden Death

• Animals can "suddenly die" but the primary differentiation must be between "sudden death" and "suddenly found dead" to enable the attending clinician to highlight the possibility of "selection failure" or "delayed detection" to the stock attendants. Histophilosis cases in the form of bronchopneumonia, myocarditis, pleuritis, septicemia, and meningoencephalitis can all die acutely without any apparent premonitory signs.
• The exercise intolerance so characteristic of extensive *H. somni* pleuritis and myocarditis can be confused with severe viral interstitial pneumonia, overwhelming bronchopneumonia caused by *Mycoplasma bovis*, and monensin sodium toxicity.

Central Nervous System Disease

• *H. somni* meningoencephalitis must be differentiated from listeria meningoencephalitis, the nervous form of coccidiosis, hypovitaminosis A, polioencephalomalacia, including that caused by salt toxicity/water deprivation, and other toxicities (lead, nitrate, urea). Some systemic conditions, such as ruminal overload, may resemble CNS disease on first examination by the attending clinician.
• In North America, nonsuppurative encephalopathies in the bovine can also be caused by viruses such as rabies, malignant catarrhal fever virus, Astrovirus, and West Nile virus. In addition, the nervous system vasculitis caused by bovine virus diarrhea virus must be ruled out.
• Protozoal causes of bovine meningoencephalitis such as *Neosporum caninum* and *Sarcocystis,* as well as parasites such as *Baylisascaris procyonis*, should not be overlooked.
• Swollen joints caused by *H. somni* usually resolve with treatment. If not, the putative pathogen is more likely to be *Mycoplasma bovis* and treatment is more likely to be more unsuccessful.
• Animals with a "wild" disposition may present with apparent CNS disease from cranial or upper spinal trauma of varying degrees.

Reproductive

• An *H. somni* abortion must be differentiated from other bacterial causes of abortion: *Leptospira* spp., *Listeria monocytogenes*, *Brucella abortus*, and *Campylobacter* spp.
• Other routine causes of abortion must be considered and ruled out as well—protozoa such as *Neospora caninum*; viruses such as IBR, BVDV; toxicities such as mycoses, pine needle, nitrate; and the oft incriminated, but rarely defined, trauma.

CBC/BIOCHEMISTRY/URINALYSIS

No unique or specific changes. Nonspecific changes associated with inflammation may be seen—increased fibrinogen, leukocytosis, increased neutrophil : lymphocyte ratio, increased serum globulin.

OTHER LABORATORY TESTS

• The slow-growing nature of bacterial culture can lead to overgrowth of contaminants. Similarly, previous antibiotic treatment may decrease ability to isolate organism and increase the use of molecular modalities such as polymerase chain reaction (PCR) or immunohistochemistry (IHC) to identify the organism in the lesion. Most current diagnoses of histophilosis are confirmed using IHC.
• Presence of bacteria, increased total protein, increased globulin, and a heavy concentration of neutrophils from a cerebrospinal fluid (CSF) tap at either the lumbar-sacral site or via the cisterna magna would confirm the diagnosis of meningoencephalitis.
• Similarly, isolation of the pathogen from blood, CSF, or urine of a febrile animal is much more likely if the sample is taken prior to antimicrobial treatment and confirms the diagnosis of histophilosis.
• Given the use of troponin I to confirm acute myocardial necrosis in other species in other applications, sampling of suspect histophilosis cases would help to determine the extent of clinical and subclinical myocardial disease.
• Serology—requires both acute and convalescent samples for accurate interpretation.

PATHOLOGIC FINDINGS

Sudden Death or Acute Cases

• Excessive petechiation and fibrinous synovitis is often associated with septicemia.
• Grossly visible hemorrhagic infarcts in the cerebrum are good presumptive evidence of encephalitis or TME.
• A finding of fibrinous pleuritis without pneumonia would support a tentative diagnosis of *H. somni* pleuritis.
• A gross pathologic finding of fibrinosuppurative bronchiolitis and bronchopneumonia would need further diagnostic support, such as culture and/or IHC, to definitively rule in a diagnosis of *H. somni* bronchopneumonia.
• The very common finding of extensive pulmonary edema or left-sided heart failure (LSHF) (see Web Figure 8) and focal myocardial necrosis confirms a diagnosis of *H. somni* myocarditis (see Web Figure 9). On occasion, field necropsy may demonstrate a more extensive peracute myocardial necrosis without LSHF referred to as pan-myocarditis (see Web Figure 10).
• When the synovial fluid of the major joints is cloudy and discolored with flecks of fibrin, portions of the joint capsule should be sampled and submitted for *H. somni* IHC to confirm a diagnosis of *H. somni* polyarthritis, recognizing that some diagnostic laboratories would still only use standard culture to identify the organism.
• Occasionally all organ systems or spaces lined by mucus or smooth membranes, e.g., joints, pericardium, inner ear (see Web Figure 11), mammary gland, thorax, and abdominal space, may be affected and *H. somni* polyserositis may be the most probable consideration.

HISTOPHILUS SOMNI COMPLEX (CONTINUED)

• A diagnosis of *H. somni*-caused abortion is characterized by a necrotizing placentitis and nonspecific lesions in the usually semi-autolyzed fetus that must be confirmed by additional diagnostic support.

Chronic Cases

• Over time, the fibrinous pathologic process will be replaced by fibrosis, which may add to the repertoire of clinical signs, e.g., more free gas bloat and congestive heart failure. Thus, previous fibrinous pathologic processes will have become fibrotic adhesions.
• Necrotic foci in the lung and heart may sequestrate (see Web Figure 9), or an extensive fibrinous pleuritis may effectively eliminate the pleural space. The animal's demise is then caused by compression pulmonary atelectasis.

Musculoskeletal System

An *H. somni* septicemia may cause pale areas in the semimembranosus or semitendinosus muscles that are grossly visible muscle infarctions that can usually be confirmed with IHC examination of the sampled muscle tissue. Similarly, *H. somni* arthritis can usually be confirmed with IHC examination of the synovial membrane of an affected joint.

TREATMENT

THERAPEUTIC APPROACH

• For histophilosis in general, more important than the treatment of choice is the length of treatment and early detection. For example, atreatment protocol for animals in recumbency, animals losing weight, or animals whose lameness does not resolve, should be developed by the attending veterinarian with sound animal welfare, appropriate nursing care, and a definitive diagnosis in mind.
• Treatment for *H. somni* infection should be started as soon as signs are noted.

MEDICATIONS

DRUGS OF CHOICE

Respiratory Disease

• Treatment for pneumonia would resemble treatment for pneumonias of all other causes. Typically, affected animals are treated for undifferentiated BRDC with many antibiotics labeled for that treatment.
• Several antibiotics are specifically labeled for treatment of *H. somni:*
  ◦ Ceftiofur (1.1–2.2 mg/kg SQ for 3–5 days)
  ◦ Enrofloxacin (7.5–12.5 mg/kg SQ)
  ◦ Florfenicol (40 mg/kg SQ).

Neurologic Disease

• Treatment for *H. somni* meningoencephalitis as well as the other manifestations of the infection should be started as soon as signs are noted. While common antimicrobials at labeled doses are all good choices, in Canada, florfenicol is recommended.
• However, no drugs are labeled for this use in the US. Extra-label use requires that the practitioner provide an appropriate drug withdrawal timetable.
• Common antibiotics that will cross the blood–brain barrier: Florfenicol and oxytetracycline should be considered.
• To limit or reduce the development of the cerebral edema that sometimes occurs with TME, the labeled dose of dexamethazone is indicated.

Herd Medication

• Mass medication with sustained-action oxytetracycline injections in the face of a histophilosis outbreak has not been shown to be an effective control of histophilosis; however, it was significant in controlling death loss due to undifferentiated BDRC.
• Medicating the feed with chlortetracycline or oxytetracycline at 5–6 g per head (~ 250 kg calf) per day has given equivocal results in controlling an outbreak of histophilosis.

PRECAUTIONS

Appropriate milk and meat withdrawal times should be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Generally, cattle treated in the early stages of disease have a better chance of recovery than those with more advanced disease, regardless of the affected system.
• Cattle with advanced neurologic disease have a poor to grave prognosis even with aggressive treatment, and "other-than *H. somni* caused" CNS disease should be contemplated and ruled out.
• If the polyarthritis-like syndrome being treated has a poor response to therapy, leading to chronic lameness, it is unlikely to be *H. somni* disease, and the diagnosis should be re-evaluated.

PATIENT CARE

• Typically involves evaluation of improvement or deterioration of clinical signs (attitude, appetite, ambulation, rectal temperature, system-associated signs).
• Clinically affected animals should have constant access to fresh, palatable feedstuffs and clean water.
• Animals should be removed from their "home" pens and confined in a low-stress, low-competition environment; preferably sheltered from the ambient local climate.
• If affected individuals become laterally recumbent and are unable to rise, or if their condition has severely deteriorated, euthanasia is appropriate. Euthanasia is especially indicated if the patient is subject to a very cold ambient environment.

PREVENTION

• The risk of histophilosis could potentially be reduced by minimizing the amount of commingling that normally occurs when calves are weaned, sorted, mixed, and transported during the sale process.
• Post-arrival metaphylaxis with sustained-action injectable antibiotics or feed additives are commonly used when a high BRDC morbidity is expected, but have given equivocal results in preventing histophilosis.
• Appropriate *H. somni* immunization, requiring two doses at a 2- to 3-week interval, has been shown in challenge models to prevent the disease.
• Results of field trials to evaluate clinical efficacy have yielded conflicting results and often demonstrated significant vaccination failure.
• Vaccination failure in field trials may be explained because immunization and challenge likely occur spontaneously.

MISCELLANEOUS

AGE-RELATED FACTORS

• Systemic disease typically is seen in feedlot cattle (age 6–12 months).
• Reproductive disease is seen in breeding-age animals.

ZOONOTIC POTENTIAL

None

PREGNANCY

Organism can cause abortion.

BIOSECURITY

Biosecurity is difficult to attain in a feedlot setting due to movement of cattle from multiple sources onto the premises.

PRODUCTION MANAGEMENT

H. somni plays a role in BRDC, which is the most economically significant disease in the beef industry.

SYNONYMS

Neurologic disease "brainer," "sleeper", "downer"

ABBREVIATIONS

• BRDC = bovine respiratory disease complex
• BRSV = bovine respiratory syncytial virus
• BVDV = bovine viral diarrhea virus
• CNS = central nervous system
• CSF = cerebrospinal fluid
• DOF = days on feed
• IBR = infectious bovine rhinotracheitis (bovine herpesvirus-1)
• IHC = immunohistochemistry
• PCR = polymerase chain reaction

HYDROMETRA

BASICS

OVERVIEW
• Hydrometra is an accumulation of aseptic fluid in the uterine lumen in absence of pregnancy and in the presence of a persistent corpus luteum (CL).
• Also known as pseudopregnancy, it can occur in all ruminants, but is most common in goats.
• It is one of the major causes of anestrus in goats during the breeding season.
• May also be referred to as "cloud burst."
• Hydrometra and mucometra may also be seen in animals with segmental aplasia of the tubular genitalia.

INCIDENCE/PREVALENCE
• Incidence of congenital abnormalities associated with hydrometra/mucometra is not known, but seems to be frequent in SAC.
• In goats, the reported incidence of hydrometra varies between 6.0% and 30%.
• Hydrometra is more prevalent in aged does.
• In a large study on 40,340 early pregnancy diagnoses in dairy goats, the mean incidence of hydrometra was 10.4% and varied from 0 to 66.6%. Incidence after breeding was higher in older goats (18.8%) than in yearlings (4.5%).

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Hydrometra is an accumulation of fluid in the uterus resulting from an abnormality (segmental aplasia) or persistence of the CL.
• Fluid accumulation in the uterus may also be observed with cystic ovarian disease.
• The etiology and pathophysiology of hydrometra in cycling animals is poorly understood. Hydrometra was induced in goats following immunization against $PGF2_{\alpha}$.
• There is no correlation between prolactin concentration and development or persistence of the CL.
• The following have been suggested as contributing factors:
  ◦ Mechanisms that decrease the production or release of $PGF2_{\alpha}$ from the endometrium.
  ◦ Exposure to phytoestrogens.
  ◦ Early fetal death with subsequent fetal resorption and a persistent CL; however, this condition has been identified in unmated females.
  ◦ Out of season breeding.
  ◦ Overuse of hormones for manipulation of the reproductive cycle.
  ◦ Congenital malformations of the cervix and uterus.

GENETICS
• A genetic predisposition has been suggested for the incidence of pseudopregnancy.
• In a study on Dutch Saanen goats, there was a 16.3% repeatability of hydrometra, and daughters of does that experienced pseudopregnancy had a significant frequency compared to controls.

HISTORICAL FINDINGS
• Anestrus in absence of pregnancy
• Failure to deliver after mating and/or a positive pregnancy diagnosis
• History of synchronization

SIGNALMENT
• Adult female goat with bilateral abdominal distention.
• Occasionally found in other ruminant species.
• Occurs most commonly in pet and dairy goats who experience estrous cycles with no opportunity to be bred.

PHYSICAL EXAMINATION FINDINGS
• Early cases may be diagnosed during pregnancy diagnosis by ultrasonography.
• Advanced cases may show signs of pregnancy (abdominal enlargement), udder development.
• Signs of parturition and spontaneous evacuation of large amount of fluid from the vagina.
• Persistent anestrus with elevated progesterone levels.
• Purulent vaginal discharge when the accumulated uterine fluid is discharged either due to $PGF2_{\alpha}$ administration or the CL spontaneously lyses and the prolonged luteal phase comes to an end.

CAUSES AND RISK FACTORS
• Age, out-of-season breeding, overuse of hormonal manipulation on the reproductive cycle, and exposure to phytoestrogens are suspected predisposing factors in cyclic goats.
• Congenital abnormalities such as unperforated hymen and segmental aplasia of the tubular genitalia (vagina, cervix, uterus) result in accumulation of various amounts of fluid (mucometra or hydrometra).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other causes of anestrus: Ovarian hypoplasia, mineral deficiencies, pituitary adenoma, pregnancy, fetal mummification.
• Other causes of fluid accumulation in the uterus: Mucometra, pyometra.
• Fluid accumulation in the uterus may be due to congenital (cervical aplasia, persistent hymen, vaginal aplasia) or acquired (cervical stenosis, vaginal adhesions) disorders.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Serum progesterone level will confirm the presence of a CL, but will not rule out a true pregnancy.
• Estrone sulfate (blood and urine) should only be present with a true pregnancy.
• Pregnancy-associated glycoproteins (PAGs) would be low in the case of hydrometra and would confirm absence of viable pregnancy.

IMAGING
• Transabdominal ultrasonography: Uterine enlargement with anechoic fluid in the lumen and no evidence of placentomes or a fetus.
• The character of fluid in the uterus varies from anechoic to echogenic with hyperechoic debris.

PATHOLOGIC FINDINGS
• The uterus is thin walled and contains thin, clear fluid.
• The amount of fluid varies from less than 250 mL to several liters (12 liters).
• The endometrium is thin and the glands are slightly dilated.
• The cervical glands and lumen are often filled with mucus.

TREATMENT

THERAPEUTIC APPROACH
• A single injection of $PGF2_{\alpha}$ is usually effective, but repeated doses may be necessary. In one study 59% of does responded to the first injection and 89.5% following two injections.
• In the case of congenital malformations of the cervix and uterus, consider culling the animal to prevent further complications in the future.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Ovariectomy or ovariohysterectomy may be considered in pet or service animals with recurrent hydrometra.

MEDICATIONS

DRUGS OF CHOICE
• Dinoprost tromethamine (5–10 mg) or cloprostenol sodium (75–100 µg/45 kg of body weight).
• Oxytocin 50 IU q12h for 4 days results in luteolysis and evacuation of fluid but this treatment is not commonly used.

CONTRAINDICATIONS
Pregnant animals or animal with congenital defects

PRECAUTIONS
Confirm pregnancy status prior to treatment.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Some cases may resolve spontaneously.
• Animals treated with $PGF2_{\alpha}$ will experience luteolysis. The fluid is expelled following decreased progesterone level and cervical dilation. Various amount of clear or cloudy fluid may be observed. The hindquarters of the female may appear soiled or wet.
• Prognosis is fair to good for fertility. Some females may develop hydrometra again if not mated.
• Culling of affected goats is generally not indicated unless a congenital malformation is detected.

POSSIBLE COMPLICATIONS

Infertility

CLIENT EDUCATION

• Importance of pregnancy diagnosis
• Wellness examination for pet goats
• SAC should undergo prebreeding examination of the reproductive system because of the high incidence of congenital abnormalities

PATIENT CARE

Observe for return to estrus

PREVENTION

• Ovariectomy
• Since the etiology of hydrometra is poorly understood, the following are suggestions for possible modes of prevention:
  ◦ Limit exposure to phytoestrogens.
  ◦ Limit out-of-season breeding.
  ◦ Limit use of hormonal manipulation on the reproductive cycle.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Mucometra: These uterine conditions are only differentiated by the gross characteristics of the fluid present in the uterus.
• Infertility.
• Early pregnancy loss.
• In SAC, congenital defects may result in other clinical signs: Systemic disease in neonates with vulvar aplasia and urine accumulation in the uterus. Vaginal aplasia and unperforated/persistent hymen can result in tenesmus and rectal prolapse.

AGE-RELATED FACTORS

• Older does are overrepresented.
• Congenital defects are seen in neonates and nulliparous females.

ZOONOTIC POTENTIALL

N/A

PREGNANCY

The affected does are anestrous with elevated progesterone levels similar to those in pregnant ewes at 5 months' gestation.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

• Hydrometra is considered a very important pathologic condition because it represents one of the main causes of temporary infertility in goats.
• It is recommended to perform pregnancy examination via transabdominal ultrasonography at 35–45 days' gestation to verify the presence of a viable fetus and confirm pregnancy.

SYNONYM

Cloud burst

ABREVIATIONS

• $PGF2_{\alpha}$ = prostaglandin $F2_{\alpha}$
• CL = corpus luteum
• PAG = pregnancy-associated glycoprotein
• SAC = South American camelids

HYDROPS

BASICS

OVERVIEW
• Hydrops or dropsical condition ("dropsy") is a pregnancy disorder characterized by excessive fluid accumulation in either the allantoic or the amniotic cavity.
• Hydrallantois (hydrops allantois) is related primarily to placental dysfunction or insufficiency.
• Hydramnios (hydrops amnion) is attributable to congenital abnormalities of the fetus that contribute directly to fluid accumulation, such as impaired swallowing or renal dysgenesis/agenesis.

INCIDENCE/PREVALENCE
• Hydrallantois represents 85–90% of dropsical conditions in the bovine.
• Hydramnios is rare, accounting for only 5–10% of uterine dropsy cases.
• In the bovine, incidence of dropsical conditions is estimated at 1 in 7,500 pregnancies.
• Increased incidence (1 in 200 pregnancies) has been reported in pregnancies resulting from embryos produced by SCNT.
• Hydrops is relatively rare in sheep, goats, and camelids.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Reproductive
• Musculoskeletal
• Multisystemic in advanced cases

PATHOPHYSIOLOGY
• Dysfunction of either the placenta or the fetus results in accumulation of excessive amounts of allantoic or amniotic fluid. The excessive weight from the rapid fluid accumulation is detrimental to the dam's health, leading to dyspnea, dehydration, and compromised GI function.
• The cause of hydrallantois is not certain. Adventitious placentation is commonly present and there may also be a deficient number of caruncles. This deficiency may be due to either a congenital lack of development or uterine disease acquired in later life.
• Hydramnios has been associated with a genetic (autosomal recessive) or congenitally defective fetus in which swallowing is impaired.
• Increased risk for hydrops in pregnancies obtained by nuclear transfer reconstructed embryos is due to errors in reprogramming of the donor genome.
• Hybrids produced by mating of an American bison bull with a domestic cow.
• Hydrops amnii in sheep may be associated with hydranencephaly due to Wesselsbron disease and Rift Valley fever.

HISTORICAL FINDINGS
• Rapid increase in abdominal girth during pregnancy
• Respiratory distress
• Reluctance or inability to stand

SIGNALMENT
• Reported in both dairy and beef cattle.
• Not as common but reported in sheep and goats usually after mid-gestation.
• Hydrallantois is seen in older cows that may lack caruncles due to prior uterine damage/trauma.

PHYSICAL EXAMINATION FINDINGS
• The major outward sign of hydrops is excessive abdominal distention during the last trimester that progressively worsens and can result in decreased appetite and difficulty in moving or rising.
• Hydrallantois: Affected cows show bilateral, rapid ventral distension of the abdomen. They are distressed, anorexic, and have no rumen activity due to compression. Dehydration and constipation follow and they eventually become recumbent. Transrectal palpation is difficult because of uterine distension and some cows may strain during the examination. The fetus and placentomes are generally not palpable. Rupture of the prepubic tendon may occur in advanced cases.
• Hydramnios: Due to the gradual nature of the increase in amniotic fluid, the cow does not show any overt clinical signs, except when viewed from the rear she shows a pear-shaped abdomen in the last 6 weeks of gestation.

GENETICS
• Hydrallantois: Pregnancies from cloned or transgenic embryos are more commonly affected by abnormal placentation and subsequently have a higher risk for hydrops allantois. Risk is also increased in pregnancies with multiple fetuses.
• Hydramnios has been associated with a genetic (autosomal recessive) mode of inheritance. Fetal abnormalities that cause this defect include bulldog calves (Dexter cattle), brachygnathic calves (Angus cattle), muscle contracture monsters (Red Danish cattle), pituitary hypoplasia/aplasia (Guernsey cattle), and hydrocephalic calves (Hereford cattle).
• Hydrops has been described in interspecies pregnancy (bison × cattle; sheep × goat).

CAUSES AND RISK FACTORS
• Pregnancy with multiple fetuses
• Mating of an American bison bull with a domestic cow
• Cloning (SCNT)
• Genetics: Certain breeds are overrepresented

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Dropsical conditions should be differentiated from other conditions characterized by abdominal distention such as:
  ◦ Ascites
  ◦ Uroperitoneum due to bladder rupture
  ◦ Abdominal masses
  ◦ Gastrointestinal problems resulting in bloat (intestinal obstruction, vagal indigestion)
  ◦ Uterine distension due to hydrometra, pyometra or multiple fetuses
• History (breeding, onset of symptoms), transrectal palpation, and transrectal and transabdominal ultrasonography are usually sufficient to make a diagnosis.

CBC/BIOCHEMSTRY/URINALYSIS
• Cases of hydrallantois may show hypoglycemia and/or hypocalcemia.
• Ketosis is a potential complication of significant abdominal distention.

OTHER LABORATORY TESTS
In an academic setting, differentiation between hydrallantois and hydramnios may be achieved by biochemical analysis of fetal fluids.

IMAGING
• Ultrasonography may help distinguish between hydrallantois and hydramnios (location and echogenicity of fluid). Also, placentome abnormalities may be detected. In hydramnios, the amnion may be thickened.
• Fetal abnormalities may be visualized.

OTHER DIAGNOSTIC PROCEDURES
Transrectal palpation: In cases of hydrallantois, the uterine wall is too tight and does not allow ballottement of the fetus or palpation of fetal parts and placentomes. In hydramnios, the fetus and placentomes can still be palpated.

PATHOLOGIC FINDINGS
• Hydrallantois:
• Fluid is watery, clear and may be amber in color.
• Presence of adventitious placentation.
• Fetus is normal but small.
• Hydramnios:
• Fluid is thick and viscous and may contain meconium.
• Placentation is normal.
• Fetal malformations may be present.

TREATMENT

THERAPEUTIC APPROACH
• Induction of parturition with dexamethasone and $PGF2_{\alpha}$. Overstretching of the myometrium due to excessive fluid accumulation may result in primary uterine inertia.
• Cervical relaxation may be enhanced by application of misoprostol.
• Supportive therapy to correct other abnormalities caused by the abdominal distention (hypoglycemia, hypocalcemia).

• Fluid replacement therapy is essential in management of hydrallantois.
• Extreme cases of hydrallantois should be humanely euthanized.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Cesarean section may be considered. However, fluid must be removed and replaced slowly and simultaneously to avoid hypovolemic shock.

MEDICATIONS

DRUGS OF CHOICE

• Dexamethasone
• $PGF2_{\alpha}$ (dinoprost tromethamine) or cloprostenol.
• Misoprostol, a synthetic PGE1, topical application onto the cervix.
• Prophylactic antibiotics to treat the metritis and/or retained fetal membranes that occurs commonly with hydrallantois.

CONTRAINDICATIONS

• Misoprostol is not labeled for use in food-producing animals in some countries.
• Appropriate milk and meat withdrawal times must be followed.

PRECAUTIONS

Hypovolemic shock

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Spontaneous abortion may occur in hydrallantois. The condition may recur in subsequent pregnancies. Prognosis for life and fertility is guarded to poor. The fetus is usually dead at birth or dies shortly after. Humane euthanasia is often the best approach in advanced cases.
• Cows may deliver normally in cases of hydramnios. The fetus is abnormal and, in most cases, nonviable. The prognosis for fertility is fair to good.

POSSIBLE COMPLICATIONS

• Prepubic tendon rupture
• Abortion
• Dystocia
• Retained placenta
• Metritis
• Infertility
• Metabolic, respiratory, and circulatory complications resulting in death

CLIENT EDUCATION

• Rare condition except when pregnancies are obtained from SCNT-produced embryos or with hybridization.
• Clients should be aware of risk factors and early signs.

PATIENT CARE

• Close monitoring and supportive care may be required following induction of parturition or abortion.
• Humane euthanasia may be the only option for some advanced cases.

PREVENTION

• Culling
• Do not rebreed to same sire

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Adventitious placentation
• Fetal abnormalities
• Dystocia

AGE-RELATED FACTORS

Hydrallantois is seen in older cows that may lack caruncles due to prior uterine disease or damage.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

• The affected animals (primarily bovine) show signs in mid to late gestation.
• Prognosis for viable offspring is grave for both conditions.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

• Cull affected animals
• Fetal and placental evaluation in high risk animals (pregnancies from SCNT produced embryos, hybrids)

HYPOCALCEMIA: BOVINE

BASICS

OVERVIEW
Hypocalcemia, also known as milk fever and postparturient paresis, is a metabolic disease affecting mostly dairy cows which occurs around parturition. It is characterized by low plasma calcium concentration and neuromuscular dysfunction.

INCIDENCE/PREVALENCE
Depending on prepartum feed management and other factors, the incidence of hypocalcemia is highly variable. Subclinical hypocalcemia may range from 25% in primiparous cows to over 53% in multiparous cows. Milk fever may range from 0.7% in primiparous cows to 5% or more in multiparous cows.

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEM AFFECTED
- • Musculoskeletal
- • Digestive
- • Cardiovascular
- • Reproductive

PATHOPHYSIOLOGY
• Calcium is essential for neuromuscular physiology, primarily for the muscular contraction mechanism.
• Circulating concentrations of calcium and phosphorus are precisely regulated by parathyroid hormone (PTH) secreted by the parathyroid glands, calcitonin secreted by the C cells of the thyroid gland, and 1,25-dihydroxycholecalciferol (1,25-$[OH]_2D$; vitamin D) produced by the kidney. Phosphorus is less strictly controlled than is calcium. Both minerals are absorbed in the small intestine, with phosphorus being absorbed in the proximal small intestine.
• Hypocalcemia stimulates production of PTH, which in turn stimulates synthesis of vitamin D by the kidney. The efficiency of calcium absorption is increased by vitamin D. When excess calcium is present, calcitonin inhibits resorption of calcium by the kidney, leading to urinary loss.
• During the final days of gestation, the mammary gland extracts large amounts of calcium from blood for colostrum production. Normally, total plasma contains 3 g of calcium and colostrum contains 2 g of calcium per liter, or 30 g total (15 liters of colostrum). At the same time, fecal and urine losses may account for another 5–8 g of calcium. Additionally, feed intake is markedly depressed in periparturient cows. If a typical nonanionic diet (rich in potassium and sodium and low in chloride and sulfur) is fed to prepartum animals, parathyroid hormone and vitamin D activity are compromised; therefore, calcium absorption and its bioavailability is reduced. This is the result of a more alkaline blood (pH = 7.45) induced by high potassium levels or low content of dietary magnesium. As a result, a negative calcium balance is established with a decrease in the concentration of plasma calcium (<8.0 mg/dL). Signs will depend on the degree of hypocalcemia.

HISTORICAL FINDINGS
• This condition occurs mostly within the first 24–48 hours postpartum, although some high producing multiparous cows will develop clinical hypocalcemia just prior to signs of parturition. Signs will depend on the degree of hypocalcemia. A common history includes a postpartum animal becoming recumbent in the milking parlor just after completion of milking.
• A history of changes within the dry cow ration may precede an increased prevalence of clinical hypocalcemia within a herd. Subclinical hypocalcemia may be suspected in a herd with a high incidence of retained fetal membranes, displaced abomasum, and other postpartum disease.

SIGNALMENT
• Bovine (see separate chapter, Hypocalcemia: Small Ruminant)
• All dairy breeds but highest incidence in Jerseys
• Highest risk in multiparous cows 3rd lactation and greater

PHYSICAL EXAMINATION FINDINGS
• When examining a cow with suspected hypocalcemia, it is judicious to obtain a blood sample to hold for testing in the event she does not respond to calcium treatment.
• Subclinical hypocalcemia is present with blood calcium levels between 5.5 and 8.0 mg/dL. Animals will have decreased feed intake and be at increased risk of secondary diseases such as retained fetal membranes, uterine prolapse, and displaced abomasum.
• Hypocalcemia is considered clinical when neuromuscular signs develop and is generally broken down into three stages:
• Stage I (4.5–5 mg/dL) is short in duration and animals exhibit hypersensitivity, excitability, and muscle tremors. Head bobbing, ear twitching, and fine tremors over flank will be seen. Affected animals have a reduced appetite and most resist walking. If affected animals are willing to move, they tend to be ataxic and fall easily. Animals will proceed into stage II, if treatment is not instituted.
• Stage II (2–4.5 mg/dL) milk fever is characterized by sternal recumbency and the inability to rise. Many cows appear drowsy with a characteristic kink (S-curve) in their neck. The muzzle is dry, ears and other extremities are cold with a body temperature of 97–101°F (36.1–38.3°C), and pupils are dilated. Most affected cows have a faint pulse and the heart rate is increased (80 beats/min). Constipation and rumen stasis are common findings.
• Stage III milk fever is characterized by lateral recumbency and progression to a comatose state. Bloat may result due to an inability to eructate gas. Cardiac output decreases, the heart rate may reach 120 beats/min, and the pulse is nearly undetectable. If treatment is not instituted quickly, affected cows will die from cardiac arrest or respiratory failure within a few hours.

GENETICS
Jersey breed is the most susceptible.

CAUSES AND RISK FACTORS
• Prepartum diets rich in cations (mostly potassium) and low in magnesium, especially in high-producing animals that have had 3 or more parities.
• Management, breed, parity, milk production, nutrition or acid-base status around calving, season, herd size, geographic location.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Downer cow syndrome, trauma, lymphosarcoma (spinal), hypomagnesemia, infectious diseases (rabies, listeriosis, BSE, TEME)

CBC/BIOCHEMISTRY/URINALYSIS
Plasma calcium levels for subclinical hypocalcemia are <8.0 mg/dL (<2.0 mmol/L) (see Table 1). In cases with neuromuscular signs, mostly recumbency, Ca levels are below 4.0 mg/dL (1.0 mmol/L). In recumbent animals it is common for CK and AST to be elevated in association with muscular damage.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Variable. Muscular necrosis, gastrointestinal atony, and gas accumulation. Pericardial hemorrhages.

TREATMENT

THERAPEUTIC APPROACH
• Treatment efforts are aimed at returning serum calcium to within the normal range. The treatment should be administered as soon as possible to avoid muscular and nerve damage.
• Calcium borogluconate is commonly administered IV but can be administered via subcutaneous and intraperitoneal (IP) routes. Subcutaneous administration allows for slow

Table 1

Blood Serum Analysis of Normal Dairy Cows and Dairy Cows with Milk Fever

	Mineral (mg/dL)		
Condition	*Calcium*	*Phosphorus*	*Magnesium*
Normal	8.4–10.2	4.6–7.4	1.9–2.6
Normal at parturition	6.8–8.6	3.2–5.5	2.5–3.5
Milk fever			
Stage I	6.2 ± 1.3	2.4 ± 1.4	3.2 ± 0.7
Stage II	5.5 ± 1.3	1.8 ± 1.2	3.1 ± 0.8
Stage III	4.6 ± 1.1	1.6 ± 1.0	3.3 ± 0.8

Note: Mean ± standard deviation.

Adapted from Church DC, The Ruminant Animal. Prospect Heights, IL: Waveland Press, 1993, table 24.1, p. 494.

calcium absorption, which may reduce the risk of cardiac arrest. Animals that relapse or fail to respond should be reexamined and treated in 8–12 hours.

• Calcium is directly cardiotoxic; any calcium-containing solution should be administered slowly (over about 10–20 min) during cardiac auscultation. Administration of calcium should be discontinued if dysrhythmias develop. To eradicate cardiac dysrhythmias associated with administration of calcium, atropine can be given intravenously. The cardioexcitatory consequences of intravenous calcium can be reduced by rapid administration of $MgSO_4$.

• In the case of mild parturient paresis, oral calcium can be administered. Oral calcium administration will decrease the risk of cardiotoxicity. The best combination of calcium preparation is calcium propionate in a propylene glycol gel. In order to achieve a 4 g rise in blood calcium levels, oral administration of 50 g of soluble calcium is required. Calcium propionate is a better alternative than calcium chloride.

• The administration of calcium chloride has a tendency to cause a slight metabolic acidosis.

Chronic Cases

• Any case that does not correct immediately with calcium administration should be safely moved to a clean, dry area with adequate bedding, mattresses, or pasture. Muscle and nerve damage from recumbency starts as early as 6 hours after the onset and may be irreversible; therefore, prevention with proper nursing care is imperative. Animals should be assisted to stand and rotated 3–4 times per day and kept on a soft surface.

• For the 15% of parturient paresis cows that do not react to calcium therapy, administer 1α- hydroxycholecalciferol, $1\alpha\text{-}(OH)_3$, a synthetic analog of vitamin D_3. It should be administered at 1 μg/kg of body weight, half IV and half IM.

• The advantages and disadvantages of vitamin D_3 in treating milk fever have been reported elsewhere.

• It is also judicious to test serum phosphorus, potassium and magnesium levels (see Table 1) to rule out concurrent deficiences as causes of recumbency.

SURGICAL CONSIDERATIONS AND TECHNIQUES

N/A

MEDICATIONS

DRUGS OF CHOICE

Injectable

Solutions of calcium salts supplying 10 g of Ca for intravenous application (Ca borogluconate, CMPK) in the case of clinical conditions (recumbency).

Oral

Calcium salts for oral supplementation (calcium propionate 510 g, calcium chloride 300 g) in the case of subclinical conditions. These salts may be accompanied with glucose precursors such as propylene glycol (250–400 mL). Oral calcium may be formulated as a dissolvable salt, gel, or bolus. More recently, fat-coated oral calcium boluses have gained popularity as they are less likely to cause chemical irritation in the esophagus. See "Precautions" regarding oral products.

CONTRAINDICATIONS

N/A

PRECAUTIONS

IV solutions must be applied slowly to avoid cardiac arrest. Some oral products may be irritants (calcium chloride), causing esophageal ulceration, and are therefore not recommended in recumbent animals whose ability to swallow may be impaired. Aspiration pneumonia must be considered as normal neuromuscular function of the oropharyngeal and esophageal regions will be impaired, especially in moderate to severe cases.

POSSIBLE INTERACTIONS

Phosphorus and magnesium metabolism.

FOLLOW-UP

POSSIBLE COMPLICATIONS

In clinical cases without treatment, death is very likely.

EXPECTED COURSE AND PROGNOSIS

Good prognosis when diagnosis and treatment are adequate.

PATIENT CARE

Nursing care and proper handling of the down animal are extremely important. After 30 minutes of IV treatment, recumbent animals should have experienced certain improvement. A second treatment might be recommended. See "Treatment."

PREVENTION

Proper prepartum nutritional management. Anionic salts to establish a cation-anion difference between –25 and –75 mEq/kg of dry matter. This diet will induce a mild metabolic acidosis with a consequent increase in calcium bioavailability. Monitor the anionic diet program by evaluating the urine pH of prepartum cows (~10–20% of the animals) on a weekly basis. Urine pH should be between 6.0 and 7.0, otherwise the diet should be modified. Alternatively, a low calcium diet can be fed prepartum when the forage profile allows.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Gastrointestinal and reproductive conditions such as displacement of abomasums, retained fetal membranes, metritis, and mastitis.

HYPOCALCEMIA: BOVINE (CONTINUED)

AGE-RELATED FACTORS
Parity 3 or older are more likely to develop this condition.

PRODUCTION MANAGEMENT
See "Prevention"

SYNONYMS

HYPOCALCEMIA: SMALL RUMINANT

BASICS

OVERVIEW
• Hypocalcemia in ewes and does is most common during the last 4–6 weeks of gestation. The developing ovine/caprine fetus has a relatively high demand for calcium.
• Hypocalcemia may occur during the first 6 weeks of lactation even in the face of relatively low milk yield.
• In dairy goats during lactation, hypocalcemia may occur and can be diagnosed several weeks into lactation.
• Stressful events may precipitate clinical hypocalcemia in sheep and goats.
• Plasma calcium tends to be higher during pregnancy and peaks at 5–7 weeks prepartum in cervidae. In these species, hypocalcemia can be observed 1–2 weeks postpartum.
• Nonparturient hypocalcemia makes up a higher proportion of cases in small ruminants.
• Prompt hypocalcemia therapy reduces the incidence of secondary complications.

INCIDENCE/PREVALENCE
• Typically <5% of animals in a herd or flock are affected, but rates of up to 20% have been documented.
• The incidence of hypocalcemia is increased in ewes or does carrying multiple fetuses during late lactation.
• In one study of the hypocalcemic cases that recovered, approximately 25% required more than one treatment. Ewes that developed hypocalcemia before lambing and that recovered, lost 22% of their lambs, the main reason probably being premature birth.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Metabolic
• Musculoskeletal

PATHOPHYSIOLOGY
• Muscular contraction is impaired several ways by hypocalcemia: (1) loss of the membrane-stabilizing effect of calcium on peripheral nerves resulting in hyperesthesia and mild tetany, and (2) impaired role of calcium in the release of acetylcholine at the neuromuscular junction resulting in paralysis due to blockade of the transmission of nerve impulses to the muscle fibers.
• Increased disease susceptibility has been observed around the time of parturition. Low extracellular calcium in vitro decreases phagocytosis and intracellular killing in polymorphonuclear neutrophils.
• In contrast to most species, ruminants must secrete excess phosphate in the saliva and, to a lesser extent, in the urine. A fraction of phosphate excreted in saliva is resorbed in the small intestine while the remainder is eliminated from the body in the feces.
• Sheep with chronic hypomagnesemia also have profound alterations in calcium homeostasis. Hypomagnesemia prevents production or secretion of both PTH and 1,25-dihydroxyvitamin D_3.

HISTORICAL FINDINGS
• Periparturient most common
• History of stressful event (e.g., transport, group handling, adverse weather)

SIGNALMENT
• Potentially all small ruminant species.
• Predominantly female.
• The effect of age and parity is likely related to capacity for milk yield and the ability to mobilize calcium.
• In sheep and goats, the tendency to develop hypocalcemia increases with increasing age.

PHYSICAL EXAMINATION FINDINGS
• Early clinical signs
  ◦ Hyperexcitability
  ◦ Ataxia
  ◦ Tetany
• Later signs
  ◦ Dilated pupils with slow PLR
  ◦ Mild depression
  ◦ Bloat, rumen stasis, and no fecal passage
  ◦ Rapid muffled heart sounds
  ◦ Recumbency and coma
• Transit tetany may occur in pregnant ewes and lambs following the stress of transportation. Lambs will present with muscle tremors and tetany rather than flaccid paralysis.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Inappropriate calcium homeostasis around the time of parturition.
• The developing fetuses have a high demand for calcium that may exceed dietary intake and availability.
• Excessive ingestion of plants that bind calcium such as oxalates (i.e., beet pulp, alfalfa leaves and sugar beet leaves).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Pregnancy toxemia
• Hypomagnesemia

CBC/BIOCHEMISTRY/URINALYSIS
• Decreased total (<6 mg/dL) or ionized calcium
• Magnesium levels variable but often low (<1.5 mg/dL)

OTHER LABORATORY TESTS
Hypocalcemia may be difficult to differentiate from pregnancy toxemia, so assessment of urine or blood for ketones may be helpful.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
No significant pathologic findings at necropsy are directly attributable to hypocalcemia.

TREATMENT

See "Medications"

MEDICATIONS

DRUGS OF CHOICE
• Calcium: 1 g Ca/45 kg of BW intravenous, response to therapy should be rapid (within 5–10 minutes).
• Subcutaneous or oral calcium may be administered subsequently for a longer-acting effect in severe cases. Care must be taken to administer in small boluses (no more than 50 mL per site) using clean technique or to ensure oral calcium is administered carefully or directly into the rumen (avoid calcium chloride boluses due to esophageal irritation).

CONTRAINDICATIONS
• Subcutaneous calcium may rarely cause irritant reactions or skin sloughing subsequent to administration by this route.
• Steroids should not be used in pregnant animals.

PRECAUTIONS
• IV calcium solutions must be given slowly over 5–7 minutes to avoid cardiac arrhythmia/arrest.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Animals are expected to recover if treatment is instituted early in the course of disease.

POSSIBLE COMPLICATIONS
Recumbency progressing to death may occur if inadequately treated, or untreated.

CLIENT EDUCATION
Prevention of hypocalcemia through proper transition management should be the focus since clinical and subclinical hypocalcemia will lead to a cascade of negative health implications.

PATIENT CARE
• Response to therapy is suggestive of at least a temporary cure.

HYPOCALCEMIA: SMALL RUMINANT (CONTINUED)

• Recheck calcium +/− magnesium levels if unresponsive to treatment or if relapse occurs.
• Some animals will require multiple treatments, especially if dietary calcium has not been adequately managed.

PREVENTION

• Little work specific to small ruminants is available. Most recommendations are borrowed from prevention strategies in dairy cattle.
  ◦ A continuously increasing plane of nutrition during the last 6 weeks of gestation will increase calcium intake and prevent hypocalcemia and pregnancy toxemia in most cases.
  ◦ Alternatively, limiting calcium intake for 30 days before parturition can be helpful in prevention programs. Utilizing hay from cereal crops rather than alfalfa hay will lower the concentration of calcium in the diet, stimulating mobilization of calcium from bone which may reduce hypocalcemia.
• Avoid stressful events in late gestation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Pregnancy toxemia
• Hypomagnesemia
• Vaginal prolapse—some data would suggest no association

AGE-RELATED FACTORS

• The effect of age and parity is likely related to capacity for milk yield and mobilization of calcium.
• In sheep, the tendency to develop hypocalcemia increases with increasing age.

PREGNANCY

Commonly occurs in all small ruminant species in the last month of gestation.

PRODUCTION MANAGEMENT

This can occur as a herd problem if diet is inappropriate.

ABBREVIATION

• BW = body weight

INDIGESTION

BASICS

OVERVIEW
• Simple indigestion is a form of gastrointestinal distress causing transient anorexia, usually with minimal signs of systemic illness.
• Defined as a less severe illness than other forms of rumen (vagal) indigestion.
• Results from an abrupt change in the feed regimen in regard to type, amount, and/or frequency.

INCIDENCE/PREVALENCE
• Simple indigestion is a common disorder of nongrazing animals and is the most common sequela to an abrupt change in ration.
• This condition may present as an individual animal problem, but more often affects several members of a herd.

GEOGRAPHIC DISTRIBUTION
Occurs in regions in which conditions or production systems limit grazing or feed availability.

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• Animals are suddenly exposed to feedstuffs to which they are previously unaccustomed in either type or amount.
• This results in a change in the rumen environment, including pH, as a result of the presence of unusual substrates.
• The rumen microflora change in population as a result of change in feed substrate.
• Microflora then produce fermentation products which have deleterious effects on rumen motility, digestion, and nutrient absorption.
• Simple indigestion can also arise from the accumulation of relatively indigestible feedstuffs in the rumen that can physically impair rumen function.

HISTORICAL FINDINGS
• Change in feeding regimen.
• Acute onset of anorexia of 1–2 days duration, potentially with malodorous diarrhea or reduced fecal production12–24 hours after signs commence, and decreased milk production in lactating animals.

SIGNALMENT
Any ruminant species of any age, breed or gender are susceptible. Young animals being intensively fed for growth, and adult dairy cattle being fed for production, are at greatest risk.

PHYSICAL EXAMINATION FINDINGS
• Signs are generally less severe and more transient than other rumen indigestion disorders such as grain overload.
• Generally there is minimal evidence of significant systemic illness.
• Rumen motility is typically reduced, reflected by decreased frequency and strength of contractions.
• Rumen fill is nearly normal, but contents are fluid and may slosh with succussion, or the rumen may feel full, firm or doughy on palpation/ballottement.
• Mild bloat may occur.
• Malodorous diarrhea may be noted.
• Vital signs (temperature, pulse, respiration) and demeanor are typically normal.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Condition arises due to an abrupt change in feed type or amount, exposing rumen microflora to substrates to which they are not accustomed, or in greater quantities than those to which they are acclimated.
• This can occur when high-quality feeds are suddenly provided in large amounts or with a change in one or more components.
• Provision of compromised feeds such as those that are moldy or overheated; frosted forages; or incompletely fermented, spoiled, sour silage may also cause indigestion.
• Risk factors include minimal or complete lack of grazing time or hay availability, or accidental exposure to large amounts of novel feeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Traumatic reticuloperitonitis
• Left displaced abomasum
• Ketosis
• Lactic acidosis
• Rumen alkalosis
• Rumen putrefaction
• Vagal indigestion
• Peritonitis
• Any early systemic illness causing anorexia

CBC/BIOCHEMISTRY/URINALYSIS
May indicate mild dehydration and prerenal azotemia reflected by increases in serum total protein concentration, hematocrit, urea nitrogen, and creatinine.

OTHER LABORATORY TESTS
• Rumen fluid might display a decrease in size, numbers, and activity of protozoa under light microscopy.
• Rumen fluid pH may be slightly acidic (<6) or alkaline (>7), depending on the nature of the offending feedstuff and the duration of imbalance.
• Prolonged methylene blue reduction time might be evident in rumen fluid samples.

IMAGING
Radiographs or ultrasound might be indicated in some cases to rule out specific differential diagnoses such as traumatic reticuloperitonitis.

OTHER DIAGNOSTIC PROCEDURES
Abdominocentesis might be indicated to rule out peritonitis and other potential differential diagnoses.

PATHOLOGIC FINDINGS
Uncomplicated cases of simple indigestion are transient and rarely result in death.

TREATMENT

THERAPEUTIC APPROACH
• Supportive care (fluid and acid-base therapy, transfaunation) and dietary modifications are typically sufficient to manage uncomplicated cases of simple indigestion.
• Animals with simple indigestion may be treated as outpatients, though valuable animals may warrant hospitalization for monitoring of their condition and to facilitate intervention if their condition should deteriorate.
• Transfaunation with 8–16 L (2–4 gallons) of rumen fluid from a healthy cow can help reestablish normal rumen flora and function.
• The remainder of the herd should be closely monitored for additional incidence.

SURGICAL CONSIDERATIONS AND TECHNIQUES
In cases of simple indigestion, surgery (rumenotomy) is rarely required.

MEDICATIONS

DRUGS OF CHOICE
• If rumen pH alterations are confirmed, acidic pH may be addressed by providing magnesium hydroxide or magnesium oxide (450 g per adult cow) PO or by ororuminal tube; alkalotic pH can be managed by providing acetic acid (4–10 L) PO or by ororuminal tube.
• Administration of mineral oil (4–6 L) by ororuminal tube may reduce absorption and facilitate excretion of offending feedstuffs.
• Probiotic products are frequently used, but their utility is limited due to low volume and narrow spectrum of organisms provided.
• Ruminatorics including nux vomica, ginger and tartar can be used but are likely of limited use.
• Parasympathomimetic agents, such as neostigmine, are not useful in rumen atony, but may stimulate motility in cases where some motility remains.

CONTRAINDICATIONS
• Rumen pH should be confirmed before administering corrective substances. Magnesium hydroxide is contraindicated in absence of rumen acidosis, to avoid iatrogenic systemic alkalinization.

INDIGESTION (CONTINUED)

• Rumen motility agents are contraindicated if potential obstruction has not been ruled out.

PRECAUTIONS
• Rumen fluid for transfaunation should be obtained from healthy cows only, with regard to biosecurity concerns.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Typical course of anorexia is 1–2 days, with diarrhea occurring 12–24 hours after onset.
• If uncomplicated and managed by removal of offending feedstuffs, prognosis is good.
• Animals return to normal once rumen microflora and fermentation products achieve homeostasis and inhibitory products have been eliminated.
• Transfaunation encourages a more rapid return of a stable rumen environment.

POSSIBLE COMPLICATIONS
• Rumen environment may further deteriorate requiring more intensive therapy.

CLIENT EDUCATION
• Animals being fed for production should be introduced to concentrated feeds gradually and also provided quality forage.
• When new feedstuffs are incorporated into a production system, they should be incorporated prior to full depletion of previous feedstuffs, in order to allow gradual introduction.
• Feed should be inspected immediately prior to feeding for signs of damage or contamination.
• Silage and other stored feeds should be properly protected from environmental damage (moisture, oxygen, feces).

PATIENT CARE
• Oral or parenteral polyionic fluid therapy may be indicated depending on severity of dehydration and acid-base or electrolyte imbalances.
• Offending feedstuffs should be identified and removed.
• Animals should be provided unlimited access to good-quality grass hay or straw.
• Unless the offending feedstuff is inherently damaged (ie. moldy, spoiled, contaminated) it may be reintroduced in small, graduated amounts, along with good-quality hay or other forage source.
• Monitor closely for return to feed in 24–48 hours.

PREVENTION
• Any concentrate feeds should be gradually increased to the desired feeding rate over 10–14 days.
• Avoid rapid changes in feeding practices.
• Provide animals on feed with smaller volumes more frequently, to more closely mimic grazing.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Lactic acidosis
• Rumen alkalosis

AGE-RELATED FACTORS
Young animals may be more inclined to overindulge in concentrated feeds.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Unlikely to be affected in mild disease.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Silage and other processed feeds should be properly prepared and stored to prevent spoilage.
• Animals should be gradually introduced to increasing amounts or different types of feeds.
• New feedstuffs should be ordered and introduced prior to depletion of previous feed to allow for mixing and gradual introduction.

SYNONYMS

INDUCTION OF PARTURITION

BASICS

OVERVIEW
• Induction of parturition involves the pharmacologic initiation of parturition.
• Protocols to induce parturition in ruminants are aimed at mimicking the physiology of normal parturition by either inducing luteolysis to remove the luteal source of progesterone (goats and camelids), initiating hormonal cascades to remove placental progesterone (sheep), or both (cattle).
• Treatment used before term can terminate pregnancy and result in a nonviable fetus.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Parturition is initiated by fetal stress which leads to cortisol secretion from the fetal adrenal glands.
• Cortisol promotes the conversion of placental progesterone to estradiol, effectively removing placental progesterone and increasing uterine contractility.
• Fetal cortisol also initiates placental synthesis of $PGF2_{\alpha}$, which causes luteolysis and further decreases progesterone.
• Rising levels of $PGF2_{\alpha}$ and estradiol cause strong myometrial contractions that apply pressure upon the cervix to simulate oxytocin release (Ferguson's reflex), causing more uterine contractions and facilitating movement of the fetus through the birth canal.

HISTORICAL FINDINGS
• Management decision to synchronize parturitions and enable personnel to more closely attend to the dam and fetus during delivery or to ensure parturition coincides with peak pasture availability in seasonal grazing systems.
• Maternal compromise such as pregnancy toxemia, traumatic injury, or periods of prolonged recumbency.
• Prolonged pregnancy (to prevent dystocia due to fetal oversize) or other abnormalities of pregnancy.
• High risk pregnancies (SCNT embryo transfer).
• Breeding and accurate pregnancy diagnosis dates should be obtained.

SIGNALMENT
Induction of parturition is performed when indicated in all species of ruminants and camelids.

PHYSICAL EXAMINATION FINDINGS
• Normal pregnancy at stage compatible with extrauterine life.
• Mammary gland development and presence of colostrum.
• Findings vary depending on pregnancy disorder in compromised females.

PATHOLOGIC FINDINGS
Depends on reason for induction

TREATMENT

THERAPEUTIC APPROACH

Cattle
• Long- or short-acting corticosteroids, $PGF2_{\alpha}$, or a combination of $PGF2_{\alpha}$ and dexamethasone.
• Calf survival is optimal when parturition is induced no earlier than 2 weeks prior to gestational term.
• Induction of parturition with short-acting corticosteroids and/or prostaglandin results in a high rate (50–75%) of retained fetal membranes due to lack of placental maturation.

Sheep
• Normal gestation length in sheep is 145–150 days. Breeding dates should be accurate.
• CL functions as a source of progesterone only until 50–60 day gestation. At term, the placenta is the primary source of progesterone and prostaglandin alone is ineffective at inducing parturition.
• Induction can be achieved with dexamethasone after 137 days gestation. However, fetal viability is better if treatment is given after 142 days.

Goats
• Normal gestation length in goats is 147–155 days. Breeding dates should be accurate.
• Goats are CL-dependent throughout gestation and induction of parturition may be achieved with a luteolytic dose of $PGF2_{\alpha}$.
• In does suffering from pregnancy toxemia, treatment with dexamethasone (10–20 mg IM) prior to induction with $PGF2_{\alpha}$ may enhance maturation of fetal lungs and improve neonatal survival.
• Retained fetal membranes are rare in goats following induction of parturition.

Camelids
• Normal gestation length is highly variable. Induction of parturition should only be considered if there is sufficient mammary development and presence of colostrum.
• Camelids are CL-dependent throughout gestation. $PGF2_{\alpha}$ or analogs induce abortion or parturition reliably.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Induction of parturition may be an initial step before planned cesarean section.

MEDICATIONS

DRUGS OF CHOICE

Cattle
• Long-acting corticosteroids should only be used when calf survival is not the primary goal of induction. Reported calf survival rates are around 64%. Fetal dysmaturity contributes to high calf mortality rates.
  ◦ Dexamethasone trimethylacetate (25–30 mg IM) or triamcinolone acetonide (4–8 mg IM) can be administered 2–4 weeks prior to term. Timing of parturition after injection is variable, although most will calve within 10–14 days following induction (range = 3–30 days).
  ◦ Calving occurs 48–72 hours after administration of $PGF2_{\alpha}$ (dinoprost tromethamine, 25 mg IM or SC) or cloprostenol sodium (500 µg IM) 9–14 days following induction with a long-acting corticosteroid.
• Short-acting corticosteroids, dexamethasone (20–30 mg IM), can be used to induce parturition within 2 weeks of gestational term with no increase in dystocia rates or neonatal mortality. Response rate to a single injection is 80–90% with cows calving 24–72 hours following administration.
• $PGF2_{\alpha}$ (dinoprost, 25 mg IM or SC) or cloprostenol sodium (500 µg IM) can be used for induction of parturition in the last 2 weeks of gestation. Parturition occurs within 24–72 hours in 80–90% of cows after a single injection.

INDUCTION OF PARTURITION (CONTINUED)

• The combination of corticosteroids and prostaglandin results in a more predictable time from administration to onset of parturition (25–42 hours) and a lower rate of induction failure.

Sheep

Dexamethasone (15–20 mg IM) will result in onset of parturition 36–48 hours following administration.

Goats

• Administration of $PGF2_{\alpha}$ (dinoprost, 15 mg IM) or cloprostenol sodium (75–100 µg IM) results in onset of parturition within 30–35 hours, on average.
• Although lower doses of prostaglandin (dinoprost, 2.5–5 mg) have been used successfully to induce parturition in goats, a higher dose of 15 mg results in a more reliable and predictable onset of parturition.

Camelids

• A luteolytic dose of $PGF2_{\alpha}$ (dinoprost, 5 mg IM) or analog (cloprostenol sodium, 250 µg IM) can be used to induce parturition.
• Parturition will occur, on average, 20 hours after prostaglandin injection with a range of 8–30 hours.
• Fetal viability may be assessed using transabdominal ultrasonography at 12 and 20 hours post-induction if parturition has not occurred. If fetal distress is suspected or parturition has not occurred by 24 hours post-induction, a C-section is indicated.

CONTRAINDICATIONS

• Appropriate milk and meat withdrawal times must be followed.
• Dexamethasone is contraindicated in induction of parturition in camelids due to an association with fetal death.
• In camelids, it is important to rule out uterine torsion and ensure that colostrum is present in the udder prior to induction of parturition. Viscous, sticky colostrum is most likely to result in adequate transfer of passive immunity to the neonate following parturition. In compromised females, synthetic analogs should be used for induction as natural prostaglandin (dinoprost) may cause respiratory distress or pulmonary edema and its use should be avoided.

PRECAUTIONS

Accuracy of breeding dates and viability of the fetus should be verified before induction.

POSSIBLE INTERACTIONS

Induction of parturition in compromised females may result in dystocia. Measures should be taken to proceed with cesarean section in case of complications.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Response to induction of parturition treatment is very reliable if the prerequisite conditions are fulfilled.

POSSIBLE COMPLICATIONS

• Retained placenta is the major complication. Lower rates of retained placenta are observed with long-acting corticosteroids than with short-acting ones because they allow more time for placental maturation prior to parturition.
• Retained fetal membranes are uncommon in ewes following induction of parturition.
• Females with compromised health or abnormal pregnancies are at higher risk for dystocia.

CLIENT EDUCATION

• Natural parturition should be promoted whenever possible.
• Proper breeding record keeping.
• Welfare issues are raised in some countries.

PATIENT CARE

• Depends on reason for induction and complications.
• Monitor fetal viability, and emergency cesarean section should be planned if any complications arise.

INFECTIOUS BOVINE RHINOTRACHEITIS

BASICS

OVERVIEW

• Infectious bovine rhinotracheitis (IBR) is a mild to severe upper respiratory disease in cattle caused by bovine herpesvirus 1 (BHV-1). This viral infection is one of the viral factors in bovine respiratory disease complex.
• BHV-1 can also cause conjunctivitis, reproductive disease, and abortion.
• Although of the same antigenic type, respiratory and genital strains can be differentiated by molecular methods and have been divided into subtypes BHV-1.1 (respiratory) and BHV-1.2 (genital). It is uncommon to see both strains circulating concurrently within the same herd.
• Bovine herpesvirus 5 (BHV-5), a cause of viral encephalitis, was previously classified as another variant of BHV-1 (BHV-1.3) but has since been given its own designation.

INCIDENCE/PREVALENCE

• BHV-1 is endemic in cattle.
• Symptoms in BHV-1 infected calves can vary from subclinical to severe disease with 100% morbidity and 10% mortality.
• Nonvaccinated pregnant cattle are highly susceptible to BHV-1 infection and up to 25% can abort (so-called "abortion storm").

GEOGRAPHIC DISTRIBUTION

Worldwide. Several European countries and regions within the European Union have achieved "IBR-free" status; however, sporadic outbreaks still occur in states contiguous with infected areas.

SYSTEMS AFFECTED

• Nervous
• Ophthalmic
• Respiratory
• Reproductive

PATHOPHYSIOLOGY

• BHV-1 is spread through nasal exudate, droplets, genital secretions, embryos, semen, and fetal fluids. BHV-1 multiplies in the nasal cavities and upper respiratory tract, resulting in rhinitis, laryngitis, and tracheitis.
• The virus spreads from the nasal cavity to the ocular system by the lacrimal gland. BHV-1 induces damage to the upper respiratory tract (URT) epithelium and conjunctiva of the eye (Figure 1).
• The damage to URT epithelium coupled with inflammatory changes increases the susceptibility of the lung to secondary bacterial infection.
• Conjunctivitis results from inflammation and edema of the conjunctiva.
• BHV-1 can induce late-term abortions in pregnant cattle by causing a viremia that results in BHV-1 infection of the ovary, placenta, and the corpus luteum (Figure 1).

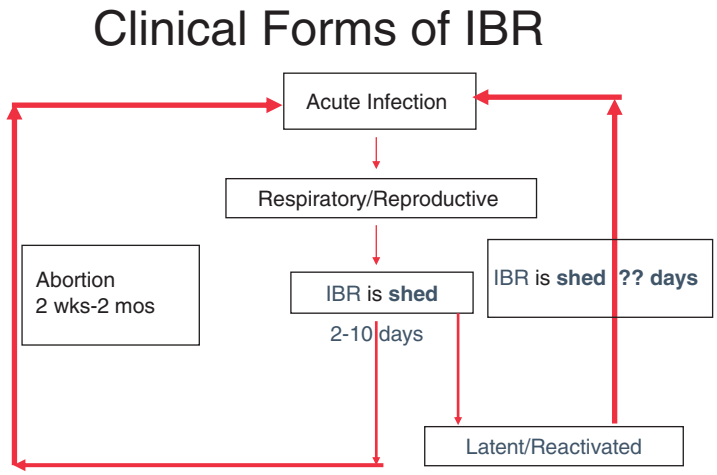

Figure 1.

Clinical Outcomes of IBR Infection.

The genital strain of BHV-1 is associated with genital tract infections of both the male [infectious pustular balanoposthitis (IPB)] and female [infectious pustular vulvovaginitis (IPV)].
• Once animals are infected with BHV-1, the virus spreads to the nervous system, becomes latently infected in the nervous and lymphoid system, and the animals are a lifelong source of infectious virus. The site of latent infection can vary depending on the initial tissue infected.

SIGNALMENT

• Bovine
• IBR is seldom seen in calves <6 months of age and is most prevalent and severe in animals between 6 and 18 months of age.
• Goats and buffalo can act as reservoirs for BHV-1.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs of rhinotracheitis can occur within one or two days of infection and are characterized by a mucopurulent nasal discharge, sneezing, conjunctivitis, and ulcerative lesions in the nasal mucosa.
• An increased rectal temperature (104–108°F; 40–42°C) often occurs from 2 to 7 days following infection.
• Anorexia with depression occur early following infection. A cough may be observed later in the course.
• Secondary pneumonia with bacterial pathogens (*Mannheimia haemolytica, Pasteurella multicida, Histophilus somni*) or *Mycoplasma bovis* is a frequently sequela.
• Conjunctivitis can occur with respiratory disease or it may appear alone. Conjunctivitis originates from the corneoscleral line and is usually bilateral.
• Abortion usually occurs in the last trimester of gestation (range 4–8 months) in response to the respiratory strain (BHV-1.1) rather than an extension of the genital strain (BHV-1.2) into the fetoplacental unit. Fetal death occurs within 48 hours of viral invasion of the reproductive tract but expulsion may take up to 7 days, resulting in pronounced fetal autolysis.

CAUSES AND RISK FACTORS

• BHV-1 is an enveloped double-stranded DNA virus in the subfamily alphaherpesvirus of the Herpesvirus family. The virus is easily inactivated by desiccation, heat, and disinfectants.
• Stress (weaning, shipping, etc.) will increase the risk. Maternal antibody will inhibit vaccine response. Dexamethasone administration has been shown to reactivate latent infections, resulting in viral shedding and potentially clinical disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Three other bovine viruses—bovine viral diarrhea virus, bovine respiratory syncytial virus (BRSV), and bovine parainfluenza-3 virus (PI-3)—commonly cause similar respiratory disease.
• BVDV is associated with oral ulcers, mucopurulent discharge and upper respiratory disease.
• BRSV is characterized by increasing harshness in respiratory sounds to severe distress with dyspnea, forced expiration, and open-mouth breathing. Spontaneous cough can be easily induced and can vary from dry and nonproductive to moist.
• PI-3 infection is usually a mild lower respiratory disease.
• Bovine coronavirus (BCV) has also been associated with respiratory disease. In younger

INFECTIOUS BOVINE RHINOTRACHEITIS (CONTINUED)

calves it is also seen with calves suffering from enteritis and diarrhea. BCV in 5- to 13-month-old cattle causes symptoms of dyspnea, nasal discharge, and increased respiratory rate.
• Abortion: The differential diagnosis would include BVDV, mycotic abortion, *Neospora caninum*, and leptospirosis.

CBC/BIOCHEMSTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• BHV-1 is readily detected by virus isolation. Clinical specimens should be collected during the febrile, acute phase of infection. Respiratory and ocular specimens can be collected antemortem using swabs. Swabs can also be used for the detection of genital infections. On postmortem, virus isolation samples from IBR animals can be collected from the upper respiratory tract and trachea.
• From aborted fetuses, the liver, adrenal, kidney, and lung are the preferred tissues. However, the marked fetal autolysis that often accompanies abortion can make virus isolation more difficult in these tissues. In animals with encephalitis, several regions (olfactory lobes, midbrain, cortex, etc.) should be sampled.
• BHV-1 can also be detected using polymerase chain reaction (PCR).
• Other procedures that have proved useful in detection of BHV-1 are fluorescent antibody tests of fresh tissue and immunohistochemistry staining of cell cultures or formalin-fixed paraffin embedded tissues. Intranuclear inclusion bodies are often present in the liver of BHV-1 infected fetuses.
• A rise in serum neutralizing antibody titer also can be used to confirm BHV-1 infection. Paired serum samples collected 2–3 weeks apart are necessary; a single sample, even if it has a high titer, is of little value. It is not possible to detect a rising antibody titer in abortions, because infection generally occurs a considerable length of time before the abortion, and titers are already maximal. BHV-1 ELISA antibody detection tests are also available.
• The presence of characteristic venereal lesions is sufficient for a clinical diagnosis of the genital strain.

PATHOLOGIC FINDINGS
• Gross lesions of uncomplicated IBR are restricted to the upper respiratory tract and trachea. Petechial to ecchymotic hemorrhages with edema are found in the mucus membranes of the nasal cavity and the sinuses.
• There may be focal areas of necrosis in the nose, pharynx, larynx, and trachea that may coalesce to form plaques. The sinuses may be filled with a serous or serofibrinous exudate. As the disease progresses, the pharynx becomes covered with a serofibrinous exudate, and blood-tinged fluid may be found in the trachea.
• The pharyngeal and pulmonary lymph nodes may be acutely swollen and hemorrhagic. The tracheitis may extend into the bronchi and bronchioles; when this occurs, epithelium is sloughed in the airways. In animals with bacterial bronchopneumonia, the viral lesions are often masked. Aborted fetuses may have pale, focal, necrotic lesions in all tissues, which are especially visible in the liver, and serosanguinous fluid in the body cavities. Placental edema is sometimes seen.
• Histologic examination of IBR tissues reveals acute catarrhal inflammation of the mucosa with rare inclusion bodies.
• In encephalitic calves, histologic changes consisted of a widespread nonsuppurative meningoencephalitis, more severe in the anterior cerebrum, the dorsolateral cortex and, to a lesser extent, the posterior cerebrum and the midbrain. The lesions are characterized by gliosis, disruption of the neuropil and perivascular cuffing, consisting of macrophages, histiocytes, and lymphocytes.
• In aborted fetuses, intranuclear inclusion bodies are often present in the liver. Marked autolysis of aborted fetuses is common, which can complicate histologic examination.

TREATMENT

THERAPEUTIC APPROACH
The therapy for IBR is supportive. Severely diseased animals that are dehydrated may receive oral and/or intravenous fluids.

MEDICATIONS

DRUGS OF CHOICE
• Nonsteroidal anti-inflammatory drugs (NSAIDs) may have some benefit to lessen the severity of BHV-1 disease.
• Antimicrobial treatment is used to reduce secondary bacterial infections.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Uncomplicated BHV-1 respiratory infections will resolve in 5–7 days.
• Animals that have secondary infections usually will develop bronchopneumonia with varying levels of morbidity and mortality.

POSSIBLE COMPLICATIONS
• Intramuscular (IM) modified-live virus (MLV) BHV-1 vaccines may cause abortion in pregnant cattle.
• Maternal antibodies in calves interfere with development of an effective IBR immune response with parenterally administered MLV vaccines. Maternal antibodies have no effect on intranasal (IN) MLV vaccines.

PATIENT CARE
• Respiratory characteristics along with rectal body temperature should be frequently monitored to assess IBR clinical progression and also the development of secondary bacterial infections that would result in bovine respiratory disease complex (BRDC).
• Minimize handling of animals and use preventive vaccines.

PREVENTION
• Vaccination is an important part of a BHV-1 control plan. Both MLV and inactivated virus BHV-1 vaccines are on the market. The MLV vaccines are available as either parenteral (IM or subcutaneous, SC) or intranasal (IN) vaccines.
• Use of MLV vaccines is not without risk due to persistence of the virus and its potential for reactivation.
• Eradication of the virus is possible by serologic testing and culling reactors. Eradication programs have been implemented in Europe. To aid in eradication, deletion mutant vaccines have been developed that permit antibody discrimination between BHV-1 vaccine and natural exposure. BHV-1 vaccines are cross-reactive and should be efficacious against BHV-5.

MISCELLANEOUS

ASSOCIATED CONDITIONS
BRDC is a frequent sequela to IBR. Retained placenta and metritis are possible sequelae to BHV-1 abortion.

AGE-RELATED FACTORS
A rare generalized disease may occur in neonatal calves <2 weeks of age. Most IBR disease is seen in animals >6 months of age.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
BHV-1 infections result in late-term abortions that can occur as long as 100 days following infection.

BIOSECURITY
BHV-1 survives very poorly in the environment and is susceptible to UV light, desiccation, heat, and disinfectants. The virus will survive better in the winter. Animals exhibiting clinical signs of IBR should be isolated from other cattle as transmission of these viruses occurs by the oronasal route. Semen and embryos should be from BHV-1-free donors or prepared according to IETS guidelines for the control of infectious diseases.

(CONTINUED) INFECTIOUS BOVINE RHINOTRACHEITIS

PRODUCTION MANAGEMENT

In herds with a history of IBR or BHV-1 abortion, a BHV-1 vaccine program should be implemented

INFECTIOUS NECROTIC HEPATITIS

BASICS

OVERVIEW
Infectious necrotic hepatitis is a disease affecting mainly ruminant animals on pasture and causing sudden death. Rare cases have been reported in horses.

INCIDENCE/PREVALENCE
• Tends to be a seasonal disease related to the liver fluke life cycle, occurring in the warmer months when fluke transmission is active. Cases may, however, occur throughout the year. Occasionally, cases of necrotic hepatitis have been reported in animals without liver fluke.
• Incidence in affected sheep flocks is usually low, but the lethality of affected animals is close to 100%. Individual cases of the disease occur rarely in cattle and horses.

GEOGRAPHIC DISTRIBUTION
• Worldwide wherever liver flukes are present and occasionally in liver fluke-free areas.
• Important problem in Australia, New Zealand, and several South American countries; lesser importance in Europe, the United Kingdom, and the United States.

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• *Clostridium novyi* type B is a Gram-positive spore-forming anaerobic bacterium, which may be found in soil, where the spores are very resistant to environmental conditions and can survive for long periods of time. The spores are more prevalent and resistant in poorly drained pastures with alkaline water pH. The spores are ingested by animals and absorbed through the intestinal mucosa into the bloodstream, reaching the liver via the portal circulation. In the liver, they are phagocytized by Kupffer cells, in the cytoplasm of which they can survive for several years.
• Liver damage, typically from larval migration of *Fasciola hepatica*, and occasionally from other liver parasites such as *Fascioloides magna*, *Dicrocoelium dendriticum* and *Cysticercus tenuicolis*, produces anaerobic conditions, allowing the clostridial spores to germinate and proliferate, producing exotoxins, mainly lethal and edema-inducing alpha-toxin and, to a lesser extent, the necrotizing and hemolytic beta-toxin, which cause coagulative necrosis in the liver. The exotoxins enter the general circulation, damaging vascular endothelium in multiple organs.

HISTORICAL FINDINGS
• Sudden death is the most common presentation.
• Presence of liver fluke in the flock is common.

SIGNALMENT
• Mainly sheep. Occasionally cattle.
• Mostly animals >1 year but can occasionally affect younger animals. Usually animals in good body condition.

PHYSICAL EXAMINATION FINDINGS
• Animals most often found dead, in ventral recumbency.
• When observed, clinical signs are nonspecific and include reluctance to move, weakness, anorexia, hyperthermia, tachypnea, tachycardia, and eventual recumbency. Affected animals tend to get separated from the flock. Jaundice and hemoglobinuria are not observed.

GENETICS
The so-called molecular Koch postulates have not been fulfilled for necrotic hepatitis and the definitive role of the toxins mentioned above in the virulence of *C. novyi* type B remains, therefore, unconfirmed.

CAUSES AND RISK FACTORS
• Causes: Toxins alpha and, to a lesser extent beta, produced by *Clostridium novyi* type B proliferating in liver tissue damaged by migrating liver flukes or, occasionally yet unidentified factors.
• Risk factors: *Fasciola hepatica*, other liver parasites or unidentified factors. Lack of or improper *C. novyi* type B vaccination.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Bacillary hemoglobinuria. Icterus and hemoglobinuria characteristic of bacillary hemoglobinuria is not usually seen in necrotic hepatitis.
• Other diseases causing sudden death: anthrax, toxic plants, others.

CBC/BIOCHEMISTRY/URINALYSIS
Neutrophilia with left shift, metabolic acidosis, azotemia, and increase in liver and muscle enzymes.

OTHER LABORATORY TESTS
• Anaerobic culture followed by PCR.
• PCR.
• Fluorescent antibody test.
• Gram-stain and microscopic inspection of an impression smear of the liver shows numerous large Gram-positive rods with central or subterminal spores.
• Histopathology and immunohistochemistry.

PATHOLOGIC FINDINGS
• Foci of coagulative necrosis in the liver, well delimited, usually small and multifocal.
• Migrating fluke lesions in the liver.
• Congested subcutaneous blood vessels giving a dark aspect to the carcass ("black disease").
• Blood-tinged fluid in all body cavities (urine appears normal in color; no hemoglobinuria).

TREATMENT

THERAPEUTIC APPROACH
• Rarely treated since the disease is usually acute and animals are frequently found dead.
• High doses of procaine penicillin and supportive care. Antibiotic effectiveness is usually poor due to the presence of toxins in tissues and bloodstream.

MEDICATIONS

DRUGS OF CHOICE
• Penicillin 20,000–40,000 IU/kg IV q6h.
• Clorsulon 7 mg/kg, PO.
• Mass medicate herd with long-acting penicillin or tetracycline when cases occur. Flukicide use (e.g., clorsulon).
• Vaccinate flock/herd.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is grave in animals showing clinical signs.
• Rapid clinical course in sheep, usually found dead before clinical signs noted.
• Short clinical course in cattle, with nonspecific clinical signs (depression, anorexia), occasionally seen just before death.

CLIENT EDUCATION
• Routine vaccination against clostridia, making sure *C. novyi* type B antigens are included in the vaccine used.
• Control of liver fluke infestation by pasture management, limiting access to streams and ponds, and strategic flukicide treatment.

PATIENT CARE
Restrict movement of animals being treated, since stress of physical exertion can precipitate sudden death.

PREVENTION
• Vaccination with clostridial toxoid with booster in 4–6 weeks and annual revaccination, preferably in early spring at least 1 month before expected fluke exposure.
• Use of flukicides in animals.
• The effectiveness of the use of molluskicides in streams and drainage of marshy areas is very limited.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Fascioliasis

AGE-RELATED FACTORS
Typically adult animals 1 year and older

ZOONOTIC POTENTIAL
None known

BIOSECURITY
Carcasses should be deeply buried, burned, or removed from the premises to avoid spread of spores.

INFECTIOUS PUSTULAR VULVOVAGINITIS

BASICS

OVERVIEW
• Infectious pustular vulvovaginitis (IPV) is characterized by vulvitis and vaginitis and it is one of the granular venereal diseases.
• IPV is caused by alphaherpesvirus, bovine herpes virus (BoHV) type 1, subtype 2, of the Herpesviridae family.
• BoHV-1 is divided in two subtypes (BoHV-1.1 and BoHV-1.2) according to genetic differences and the systems that they affect.
• BoHV-1.1 affects the respiratory system causing infectious bovine rhinotracheitis (IBR), while BoHV-1.2 affects both the respiratory and the reproductive system, causing IPV in females and infectious pustular balanoposthitis (IPB) in males.
• BoHV-5, which is responsible for the encephalitic form of the disease, was previously classified as BoHV-1.3.
• IPV and IBR rarely occur concurrently within the same herd.

INCIDENCE/PREVALENCE
• IPV was considered endemic in Europe during the 1960s and 1970s. Control measures (vaccination and elimination of serologically positive animals) have greatly reduced its prevalence and the disease has been completely eradicated in some countries.
• Seroprevalence surveys have indicated that 10–50% of cattle may be serologically positive for BoHV, but the prevalence depends on vaccination practices.

GEOGRAPHIC DISTRIBUTION
Bovine herpesvirus has been isolated in Africa, Asia, North America, Australia, New Zealand, and Europe.

PATHOPHYSIOLOGY
• The virus establishes latency in sacral spinal ganglia following genital infection and may reactivate, resulting in viremia and shedding.
• The incubation period for BoHV-1.2 is usually between 1 and 3 days.
• The virus produces an acute catarrhal inflammation with a neutrophilic infiltration of the mucosa and lymphocytic and plasmocytic infiltration of the submucosa.
• Experimental infection in heifers results in oophoritis, decreased luteal function, and early pregnancy loss. Cervicitis and endometritis have been reported. The inflammatory process may result in short cycles and, rarely, abortion.
• Insemination with virus-contaminated semen results in poor-quality embryos.

HISTORICAL FINDINGS
• Introduction of new animals or untested semen
• Poor reproductive performance (return to estrus after AI)
• Clinical signs: Frequent posturing for urination, constant tail twitching

SIGNALMENT
• Species affected include bovine, ovine, and wild ruminants.
• Animals of breeding age are more likely to be infected.
• Nonbred animals can also be affected.
• Bovine females infected with BoHV-1.2 usually develop IPV.
• Male infected with BoHV-1.2 develop IPB.

PHYSICAL EXAMINATION FINDINGS
• Vulvitis and vaginitis: Swelling of the vulva and hyperemic mucosa surface of the vestibular area.
• Mucopurulent vaginal secretion may develop secondary to bacterial infection.
• Lymphoid tissue develops pustules that become small ulcers (<3 mm) and may result in coalescing erosions. The vulvar mucosa in the latter stages of the disease presents small but numerous necrotic focal areas.

GENETICS
• Bovine herpesvirus 1 is the herpesvirus serologically related to IBR and IPV/IPB, and is divided in two main subtypes according to genetic differences (BoHV-1.1 and BoHV-1.2).
• The genetic differences may be responsible for the diverse epidemiologic and pathologic patterns of virus behavior. While BoHV-1.1 is related to IBR, the respiratory form of the disease, BoHV-1.2, is related to the genital form of the ailment (IPV/IPB).
• Bovine herpesvirus 1.2b is a different strain of the virus and it is usually related to the occurrence of IPV/IPB and outbreaks of low/medium virulence of IBR.
• Some specific genotypes of bovine animals are more resistant to challenges with BoHV-1, developing less severe disease. This is an indication that breeding programs that increase the occurrence of these specific genes may alter the sensitivity of populations to BoHV-1 infection.

CAUSES AND RISK FACTORS
• The causative agent in cattle is bovine herpesvirus type 1 subtype 2 (BoHV-1.2). A similar disease has been described in goats, caused by caprine herpesvirus 1 (CpHV-1).
• IPV is transmitted directly by coitus or artificial insemination.
• Mechanical means are also possibilities for the transmission of the causal agent.
• Transmission of BoHV-1.2 is rapid and can affect 60–90% of the herd.
• Reactivation of latent virus is observed following stress (parturition, transport, inclement weather).
• Dexamethasone administration can cause recrudescence of clinical disease and viral shedding.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Granular venereal disease caused by *mycoplasma*, *ureaplasma*, *Histophilus somni*, and *T. pyogenes*
• Transmissible fibropapilloma
• Granular vulvitis
• Necrotic vulvitis

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Indirect: Serology—ELISA and virus neutralization test; skin test—delayed-type hypersensitivity (DTH) reaction
• Direct: Fluorescent microscope; polymerase chain reaction (PCR)

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Females develop mucopurulent secretion from the vagina and inflammation of the vulva and vagina.
• Lymphoid follicles present pustules that develop from small-sized ulcers to coalescing erosions.
• Male bovines infected with BoHV-1.2 that develop infectious pustular balanoposthitis (IPB) are reluctant to mate.
• The animals tend to recover within 10–30 days of the beginning of signs and remain transiently immune.

TREATMENT

THERAPEUTIC APPROACH
• Although lavage of the vagina with antiseptic solutions and emollients has been recommended, treatment is usually not required.
• Animals usually recover within 30 days of the initial infection.

SURGICAL CONSIDERATIONS AND TECHNIQUES

PRECAUTIONS
N/A

(CONTINUED) INFECTIOUS PUSTULAR VULVOVAGINITIS

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Animals usually develop clinical signs of infection within 1–3 days after exposure.
- Spontaneous recovery occurs within 10–30 days of infection.
- Infectious pustular vulvovaginitis has a very good prognosis.
- The disease is notifiable in many countries.

POSSIBLE COMPLICATIONS
- Female bovids infected with BoHV-1.2 that develop IPV have an increased rate of return to estrus after insemination. This can have a major impact in the breeding programs and consequently to the profitability of dairy and beef operations.
- It is rare for IPV to be followed by abortion outbreaks.

CLIENT EDUCATION
Educate client on biosecurity measures.

PATIENT CARE
N/A

PREVENTION
- Vaccination can be of benefit. However, in the face of an outbreak, vaccination has little effect.
- Avoid mating among infected animals to decrease the risk of dissemination of the disease.
- The virus can be spread via fomites such as contaminated breeding equipment. Strong biosecurity protocols are essential.
- BoHV-1.2 can survive cryopreservation. Therefore, semen donors and semen should be tested and free of BoHV-1.2, and semen from these bulls should not be stored in the same tank as semen of unknown status.
- Eradication of the disease requires vaccination and often elimination of animals that are carriers of the genital form of BoHV.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- During the initial phases of the disease, animals may present less-specific signs such as pyrexia and decreased milk production.
- Animals of breeding age infected with BoHV-1.2 may present increased rate of return to estrus.
- Conjunctivitis with serous discharge and bilateral nasal discharge are signs of BoHV-1.2 when the respiratory tract is affected.

AGE-RELATED FACTORS
Although breeding-age animals are more likely to develop the condition, unbred heifers can also be infected.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Infectious pustular vulvovaginitis is rarely related to abortion outbreaks.

BIOSECURITY
- Vaccination (vaccination is prohibited in countries that have eradicated the disease)
- Testing of bulls and frozen semen
- Avoid the use of shared hired bulls
- Proper sanitation of breeding and collection equipment

ABBREVIATIONS
- AI = artificial insemination
- BoHV = bovine herpesvirus
- DTH = delayed-type hypersensitivity
- ELISA = enzyme-linked immunosorbent assay

INFERTILITY AND SUBFERTILITY ISSUES

BASICS

OVERVIEW
• Infertility is defined as the inability to produce young. Subfertility is a condition of less than normal or desired fertility, that is, a relative infertility. In common veterinary parlance, however, the terms are used interchangeably to describe less than optimal functioning of a reproductive system and we will make no distinction between them here.
• Sterility is a term generally reserved for cases of profound, permanent infertility in individual animals. It is important to keep in mind that while producing a single offspring defines a male or female animal as fertile, this level of performance is seldom satisfactory for livestock systems.
• Fecundity defines a livestock system that is functioning well from a reproductive point of view and infertility/subfertility (I/S) describes a system in need of improvement.

INCIDENCE/PREVALENCE
• Poor reproductive performance is one of the major areas in production medicine.
• Incidence is highly variable with local conditions and farm management.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• The etiology and pathophysiology of I/S are highly complex. Investigation of fertility problems is a highly reductive process.
• Initial problem identification and refinement must account for all three elements of the fertility equation (the male animal; the female animal; and the human/management element) as well as the fundamental nature of the problem—usually expressed as either a failure to breed, a failure to become pregnant, or a failure to maintain pregnancy/stillbirth.
• Many approaches are used to further develop a diagnosis but expert systems tend to focus on cause (e.g., use of the DAMNIT system), timing of the problem within the reproductive life cycle, and anatomic localization. Further diagnostic tests are almost invariably necessary to make a specific diagnosis.
• Both the quality and the quantity of feed and water should be a major concern and subject of investigation in any herd-level problem with I/S in production animals.

HISTORICAL FINDINGS
• Vary with species, sex of the animal, and disease but can be broadly categorized as:
  ◦ A failure to copulate or express estrus
  ◦ A failure to conceive a pregnancy after copulation, insemination, or embryo implantation
  ◦ A failure to maintain a viable pregnancy to term, or fetal death within 48 hours of delivery (stillbirth)
  ◦ Disorders of lactation are not covered here.
• Herd infertility investigation may reveal a poor pregnancy rate, increased services per conception, or an elevated rate of abortion.

SIGNALMENT
Any intact animal at any stage of sexual development or the reproductive cycle

PHYSICAL EXAMINATION FINDINGS
• General physical examination may show underlying cause: Poor BCS, poor health
• Examination of the reproductive tract:
  ◦ Male—testicular or penile abnormalities
  ◦ Females—abnormal vaginal discharge, abnormal ovarian activity or uterine disorders

GENETICS
• Some I/S issues have a direct genetic causation (e.g., DUMPS, BLAD, CVM, and brachyspina in Holstein cattle), some have a less definitive genetic predisposition (e.g., the influence of offspring size on dystocia and subsequent stillbirth incidence), while others (e.g., infectious abortion, toxin ingestion) have little or no genetic influence.

CAUSES AND RISK FACTORS
• Suboptimal management, especially nutritional but including all aspects of reproductive program management
• Local infectious disease prevalence and virulence factors
• Trauma at mating or parturition
• Heredity

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Establishing a differential list at the herd level requires a detailed epidemiological approach, including a review of records, management, nutrition and disease prevention programs as well as a careful evaluation of specific breeding practices.
• Individual animals need to undergo a complete breeding soundness examination (BSE).

CBC/BIOCHEMETRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Genomic testing where available
• Hormone analysis and response to stimulation tests
• Microbial culture and sensitivity
• Serology
• Virus isolation
• Molecular diagnostics
• Toxicology
• Feed/water analysis

IMAGING
• Ultrasonography has become the standard for imaging reproductive tissues in both male and female animals. Specific methods and applications will vary with species and suspected disease.
• While radiography is seldom indicated in ruminant I/S work-ups, contrast radiography can assist with diagnosis of penile disorders.

OTHER DIAGNOSTIC PROCEDURES
• A thorough reproductive examination of affected individuals (BSE).
• Diagnosis of herd-level I/S problems focuses on signalment, history, and records analysis and places a premium on local knowledge and professional acuity.
• Obtaining a specific diagnosis is complicated by the fact that the signs of reproductive disease are not specific or pathognomonic and there is often considerable time lag from the disease insult to the manifestation of the signs of disease.
• Diagnostic efforts are often delayed so that by the time a diagnostic investigation is begun, the trail may have gone cold.
• Palpation per rectum is a critical diagnostic skill for investigation of bovine I/S and is used variably in llamas and alpacas depending on size of the animal and the examiner.

PATHOLOGIC FINDINGS
• Vary with species and disease or disorders.
• Local or regional veterinary diagnostic laboratory should be contacted for advice on sample selection and handling.

TREATMENT

THERAPEUTIC APPROACH
• Depends on the specific disease condition responsible for the problem.
• Assisted reproductive technologies (e.g., ET, IVF and SCNT) are options for highly valuable animals with poor prognoses with more conventional breeding options.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgical correction is possible for some specific disorders.

MEDICATIONS

DRUGS OF CHOICE
• Antibiotics are indicated for primary bacterial diseases. Culture and sensitivity testing are ideal but many cases are treated empirically, for economic reasons.
• Hormonal treatments can be used to stimulate and inhibit reproductive functions. Classes of hormones available for use in ruminants include GnRH, gonadotropins

(eCG and hCG), PGF, and the sex steroids or their agonist and antagonists.
• The choice of drug varies with the condition and regional availability.
• In general, prevention is a more economical approach to I/S management than is treatment.

CONTRAINDICATIONS
• Abortifacients and teratogenic agents should not be used in pregnant animals unless the life of the dam is the higher priority.

PRECAUTIONS
• Milk and meat withdrawal times should be observed.
• Extra-label drug use in food animals is not permitted in the United States in the absence of disease, and suboptimal reproductive function is not considered a disease.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Highly variable depending on the specific disorder and treatment options.
• Animals of minimal value (financial or genetic) may be culled quickly; more valuable animals may merit specific treatment or be given time to recover spontaneously.

POSSIBLE COMPLICATIONS
• The majority of I/S conditions are not life-threatening but some (e.g., dystocia) are both emergent and potentially serious if not fatal disorders.
• The greatest risk for animals experiencing I/S is that they will be involuntarily culled for economic reasons.
• Loss of genetic value of culled breeding animals.

CLIENT EDUCATION
• Record keeping
• Sound breeding management protocols
• Breeding soundness examination

PATIENT CARE
Individual animals and groups of animals should be monitored by appropriate physical examination and records to assess recovery.

PREVENTION
• Adequate biosecurity including pre-entry testing of new arrivals, adequate quarantine procedures and duration, and re-testing before entry to the herd.
• Biologically sound vaccination programs.
• Use semen and embryos that are certified to be free of diseases of concern. At the very least, be sure of the disease status of the facility where germplasm originates.
• Reproductive management protocols on the farm should include training, monitoring, and establishing performance standards that will trigger rewards or remediation.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Reproductive efficiency tends to increase for a period of years after puberty, followed by a plateau, and then a gradual decline with age. The inflection point will vary with species and management systems employed on each farm.

ZOONOTIC POTENTIAL
Many infectious reproductive diseases are capable of infecting humans. Special care should be taken when examining females that are aborting.

PREGNANCY
Pregnancy wastage is a common manifestation of reproductive disorders. Treatment and prevention programs often target pregnant animals and in such cases the potential for negative drug/vaccine effects on the fetus should be carefully considered before treatment is instituted.

BIOSECURITY
• Biosecurity is an obvious component of management for infectious disease control.
• The specific measures will vary with the cost and severity of the diseases one is trying to avoid. Tuberculosis and brucellosis are examples of diseases with an extremely high cost to ruminant production systems and grave zoonotic potential, so the tolerance for these diseases is essentially zero. The best approach to managing these diseases is a national disease eradication effort and continuous surveillance. Less serious diseases or those that do not affect humans as severely may be managed more economically by test and cull programs at the farm level. Others may respond well to vaccination or other disease prevention programs.
• Special attention should be paid to the disease status of semen, ova, and embryos used in ART programs.

PRODUCTION MANAGEMENT
• Adequate record systems that allow evaluation of reproductive efficiency and track disease occurrence. Computerized record systems are essential for large-scale operations.
• Local, regional and national recording and management systems are available that can help with interpretation of farm-level metrics. These systems can establish farm performance benchmarks and assist with setting goals for the future. They can also be useful in determining when interventions are necessary and assessing the performance of the interventions.

ABBREVIATIONS
• AI = artificial insemination
• ART = assisted reproductive technology
• BCS = body condition score
• BLAD = bovine leukocyte adhesion deficiency
• BSE = breeding soundness examination
• CVM = complex vertebral malformation
• DAMNIT = (D)egenerative, (A)utoimmune, (M)etabolic, (N)eoplastic, (I)nfectious/(I)atrogenic, (T)raumatic; an organizational system for developing a diagnosis, commonly expanded beyond this initial list
• DUMPS = deficiency of uridine monophosphate synthetase
• eCG = equine chorionic gonadotropin (primarily FSH activity)
• ET = embryo transfer
• GnRH = gonadotropin releasing hormone
• hCG = human chorionic gonadotropin
• I/S = infertility and subfertility
• IVF = in vitro fertilization
• PGF = prostaglandin F2α and its analogs
• SCNT = somatic cell nuclear transfer (cloning)

INJECTION SITE LESIONS

BASICS

OVERVIEW
• Injection site lesions occur due to disruption of tissue constituents and architecture in response to physical or chemical trauma associated with the injection process or medications.
• Injection of any substance has the potential to result in immediate or delayed clinical symptoms and/or long-term changes in tissue structure.
• The term "injection site lesion," in ruminants, most commonly refers to the scar tissue found after almost any intramuscular injection, leading to the development of a tough, gristly area of meat.
• IM injection site lesions are of most significance in food-producing animals when located in the top sirloin, blade, and round cuts of meat as they cause economic losses due to trimming.
• Injection site lesions that occur after treatment of young animals persist into adulthood and can enlarge with time as the animal grows. They may be readily apparent in harvested carcasses.

INCIDENCE/PREVALENCE
• Unknown in many ruminant species, but substantial in cattle where injection sites include primary economic muscle groups.
• Investigators of a 3-year audit (1998–2000) reported frequencies of injection site lesions in outside round muscles from beef cow carcasses and dairy cow carcasses to be 26% and 49%, respectively. Higher frequencies in dairy cows are associated with greater injection frequencies linked to production management.
• A trend in declining frequencies is associated with educational programs and continued improvements in beef quality assurance practices among beef and dairy producers.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Musculoskeletal

PATHOPHYSIOLOGY
• Short-term and clinically evident effects of injections are uncommon but include local inflammation, hyperemia, hematoma formation, cellulitis, necrosis, and lymphadenitis.
• Most commonly, the long-term result of IM injections have no clinical consequence to the animal, but lesions are present and grossly identified at slaughter as a clear scar, woody callus, or cyst.
• A fibroproliferative process occurs subsequent to IM injection of a pharmacologic agent resulting in significant increases in total, soluble, and insoluble collagen concentrations at the lesion center, which decrease in concentration as the radius from the lesion center increases.
• Histologically, lesions can be classified as clear, woody, nodular, metallic, or cystic.
• Clear and woody lesions are typical of injections given to animals in earlier stages of their life (as calves or during the time before weaning); metallic and nodular lesions are typical of pharmaceuticals administered to cattle in mid-to-late feeding phases; and cystic lesions are typical of injections given to cattle late in the finishing phase.
• IM injections significantly reduce the tenderness of affected tissues in an area up to 7.62 cm away from the lesion center.

HISTORICAL FINDINGS
Parenteral administration of pharmaceutical products

SIGNALMENT
Meat-producing livestock species: bovine, ovine, caprine, and camelids

PHYSICAL EXAMINATION FINDINGS
Palpation and/or observation of fibrous/cystic muscle tissue or a reduction in tenderness of muscle

GENETICS
N/A

CAUSES AND RISK FACTORS
• Administration of IM pharmaceuticals in regions of high value for meat processing
• Multiple use needles
• Injections >10 mL of any product at a single site and use of needles larger than 16 G
• IM injections in young animals that may enlarge with time
• Clostridial bacterin/toxoids, *Mycobacterium avium* subsp. *paratuberculosis* vaccination, oxytetracycline, vitamin A/D

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Any disease or trauma causing a fibroproliferative tissue response
• Abscess
• Cyst
• Neoplasia

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Radiography and ultrasonography may reveal increased soft tissue density and mineralization of some lesions.

OTHER DIAGNOSTIC PROCEDURES
Biopsy, resection, or evaluation of tissue at time of meat processing

PATHOLOGIC FINDINGS
• Histologic section of lesions in affected cattle musculature have sheets of fibroblasts with extensive collagen deposition at the core; a combination of dense fibrous connective tissue and mature adipose tissue progressing outwards; and a mixture of partially degenerated muscle fibers, mature connective tissue, and occasional adipose cells on the outside border.
• Tissue ossification and granulation may be identified.
• Alterations in relative proportions of muscle, connective tissue, and fat to a distance of 5.08 cm from the site of the lesion center may be present in beef cattle and confirm severe disruption of muscle tissue constituents and architecture.

TREATMENT

THERAPEUTIC APPROACH
• Surgical resection
• Trimming of affected tissue at meat processing

MEDICATIONS

N/A

FOLLOW-UP

PREVENTION
• All possible injections, especially those of potentially irritating animal health products, should be give via the SC route or by transdermal needleless injection.
• Use the "tent method" for SC injections to avoid injection into the muscle.
• SC injections in non-prime cut areas should start with baby calves and be practiced for the life of the animal.
• All injections should be given in the neck in front of the point of shoulder when possible.
• Choice of IM injection site should be based on minimal loss of retail product. Do not administer IM injections in the rear leg or hip areas. Administer IM injections in the neck area, but avoid the following landmarks: neck vertebrae, nuchal ligament, front edge of the scapula, the lymph node at the point of the shoulder.
• Inject in a clean and dry site.
• Select the needle gauge to fit animal size and liquid viscosity. Use the smallest practical size without risk of bending or breakage.
• If using multi-dose injectors, change needles when dull or damaged or in a manner consistent with disease transfer minimization.
• Use proper injection equipment, which is cleaned and functioning properly.
• Use a clean needle to fill syringes with drugs and vaccines.

• Use products as labeled in their appropriate manner in consideration of route of administration and frequency.
• Use low dosage products, with a recommended space of 10 cm between injection sites, and do not exceed the recommended volume per injection site.

POSSIBLE COMPLICATIONS
Abscessation at injection site

EXPECTED COURSE AND PROGNOSIS
Injection site lesions rarely cause clinical problems for the affected animal but result in economic losses for the producer at time of slaughter.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
IM injection site lesions in calves may enlarge with age, resulting in greater trim at slaughter.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Use strategies that do not compromise beef quality by reducing bruises, decreasing hide damage, preventing drug residues, and eliminating injection site lesions.
• Avoid giving medications close to slaughter that could cause injection site lesions and residue violations in meat.
• Use of products, where possible, that are approved for SC, IV, or oral administration.
• SC injections should be given in front of the shoulder.
• IM injections should be given in the neck region with no more than 10 mL administered in one site, using the smallest gauge needle possible.

ABBREVIATIONS
• IM= intramuscular
• IV = intravenous
• SC= subcutaneous

IODINE DEFICIENCY AND TOXICITY

BASICS

OVERVIEW
• Iodine is an essential micronutrient whose primary function is the synthesis of thyroxine (T4) and tri-iodothyronine (T3).
• Iodine cannot be synthesized by the body, thus diet is the primary source.
• Deficiency occurs when animals inhabit areas of iodine-deficient soil.
• Daily iodine requirement for cattle is 0.016 mg/kg body weight.
• Toxicity occurs through intake above the daily requirement either thru long-term consumption of diet with an excess, incorrect management of mineral feed mix, or chronic use of therapeutic iodine compounds.
• Toxic doses:
  ◦ Adult cattle prolonged administration at 0.12–1 mg/kg BW daily
  ◦ Calves prolonged administration at 0.4–2.2 mg/kg BW daily
  ◦ Sheep prolonged administration at 13.1 mg/kg BW daily
• Clinical signs associated with toxicity can be affected by the amount and length of administration, the type of compound administered, and the physiologic and metabolic status of the animal.

INCIDENCE/PREVALENCE
Since this is a nutritional issue, morbidity can vary greatly in a herd.

GEOGRAPHIC DISTRIBUTION
Iodine-deficient soil areas within the United States may include Texas, California, Pacific northwest, mountain states, North Dakota, and some of the Midwestern states.

SYSTEMS AFFECTED
• Hemolymphatic
• Reproductive

PATHOPHYSIOLOGY
• Iodine is an essential micronutrient whose primary function is the synthesis of thyroxine (T4) and tri-iodothyronine (T3). These hormones have a role in controlling metabolism, cell growth, and maturation as well as growth and development of tissues.
• Iodine additionally has a role in the immune system, especially in the functioning of leukocytes. Deficiency thus results in a depression of cellular and humoral immunity, leading to a decreased response to infectious agents.

HISTORICAL FINDINGS
• History of iodine-deficient diet, such as areas located with iodine-deficient soil without supplementation.
• Prolonged administration of iodine compounds such as EDDI (organic) or calcium or potassium iodate (inorganic) for therapeutic uses.
• Improper supplementation of iodine in the diet, potentially through improper mineral mix or diet concentrations.

SIGNALMENT
Cattle and sheep. The developing fetus is particularly susceptible to iodine deficiency.

PHYSICAL EXAMINATION FINDINGS
• Deficiency
  ◦ Goiter or thyroid enlargement especially in newborn calves and lambs
  ◦ Reproduction issues such as decreased conception rates and stillbirths
  ◦ Increased newborn mortality
  ◦ Ill-thrift in growing animals
• Toxicity
  ◦ Cattle
    ▪ Persistent cough
    ▪ Nasal discharge
    ▪ Lacrimation
    ▪ Salivation
    ▪ Hyperthermia
    ▪ Inappetence
    ▪ Depression
    ▪ Dermatitis (dry, scaly) and alopecia
    ▪ Infectious disease especially of the respiratory system
    ▪ Reduction in milk production
  ◦ Sheep
    ▪ Depression
    ▪ Anorexia
    ▪ Hyperthermia
    ▪ Changes in respiratory system

CAUSES AND RISK FACTORS
• Iodine is required for production of thyroid hormones
• Areas with iodine-deficient soils
• Feeding of goitrogenic feeds that interfere with the availability of iodine (brassica fodder crops—bok choy, kale, rape, sugar beet pulp, turnips—and vegetable crop residues of cauliflower and broccoli)
• Excess iodine supplementation

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Infectious respiratory disease

CBC/BIOCHEMISTRY/URINALYSIS
• Toxicity may result in leukopenia with neutrophilia and lymphopenia on full blood count
• Toxicity may result in:
  ◦ Increase in serum glucose, AST and BUN
  ◦ Decrease in serum cholesterol and urinary creatinine

OTHER LABORATORY TESTS
• Plasma inorganic iodine (PII) measures current daily iodine intake (short-term), and is thus susceptible to changes in feed intake.
• T_4 levels reflect the thyroid and iodine status of the animal (>50 nmol/L, normal; <20 nmol/L, abnormal), and are useful in the diagnosis of deficiency. Care must be taken in interpretation of T_4 values, as there is natural variation according to stage of lactation (levels are much lower in early lactation), season, age of animal, etc.

OTHER DIAGNOSTIC PROCEDURES
Clinical signs

TREATMENT

THERAPEUTIC APPROACH
• Deficiency: Supplement as needed.
• Toxicity: Remove source and return diet to daily intake requirement levels.

MEDICATIONS

DRUGS OF CHOICE
• Oral dosing using potassium iodide is relatively short-acting and laborious. Intraruminal boluses provide slow release of iodine for 6 months. Painting 5% tincture of iodine onto the flank skinfold once a week in milking dairy cattle can work well, but is too labor-intensive in dry cows and beef animals. Free-access minerals, medication of water supplies, and pasture fertilizers can all be used to varying effect.
• For suckling lambs and calves with goiter, tincture of iodine can be applied to the teats for up to 2 weeks to treat iodine deficiency.

FOLLOW-UP

PREVENTION
• Iodine is frequently added to concentrate rations for feeding to cattle and sheep, for example using seaweed preparations. Rapeseed meals are usually treated to eliminate goitrogens prior to feeding, and newer "double-zero" oilseed rape varieties are lower in goitrogens.
• On the label of free-choice mineral mixes, iodine may be in the form of calcium iodate or ethylenediamine dihydroiodide, which are both quite stable and available. Additional supplementation of iodine in less stable forms (more susceptible to loss of iodine with exposure to light, heat, moisture, or other factors) includes potassium or sodium iodide, which are often used to fortify salt with iodine.
• If 25% or more of the diet is made up of feedstuffs associated with goitrogenic crops, then dietary iodine levels should increase to 1.0 ppm, especially for cows and ewes in late gestation or early lactation.
• Dosing ewes with iodine compounds in the fourth and fifth months of pregnancy prevents goiter in their lambs. The iodine compounds can be given directly or mixed

with worm drenches. Recommendations on the dosage and the compatibility of iodine compounds with various drenches can be obtained from your local veterinarian.

MISCELLANEOUS

PREGNANCY

Iodine deficiency results in abortion and stillbirths.

PRODUCTION MANAGEMENT

- Iodized salt is still a recommended source of supplemental iodine for all parts of the country, especially where origin of crops is unknown.
- If practical, avoid grazing pregnant livestock over "at risk" areas such as the sandier soil types, especially during the latter half of pregnancy.
- Sheep or cattle fed on brassica fodder crops such as bok choy, kale, rape, sugar beet pulp, turnips and vegetable crop residues of cauliflower and broccoli are likely to produce goiter in their progeny if access to these crops is prolonged. This is because brassicas contain goitrogens which interfere with the availability of iodine.

SYNONYM

Goiter

JIMSONWEED TOXICITY (*DATURA STRAMONIUM*)

BASICS

OVERVIEW
• Caused by ingestion of jimsonweed (Jamestown weed, thorn apple, downy thornapple, devil's trumpet, angel's trumpet, mad apple, stink weed, tolguacha or *Datura stramonium*) and its toxic tropane alkaloids. • All parts of the green or dried plant are toxic including the seeds. Plants become more toxic as they mature. Seeds are considered to be the most toxic part of the plant. • The green plant is generally unpalatable due to its strong odor. Thus, lack of other forage, drying of the plant in hay, or contamination of cereal grains or feed with the seeds are the primary routes of ingestion and toxicity. • Toxicity is often somewhat self-limiting as anorexia is induced early in the toxic process, limiting ingestion of further toxins. • Signs predominantly involve the neuromuscular, ophthalmic, and gastrointestinal systems.

INCIDENCE/PREVALENCE
Plant is unpalatable. Dried material in hay may be eaten inadvertently. This is particularly true for ruminants. Up to 1% of body weight per day of leaves or fruits fed to sheep or goats produced clinical signs after 2 or more days, but it was not lethal unless fed for several weeks or longer.

GEOGRAPHIC DISTRIBUTION
Jimsonweed is commonly found in fencerows, barnyards, and roadsides throughout much of the United States.

SYSTEMS AFFECTED
Nervous

PATHOPHYSIOLOGY
• Contain two tropane alkaloids: (1) L-hyoscyamine (atropine) and (2) scopalamine (L-hyoscine). • Tropane alkaloids act as a competitive antagonist of acetylcholine at muscarinic cholinergic receptors of the parasympathetic nervous system. • Clinical signs are attributable to this receptor blockade and are manifest as (1) blockage of contraction of the muscles of the iris and mydriasis, (2) decreased smooth muscle contraction of the gastrointestinal system, (3) decreased salivary secretions, and (4) increased vagal tone.

SIGNALMENT
• All ruminant species can be affected. • Cattle appear to be more susceptible than other ruminants. • No sex, age, or breed predilection among animals consuming the plant.

SIGNS
• Mydriasis • Depression • Restlessness • Anorexia • Sinus tachycardia • Weakness • Photophobia • Dry mucus membranes • Constipation/ileus • Rumen atony

CAUSES AND RISK FACTORS
Associated with ingestion of toxin-containing plant. Consumption of feed or cereal grains containing 1,000 seeds/kg can be toxic in cattle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other toxic plants with tropane alkaloids including moonflower, angel's trumpet, deadly nightshade, belladonna, black henbane, horse or bull nettle, Texas thistle, tropical soda apple, and ground cherries. • Parenteral or topical atropine therapy.

CBC/BIOCHEMISTRY/URINALYSIS
No changes specific for jimsonweed toxicity

OTHER LABORATORY TESTS
• Urine and gastrointestinal contents can be tested for tropane alkaloids. • Test administration of parasympathomimetic drugs *may not* cause appreciable improvement.

OTHER DIAGNOSTIC PROCEDURES
• If acute consumption is suspected, a rumenotomy with confirmation of plant material or seeds in the ingesta would be diagnostic and may be indicated. • Urine from affected animal is said to induce mydriasis if applied topically to the eye of a test animal.

PATHOLOGIC FINDINGS
• Identification of seed or plant material in the rumen • No distinct lesions • May see hemorrhages of the liver or kidney or effusions of the pericardium

TREATMENT

THERAPEUTIC APPROACH
• Remove animals from source of toxin (plants or seed). • If acute ingestion of large volumes of toxin is suspected, rumenotomy with evacuation of the ingesta may be beneficial. • Often self-limiting due to anorexia, an early sign.

MEDICATIONS

DRUGS OF CHOICE
• Orogastric administration of mineral oil or activated charcoal may decrease absorption of the toxin. • Rarely administration of a cholinergic drug (such as physostigmine, pilocarpine, or arecoline) is used; however, no clear benefit from the use of these drugs has been demonstrated.

CONTRAINDICATIONS
Atropine

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Often self-limiting due to decreased ingestion of the toxin after initial signs of toxicity. • Most have a good prognosis with supportive care.

PATIENT CARE
Monitor for signs of continued ileus or intestinal obstruction secondary to ileus.

PREVENTION
Do not pasture animals on fields with jimsonweed or feed hay or grain containing the plant or seeds.

MISCELLANEOUS

ZOONOTIC POTENTIAL
N/A

PREGNANCY
• Some studies have demonstrated teratogenic properties of tropane alkaloids; however, more recent studies have not been able to clearly demonstrate a cause and effect relationship. • Until further work is done, tropane alkaloids should be considered possible teratogens.

JOHNE'S DISEASE

BASICS

OVERVIEW

• Johne's disease (pronounced Yo-nees) is a serious disease of most ruminants that can cause significant economic loss if not controlled.
• Johne's disease is caused by the bacteria *Mycobacterium avium* subsp. *Paratuberculosis* (MAP).
• The primary source of infection is feces that contain MAP. Infected animals can produce large amounts of the bacteria and shed this organism in their feces.
• Most infected animals do not begin shedding the Johne's organism until they are adults.

INCIDENCE/PREVALENCE

It is estimated that >50% of the dairy and 20% of the beef cow-calf operations in the United States have at least one animal infected with Johne's disease. The prevalence is higher in larger dairy operations.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Digestive

PATHOPHYSIOLOGY

• The primary source of infection is feces that contain MAP. Infected animals can produce large amounts of the bacteria and shed this organism in their feces.
• After ingestion and uptake in the Peyer's patches of the lower small intestine, this intracellular pathogen infects macrophages in the GI tract and associated lymph nodes. It is possible that some animals may eliminate infection through a cell-mediated immune response that encourages microbiocidal activity in macrophages, but the frequency with which this occurs is unknown.
• In most cases, the organisms multiply and eventually provoke a chronic granulomatous enteritis that interferes with nutrient uptake and processing, leading to the cachexia typical of advanced infections.
• This may take months to years to develop and is usually paralleled by a decline in cell-mediated immunity, a rise in serum antibody, and bacteremia with dissemination of the infection beyond the GI tract.
• Fecal shedding begins before clinical signs are apparent, and animals in this "silent" stage of infection are important sources of transmission.

SIGNALMENT

• All breeds of cattle, sheep, and goats are susceptible to Johne's disease. Camelids are also susceptible.
• Newborn animals are most susceptible to infection with MAP. As they get older, risk of infection decreases. In cattle, most infections likely occur in the first 6 months of life.
• Following a long incubation period of months to years, clinical disease typically occurs in an adult animal.

PHYSICAL EXAMINATION FINDINGS

• There is a long incubation period between infection with MAP and the appearance of clinical signs. In cattle, this period of time may range from 1 year to several years.
• Prior to the development of observable clinical signs, animals may be affected subclinically. Syndromes that have been associated with subclinical Johne's disease in cattle include reduced milk production, reduced reproductive performance, and increased disease susceptibility.
• The classical clinical sign of Johne's disease in cattle is chronic, watery diarrhea. This diarrhea may be intermittent at first, but eventually progresses to chronic and unrelenting. Diarrhea is not as evident in sheep and goats.
• The diarrhea has no distinguishing characteristics such as blood, mucus, or foul odor. It is often referred to as "pipe stream" in nature because of its watery and projectile appearance.
• Secondary to diarrhea, animals lose weight despite the maintenance of a good appetite. Weight loss is the primary clinical sign in sheep and goats.
• Depending on concurrent metabolic loads (milk production, pregnancy), weight loss may occur gradually over months or very rapidly over the course of a few weeks.
• In advanced cases, the development of submandibular edema may occur secondary to a decrease in total serum protein.

CAUSES AND RISK FACTORS

• Johne's disease is caused by the bacteria *Mycobacterium avium* subsp. *Paratuberculosis* (MAP).
• Animals <6 months of age are most susceptible to infection. Older animals are less susceptible to infection.
• Any method by which young stock become exposed to fecal material from adult animals may serve as a source of infection with MAP.
• This may include being born in a dirty maternity pen, nursing a dirty teat, being housed in direct contact with adult animals, using common feeding/manure handling equipment (skid-loader), or having manure run-off from mature cow areas going through the environments of young stock.
• Another important source of transmission is milk and colostrum. About one third of cows infected with MAP, whether they are showing clinical signs or not, will shed the bacteria in their colostrum or milk.
• Approximately 20% of cows with Johne's disease will pass MAP across their placenta to the developing fetus. The risk of this happening increases dramatically in cows with clinical signs of Johne's disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Parasitism
• Copper deficiency
• Bovine leukosis
• Salmonellosis
• Amyloidosis
• Chronic reticuloperitonitis/peritonitis

CBC/BIOCHEMISTRY/URINALYSIS

Hypoproteinemia, characterized by low serum albumin, may be present in advanced clinical cases of Johne's disease.

OTHER LABORATORY TESTS

• MAP can be cultured from feces using standard solid media culture methods, which require 10–16 weeks to complete, or new rapid liquid media culture methods that shorten the culture time to 7–10 weeks.
• PCR/DNA probe—organism detection assay used on feces or tissue.
• Antibody detection ELISA, agar gel immunodiffusion, and complement fixation assays on serum.
• The antibody ELISA assay can also be used on milk to screen individual animals or herds.
• Acid-fast stains can be used for direct visualization of organism in appropriate tissue samples such as ileum or ileal cecal lymph nodes.
• The specificity of all the assays for Johne's disease is high (>98%) whereas the sensitivity is generally low (30–50%).

PATHOLOGIC FINDINGS

• In cattle, gross lesions are primarily found in the distal jejunum, ileum, cecum, proximal colon, and associated lymph nodes.
• Thickening of the intestine three to four times normal thickness is characteristic.
• Affected mucosa takes on a corrugated appearance.
• The ileocecal valve is typically thickened and often reddened in color.
• In sheep, intestinal mucosa may be thickened, but it does not typically become corrugated.
• Mesenteric lymph nodes are enlarged and edematous in cattle. In sheep, they have areas of necrosis and calcification.
• Histologically, the earliest cellular changes are increased numbers of macrophages and lymphocytes.
• As the infection progresses, the mononuclear inflammatory infiltrate becomes pronounced and giant cells become more numerous. The inflammation is diffuse; the lesions are not walled off or circumscribed by fibrous connective tissue.
• Acid-fast bacteria will be present in areas of mononuclear inflammation.

JOHNE'S DISEASE (CONTINUED)

TREATMENT

THERAPEUTIC APPROACH
There are no chemotherapeutic agents approved for use in food-producing animals for the treatment of MAP.

MEDICATIONS

DRUGS OF CHOICE
There are no approved drugs for the treatment of MAP. Use of antimycobacterial chemotherapeutic agents has largely been ineffective. Isoniazid, rifampin, clofazimine, dapsone, aminoglycosides, and ethambutol may result in transient reduction in clinical signs and slowing of disease progression, but response is inconsistent and they have failed to cure the disease.

PRECAUTIONS
Drug withdrawal times must be determined and maintained for food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Johne's is a chronic progressive disease.
- Progression of Johne's disease typically occurs over a 2–3-year period.
- Johne's disease progression can be divided into four stages. Stage 1 is the period of inapparent infection that occurs early in the disease progression. Stage 2 is a subclinical phase where shedding of the organism is intermittent. Stage 3 is characterized by consistent heavy shedding. Stage 4 is the clinical stage of the disease.
- Johne's disease is inevitably fatal if allowed to progress.

PREVENTION
- Stopping the transmission of MAP from infected cattle that are shedding the bacteria (generally adult animals) to susceptible animals (generally young animals) is key to controlling the disease.
- Specific recommendations include making sure newborns are born into and housed in a clean environment, reducing the chance of spread through colostrum and milk by not sharing colostrum and milk between multiple young stock or feeding only pasteurized sources of milk or milk replacers, making sure that weaned young stock are separated from adult animals.
- Feed and water sources for young stock should be protected from contamination with adult cow feces.
- Infected animals should be identified and either culled or managed so as to reduce the chances that they spread MAP to susceptible animals, primarily young stock.
- Calves born to known MAP-infected cattle should be considered at high risk for being infected with MAP, and managed accordingly.

MISCELLANEOUS

AGE-RELATED FACTORS
- Calves are most at risk for becoming infected with MAP. As cattle get older, infection becomes less likely.
- Because of the long incubation period, clinical signs of disease typically do not appear until adulthood.

ZOONOTIC POTENTIAL
There has been some association of MAP with Crohn's disease in humans, but no definitive link has been made.

PREGNANCY
MAP can cross the placenta and infect the fetus. This occurs about 20% of the time in Johne's-infected cows. The risk of fetal transmission in utero increases as the disease progresses in the dam.

BIOSECURITY
- The primary source of infection is feces that contain MAP. Infected animals can produce large amounts of the bacteria and shed this organism in their feces.
- The primary source of new infection into a herd is the acquisition of infected cattle.
- Studies have demonstrated that MAP can survive for months in the environment.
- Cleaning and disinfection is essential for MAP control.

SYNONYM
Paratuberculosis

JUVENILE LLAMA IMMUNODEFICIENCY SYNDROME

BASICS

OVERVIEW
• Juvenile llama immunodeficiency syndrome (JLIDS) is a syndrome in young llamas characterized by failure to grow or gain weight as expected, and generalized ill thrift, which routinely progresses to multiple and/or chronic systemic infections and eventually to death.
• Research suggests an inherited impairment in B-cell development as a potential primary cause.

INCIDENCE/PREVALENCE
Not well established. Confirmed cases have greatly decreased since the late 1990s though this may be due to decreased intensive management of unthrifty llamas.

SYSTEMS AFFECTED
• Hemolymphatic
• Respiratory
• Digestive
• Musculoskeletal
• Urinary
• Reproductive
• Ophthalmic

PATHOPHYSIOLOGY
• Poorly understood.
• The specific immunodeficiency has not been determined, but an autosomal recessive defect in B-cell development has been proposed.
• Immunodeficiency leads to opportunistic or overwhelming systemic infections, and failure of the animal to respond to appropriate therapies, ultimately resulting in death.

SIGNALMENT
• Juvenile llamas, usually between the ages of 6 and 18 months, of either sex
• Not well documented in alpacas but occasionally suspected

GENETICS
An autosomal recessive inherited basis is suspected but not proven.

PHYSICAL EXAMINATION FINDINGS
• There are no pathognomonic signs—signs vary with the organ system(s) involved and the stage of the disease, including respiratory signs, lameness, dermatitis, ocular signs, or CNS signs/ataxia.
• Common reported complaints include:
  ◦ Poor body condition and/or poor growth as compared to herdmates
  ◦ Recurring infections or infections that fail to respond to treatment, particularly *Mycoplasma haemolamae*, ocular infections, and tooth root abscesses
  ◦ Anemia, with pale mucus membranes, tachycardia, and mild heart murmur
  ◦ Lethargy, depression
  ◦ Occasionally, peracute infection may lead to rapid weight loss and death without prior signs.

CAUSES AND RISK FACTORS
• A hereditary component to the development of the clinical disease is likely, but a specific inheritance pattern has not been identified.
• No specific risk factors have been identified.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Malnutrition, nutritional deficiency (copper, zinc, or selenium), iron deficiency, intestinal parasitism, and *Mycoplasma haemolamae.*

CBC/BIOCHEMISTRY/URINALYSIS
• Anemia—usually mild, normocytic, normochromic, and nonregenerative, though if the animal is infected with *M. haemolamae* the anemia can be severe and mildly regenerative.
• Hypoproteinemia with hypoalbuminemia and low to low-normal globulin levels, even in the face of infection.
• Low serum iron concentration with low to low-normal total iron binding capacity.

OTHER LABORATORY TESTS
• *Clostridium perfringens* C and D antibody ELISA: Paired serum samples are collected prior to and 2 weeks after vaccination with *C. perfringens* C and D toxoid, and antibody levels are measured. Healthy llamas show at least a twofold increase in titers, while JLIDS llamas have a low initial titer and fail to show any significant rise in titer after vaccination.
• Immunologic testing: Lymphocyte blastogenesis assays, serum protein electrophoresis, and flow cytometry can be used to characterize the specific immunodeficiency in an affected llama. Although these tests are still in the process of being validated for camelids, initial reports suggest consistent findings in JLIDS llamas including low levels of serum IgG and low numbers of B-lymphocytes.

IMAGING
Radiography may be indicated if clinical signs of lower respiratory tract disease and/or septic arthritis are present.

OTHER DIAGNOSTIC PROCEDURES
Lymph node biopsy: Affected llamas show regions of paracortical lymphocyte depletion.

PATHOLOGIC FINDINGS
• Gross lesions include muscle wasting, lack of body fat stores, and poor body condition.
• Since these animals usually have bacterial infections there is often evidence of bacterial septicemia or embolic bacterial spread in multiple organ systems. These appear as multiple foci of hemorrhage or inflammation within the parenchyma of various organs (kidney, spleen, and liver). Serosal surfaces of the thoracic and abdominal cavity and pericardium are usually reddened, with multifocal petechial hemorrhages and variable amounts of adherent fibrin. Joint spaces may also be involved in a similar manner. Mild to moderate suppurative bronchopneumonia is often seen. Chronic dermatitis, embolic hepatitis, and both fibrinous and nonsuppurative leptomeningitis are other septicemia sequelae observed with JLIDS.
• Histologically, the major lesion is paracortical lymphocyte depletion. There is a lack of secondary follicles and germinal center formation. Ocular lesions including fibrinous anterior uveitis and neutrophilic choroiditis may also be seen.

TREATMENT

THERAPEUTIC APPROACH
• In the early stages, rule out intestinal parasitism as a cause for ill thrift with appropriate anthelmintic therapy.
• Lack of a functional immune system requires life-long antimicrobial intervention.

MEDICATIONS

DRUGS OF CHOICE
Antimicrobial therapy is indicated to treat systemic infections, with the caveat that infections in llamas with JLIDS routinely fail to respond to therapy and ultimately are fatal.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals, though withdrawal times are not established for camelids.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
This is a fatal disease. Animals diagnosed with this syndrome should be euthanized.

PREVENTION
Since this is likely a recessive genetic disorder, careful consideration should be taken in purchasing animals from herds with a history of JLIDS.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• *Mycoplasma haemolamae* is prevalent in camelids in North America, but is rarely associated with clinical anemia except in animals with underlying disease.
• Secondary infections with typically nonpathogenic organisms, such as *Pneumocystis carinii, Bordetella* sp., or fungal

J

JUVENILE LLAMA IMMUNODEFICIENCY SYNDROME (CONTINUED)

organisms, are commonly associated with JLIDS.

AGE-RELATED FACTORS

Juvenile llamas (aged 6–18 months, typically)

PRODUCTION MANAGEMENT

- The specific immunodeficiency has not been determined, but an autosomal recessive defect in B-cell development has been proposed.
- Recent research suggests an inherited impairment in B-cell development as a potential primary cause.
- Cull/euthanize affected animals; evaluate parental records for possible genetic correlation.

SYNONYM

Failure to thrive

KETOSIS: DAIRY CATTLE

BASICS

OVERVIEW

• Ketosis is a metabolic disorder characterized by high levels of ketone bodies affecting dairy cows mostly from parturition to 6 weeks postpartum. The ketone bodies, acetone, acetoacetate, and ß-hydroxybutyrate (BHB), are synthesized in the liver during oxidation of fatty acids. Acetone, a three-carbon compound, is produced in small quantities and is exhaled to the environment. Acetoacetate (four carbons) is either reversibly reduced to BHB in mitochondria, or is enzymatically or spontaneously decarboxylated to acetone. BHB is the most stable and important ketone body that can be tested in blood or milk.
• Historically, ketosis has been classified as primary or secondary, in which cows with primary ketosis have a decreased appetite and elevated serum, milk, urine, or breath ketones in the absence of another concurrent disease. Today, the words subclinical and clinical ketosis are more common terms for ketosis definition. Clinical ketosis is characterized by high levels of ketone bodies in blood, urine, or milk in combination with other signs, such as off-feed, severe body condition loss, depression, or altered behavior. Subclinical ketosis (SCK) is defined as an increase in blood, urine, or milk ketone bodies, above a threshold (e.g., 1.0–1.4 mmol/L of serum BHB) associated with lower milk yield, infertility and other conditions (e.g. displacement of the abomasum, metritis, mastitis) in the absence of noticeable clinical signs.
• Another classification for this metabolic disorder is type 1 and type 2 ketosis. Type 1 ketosis occurs when the cow experiences a sudden drop in energy intake. This is the case of underfeeding or poor cow comfort that prevents the cows from eating sufficient amounts of energy. Type 2 ketosis generally occurs around parturition when the cow is mobilizing excessive body fat in the form of nonesterified fatty acids (NEFA). Cows that are too fat at calving (BCS >3.75, scale 1–5) or cows that have been overfed during the dry period are at higher risk to develop this condition.

INCIDENCE/PREVALENCE

Incidence of SCK (≥1.2 mmol/L of BHB) can go between 15% and 60% of lactating dairy cows, while clinical ketosis may reach incidences between 2% and 15% of lactating dairy cows.

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on production management. Ketosis has been diagnosed in both confined and grazing cattle.

SYSTEMS AFFECTED

Multisystemic

PATHOPHYSIOLOGY

• Every cow, starting around parturition, experiences a typical period of negative energy balance (NEB). Fat is mobilized from adipose tissue in the form of NEFA. This occurs because the activation of hormone-sensitive lipase (HSL) stimulates the breakdown of the ester link between NEFA and glycerol in the triglycerides (TAG).
• Once liberated, circulating NEFA is a significant energy precursor for several body tissues. In addition, it is a contributor to almost half of the milk fat produced in the mammary gland. NEFAs are also metabolized in the liver. Uptake of NEFA from plasma by the hepatocytes is proportional to the plasma concentration and the rate of blood flow. Consequently, when plasma NEFAs are extremely high, the uptake by the liver is also increased.
• Once taken up by the liver, NEFAs are oxidized to a number of molecules of acetyl-CoA (two carbon units) depending on the number of carbons present in the NEFA (16 or 18). Acetyl-CoA has four possible fates: complete oxidation through the Krebs cycle, incomplete oxidation through ketogenesis, TAG synthesis and packing as very low density lipoprotein (VLDL) for export from the liver, or TAG synthesis for storage in the liver. When oxaloacetate is depleted from the Krebs cycle, because of insufficient glucose availability, acetyl-CoA cannot continue its oxidation process and is accumulated and re-directed to form ketone bodies. This metabolic pathway is a normal secondary strategy to supply energy to the heart, brain, liver, and mammary tissue when the Krebs cycle is shut down. When excessive ketone bodies are built up, a negative impact on animal health, fertility, and productivity may occur.
• Simultaneously, accumulation of TAG in the liver may occur and it can be as high as 10% on wet weight basis during the peripartum period. Fatty liver is the result of a combination of increased fatty acid synthesis within the liver, decreased oxidation of hepatic fatty acids, and decreased export of hepatic TAG as VLDL.
• The evolution and extent of ketosis and hepatic lipidosis is finally the result of the level of adaptation from gestation to lactation.

HISTORICAL FINDINGS

For SCK, although there are no evident clinical signs, herd or individual animal history may indicate further investigation. Affected cows are at higher risk of developing several related conditions including displacement of the abomasum, metritis, mastitis, etc. In addition, cows with SCK are more likely to be culled during the first third of lactation, and less likely to conceive at first service than cows without SCK. Furthermore, cows with SCK produce less milk compared to cows without SCK.

SIGNALMENT

Female bovine, small ruminants, and camelids.
• Due to their high genetic merit for milk production, ketosis can be more prevalent in American Holsteins than other dairy breeds.
• Older cows are more prone to ketosis due to their greater potential milk yield.

PHYSICAL EXAMINATION FINDINGS

For clinical ketosis, the most common clinical signs are: drop in dry matter intake, constipation or loose feces, depression, gawking expression, evident losses in body condition, decreased milk production, odor due to ketones, neurologic signs such as circling, staggering, licking, chewing, bellowing, hyperesthesia, compulsive walking, and head pressing.

GENETICS

Ketosis has a certain genetic component. Heritability estimates for milk and plasma BHBA at different stages of early lactation have been determined to be between 0.10 and 0.29. Higher genetic merit for milk yield is associated with higher milk and plasma BHB concentrations.

CAUSES AND RISK FACTORS

• Risk factors for both clinical and SCK are over-conditioned animals at calving, development of other postpartum diseases, high milk production, poor cow comfort, stress, unbalanced diets, improper feed and nutritional management, and poor overall management. Ketosis may occur as either primary or secondary ketosis.
• Primary ketosis is caused either by a severe negative energy balance and/or obesity at parturition accompanied by a marked reduction in feed intake. In contrast, secondary ketosis occurs due to a decrease in feed intake, commonly due to a preexisting condition such as metritis, mastitis, lameness, traumatic reticulitis, or displacement of the abomasum.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Differential diagnoses for nervous ketosis include listeriosis, polioencephalomalacia, hypomagnesemia, and hypocalcemia.
• Differential diagnoses based on the nonspecific examination findings listed above and signalment should include postpartum diseases such as displaced abomasum, metritis, and mastitis.

CBC/BIOCHEMISTRY/URINALYSIS

• Biochemistry may show hypoglycemia.
• Urinalysis will show ketonuria in the vast majority of cases.

KETOSIS: DAIRY CATTLE (CONTINUED)

OTHER LABORATORY TESTS
BHBA testing is routinely performed using a handheld glucometer/ketonometer (e.g., Precision Xtra) and 0.1 mL of whole blood. Levels above 1.2 mmol/L are considered to be abnormal.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Several treatments have been recommended for ketosis in dairy cattle, with varying degrees of efficacy. However, in the scientific literature there is lack of well-designed clinical trials to answer this question.
• The only treatment of ketosis that has been scientifically shown to improve resolution of this metabolic disorder is oral propylene glycol (1,2 propanediol), in a dose of 300 g q24h. Although the duration of treatment may vary on a case-by-case basis, 5 days of treatment has yielded good response rates in numerous studies.
• The use of dextrose should be considered for animals with severe ketosis with concurrent hypoglycemia, especially in animals with nervous signs. The dose recommended is 250–500 mL 50% dextrose IV. Administration of IV dextrose leads to an immediate hyperglycemic state, lasting approximately 2 hours, and leading to excretion of excess dextrose in the urine. Dextrose for type 2 ketosis (related to insulin resistance) is not a recommended treatment, because glucose cannot enter the liver.
• Corticosteroids have long been used as an adjunctive therapy for ketosis based on their role in inducing hyperglycemia and catabolism of fat and protein stores. Few studies have evaluated the effect of corticosteroid use for ketosis in cattle and no significant benefit was found in the latest review in the *Veterinary Clinics of North America* in 2013. Due to the potential for immunosuppression secondary to corticosteroid use and the frequency of underlying postpartum disease in ketotic patients, corticosteroid use is not recommended as part of routine ketosis treatment.
• Insulin has been used in conjunction with dextrose and corticosteroid therapy due to its anabolic effects (decreases fat breakdown, increases ketone body utilization, increases fat synthesis). Benefits have been shown, albeit in limited studies. Insulin is best reserved for chronic cases that are refractory to the above treatments or those where hepatic lipidosis is suspected. Note that the high cost and labile nature of insulin products may prohibit its use on farm.
• Vitamin B12 (cyanocobalamin) and phosphorus (butaphosphan) are often used in combination as a supportive therapy for ketosis since they are integral to the Krebs cycle. Their use in prevention of ketosis has been shown and preliminary studies show benefit as an adjunctive treatment for ketosis.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
See "Therapeutic Approach"

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
• Corticosteroids should not be administered to pregnant animals.
• Use care when administering dextrose 50% IV as it causes severe tissue irritation and risk of abscessation when administered perivascularly.
• Do not use insulin without concurrent glucose support.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
With rapid diagnosis and treatment, as well as treatment of any underlying disease, the prognosis is good. If hepatic lipidosis has developed as a result of profound negative energy balance, the prognosis for return to productivity is worse.

POSSIBLE COMPLICATIONS
Ketosis will increase the risk of developing a displaced abomasum due to its effect on feed intake and gut motility. A study in 2012 found 95% of cows to be hyperketonemic prior to diagnosis of displaced abomasum.

CLIENT EDUCATION
See "Prevention"

PATIENT CARE
Insure that animals have easy access to fresh, palatable feed at all times to encourage increased feed intake. Optimize cow comfort and insure that the underlying cause of disease is being properly addressed in the case of secondary ketosis.

PREVENTION
• Ketosis must be prevented through rational feed management programs and adequate cow comfort. Diets should be properly balanced in energy, protein, vitamins, and minerals. Feeding programs should be designed to promote good body condition scores at calving (3.25–3.5). Avoid excess of energy during the dry period.
• Inclusion of gluconeogenic precursors that increase the energy density of the diet and plasma glucose concentrations during the entire transition period is recommended. Supplementation of glucose precursors should promote hepatic gluconeogenesis and increase circulating concentrations of insulin. This should decrease hepatic triglyceride accumulation and NEFA mobilization.
• Additives based on glycerol, calcium propionate, and/or propylene glycol have been used efficaciously. These products work better when they are top-dressed instead of mixed with the entire TMR.
• The use of sodium monensin (ionophore) either as a powder or as slow-release rumen bolus has also been demonstrated to be efficacious in controlling ketosis. Monensin stimulates the synthesis of rumen propionate. This effect spares oxaloacetate in the liver; consequently, the Krebs cycle continues in progress and ketogenesis is reduced.
• Another feed additive with secondary positive effects is niacin (6 g/day) incorporated into the ration for up to 10 weeks after calving.
• During recent years the use of rumen-protected choline (60 g/day), especially during the prepartum period, have been shown to be effective in the prevention of fatty liver and ketosis in dairy cattle, especially in obese animals.
• Propylene glycol administration protocols should be in place in dairy herds and should be based on herd ketosis incidence. If the herd incidence of ketosis is 15–50% then twice-weekly testing of cows 3–9 DIM is most economical. If incidence is above 50% then it is more economical to use blanket treatment for all cows starting at 5 DIM. The above management recommendations are integral to lowering the incidence of ketosis.

LACTATION FAILURE (DYSGALACTIA, AGALACTIA, HYPOGALACTIA)

BASICS

OVERVIEW

• Agalactia is a clinical sign characterized by the absence of milk secretion, or the inability of a dam to lactate after parturition.
• Hypogalactia refers to an abrupt reduction in the normal amount of milk produced, and the term "dysgalactia" is sometimes used as a synonym.
• True agalactia can be present in situations of mammary gland aplasia or endocrinologic problems that compromise milk synthesis.
• Secondary agalactia is much more common and is present as one of the clinical signs of infectious diseases, intoxications, or neoplasia.
• Contagious agalactia (mycoplasma mastitis) of small ruminants is a syndrome that principally affects the mammary glands, joints, and eyes. The main causal agents are *Mycoplasma agalactiae* in sheep, and *M. agalactiae, M. mycoides* subsp. *mycoides* large colony type, and *M. capricolum* subsp. *capricolum* in goats. *M. putrefaciens* can produce a similar clinical picture, particularly in goats.
• In alpacas and llamas, agalactia may be seen in maiden females or in multiparous animals maintained on exogenous progesterone during pregnancy.

INCIDENCE/PREVALENCE

Will vary depending on etiology. With the small ruminant lentiviruses, CAEV and OPP (also known as Maedi-Visna), prevalence increases with age.

GEOGRAPHIC DISTRIBUTION

Contagious agalactia occurs worldwide and is often enzootic.

SYSTEMS AFFECTED

Mammary

PATHOPHYSIOLOGY

Will vary depending on etiology.

HISTORICAL FINDINGS

Will vary depending on etiology.

SIGNALMENT

Postparturient females are most commonly affected.

PHYSICAL EXAMINATION FINDINGS

In secondary agalactia or hypogalactia, some of the specific signs for the primary disease can be present, including:
• Depression
• Inappetence
• Fever
• Swollen or inflamed quarter(s)
• Conjunctivitis and arthritis (contagious agalactia of small ruminants)

GENETICS

Can be cause of mammary gland aplasia. Affected animals should be culled.

CAUSES AND RISK FACTORS

Common

• Mammarian aplasia, dysplasia
• Peracute toxigenic mastitis (agalactia)
• Clinical mastitis (hypogalactia)
• Contagious agalactia in small ruminants (mycoplasma mastitis)
• Lentiviruses (CAEV and OPP)
• Caseous lymphadenitis (caprine, ovine)
• Agalactia due to exogenous progesterone (camelids)

Less Common

• Leptospirosis (hypogalactia)
• Self-suckling or others suckling
• Water deprivation
• Endocrine dysfunction
• Intoxication (fungal toxins)
• Nutritional deficiency or imbalance (hypogalactia)
• Injury
• Neoplasia (lymphosarcoma, malignant melanoma, squamous cell carcinoma)
• Chapped teats, teat dip irritation
• Milk allergy
• Fescue toxicity
• Papillomatosis
• Anemia
• Severe toxicity

Risk Factors

• Cows affected by peracute toxigenic mastitis caused by *Staphylococcus aureus, Escherichia coli,* or *Klebsiella* spp. show signs of severe toxemia. Although not all quarters are usually affected, agalactia as a consequence of severe systemic illness can be present. The lactation curve is compromised and loss of the affected quarter is not uncommon. However, if treatment is successful, cows can reestablish milk production within 1–3 days.
• Contagious agalactia of sheep and goats is caused by *Mycoplasma agalactia* and can manifest in an acute, subacute, or chronic form. The udder shows signs of inflammation at the beginning of infection, milk secretion is watery and becomes purulent as the disease progresses, and agalactia is observed in the latter stages. Herd outbreaks may be accompanied by conjunctivitis and lameness.
• Dysgalactia and agalactia caused by leptospirosis outbreaks have been described in cow and sheep herds.
• Grazing of tall fescue (*Festuca arundinacea*) that is contaminated with an endophytic fungus (*Acremonium coenophialum*) has been shown to cause hypogalactia in cows. Feeding of grains contaminated with ergot (*Claviceps purpurea* in rye or *Claviceps africana* in sorghum) has produced clinical symptoms characterized by hypogalactia and eventual gangrene of extremities.
• In llamas and alpacas, exogenous progesterone may alter proper mammary development because of hormonal interactions, resulting in agalactia. Exogenous progesterone is used for treatment of luteal insufficiency in these species. Despite cessation of exogenous progesterone at 300 days of pregnancy, often these females do not develop adequate production of milk to meet their cria's needs.
• Risk factors for CAEV and OPP include feeding pooled colostrum, feeding virus-infected colostrum from a single dam to multiple kids or lambs, and addition of unscreened animals into herd.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Inability to secrete milk needs to be differentiated from inability to release milk from the alveolus or to pass it through the teat canal. Blockages need to be more fully examined.
• Primiparous females may have trouble adapting to the environment in the milking parlor and the administration of exogenous oxytocin (20 IU) may be necessary the first few days of lactation. This may need to be repeated for some days until the animal has adapted.
• Proliferative granulation tissue or fibrosis (pencil obstruction, "teat spider") after teat injury can cause partial or total obstruction of a teat canal. This is more common in one or two teats rather than the entire gland.
• Any systemic illness or stress may compromise lactation.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• California Mastitis Test (CMT).
  ◦ CMT is not useful in llamas and alpacas due to false negatives.
  ◦ CMT may not be useful in goats due to false positives. Goats have a propensity for high milk somatic cell counts that may protect from mastitis.
• Culture and sensitivity of milk, including for mycoplasma.
• Bulk tank testing.
• CAEV AGID and ELISA.
• CAEV virus isolation (PCR).
• Microscopic examination of fescue for endophytic fungus.

IMAGING

• Ultrasound, using a 5–10 MHz linear probe. Can use contralateral teat as control.
• Radiology (contrast and double contrast).
• Teat endoscopy.

OTHER DIAGNOSTIC PROCEDURES

Diagnostics should be based on case history and specific laboratory analyses.

(CONTINUED) LACTATION FAILURE (DYSGALACTIA, AGALACTIA, HYPOGALACTIA)

TREATMENT

Treatment should be directed against the underlying disease.

MEDICATIONS

DRUGS OF CHOICE

N/A

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Will vary depending on etiology.

POSSIBLE COMPLICATIONS

Culling may be indicated if production is not reestablished.

PREVENTION

See prevention strategies in appropriate chapter based on underlying disease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

CAEV and OPP are lentiviruses that can manifest as "hard bag" (indurant mastitis).

AGE-RELATED FACTORS

Will vary depending on etiology. For example, prevalence of CAEV infection increases with age.

ZOONOTIC POTENTIAL

Certain strains of *Leptospira* and *Mycoplasma* are zoonotic.

PREGNANCY

Mycoplasma spp. and *Leptospira* spp. can cause abortions in ruminants.

BIOSECURITY

Will vary depending on etiology (e.g., screening new additions to herd with ELISA or milk culture).

PRODUCTION MANAGEMENT

- Will vary depending on etiology. Feeding heat-treated colostrum and isolation of kids at birth are control measures for both contagious agalactia and CAEV, for example.
- Mammary development in females often is minimal until immediately before or after parturition, although glandular development is palpable during late gestation and should be monitored.

ABBREVIATIONS

- AGID = agar gel immunodiffusion
- CAEV = caprine arthritis encephalitis virus
- CMT = California mastitis test
- ELISA = enzyme-linked immunosorbent assay
- OPP = ovine progressive pneumonia
- PCR = polymerase chain reaction

LAMENESS: BOVINE

BASICS

OVERVIEW
• Lameness is a leading cause of culling and welfare problems in dairy cattle.
• Although less common in beef cattle, lameness remains an important welfare concern and can result in significant loss of productivity.
• In dairy cattle, 90% of lameness is associated with the foot, with 90% of that being associated with the hind foot lateral claw.
• In cow-calf operations the majority of lameness is associated with upper leg issues.
• In beef feedlots, approximately 70% of lameness is foot-associated with the remainder being related to lesions of the proximal limb.

INCIDENCE/PREVALENCE
• The incidence and prevalence varies widely between production systems and operations. Cattle confined on hard surfaces such as concrete tend to have more lameness compared with cattle housed on pasture.
• In many dairy operations the annual incidence of lameness varies between 15% and 30%. Lameness is the leading cause of culling in dairy operations and represents the most costly clinical disease process of dairy cattle, surpassing mastitis, when chronic lost production is considered.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Musculoskeletal
• Integument

PATHOPHYSIOLOGY
• The majority of lameness in the foot is associated with uneven weight bearing between the claws. In the hind feet the normal posture of a cow results in increased weight bearing on the lateral claw. This results in compensatory overgrowth of horn on the lateral claw, which further exacerbates the disparity in weight bearing. In the front limb the medial claw bears the most weight.
• Bovine lameness can be subdivided into three major classifications:
  ◦ Upper leg lameness—generally associated with trauma to the musculoskeletal system of the upper leg. This type of lameness is generally associated with a characteristic altered gait and a lack of sensitivity to hoof testers on the hoof capsule.
  ◦ Claw horn lesions—generally associated with disease of the white line or a combination of mechanical and metabolic disease resulting in sole ulceration. The white line is the weakest portion of the claw horn capsule and in some cases allows foreign bodies to penetrate the white line and cause abscessation of the corium.
  ◦ Infectious skin disease—most commonly associated with either bovine foot rot or bovine digital dermatitis. These diseases are bacterial in nature and result in infectious transmission between animals when environmental conditions are favorable.

HISTORICAL FINDINGS
• Upper leg lameness is often associated with a history of trauma, slipping or falling during movement, or calving.
• Housing in environments that keep the hoof moist and allow excessive buildup of mud or manure slurry are associated with an increased risk of infectious foot disease.
• Housing on concrete pads or confinement barns are associated with increased risk of lameness compared to housing on pasture. Housing cattle where they spend excessive periods of time standing due to a lack of comfortable areas on which to lie down is also associated with an increased risk of lameness.
• Introduction of cattle to an operation from outside operations is often identified as a source of new infectious disease, especially digital dermatitis.

SIGNALMENT
• Reported in all types of cattle.
• Disease is often most severe in mature heavier cattle compared to calves.
• Beef cows on grass most commonly present with upper leg lameness.
• Dairy cattle most commonly present with claw horn lesions or infectious skin disease.
• Feedlot cattle most commonly present with foot rot, digital dermatitis, or toe lesions.
• Particular causes of lameness may show breed predilections.
• Digital dermatitis is most often reported in Holstein dairy cattle, compared with other dairy and/or beef breeds.
• Lameness is more common in adults than in juveniles.

PHYSICAL EXAMINATION FINDINGS
• Lameness is generally recognized as unwillingness to place normal weight on one or more limbs.
• Lameness is best assessed by observation of animals walking on a solid surface (concrete) and evaluating gait for evidence of a shortened or inconsistent stride length, arched back while moving, head bob, and in severe cases a complete reluctance to place weight on a limb.
• Multiple schemes have been developed for classifying the severity of lameness; however, the easiest to apply is a three-point grading system. In this system animals are classified as normal, lame (one or more of the signs listed above but still willing to bear weight on the limb), or severely lame (unwillingness to bear weight on the limb).
• In cases of claw horn lesions, use of hoof testers applied to all areas of the sole will generally result in a withdrawal response associated with pain.
• In cases of infection involving the deep tissues of the foot or distal limb, a key clinical indicator is severe swelling in comparison to the contralateral foot. In foot rot, the swelling is most commonly symmetrical, while other infectious processes secondary to sole ulcers or white line disease often result in asymmetrical swelling confined to one claw of the foot.
• Careful examination of the interdigital skin, skin of the heel adjacent to the interdigital cleft, and the coronary band will be abnormal in cases of infectious foot disease. Lesions may vary from overt breaks in the skin with bovine foot rot to more ulcerative lesions or papillomatous lesions with bovine digital dermatitis.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Upper leg lameness can occur from a variety of causes, the most common of which include fractures to the axial skeleton or pelvis, luxated or subluxated femorocoxial joint, ruptured cruciate ligaments and collateral ligaments of the stifle. In some cases, neurologic disease may induce clinical signs similar to lameness and should be ruled out.
• Hoof horn lesions
  ◦ Sole ulcers are most commonly associated with ischemia and contusive effects damaging the corium between the flexor tuberosity of P3 and the floor or standing surface. As a consequence, these lesions are located beneath the anatomic location of the flexor tuberosity (located on the axial-caudal portion of the weight-bearing surface) and are typically located on the lateral hind claws or medial front claws because of greater weight bearing on these claws.
  ◦ White line lesions typically form in the abaxial-caudal portion of the white line secondary to the penetration of foreign material from the environment. This area of the white line is vulnerable to penetration by foreign debris because of heel strike during locomotion. Laminitis predisposes to white line disease by further softening the white line and making it easier to penetrate. The foreign material results in formation of a deep anaerobic pocket that then migrates to the corium and causes an abscess.
• Infectious skin disease
  ◦ Digital dermatitis is polybacterial in nature, meaning that there is no single bacterial organism that has been identified as an etiologic agent. Mature lesions are predominated by bacteria of the *Treponema* spp.; however, earlier lesions have small numbers and different treponemes, suggesting that this family is not exclusively causal for the disease.
  ◦ Foot rot is caused by a deep infection of the soft tissue structures of the foot by *Fusobacterium necrophorum.*
• Once digital dermatitis is in the herd it is thought to spread through unsanitary conditions in the barn.

• Muddy or wet conditions and purchasing animals from off premises are the two most common risk factors for digital dermatitis.
• Poor freestall and bedding management will exacerbate lameness problems since cows will spend more time standing in the manure slurry, not allowing the feet to dry out periodically.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Neurologic disease
• Myositis

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
In some cases of upper leg lameness or distal limb swelling, radiographs of the affected region may aid in diagnosis of fractures or infectious disease impacting the joints or bone.

OTHER DIAGNOSTIC PROCEDURES
• Observation of the animal in motion and the limb for swelling.
• Thorough evaluation of the lame foot with hoof testers, paying special attention to common areas of lesions (i.e., the abaxial white line for white line disease and the area of the flexor tuberosity of P3 for sole ulcers).
• Corrective hoof trimming and balancing of weight bearing will often identify underrun sole or loose tissue that will assist in identifying the lesion for claw horn lesions.
• Careful observation of the skin around the corium for evidence of breaks in the skin, ulceration, or abnormal appearances.
• In cases where it may be difficult to discern from the above procedures if the lesion is in the foot or proximal limb, intravenous regional anesthesia may be useful. If gait improves subsequent to anesthesia of the foot, the problem is likely in the foot.

PATHOLOGIC FINDINGS
Histopathology is typically unnecessary to identify the cause of lameness.

TREATMENT

THERAPEUTIC APPROACH
The treatment for lameness varies by cause and the reader is referenced to individual chapters in this text related to each condition, for more details.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Readers are referred to the individual chapters related to each process for details on medications.

PRECAUTIONS
When using any antibiotics or anti-inflammatories for therapy, appropriate milk and meat withdrawal times should be followed for food-producing animals.

CONTRAINDICATIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Simple, uncomplicated white line abscesses typically resolve without complication in 4–6 weeks with corrective trimming and the application of a foot block to the healthy claw.
• Simple sole ulcers typically take longer to fully resolve but should heal within 2 months.
• The prognosis for infections that involve the deep structures of the claw or foot are always guarded. Since many of these cases typically present late in the disease course, the infection is well established and there is already significant pathology.
• Aggressive antibiotic therapy is warranted when deep structures of the hoof are involved, but it is rarely successful alone.
• Animals treated for digital dermatitis with topical antibiotics typically show increased discomfort immediately after treatment, but lameness should resolve almost fully within 48 hours.

POSSIBLE COMPLICATIONS
Some claw horn lesions will progress to deep-seated infectious arthritis cases.

CLIENT EDUCATION
Clients should be educated regarding diagnosis, risk factors, and treatment strategies. Importance should also be placed on prevention and degree of economic losses associated with lameness.

PATIENT CARE
• Lameness is a significant welfare issue and animals need to be treated promptly and given appropriate medication for pain control.
• Claw horn lesions treated with corrective trimming and having an orthopedic block applied to the opposite claw generally show significant improvement in lameness once weight bearing on the claw with the lesion has been removed. If the animal remains lame after trimming and placement of the block they should be promptly reevaluated for an alternate cause of lameness or incorrect block placement. They should be monitored regularly for evidence of increased lameness.
• Most cases of digital dermatitis treated with topical antibiotics will show rapid improvement in lameness. Animals that remain lame after 72 hours should be reexamined for an additional cause of lameness.
• Cows should be monitored for recurrence of all types of lameness and re-treated as necessary.

PREVENTION
• Providing housing conditions that promote the animals' lying and spending less time standing.
• Minimizing accumulation of excessive amounts of mud or manure and keeping standing areas dry.
• In cases of digital dermatitis, preventive foot bathing will assist in control.
• Routine foot trimming of cattle will assist in early detection of lesions and will improve equal weight bearing while minimizing lameness.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Decreased milk production, increased culling
• Recumbency
• Welfare

BIOSECURITY
• Introduction of digital dermatitis commonly occurs with purchase and introduction of new animals to a herd or feedlot. For this reason, it is prudent to inquire and evaluate potential animals for purchase for the presence of DD prior to introduction.
• Any individual involved in foot care should take great care to insure that equipment is suitably disinfected between farm visits.
• DD-free herds should avoid the purchase of replacements from off-site premises.

PRODUCTION MANAGEMENT
• Recommendations that pertain to cow comfort, including well-designed and bedded freestalls or open housing.
• Prompt and aggressive treatment of lameness will reduce suffering, losses in milk yield, and culling.

ABBREVIATION
• DD = digital dermatitis

LAMENESS: CAMELID

BASICS

OVERVIEW

• Lameness is defined as an abnormality in the gait or posture of an animal. It may be related to pain or some other type of dysfunction in the locomotor system.
• Causes of lameness
  ◦ Congenital lameness—defects in nerves, bones, muscles, or other associated soft tissue structures
  ◦ Acquired lameness
    ▪ Traumatic soft tissue, bone, or neurologic injuries
    ▪ Bone or soft tissue infections
    ▪ Nutritional causes such as hypophosphatemic rickets and white muscle disease (WMD)
    ▪ Patellar luxation from abnormal skeletal growth due to early castration
    ▪ Arthritis in geriatric animals is common; animals have difficulty walking and rising; spend increased time recumbent
    ▪ Joint ill in neonates is not common in camelids, usually a single joint, non weight-bearing on affected limb with pain and swelling
    ▪ Meningeal worm infections (MW disease, MWD) resulting in spinal cord damage

INCIDENCE/PREVALENCE

One survey conducted for alpaca and llama farms in 18 different states in the United States, Canada, Australia, and New Zealand showed an incidence rate of 50% among farms surveyed and an overall prevalence of approximately 3% of the animals involved in the survey.

GEOGRAPHIC DISTRICUTION

• Worldwide
• MWD: Eastern US

SYSTEMS AFFECTED

• Musculoskeletal
• Nervous

PATHOPHYSIOLOGY

Varies depending on the nature of lameness and causes

HISTORICAL DATA

• Abnormal conformation
• Acute or chronic onset of abnormal gait
• Recent history of trauma on physical exertion
• Excessive recumbency

SIGNALMENT

• Any age and sex
• Lateral patellar luxation common in camelids castrated before 18 months of age
  ◦ Due to growing taller with more upright conformation than animals castrated later
  ◦ Leads to femoropatellar joint arthritis

PHYSICAL EXAMINATION FINDINGS

• Non-uniform gait (head nod, stilted gait) at the walk and faster.
• Decreased or lack of weight bearing on the affected limb or limbs.
• Kyphosis, excessive recumbency, and/or pain on palpation of physeal regions in crias with rickets; also may just appear to be lethargic.
• Swelling of limbs or muscles depending on etiology.

GENETICS

• Congenital defects resulting in lameness may have a hereditary basis.
• It is recommended that animals which produce offspring with congenital defects not be bred together again.

CAUSES AND RISK FACTORS

• Muscle infections and myositis
  ◦ *Sarcocystis* spp.
    ▪ Camelids are intermediate hosts with carnivores such as dogs as the final host.
    ▪ Carnivores consume feces from infected, uncooked camelid muscles and shed sporocysts in the feces after 1–2 weeks for several months.
    ▪ Camelids are reinfected through consuming the sporocysts as they eat.
    ▪ More advanced stages of the protozoa cause damage to tissues such as muscles where they migrate.
    ▪ Eliminating contaminated meat intake by carnivores breaks the infection cycle.
  ◦ *Clostridium septicum, C. chauvoei, C. sordellii,* and *C. novyi* can affect camelids depending on geographic prevalence of the species:
    ▪ Caused by exogenous introduction through wounds (such as snake envenomation) or localization in traumatized muscles from hematogenous origin.
    ▪ Death from toxemia may occur.
• Muscle and/or skeletal trauma from overcrowding and fighting among animals.
• White muscle disease (WMD) from deficiency of vitamin E and/or selenium in the diet.
  ◦ No published reports in camelids but empirically diagnosed primarily in young animals.
  ◦ Muscle weakness and excessive recumbency possible.
  ◦ Sudden death possible if heart muscles affected.
• Skeletal dysfunction
  ◦ Dietary causes
    ▪ Hypophosphatemic rickets in young growing animals between 3 and 7 months of age when exposed to low UV light conditions during rapid bone growth periods.
    ▪ Prevents activation of dietary vitamin D precursor to the active form of vitamin D3.
    ▪ Results in poor absorption and deposition of calcium and phosphorus in bones, further resulting in growth plate abnormalities and signs such as leg deviations and pain in the physeal regions of bones.
    ▪ Excessive recumbency and poor body condition and growth may be the end result.
  ◦ Traumatic causes
    ▪ Foot injuries are the most common cause of lameness: punctures, sole infections, fractured toenails, interdigital dermatitis from topical infections, space-occupying lesions (tumors)—bottom of foot, interdigital space
    ▪ Bone fractures
    ▪ Ligament, tendon, and joint injuries
    ▪ Back and neck injuries—fighting
    ▪ Congenital bone and ligament formation abnormalities: incomplete ossification of long bones—seen in the femur with no pain but abnormal gait in a neonate; arthrogryposis—unknown etiology but hereditary basis suspected
    ▪ Arthritis in mature animals may be progressive and accompanied by weight loss
  ◦ Miscellaneous causes
    ▪ Joint ill in neonates from acquired systemic infections—umbilicus most likely the entrance point for environmental contaminants
    ▪ Angular limb deformities in premature crias—mildly affected animals will recover without treatment
    ▪ MWD from consumption of *Parelaphostrongylus tenuis* infectious larval stage where intermediate host (some species of terrestrial gastropods) and definitive host (Virginia white tailed deer) are present
    ▪ Lateral patellar luxation and associated arthropathy from early castration (before 18 months of age) in alpacas and llamas

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Neurologic lameness—should observe weakness, ataxia, and/or proprioceptive deficits.
• Meningeal worm disease causing brain or spinal cord damage is seen as a lameness with abnormal locomotion, excessive recumbency, and/or inability to rise from the prone position.

CBC/BIOCHEMSTRY/URINALYSIS

Elevated muscle enzymes (CPK, LDH) from chronic time down; hypophophosphatemia with rickets, nonspecific elevations in enzymes associated with bone metabolism.

OTHER LABORATORY TESTS

• Whole blood selenium low for WMD

LAMENESS: CAMELID (CONTINUED)

• Elevated eosinophilic white blood cells in cerebrospinal fluid tap for animals with MWD
• Muscle biopsies and cultures for infectious causes of lameness

IMAGING
• Radiography for bone lesions
• Ultrasonography for soft tissue lesions

OTHER DIAGNOSTIC PROCEDURES
Neurologic examination, posture and gait observation, palpation, withdrawal response to joint flexion or sole pressure

PATHOLOGIC FINDINGS
• Heat, swelling, pain on palpation, loss of function
• Possible osteomyelitis, bone sequestration, draining tracts
• Muscle biopsies with abnormal gross and/or microscopic findings
• Inflammatory tracts and/or larvae on histologic section of the spinal cord of camelids with MWD

TREATMENT

THERAPEUTIC APPROACH
• Confinement/rest
• Support wraps, casts, internal and/or external fixation as required
• Antibiotics for infections associated with wounds
• Nonsteroidal anti-inflammatory drugs for relief of pain and swelling
  ◦ Flunixin meglumine at 0.5 mg/lb q24h by subcutaneous, intramuscular, or intravenous injection for 7–14 days
  ◦ Phenylbutazone at 4 mg/lb orally q24h
  ◦ Etodolac at 4.5 mg/lb orally q24h for 7 days, then decrease to q48h
  ◦ Meloxicam @ 0.5 mg/lb orally q48h
• Joint-specific drugs to treat arthritis—Adequan IM (Luitpold Animal Health) @ 1.0 mg per lb body weight weekly by intramuscular injection for 3–4 weeks
• Physical therapy to restore range of motion and prevent pressure sores in recumbent animals
• Corticosteroids—drug choice and dose depends on clinician preference
• Acupuncture
• Chiropractic care
• Rickets treatment
  ◦ Injectable vitamin D3 @ 1,000 IU/lb by subcutaneous injection
  ◦ Repeat weekly as needed until serum phosphorus levels are raised to the normal range
• Angular limb deformities—periosteal stripping, growth plate screws and wires or staples depending on the severity and preferences of the surgeon
• Injectable selenium (bovine selenium product BoSe ®) for WMD in acute cases, plus adequate dietary supplementation thereafter
• Lavage septic joints and use systemic antibacterial therapy for joint ill
• See chapter, Parasite Control Programs: Camelid, for treatment of MWD

CONTRAINDICATIONS
• Topical or systemic corticosteroid use in pregnant animals usually results in abortion.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Good for most injuries including fractures.
• Clostridial myositis has a grave prognosis and may cause sudden death from effects of toxin.
• Rickets cases usually respond to medical treatment if discovered and treated early in the course.
• Joint ill may result in septicemia and death.
• MWD survivors are often left with abnormal locomotion—50% of cases die or require euthanasia.

POSSIBLE COMPLICATIONS
• Septicemia from infectious causes
• Chronic non-union fractures may necessitate amputation of a limb
• Chronic, progressive arthritis due to multiple causes
• Death—WMD, Clostridial infections, joint ill, *Sarcocystis* infections, MWD

CLIENT EDUCATION
Observe gait and behavior of the animal

PATIENT CARE
• Look for improvement in gait and/or less time recumbent
• Repeat radiographs to monitor bone healing
• Serial neurologic examinations
• Serial serum phosphorus levels to monitor improvement in hypophosphatemic rickets cases

PREVENTION
• Environmental cleanliness for neonates at birthing time helps prevent joint ill.
• Use of multivalent Clostridial vaccines depending on area risk.
• MWD prevention program in at-risk locations in the US (see chapter, Parasite Control Programs: Camelid).
• Avoid overcrowding to minimize traumatic injuries.
• Vitamin D3 injections for rickets prevention—1,000 IU/lb subcutaneously every 2 months in October, December, and February in at-risk areas of the US.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Pressure sores from excessive recumbency
• Weight loss and poor growth from insufficient access to food
• Septicemia and death possible from infections

AGE-RELATED FACTORS
• Congenital incomplete ossification of femur seen rarely in crias
• Joint ill in neonates
• Angular limb deformities in premature crias
• Arthritis in mature animals may be progressive and accompanied by weight loss

ZOONOTIC POTENTIA
N/A

PREGNANCY
Increased weight as pregnancy progresses may increase lameness.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Separate animals into manageable group sizes to avoid injuries from overcrowding.
• Separate animals by body size to prevent injuries to smaller, young animals.
• Maintain a clean environment for birthing.
• Provide adequate diet for growth and maintenance.
• MWD prevention programs.

ABBREVIATIONS
• CPK = creatine phosphokinase
• LDH = lactate dehydrogenase
• MWD = meningeal worm disease
• WMD = white muscle disease

Consulting Editor Ahmed Tibary

LAMENESS: SMALL RUMINANT

BASICS

OVERVIEW
• Lameness is an important welfare and management problem of small ruminant operations.
• Most lameness observed in small ruminants is infectious in nature. Thus biosecurity is of paramount importance in limiting and managing lameness of small ruminants.
• In some jurisdictions (especially portions of Australia), active efforts to eradicate some forms of small ruminant lameness are under way and require specific reporting mechanisms with governmental oversight. No such systems are in place in the United States.
• Farms with active lameness issues should consider biosecurity implications of selling or moving animals from the farm.

INCIDENCE/PREVALENCE
• Varies greatly by disease process, season, and location.
• In severe cases of virulent foot rot, within-herd prevalence can exceed 50%.

GEOGRAPHIC DISTRIBUTION
• Varies by disease process.
• Ovine foot rot (benign and virulent) have a worldwide distribution. Efforts are under way to eradicate virulent foot rot in some regions of the world.
• Ovine contagious digital dermatitis and similar lesions in goats have been predominantly reported in Europe, although recently suggestive lesions have been identified in the US.
• White line disease, heel abscesses, and toe abscesses are reported worldwide.

SYSTEMS AFFECTED
Musculoskeletal

PATHOPHYSIOLOGY
• Most cases of small ruminant lameness are associated with an infectious agent.
• Penetration of the dermis or corium with infectious bacteria results in dermatitis or under-running of the sole and in some cases severe lameness.

HISTORICAL FINDINGS
Lameness scoring system
• Score 0 (SOUND) Bears weight evenly on all four feet and walks with an even rhythm.
• Score 1 (MILD) Steps are uneven but it is not clear which limb or limbs are affected.
• Score 2 (MODERATE) Steps are uneven and the stride may be shortened; the affected limb or limbs are identifiable.
• Score 3 (SEVERE) Mobility is severely compromised such that the sheep frequently stops walking or lies down due to obvious discomfort. The affected limb(s) are clearly identifiable and may be held off the ground.

SIGNALMENT
Sheep and goats. Any growing or mature animal is at risk.

PHYSICAL EXAMINATION FINDINGS
• Varies by disease process
• Interdigital dermatitis (also known as foot scald, benign foot rot, or grade 1–2 foot rot)
  ◦ Erythema and inflammation of the interdigital space
  ◦ Often multiple feet
• Virulent foot rot
  ◦ Distinct odor often present when foot is lifted.
  ◦ Erythematous and/or an erosive or ulcerative lesion affecting the interdigital space leading to hoof horn separation axially which may lead to necrosis of the sole and in very severe cases avulsion of the hoof capsule.
  ◦ Severe and progressive separation of the soft and hard horn from the underlying corium. Starts as a portion of the sole (stage 3) and progresses.
  ◦ Often involves the majority of the sole (stage 4) and extends up the outer wall in severe lesions (stage 5).
  ◦ Usually involves both claws and often more than one foot.
  ◦ Foot may be swollen or warm.
  ◦ In chronic cases the claw may be severely misshapen.
• Contagious ovine digital dermatitis (CODD, contagious caprine digital dermatitis)
  ◦ Ulcerative or chronic inflammatory lesion originating at the coronary band, which may extend dorsally and abaxially under the hoof wall and in many cases leads to avulsion of the hoof capsule.
  ◦ The affected digit may be swollen and shortened.
• White line disease (shelly hoof, "hoof abscess")
  ◦ Separation of the hard horn from the underlying corium without separation of the sole.
  ◦ Confined to the region of the white line.
  ◦ Pockets of manure and debris that can be cleaned out and do not have evidence of inflamed or hemorrhagic corium.
  ◦ In severe cases it may extend to the coronary band and discharge purulent material.
• Strawberry foot rot
  ◦ Ulcerative dermatitis affecting the skin of the legs from the coronet to as high as the knee or hock.
  ◦ Scabs that when removed expose an ulcerative skin lesion with the appearance on the surface of a strawberry.
• Toe granuloma
  ◦ Granulomatous mass of tissue originating from the corium at the toe end of the sole. The mass of tissue protrudes above the level of the surrounding sole and prevents normal formation of hoof horn.

CAUSES AND RISK FACTORS
• Wet environmental conditions predispose to all diseases due to softening of the hoof horn.
• Use of contaminated hoof trimming equipment is a significant risk factor.
• Purchase or housing of infected animals is the most common source of disease.
• Interdigital dermatitis: *Dichelobacter nodosus.*
• Virulent foot rot: *Dichelobacter nodosus.*
• Contagious ovine digital dermatitis: Polybacterial disease process that includes significant numbers of *Treponema* spp. organisms similar or identical to those seen in bovine digital dermatitis.
• White line disease
  ◦ Packing of manure and debris into the normally softer white line.
  ◦ Moist conditions that keep the hoof horn soft
• Strawberry foot rot: *Dermatophilus congolensis.*
• Toe granuloma: In most cases this is associated with overtrimming of the hoof. Less commonly it may be the sequela of a previous severe foot rot or undermined sole.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• See "Causes and Risk Factors"

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Radiographs are helpful when trauma or osteoarthritis are suspected, or in chronic conditions with potential joint involvement.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Segregate lame animals and do not sell.
• If possible keep lame animals in dry environment to allow hoof walls to harden.

Interdigital Dermatitis
• Preferred methods
  ◦ Topical application of oxytetracycline as a spray to interdigital region.
  ◦ Footbathing
  ◦ Formalin—2–5%, although care should be taken as higher strengths can cause irritation to the skin. Start at 2–3% and increase only if needed. Does not require animals to stand in bath for long periods.

LAMENESS: SMALL RUMINANT (CONTINUED)

- ◦ Zinc sulfate—typically 10% solution. Addition of a surfactant may benefit treatment success. Ideally have animals stand in bath for 2–20 minutes.
- ◦ Copper sulfate—should be avoided due to risk of copper toxicosis in sheep.

• Injectable antibiotics are not necessary in flocks or herds with only interdigital dermatitis and no history of virulent foot rot.

Virulent Foot Rot

• Preferred method is injection of long-acting antibiotic:
- ◦ Long-acting oxytetracycline
- ◦ Long-acting macrolide

• Ancillary treatments
- ◦ Topical application of oxytetracycline as a spray
- ◦ Footbathing—same recommendations as for interdigital dermatitis

• While trimming of infected animals used to be recommended it has now been demonstrated to slow healing and to act as a means of transmission. Therefore, this is no longer recommended.

• Vaccination is available in some countries, with variable success. There is evidence to suggest that multivalent strain vaccines have limited efficacy due to antigenic competition. As a consequence, the most effective approach is culture of strains from infected farms and the development of single or double strain autogenous vaccines. Multiple studies demonstrate that farms and individual animals are often concurrently infected with multiple strains, complicating this approach. Cattle foot rot vaccines focused on *Fusobacterium* spp. are unlikely to provide significant protection.

• Some animals remain chronically infected despite repeated treatment and should be culled to minimize maintenance within the flock or herd.

Contagious Ovine Digital Dermatitis

• Relatively new disease process with minimal evidence-based medicine data to support the benefit of specific treatments.

• Anecdotal evidence supporting the use of injectable long-acting macrolides.

• Anecdotal response to topical lincomycin and spectinomycin soluble powder or tylosin soluble powder made up at 1 g per 2 L in water and applied repeatedly.

• Footbath recommendations as outlined above.

White Line Disease

• Remove the manure and soil packed in the wall and trim away the undermined wall.

• Do not disturb or trim away at the inner wall.

Strawberry Foot Rot

• Systemic therapy with penicillin may be beneficial.

• Topical therapy standard for dermatophylosis in other species.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Toe granuloma—regional anesthesia of the limb (either ring block or IV regional) followed by placement of a tourniquet and surgical excision of the granuloma. Wrap to control hemorrhage.

MEDICATIONS

DRUGS OF CHOICE

See "Treatment"

CONTRAINDICATIONS

Foot trimming in cases of virulent foot rot is contraindicated.

PRECAUTIONS

• Be aware of human-health risks associated with formalin footbaths.

• Consideration of extra-label drug use and appropriate withdrawal times is necessary.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Disease and severity dependent

POSSIBLE COMPLICATIONS

N/A

CLIENT EDUCATION

Biosecurity with infectious causes of lameness is of paramount importance.

PATIENT CARE

Lame animals should be examined and treated promptly.

PREVENTION

Keeping a closed herd and well-drained fields or dry indoor housing.

MISCELLANEOUS

BIOSECURITY

• Minimize new animals entering herd or flock.

• Separate lame animals promptly.

PRODUCTION MANAGEMENT

• Refer to recommendations in "Follow-Up"

LAMINITIS IN CATTLE

BASICS

OVERVIEW
Laminitis is a common, multifactorial disease causing lameness in cattle. Laminitis is very common in confined dairy cattle and beef cattle on high-concentrate diets. The pathology that occurs in the hoof is the result of systemic physiologic changes that affect the functionality of the keratinocytes that produce the horn of the hoof and compromise the integrity of the collagen connecting the third phalanx (P3) to the hoof capsule. These changes lead to abnormal horn production that is often manifested as a sole ulcer, white line disease, or misshapen hooves. Acute laminitis is uncommon. Subacute, subclinical, or chronic laminitis is much more common in both dairy and beef cattle.

INCIDENCE/PREVALENCE
Uncommon in pastured cattle. Variable incidence in cattle housed on concrete or fed diets containing grain with incidence ranging from 5% to 50%.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
- Integument
- Musculoskeletal

PATHOPHYSIOLOGY
- The dermis, basement membrane, and epidermal keratinocytes are subject to physiologic and physical damage which can disrupt the production of normal hoof horn. The generally accepted mechanisms are disruption in blood flow and disruption in collagen attachment. The theories share the common endpoint of altering the function of germinal layers of the epidermis.
- Ruminal acidosis can cause laminitis. Vasoactive compounds such as histamine, released as a consequence of acidosis, are thought to decrease blood flow in the microvasculature of the hoof, either by vasoconstriction or arteriovenous shunting, which leads to local ischemia and edema. The compromise in blood flow disrupts nutrient supply to the epidermis. An increase in cytokines, specifically IL-1, has been documented to occur in the hoof following ruminal acidosis. IL-1 upregulates matrix metalloproteinases (MMP) which are involved in the turnover of collagen in the hoof. Upregulation of MMPs leads to loosening of the collagen attachment of P3 to the hoof capsule. Disruption of laminar corium attachment and support of P3 leads to damage to the corium through a combination of compressive and shearing forces.
- Dietary micronutrients such as zinc, copper, sulfur, biotin, and cysteine are critical to normal keratin production and horn formation. Deficiencies in these nutrients may contribute to the laminitis syndrome.
- Increased biomechanical load on the hoof from walking on concrete also contributes to the laminitis syndrome. Similarly, overgrowth of the hoof that causes abnormal weight bearing in the hoof will increase the risk for laminitis.
- The combination of changes in blood flow, inflammation, swelling, and loosening of attachments of P3 leads to cellular disruption in the corium which is manifested as some combination of sole ulcer, white line disease, and abnormal horn growth. It should be noted that the time from the physiologic insult until manifestation of changes in the hoof can be 2 months or more.

HISTORICAL FINDINGS
Recent feed or feeding management change can contribute to improper intakes and ruminal acidosis. Change in housing or recent bout of hot weather.

SIGNALMENT
Typically, adult dairy cows and feedlot cattle

PHYSICAL EXAMINATION FINDINGS
- Lameness.
- Overgrown hooves.
- Misshapen hooves with the hoof being broader and flatter, and dorsal wall furrowed and concave (slipper foot).
- On inspection of the hooves, sole hemorrhages, sole ulcer, or white line separation/abscess will likely be evident.
- Horizontal grooves are often evident on the dorsal aspect of the wall.
- The sole horn may be flaky or chalky.
- A double sole may be found.

GENETICS
The estimated heritability is 0.14–0.22.

CAUSES AND RISK FACTORS
- There is an interaction between diet and housing. Feeding high grain diets can cause SARA and predisposes cattle to laminitis. Housing cattle on concrete predisposes cattle to laminitis by increasing the biomechanical load on the corium. If the two conditions occur together, the risk increases substantially.
- In addition to diet, during hot weather, rumination time decreases and meal sizes increase which can exacerbate SARA.
- Also, overstocking and poorly designed stalls or resting surfaces will lead to increased standing time and thus increased biomechanical load on the foot.
- Overgrowth of hooves will change weight bearing, increase biomechanical load, and predispose to laminitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Digital dermatitis, interdigital phlegmon, hoof overgrowth, thin soles

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Hoof trimming

PATHOLOGIC FINDINGS
Postmortem examination and biopsy are not necessary in clinical cases. Sinkage of P3, decreased fat content of the digital cushion, inflammation of the corium and epidermis.

TREATMENT

THERAPEUTIC APPROACH
- Functional hoof trimming should be performed to return all the claws to a normal conformation. Sole ulcers and white line abscesses should have the surrounding horn pared away until normal horn is seen well adhered to the corium. The sole surrounding the lesion should be sloped so as not to create a deep hole that will become filled with debris.
- A block (wood, rubber or plastic) should be glued to the sound claw to relieve weight bearing on the affected claw until healing can occur.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Typically, medications are not necessary. For more severe lesions, NSAIDs can be used for pain relief. Flunixin meglumine (1.1–2.2 mg/kg once daily) or meloxicam (0.5 mg/kg PO once daily). Injectable meloxicam, ketoprofen, and carprofen are available in some countries.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Most cases of laminitis that cause lameness can be treated by functional hoof trimming and treating the lesion and will have a good prognosis for recovery. Animals should be improved within 1 week of treatment, mostly sound within 2 weeks, and sound by 3 weeks after treatment. If improvement does not

LAMINITIS IN CATTLE (CONTINUED)

proceed as expected, the animal should be re-evaluated. In some cases of chronic or severe laminitis, a shift in the position of P3 or scarring of the basement membrane may result in recurring problems with a poor prognosis for resolution.

POSSIBLE COMPLICATIONS

Granulation tissue may develop during the healing phase and, if it protrudes above the wound margin, must be removed. Sole ulcers or white line abscesses, if not treated early, can progress into deeper infections involving the bones, joints, and tendons of the foot. Deeper infections may require aggressive debridement and wound care or claw amputation as a salvage operation.

CLIENT EDUCATION

See "Prevention"

PATIENT CARE

Animals should be housed in a clean, dry area with a comfortable resting surface. They should be observed daily to ensure they are generally healthy and sufficiently mobile to access feed and water. If lameness worsens or swelling develops above the hoof, the animal should be re-evaluated promptly.

PREVENTION

• Nutrition and environmental management are the keys to preventing laminitis. The following comments are primarily for dairy cattle but can be adapted to other feeding situations. Diets should be formulated to provide adequate chemical and effective fiber and not exceed recommended maximum levels of starch or nonstructural carbohydrates. Diets should provide adequate physically effective fiber without promoting excessive sorting. Feeding diets to a low level of refusal, providing adequate bunk space, and providing heat abatement during warm weather will promote the consumption of more moderate-size meals during the day and reduce the risk of SARA. Zinc methionine and biotin have been shown to decrease lesions associated with laminitis.

• For beef cattle, there must be a gradual transition from high roughage to concentrate feeding to avoid SARA and laminitis. The use of by-product feeds to replace corn can reduce the starch level in the diet without compromising performance.

• Reducing the biomechanical load on the feet is an important component in preventing laminitis. The housing environment should provide a comfortable resting place and be stocked such that animals can be reasonably expected to lie down at least 10 hours per day. The use of rubber mats in high traffic areas to provide a yielding walking surface with good traction has been shown to improve hoof health.

• Periodic locomotion scoring of cows will alert management when lameness incidence is increasing and allow corrective action to be taken in a timely manner.

MISCELLANEOUS

ASSOCIATED CONDITIONS

SARA

PREGNANCY

Hormonal changes at parturition may affect the digital cushion and suspensory apparatus of the hoof, thus contributing to the risk for laminitis.

PRODUCTION MANAGEMENT

Lameness has significant economic consequences for all production sectors. There is also a significant animal welfare concern with lameness. The sequelae to laminitis account for at least half of the cases of lameness that occur in dairy cattle. Controlling laminitis is critical to maintaining a healthy, profitable herd. Refer to the section "Prevention" for management considerations to control laminitis.

ABBREVIATIONS

• MMP = matrix metalloproteinase
• NSAID = nonsteroidal anti-inflammatory drug
• P3 = third phalanx
• PO = per os, by mouth
• SARA = subacute ruminal acidosis

SEE ALSO

• Lameness: Bovine
• Ruminal Acidosis

LANTANA TOXICOSIS

BASICS

OVERVIEW

• Lantana is a perennial, branching herb or shrub. Both erect and creeping varieties exist, ranging between 0.5-2 meters tall.
• Lantana resides in the Verbenaceae, commonly known as the verbena or vervain family. Some 150–160 species exist, producing flowers in dense spikes from spring to fall.
• Simple leaves with serrated margins are ovate to lanceolate in shape and are arranged in opposite or whorled patterns. They emit an unpleasant odor when crushed.
• Fruits occur in clusters, initially green, then becoming dark purple to black when ripe. They are 5–7 mm in diameter. Stems are square (four-sided) and may be prickly with small hairs.
• The plants are often used as ornamentals because of their showy flowers that come in a wide variety of colors. Most lantana have flowers with two colors (yellow and orange, orange and red, purple and white), but single-colored varieties exist. "Ham and Eggs" is a common name for a variety with yellow and red flowers.
• Frequently planted as an ornamental, lantana has often escaped and become "wild."
• An uncommon cause of intoxication, lantana can be a significant cause of poisoning and death loss where it grows wild.
• Cattle are most frequently intoxicated by lantana and mortality is high in severe cases.

INCIDENCE/PREVALENCE

• Poisonings are most common in summer and fall, often due to clippings.
• The incidence is related to the availability of the plants.

GEOGRAPHIC DISTRIBUTION

• Lantana is widely spread throughout the tropical and subtropical regions of the world.
• It is primarily found in the southern portions of the United States as it is not cold tolerant.

SYSTEMS AFFECTED

• Multisystemic
• Hepatic
• Integument
• Digestive
• Urinary

PATHOPHYSIOLOGY

• Lantana produces lantadene A and B. These compounds are found in the leaves and are toxic to both the liver and gastrointestinal systems.
• Other plant parts including flowers, fruits and stems may contain other toxins.
• Toxicity varies considerably between different varieties of lantana. Those with red flowers are considered most toxic and purple/lavender flowered varieties least toxic.
• The amount of liver disease is directly related to the quantity of leaves ingested.
• As lantadenes are absorbed from the gastrointestinal tract, they cause direct irritation to the gastrointestinal mucosa.
• Lantadenes are transported to the liver, resulting in damage to hepatocytes.
• They cause inflammation of the bile ducts (cholangitis) as they are excreted and subsequently slow or stop the transport of bile (cholestasis).
• This causes phylloerythrin (a photodynamic agent from chlorophyll metabolism of plants) and bilirubin to accumulate in hepatocytes and capillary beds of the skin. When phylloerythrin is activated by sunlight, tissue damage occurs with resultant photosensitization.
• Time from ingestion to death may be several weeks.
• Death is likely due to hepatic disease and renal failure, while anorexia and metabolic acidosis contribute.

SIGNALMENT

• Although ruminants tend to be more commonly poisoned, most animal species, including sheep, goats, wildlife, and children are susceptible.
• Cattle are most frequently intoxicated during late summer and fall.
• There are no known breed, species, or sex predilections.

PHYSICAL EXAMINATION FINDINGS

• Intoxication and related clinical signs depend upon the quantity consumed and the time period of ingestion.
• Signs of acute intoxication may be seen within 24 hours post-consumption.
• Subacute poisoning over 1–2 days is more common than acute intoxication.
• Initial signs may include depression, weakness, anorexia, depressed ruminal motility, and constipation. Dehydration and electrolyte imbalances (metabolic acidosis) also play roles.
• Within 2–4 days, icterus, bloody diarrhea, skin changes associated with photosensitization, paralysis, and death can be seen.
• Chronic disease is characterized by oronasal ulcerations, keratitis, icterus and photosensitization progressing over days to weeks. Keratitis may vary from light sensitivity to complete blindness.

CAUSES AND RISK FACTORS

• Lantadenes are hepatotoxic triterpene acids. Lantadene A is considered the most toxic, while lantadene B is less toxic.
• Differing varieties exist, possessing varying amounts of lantadenes with differing levels of potency. Although flower colors are often indicative of the level of danger, it is best not to fully rely on this method for determining toxicity.
• Fresh or dry leaves are the primary source of lantadenes.
• Green fruits may possess other toxins.
• Ripened fruits and seeds are not toxic.
• Consumption of 5–10 g leaves will often produce fatal poisoning in livestock. Smaller doses, if consumed daily over several days, can be toxic as well.
• Lantadenes are absorbed primarily from the gastrointestinal tract.
• They are transformed in the liver and excreted in the bile, resulting in an obstructive cholangitis.
• The effects of lantadenes are cumulative as the hepatic and renal changes are permanent.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• The signs of lantana intoxication are nonspecific. A number of hepatotoxic plants are listed:
  ◦ *Crotalaria* spp.—rattlebox
  ◦ *Helenium* spp.—sneeze weed
  ◦ *Hymenoxys* spp.—rubber weed, bitterweed
  ◦ *Senecio* spp. and *Packera* spp.
• Oak poisoning may produce signs similar to acute lantana intoxication.
• St. John's wort—photosensitization
• Numerous other causes of liver disease
• Clinical signs, history of ingestion, finding plants in feed, hay, or rumen contents are supportive of a diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

• Serum bilirubin is elevated.
• With hepatocyte damage, serum hepatic enzymes are typically elevated, including AST, GGT and ALP.

OTHER LABORATORY TESTS

BSP clearance is decreased.

PATHOLOGIC FINDINGS

• Icteric tissues
• Skin lesions due to photosensitization
• Keratitis
• Enteritis/Abomasitis
• Obstructive cholangitis
• Enlarged green-tinted liver (bile staining)
• Enlarged gall bladder
• Enlarged kidneys with perirenal edema

TREATMENT

THERAPEUTIC APPROACH

• Remove affected animals from sunlight and provide shade for those affected by photosensitization.
• Prevent animals' access to lantana.
• Treat patients symptomatically, give supportive care, and maintain hydration and electrolyte balance with oral or intravenous fluids.

LANTANA TOXICOSIS (CONTINUED)

• Rumenotomy with evacuation of contents may be worthwhile if performed early.
• Broad-spectrum antibiotics to assist in preventing secondary bacterial infections of skin lesions associated with photosensitization.

MEDICATIONS

DRUGS OF CHOICE

• Activated charcoal—2–5 g/kg given orally to control absorption of toxins from the gastrointestinal tract (1 g charcoal per 5 mL water).
• Mineral oil administered orally to more rapidly transport plant materials from gastrointestinal tract.
• Generally, it is considered best to use either activated charcoal or mineral oil, but not both at the same time.
• Sodium thiosulfate may be beneficial.
• Systemic antibiotics are warranted in animals with photosensitization to assist in protecting them from secondary bacterial infections.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Variable, dependent upon the amount and rate of consumption.
• High mortality is expected with acute cases.
• Many animals will survive moderate cases of intoxication.

PREVENTION

• Providing a proper diet and adequate nutrition to animals will help to minimize the consumption of many toxic plants.
• Protective immunization has been studied and further research is needed.

MISCELLANEOUS

PREGNANCY

None

PRODUCTION MANAGEMENT

Removal/destruction of lantana—it is susceptible to 2,4-D and other broad-leaf herbicides.

ABBREVIATIONS

• AST = aspartate aminotransferase
• BSP = bromsulphalein
• GGT = gamma-glutamyl transpeptidase
• IV.= intravenous
• SDH = sorbitol dehydrogenase

SEE ALSO

• Oak (*Quercus* spp.) Toxicity
• St. John's Wort Toxicity

LEAD TOXICOSIS

BASICS

OVERVIEW

• Among ruminants, most cases of lead poisoning occur in cattle.
• The vast majority of lead poisoning cases are the result of acute oral exposures; chronic exposures are rare in ruminants.
• Lead sources commonly encountered by ruminants include discarded auto batteries, discarded crankcase oil, paint, solder, greases, oil-well pipe dope, lead shot, roofing material, and burn piles.
• In acute toxicosis, the onset of clinical signs is rapid and typically includes signs associated with the gastrointestinal tract and central (and to a lesser extent, peripheral) nervous systems.
• Death with few to no premonitory signs may be observed in calves and young animals.
• Antemortem diagnosis relies on elevated blood lead levels and evidence of radiodense objects in the gastrointestinal tract (more common to find in the reticulum).
• Elevated liver and kidney lead levels, evidence of lead particles in the GIT (reticulum, rumen), and histologic evidence of laminar cortical necrosis provide postmortem evidence for a diagnosis of lead poisoning.
• Treatment, if possible and economically viable, includes administration of oral magnesium sulfate, thiamine, Ca-EDTA, along with supportive care targeted to observed clinical signs.
• Prognosis is generally poor in acute cases, and care must be taken in considering home or custom slaughter due to tissue residues.

INCIDENCE/PREVALENCE

Sporadic, unpredictable incidence but most cases occur in cattle in the spring, when they are turned out in pastures with access to lead-containing sources.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Digestive
• Nervous
• Hemolymphatic
• Urinary
• Multisystemic
• Musculoskeletal
• Reproductive

PATHOPHYSIOLOGY

• Lead is relatively insoluble and poorly absorbed from the gastrointestinal tract. However, once absorbed, it is retained in the soft tissues initially and later the bone.
• In the blood, lead binds to surface proteins of red blood cells.
• Lead has a wide tissue distribution and long total body half-life, and ultimately forms deposits in bone where it resides (biologically inert) for years. Remodeling of bone can lead to its release.
• Lead is excreted primarily by the kidneys, crosses the placental barrier, and can be secreted into milk.
• Lead affects multiple systems, and the effects are varied depending on whether the exposure is acute or chronic.
• Lead interferes with sulfhydryl- and zinc-containing enzymes, leading to erythrocyte fragility, bone marrow suppression, and interference with heme synthesis (more common to see these changes with chronic exposures), along with interfering with various neurotransmitters in the CNS.
• Neurologic signs may be due to cerebral edema as a result of increased vascular permeability.
• Segmental demyelination of peripheral nerves (e.g., pharyngeal, buccal) may be seen.
• In young animals lead poisoning may result in suppression of bone growth.
• Lead interferes with calcium absorption from the gut, along with displacing calcium in multiple sites.

Toxic Dose

• The single acute lethal dose for cattle ranges from 400 to 800 mg/kg and daily intakes of 1–7 mg/kg/day can eventually result in toxicosis. These are from experimental exposures and differ from clinical cases where the amount and form of lead ingested is generally not known.
• Cattle—intakes of >6 mg/kg body weight can lead to chronic poisoning, and intakes >10 mg/kg BW may cause acute lead poisoning.
• Sheep—generally occurs in lambs; symptoms of poisoning appear at intakes >4.5 mg/kg BW.
• Goats—more resistant than sheep or cattle. Very minor signs of poisoning occur at intakes of 60 mg/kg BW. This is equal to blood concentrations of 130 µg/dL.

SIGNALMENT

• All ruminant species are at risk.
• Cattle more likely than other ruminants due to less-discriminating grazing.
• All ages are susceptible.
• Younger animals are at greater risk of intoxication due to increased capacity to absorb lead from the intestines.

PHYSICAL EXAMINATION FINDINGS

Signs appear to occur abruptly, though there may be a delay of several days (depending on the lead source) between the time of lead ingestion and the onset of signs.
• Blindness, circling, aimless wandering, head pressing
• Anorexia
• Grinding of the teeth
• Rhythmic twitching of the muscles, often involving the face (e.g., eyelids)
• Tucked and painful abdomen; rumen atony, constipation, or diarrhea may be present
• Salivation, due to pain or pharyngeal paralysis
• Excitement and/or seizures (depression may also be observed)
• Bradycardia and hypertension have both been observed in cattle

CAUSES AND RISK FACTORS

• Discarded broken batteries are by far the most common source of lead poisoning in ruminants. The interior lead plates often contain >90% lead.
• Other less common sources of lead include machinery grease, old used motor oil, paint, pesticides, caulk and putty, contamination from mines and smelters, water, and grazing pastures contaminated with lead shot.
• Burning batteries does not destroy lead; this practice only provides animals a more concentrated lead source in the remaining ash.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Polioencephalomalacia, salt poisoning and/or water deprivation, vitamin A deficiency, rabies, listeriosis, abscess, thromboembolic meningoencephalitis, nervous coccidiosis, rabies, nonprotein nitrogen poisoning, and hepatic encephalopathy.
• There are many differentials for "sudden" death in ruminants; these could include enterotoxemia, water hemlock (*Cicuta*), botulism, nonprotein nitrogen intoxication, cyanobacteria (blue-green algae), *Delphinium* (larkspur), *Zigadenus* (death camas), *Astragalus* (locoweed), and nitrate poisoning.

CBC/BIOCHEMISTRY/URINALYSIS

• Basophilic stippling is commonly mentioned as a potential alteration; however, its finding is inconsistent and may be mistaken for other disease processes.
• Anemia (subchronic to chronic lead toxicosis).
• Increased RBC fragility.

OTHER LABORATORY TESTS

• Definitive diagnosis requires detection of lead in appropriate clinical specimen.
• Diagnostic samples:
  ◦ Whole blood: >0.35 ppm (35 µg/dL) lead with compatible clinical signs is diagnostic.
  ◦ Kidneys: >10 ppm lead wet weight is diagnostic.
  ◦ Liver: >10 ppm lead wet weight is diagnostic.
• Even though blood lead levels are diagnostic for confirming exposure, blood Pb levels sometimes do not correlate with clinical signs. For instance, one might see a blood lead level

LEAD TOXICOSIS (CONTINUED)

of 0.30 ppm in a cow that is seizing; and one might see a blood lead level of 0.90 ppm in a cow that is not showing any clinical disease. Because of the variability, lead poisoning is diagnosed in an individual animal; remaining animals in the "exposed" group should be tested, regardless of whether they are showing signs.

IMAGING
Radiography carried out antemortem or postmortem may show radiographic densities in the GIT, most commonly in the reticulum.

OTHER DIAGNOSTIC PROCEDURES
Formalin-fixed tissue can still be used for lead analysis, retrospectively for diagnosis.

PATHOLOGIC FINDINGS
• No findings are pathognomonic for lead poisoning.
• Gross lesions include cerebral edema, flattened or yellow cerebral cortical gyri.
• Gastrointestinal inflammation, ulceration, and/or hemorrhages.
• Histologic lesions of the CNS include laminar cortical necrosis with swelling of the capillary endothelium within the brain.
• Kidney lesions include proximal renal tubule degeneration and necrosis. Lead inclusion bodies in the proximal renal tubules. Inclusions are described as intranuclear inclusions in the proximal tubules with periglomerular nephritis.
• Liver—centrilobular degeneration.

TREATMENT

THERAPEUTIC APPROACH
• Removal of the lead from the multicompartmental ruminant GIT is difficult.
• Treatment of lead intoxication may not be rewarding and deaths may occur prior to the initiation of therapy.
• The prolonged retention of lead may be due to continued release and absorption of lead from metal particles in the reticulum or rumen.
• Chelation therapy (enhances renal excretion)
  ◦ Ca-EDTA—55–90 mg/kg body weight slowly IV or IM, q12h.
  ◦ Treat for 3–5 days.
  ◦ If additional treatment is indicated (clinical signs still present), wait for at least 2 days before administering another round of chelation therapy. Blood lead levels should be periodically monitored to evaluate the effectiveness of the chelation therapy.
• Symptomatic therapy—thiamine HCl—administer 250–1000 mg SC or IM, q12h. Treat for 5–10 days.
• Supportive therapy—mineral supplementation may be required if there is prolonged chelation therapy.

MEDICATIONS

DRUGS OF CHOICE
• Magnesium sulfate can be added to the diet to help bind lead within the gastrointestinal tract (one recommended dosage: 0.5 g/lb BW daily).
• Depending on the severity of clinical signs, symptomatic care may include diazepam or barbiturates for seizure control, IV fluid therapy to correct dehydration, monitoring for the development of electrolyte abnormalities, monitoring feed and caloric intake, and addressing deficiencies accordingly such as zinc supplementation (1.0 mg/kg/day).
• British anti-Lewisite (dimercaprol or BAL) penetrates into the brain, and can be a helpful chelator in animals showing severe neurologic signs. One suggested dosage is 3.0 mg/kg IM as a 5% solution in a 10% solution of benzyl benzoate in peanut oil q4h for 2 days, q6h on day 3, then q12h for the next 10 days. BAL is potentially nephrotoxic and is painful when injected. It can be difficult to obtain and expensive to use.

CONTRAINDICATIONS
• Ca-EDTA is potentially nephrotoxic, so monitoring renal parameters and maintaining adequate hydration status are recommended.
• Lead may interfere with copper, calcium, zinc, iron, and selenium metabolism.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The more severely affected animals have a poor prognosis. It is often impossible to remove the lead from the gastrointestinal tract of ruminants, and patients showing severe neurologic signs often do not respond well to treatment.
• Mild or moderately affected animals may improve if one can remove the lead from the gastrointestinal tract, and enhance renal excretion through chelation therapy.

PATIENT CARE
• Blood lead levels should be monitored periodically to determine the efficacy of chelation therapy and to assist with decision making in regard to slaughter withdrawal times. Normal blood levels should be <0.10 ppm.
• Lead can be secreted into milk; milk should be tested and discarded if levels are too high.
• It is common for neurologic signs (e.g., blindness) to persist. Ill thrift may be present in "recovered" young.

PREVENTION
• Knowledge of the common sources of lead should help producers avoid this potentially devastating disease.
• Identify the source (through history, pasture examination, etc.) and remove it from the animal's environment; or remove the animals from the contaminated environment.
• Keep at-risk animals away from junk, burn, or "resource" piles located on the property.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• The half-life of lead in an intoxicated animal depends on a number of factors including age and physiologic status.
• In some references, the half-life of lead in cattle is reported to be several weeks to >2 years.
• A study from Michigan examined the half-life of lead in poisoned animals and reported that lead tended to have a shortened half-life in pregnant or lactating cattle as compared to castrated bulls.

AGE-RELATED FACTORS
Younger animals are at greater risk of intoxication due to increased capacity to absorb lead from the intestines.

ZOONOTIC POTENTIAL
• Lead is immunosuppressive and carcinogenic in people. The developing fetus and young children are very susceptible to lead's toxic effect on the nervous system. Care should be taken when using meat or milk from lead exposed animals for human consumption.
• There is potential for lead exposure in others animals from the milk and meat of poisoned animals.
• In some states, there are restrictions on movement or marketing of cattle poisoned with lead.
• The veterinarian should consult the local diagnostic laboratory or department of public health for questions specific to their practice area.

PREGNANCY
• Lead poisoning is reported to cause infertility, abortions, and fetal resorption.
• Lead crosses the placental barrier and may exert a deleterious effect on the developing ruminant fetus.
• Pregnant ruminants that suffer from lead toxicosis may transfer significant amounts of lead to the developing fetus.

PRODUCTION MANAGEMENT
Restrict animals' access to lead sources (e.g., paint-cribbing, batteries, grease, etc.). Avoid access to junk piles in the pastures.

LEPTOSPIROSIS

BASICS

OVERVIEW

• Leptospirosis is a bacterial zoonotic disease of multiple animal species caused by *Leptospira* species.
• It is an acute febrile disease with clinical manifestations depending on the animal species and the serologic variant of *Leptospira.*
• The chronic form of leptospirosis causes septicemia, agalactia, hepatitis, nephritis, and abortion in domestic livestock and wildlife hosts.

INCIDENCE/PREVALENCE

• Mature cattle could develop into renal carriers of *Leptospira* with serovars *hardjo, pomona,* and *grippotyphosa*. *L. hardjo* cause endemic reproductive problems in cattle. *L. pomona* is common in calves.
• *L. grippotyphosa* and *L. pomona* are common in dogs. Raccoons are a reservoir of *Listeria* species. *L. pomona* is common in goats and sheep but are rarely infected. Sheep also harbor *L. hardjo*.
• High seroprevalence of various leptospira serovars (10–70%) has been reported in several species and countries.

GEOGRAPHICAL DISTRIBUTION

• Worldwide distribution favoring warm, wet climates and surviving in standing water for prolonged periods.
• Different serovars predominate in different regions.

SYSTEMS AFFECTED

• Urinary
• Multisystemic
• Cardiovascular
• Nervous
• Reproductive
• Mammary

PATHOPHYSIOLOGY

• Leptospires enters the body from the exposed mucus membranes or abraded skin. Venereal or transplacental routes of transmission have also been reported. Incubation period extends from 4 to 20 days.
• The bacteria replicate in the blood and are transmitted to the liver, lungs, kidney, GI tract, and CNS. Septicemia follows for 4–7 days resulting in systemic dispersion of bacterial toxins causing fever, capillary damage, hepatic necrosis, renal tubular damage, and agalactia.
• In calves, hemolysin toxin may cause intravascular hemolysis, hemolytic anemia, and hemoglobinuria.
• Humoral response increases serum antibody level, resolving the septicemia and fever. Bacteria localize in the liver and renal parenchyma, causing hepatitis and interstitial nephritis respectively, which resuls in persistent leptospiruria.
• Animals succumb due to acute septicemia, hemolytic anemia, and interstitial nephritis.
• Leptospires can cross the placental barrier. In the second half of gestation the bacteria invade the placenta and fetus during the septicemic phase, resulting in abortion several weeks later.
• Sheep and goats develop encephalitis/meningitis due to localization of the leptospires in the nervous system.
• Leptospires colonize the proximal renal tubules and are intermittently excreted in the urine of carrier animals.

HISTORICAL FINDINGS

• Ruminants: Infertility, early pregnancy loss, increased number of service per conception, prolonged calving interval, abortion, stillbirth, and weak offspring.
• Camelids: Early pregnancy loss, abortion, poor milk production.

SIGNALMENT

• Leptospirosis is common in dogs, cats, cattle, sheep, goats, pigs, camelids, wild ruminants, and water buffalo.
• *Leptospira* is isolated at higher rates from beef cattle than dairy cattle.
• Most wildlife are the maintenance host but dogs, pigs, and cattle may also be the maintenance host.
• The host-adapted serovars generally cause a mild or unapparent disease developing into a carrier state. For example:
  ◦ *Leptospira borgpetersenii* serovar *hardjo-bovis* is adapted to cattle.
  ◦ *Leptospira interrogans* serovar *hardjo-prajitno* is adapted to sheep.
• Animals, especially young animals, infected by a non-host-adapted serovar may develop acute, severe clinical disease; it also may cause abortion in pregnant animals. Examples are *Leptospira interrogans* serovars *pomona, grippotyphosa, canicola,* and *icterohaemorrhagiae* in cattle.
• Calves and lambs are more typically affected by the acute form; the subacute form predominatesin adult cattle; and the chronic form in sheep, goats, and adult cattle. It is acute in dogs <6 months of age and most of the dogs do not develop clinical symptoms and may develop into a carrier state.
• A survey isolating *Leptospira* from kidneys of cattle at slaughter in the United States reported higher isolation rates from bulls than cows.
• Males are often nonsymptomatic carriers that may excrete *Leptospira* in the urine and semen.

PHYSICAL EXAMINATION FINDINGS

Cattle

• A sudden drop in milk production (up to 50%) in lactating cows can be noticed, which lasts 7–14 days. Sometimes the milk is thick, yellow, and may contain clots.
• It can be an acute, systemic, often febrile illness characterized by renal and/or hepatic damage depending upon the strain involved and recumbency lasting 1–7 days.
• Increased rate of abortion, retained fetal membranes, stillbirth, fetal infection, and birth of weak neonates.
• Infertility due to low conception rates or early pregnancy loss may be seen.
• Uveitis, pancreatitis, bleeding, hemolytic anemia, and respiratory disease may be noticed.

Sheep and Goats

• Sheep and goats rarely develop the clinical disease but in young stock: pyrexia, dyspnea, depression, anorexia, may be hemoglobinuria, pale or yellowish mucus membranes; death due to septicemia may occur within 12 hours.

Dogs

• Uveitis, pancreatitis.
• Fever and depression are the most common signs. Dogs feel cold, shivery, and stiff. They may carry their tummies tucked up due to pain. Some dogs may drool and vomit. They may drink excessively due to fever.
• Later in the course of disease, a few pets will develop uveitis, nervous system abnormalities, and red-tinged urine. As the disease progresses, the pet may become dehydrated due to the lack of interest in drinking. When body temperature drops to subnormal, the prognosis is very grave. Juvenile dogs may die suddenly before the clinical signs develop.
• When liver is involved the dog's skin may take on a yellowish tinge and show all the symptoms of hepatitis. When the kidneys have been severely damaged, they develop uremia.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Pathogenic serovars of the *Leptospira* species.
• Pathogenic leptospires are classified as a single species, *Leptospira interrogans,* with >200 serovars in 23 serogroups.
• Direct transmission through contact with urine, vaginal discharge, post-abortion discharge, or the fetus of an infected host. Indirect transmission through contact with contaminated environment.
• Climatic conditions (high temperature and humidity) play an important role in maintenance of the bacteria in the environment and increase risk of contamination.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Uveitis, pancreatitis: Leptospirosis is confused with the other diseases that cause hematuria, abortion, and jaundice.
• The disease should be differentiated from water toxicosis in young calves, postparturient hemoglobinuria, anaplasmosis, babesiosis,

bacillary hemoglobinuria, enzootic hematuria, acute hepatitis, and cholangiohepatitis.
• Among the reproductive signs, it should be differentiated from anaplasmosis, bluetongue, bovine viral diarrhea mucosal disease, brucellosis, campylobacteriosis, trichomoniasis, infectious bovine rhinotracheitis (IBR), malnutrition, mycoplasma, and mycosis.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC may show a hemolytic anemia and leukocytosis; there may be leukopenia.
• Urinalysis may reveal increased bilirubin, hemoglobin, and albumin. *Note:* Urine may be infectious.
• Biochemistry may show increased liver enzymes (AST and ALT), bilirubinemia, and azotemia.

OTHER LABORATORY TESTS
• Leptospirosis should be diagnosed on a herd level from several suspected animals.
• Microscopic agglutination test (MAT) on acute and convalescent (7–10 days later) serology is a commonly used test for leptospirosis. MAT titer >1:800 coinciding with clinical signs or by a four-fold rise in paired samples is diagnostic.
• In cases of abortion, MAT titer declines and identification of titer of >300 in several cows would be significant in an unvaccinated herd.
• Results of samples taken in early infection may show cross-reactivity to other serovars.
• Chronic carriers and animals that abort may be seronegative after several months of infection.
• Serologic titers due to vaccination cannot be distinguished from infection, although they tend to be lower and more transient.
• Isolation of bacteria in the kidneys from chronic carriers may not have diagnostic titer. Presence of spirochete in dark field microscopy is a tentative but not specific diagnosis.
• Diagnosis with immunofluorescence is rapid and confirmatory. Immunofluorescence detection in urine samples is fast and specific if samples arrive to the laboratory quickly and chilled. Formalin can be added to a final concentration of 0.8% to preserve the bacteria in the sample. As excretion in cattle is intermittent, a negative result does not preclude the disease. Detection of *Leptospira* in aborted fetal tissues by FA has also been reported with variable success.

IMAGING
N/A

PATHOLOGIC FINDINGS
• Calves present with fever, anorexia, depression, (with *L. hardjo*) hemolytic anemia, hemoglobinuria, icterus, and petechiae (with *L. pomona*.)
• Hemoglobinuria typically resolves within 72 hours; anemia begins to resolve at 4–5 days and is typically resolved 7–10 days later.
• Mortality rate in calves is higher than in adult cattle.
• Adult cattle present with abnormal milk (thick, yellow, blood tinged) without obvious inflammation of the mammary gland, or later with abortions.
• Aborted fetuses are usually autolyzed.
• In endemically affected herds, younger animals may have an increased incidence of abortions.

TREATMENT

THERAPEUTIC APPROACH
• Infected animals can be treated with any antibiotics to prevent irreversible liver and kidney damage, abortion, establishment of a carrier state, and hemolytic anemia. *Leptospira* are not found to be developing any antibiotic resistance. Antibiotics such as penicillin, tetracycline, and erythromycin are helpful. Doxycycline prevents dogs from becoming chronic carriers.
• Animals with acute disease may require blood transfusions, oral or intravenous fluid therapy, and other supportive nursing care.
• Treating lactating dairy cattle with agalactia may hasten return to near normal yields, but requires discarding the milk for the withdrawal period. Treatment at this time may also reduce the likelihood of abortion.
• Acute disease in calves should be treated aggressively both symptomatically and with antibiotics. Supportive care can be given through the use of antiemetics for vomiting, antidiarrheal for diarrhea, and fluid therapy usually with lactated Ringer's solution or normal saline.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Tetracycline, 10–15 mg/kg q12h for 3–5 days.
• Long-acting oxytetracycline, 20 mg/kg two doses at 10-day intervals.
• Long-acting amoxicillin, 15 mg/kg, two to three doses 48 hours apart.
• Tilmicosin, 10 mg/kg SQ.
• Ceftiofur sodium 2.2 or 5 mg/kg IM q24h for 5 days or 20 mg/kg IM q24h for 3 days.
• Streptomycin or dihydrostreptomycin, 12.5 mg/kg q12h for 3 days. A single dose of 25 mg/kg will usually clear the carrier state from *L. pomona* or other non-host-adapted serovars.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Appropriate meat and milk withdrawal times must be followed for all compounds administered to food-producing animals.
• Previously, streptomycin, dihydrostreptomycin, or dihydrostreptomycin-penicillin G was used for treatment, but is no longer available in certain countries for use in food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is good if treated early.
• Animal may become a carrier and shed the bacteria.

POSSIBLE COMPLICATIONS
Abortion, early pregnancy loss

CLIENT EDUCATION
Awareness of risk factors: Purchase or comingling with infected animal, access to contaminated water source

PATIENT CARE
Supportive treatment during convalescence.

PREVENTION
• Minimizing access to wildlife, rodents, and contaminated water sources.
• Vaccination using multiple serovars generally confers protection against abortion and death and significantly reduces renal colonization.
• Selection of seronegative replacement stock will help prevent introduction into the herd.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Prompt vaccination and antimicrobial therapy for pregnant beef cows early in the epizoonosis can prevent further abortions.
• Leptospirosis is a zoonotic agent so appropriate hygiene and sanitary methods must be followed by practitioners and owners to prevent transmission.

AGE-RELATED FACTORS
• The acute form more typically affects calves and lambs, subacute form in adult cattle, and chronic form in sheep, goats, and occasionally adult cattle.

ZOONOTIC POTENTIAL
• Leptospirosis has zoonotic potential through direct contact with contaminated urine and the environment. People are also infected by aerosol.
• People working with infected cattle should take precautionary measures such as

LEPTOSPIROSIS (CONTINUED)

protective clothing, rubber boots, latex gloves, and protective eyeglasses or facemasks.

PREGNANCY

• In endemically affected herds, younger animals may have an increased incidence of sporadic abortions.
• Animals in the second half of gestation (>4 months) can suffer invasion of the placenta and fetus during the septicemic phase, resulting in abortion several weeks later.

SYNONYMS

LEUKOCYTE RESPONSES IN CATTLE

BASICS

• Complete blood count (CBC) is indicated to evaluate cattle for the presence of inflammatory, infectious, or neoplastic disorders.
• CBC may improve diagnostic accuracy and treatment monitoring, ultimately helping clients make a more informed decision.
• CBC is a diagnostic test that should be performed based on historical and clinical findings and should never preclude a complete physical examination.
• Blood smear examination is a key component of the CBC because it allows clinicians to verify the white blood cell (WBC) count and the differential cell counts.
• Blood smear is also required to identify neutrophil precursors, neoplastic cells, blood parasites, and morphologic changes in neutrophils and lymphocytes.
• WBC count can be estimated from a blood smear using the following equation:
  ◦ WBC (cells/μL) = 2,000 × mean number of WBCs per field at the 40× objective.
• Blood leukocytes can be classified as:
  ◦ Granulocytes or polymorphonuclear cells: neutrophils, eosinophils, and basophils
  ◦ Mononuclear cells: lymphocytes and monocytes.

Neutrophils

• Neutrophils develop from stem cells located in the bone marrow in about 6 days.
• Once the neutrophil storage pool in the bone marrow is depleted, precursors including band neutrophils, metamyelocytes, and myelocytes are released into the blood.
• Neutrophils usually circulate for 5–10 hours in the blood before entering tissues to phagocytose and kill invading microorganisms.
• Neutrophils migrate very rapidly to tissues and act as a first line of defense, but are incapable of repeated phagocytosis, unlike macrophages.
• Blood neutrophils are either free (circulating neutrophil pool) or temporarily adhered to the vascular endothelium (marginal neutrophil pool).

Eosinophils

• Eosinophils develop in the bone marrow, then circulate for few minutes before entering tissues.
• Eosinophils have a high tropism for tissues, and therefore blood eosinophil counts may not truly reflect tissue eosinophilia.
• Eosinophils play a major role in defense against parasites and modulation of inflammation, especially in allergic disorders.

Basophils

• Basophils develop in the bone marrow, then circulate for a few hours before entering tissues.
• Basophils play a major role in modulation of inflammation in allergic disorders.

Lymphocytes

• Blood lymphocytes include T-lymphocytes, B-lymphocytes, and natural killer cells.
• All lymphocytes arise from a common stem cell located in the bone marrow, then mature within primary lymphoid organs.
• T- and B-lymphocytes mature in the thymus and Peyer's patches, respectively.
• Mature lymphocytes leave the primary lymphoid organs to reside in secondary lymphoid organs including lymph nodes, spleen, bone marrow, and lymphoid tissues in the digestive, respiratory, and urogenital tracts.
• Lymphocytes are specialized in recognizing foreign antigens and mediate the humoral and cellular immunity.
• Blood lymphocytes are either free or adhered to endothelial cells.
• Lymphocytes are unique because these long-lived cells are able to recirculate from peripheral tissues to their lymphoid tissue of origin for several weeks to years.

Monocytes

• Monocytes develop from stem cells located in the bone marrow, then circulate for few days before entering tissues.
• Once in tissues, they may differentiate into different macrophage subtypes including Kupffer cells, alveolar macrophages, microglia, and Langerhans cells.
• Macrophages are specialized in phagocytosing and killing invading microorganisms.
• Macrophages also initiate tissue repair and act as antigen-presenting cells.

OVERVIEW

Leukogram Interpretation Principles

• Lymphocytes are the predominant blood leukocytes in adult cattle with a neutrophil to lymphocyte (N:L) ratio of about 1:2.
• Neonatal calves usually have a N:L ratio of about 1:1.
• Cattle have a limited ability to recruit bone marrow stem cells, and therefore WBC counts are typically lower in the face of acute inflammation than in other domestic animals.
• WBC counts greater than 20,000 cells/μL are considered markedly increased.
• It should be kept in mind that WBC counts vary naturally over time, both as a result of disease processes and biologic variation (age, diet, breed, pregnancy).
• CBC provides a snapshot of a dynamic process, and therefore does not reveal whether the situation is improving or deteriorating.

Reference Intervals

• Reference intervals (RIs) typically represent the central 95% of values of 60–120 healthy animals.
• 5% of healthy animals are expected to have a result outside of the RI for any single test, and therefore a single result outside of the RI should not be overinterpreted.
• Repeat testing is recommended when a test result does not fit the clinical context.
• Use of the term "normal range" is discouraged, because a test result can be within the RI and not be appropriate for the patient's condition.

Preanalytic and Analytic Variation

• Preanalytic variation is associated with patient preparation and handling, time of collection, and sample collection, storage, and handling.
• Analytic variation is associated with accuracy and precision of the hematology analyzer.
• Assessment of the analytic performance of in-clinic analyzers is recommended following instrument purchase and should be repeated annually.
• Standardization and control of preanalytic and analytic conditions may minimize intra- and inter-individual variation.
• Participation in an external quality assurance program is recommended to help ensure accuracy of results.

Sample Collection and Handling

• Blood collected in a tube containing EDTA is the sample of choice for a CBC.
• Blood tubes should be filled to completion to insure the proper blood-to-EDTA ratio and gently inverted several times immediately after filling.
• Blood should be analyzed within 30–60 minutes of collection or stored at refrigerator temperature (4°C) and analyzed within 24 hours.
• Delayed analysis may result in nuclear lobulation or cytoplasmic vacuolization of lymphocytes and marked cellular swelling.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

PATHOPHYSIOLOGY

Neutrophilia

• Neutrophilia is usually caused by an increased production of neutrophils than an increased release from the bone marrow because cattle have a limited pool of neutrophils stored in the bone marrow.

LEUKOCYTE RESPONSES IN CATTLE (CONTINUED)

• Neutrophilia is usually due to acute or chronic inflammation caused by infectious agents, neoplasia, or tissue necrosis
• However, chronic or low-grade inflammation is not always associated with neutrophilia.
• Neutrophilia can also be due to changes in neutrophil kinetics caused by administration or endogenous release of catecholamines or glucocorticoids.

Neutropenia

• Neutropenia develops when margination or migration of neutrophils into tissues exceeds the release of neutrophils from the bone marrow.
• Neutropenia is common in the first 12–24 hours following an acute inflammatory stimulus because the pool of neutrophils stored in the bone marrow is limited.
• Persistent neutropenia is usually caused by severe acute inflammation and associated with degenerative left shift and toxic changes in neutrophils.
• Neutropenia can also be due to a shift from the circulating pool to the marginal pool caused by endotoxemia.

Left Shift

• The term "left shift" indicates the presence of neutrophil precursors in the peripheral blood including band neutrophils, metamyelocytes, and myelocytes.
• Left shift is usually due to severe, often acute, inflammation.
• Degenerative left shift is characterized by the presence of neutrophil precursors in the blood in numbers exceeding the mature neutrophils.
• It indicates an inappropriate production or release of neutrophils and is usually caused by endotoxemia or sepsis.

Right Shift

• The term "right shift" indicates an increased amount of hypersegmented neutrophils in the blood, which is usually caused by administration or endogenous release of glucocorticoids.
• Right shift has also been reported in cattle with bovine leukocyte adhesion deficiency (BLAD) and cobalt deficiency.

Toxic Neutrophils

• Toxic changes refer to morphologic abnormalities of neutrophils including cytoplasmic basophilia or vacuolization, toxic granules, Döhle bodies, and nuclear immaturity.
• It can be caused by any inflammatory disorder severe enough to stimulate neutrophil maturation.

Lymphocytosis

• Lymphocytosis is usually caused by an increased production of lymphocytes due to acute or chronic inflammation.
• Lymphocytosis can also result from neoplastic proliferation of lymphoid cells in lymph nodes, bone marrow, or other lymphoid tissues.
• Lymphoma associated with infection by bovine leukemia virus (BLV) is the most common lymphoproliferative disorder in cattle.
• BLV infection may also cause persistent lymphocytosis (7,000–15,000 cells/μL) without tumors.
• Lymphocytosis can also be due to changes in lymphocyte kinetics caused by administration or endogenous release of catecholamines.

Lymphopenia

• Lymphopenia is usually caused by an increased margination and migration of lymphocytes into tissues, increased movement of lymphocytes to lymphoid tissues, and decreased movement of lymphocytes from lymph nodes.
• Lymphopenia is usually due to changes in lymphocyte kinetics caused by administration or endogenous release of glucocorticoids.
• Lymphopenia can also be due to acute inflammation or bone marrow failure.

Reactive Lymphocytes

• Reactive changes refer to morphologic features of lymphocytes including fine cytoplasmic vacuoles, enhanced cytoplasmic basophilia, and nuclear changes.
• Reactive lymphocytes are seen in cattle with acute or chronic inflammation.
• Inflammation can cause marked lymphocyte atypia that can be very difficult to differentiate from neoplastic changes.

Monocytosis

• Monocytosis is usually caused by an increased production and release of monocytes due to acute or chronic inflammation.
• However, inflammation does not always cause monocytosis.
• Monocytosis can also be due to changes in lymphocyte kinetics caused by administration or endogenous release of glucocorticoids.

Eosinophilia and Basophilia

• Eosinophilia and basophilia are relatively rare but may be seen in cattle with parasitism or allergic disorders.
• Eosinophilia and basophilia are more commonly associated with tissue parasites than blood or gastrointestinal parasites.
• Chronic eosinophilia is usually caused by inflammation affecting mast cell-rich organs including skin, lung, and gastrointestinal tract.

Bovine Leukocyte Adhesion Deficiency

• BLAD is a hereditary disorder described in Holstein cattle.
• BLAD is caused by a single mutation in a gene that encodes an integrin controlling adherence, migration, and aggregation of leukocytes.
• Gene mutation causes neutrophils to lose their ability to adhere to vascular endothelium and migrate to tissues, leading their prolonged circulation in the blood.
• Affected cattle typically have marked neutrophilia and recurrent infections.
• PCR assays are commercially available to identify cattle with BLAD.

Chédiak-Higashi Syndrome

• Chédiak-Higashi Syndrome (CHS) is a hereditary disorder described in Hereford, Brangus, and Japanese Black cattle.
• CHS is caused by a mutation in a gene that controls lysosomal membrane fusion, leading to enlarged lysosomes in leukocytes and pigment cells.
• Presence of enlarged lysosomes in neutrophils, eosinophils, and monocytes is diagnostic.
• Affected cattle usually have a dilute coat color and light-colored irises (pseudoalbinism).
• Recurrent infections and/or excessive bleeding may be present because function of platelets, natural killer, and cytotoxic T-cells is usually altered.

SIGNALMENT

N/A

GENETICS

• BLAD is an autosomal recessive trait in Holstein cattle.
• CHS is an autosomal recessive trait in Hereford, Brangus, and Japanese Black cattle.

PHYSICAL EXAMINATION FINDINGS

N/A

CAUSES AND RISK FACTORS

Neutrophils

Causes of Neutrophilia

• Genetic disorders

(CONTINUED) LEUKOCYTE RESPONSES IN CATTLE

- ◦ Bovine leukocyte adhesion deficiency
- Increased production of neutrophils
  - ◦ Acute or chronic inflammation
    - ■ Common causes include pneumonia, peritonitis, deep digital sepsis, liver abscesses, paratuberculosis, and lymphoma
- Increased release from the bone marrow
  - ◦ Acute or chronic inflammation
  - ◦ Administration of glucocorticoids
  - ◦ Endogenous release of glucocorticoids
    - ■ Common causes include pain, circulatory shock, transportation, handling, and extreme temperatures
- Shift from the marginal pool to the circulating pool
  - ◦ Administration or endogenous release of glucocorticoids
  - ◦ Administration or endogenous release of catecholamines
    - ■ Common causes include pain, circulatory shock, transportation, handling, and extreme temperatures

Causes of Neutropenia

- Decreased production
  - ◦ Bone marrow failure
    - ■ Common causes include bracken fern toxicosis, bovine neonatal pancytopenia, irradiation, myelofibrosis, and neoplasia
- Increased margination or migration into tissues
  - ◦ Severe acute inflammation
- Shift from the circulating pool to the marginal pool
  - ◦ Common causes of endotoxemia include coliform mastitis, puerperal metritis, and salmonellosis.

Lymphocytes

Causes of Lymphocytosis

- Increased production
  - ◦ Chronic inflammation
- Neoplastic proliferation of lymphoid cells in lymph nodes or other tissues
  - ◦ Lymphoma (BLV-associated or sporadic)
- Shift from the marginal pool to the circulating pool
  - ◦ Administration or endogenous release of catecholamines

Causes of Lymphopenia

- Bone marrow failure
  - ◦ Causes of bone marrow failure include bracken fern toxicosis, bovine neonatal pancytopenia, irradiation, myelofibrosis, and neoplasia.
- Shift from the marginal pool to the circulating pool
  - ◦ Acute inflammation
  - ◦ Administration or endogenous release of glucocorticoids

Monocytes

Causes of Monocytosis

- Increased production and release
  - ◦ Acute or chronic inflammation
    - ■ Common causes include pneumonia, peritonitis, deep digital sepsis, liver abscesses, paratuberculosis, and lymphoma
- Shift from the marginal pool to the circulating pool
  - ◦ Administration or endogenous release of glucocorticoids

Eosinophils and Basophils

Causes of Eosinophilia and/or Basophilia

- Allergic disorders
  - ◦ Common causes include dermatitis, eosinophilic enteritis, and milk allergy
- Parasitism
  - ◦ External parasites
  - ◦ Mites, lice fleas or ticks
  - ◦ Internal parasites
    - ■ Lungworms
    - ■ Gastrointestinal strongyles
    - ■ Sarcocystosis

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

Common Leukogram Findings

- Severe acute inflammation is usually associated with neutropenia, degenerative left shift, toxic changes in neutrophils, and lymphopenia.
- Chronic inflammation is are usually associated with neutrophilia and lymphocytosis.
- Administration or endogenous release of glucocorticoids is usually associated with neutrophilia, lymphopenia, and monocytosis.
- Administration or endogenous release of catecholamines is usually associated with transient neutrophilia and lymphocytosis.

OTHER LABORATORY TESTS

- Determination of fibrinogen, haptoglobin, and serum amyloid A can be helpful when chronic or low-grade inflammation is suspected.

IMAGING

- Thoracic or abdominal radiography and ultrasonography may help identify inflammatory disorders including pneumonia, liver abscesses, traumatic reticuloperitonitis, urolithiasis, and lymphoma.

OTHER DIAGNOSTIC PROCEDURES

- Bone marrow examination is indicated when neutropenia persists for more than 3–4 days and/or atypical or unexplained immature cells are observed on the peripheral blood smear.
- Lymph node aspiration or biopsy is indicated in cattle with enlarged lymph node(s) and historical or clinical findings consistent with lymphoma.

PATHOLOGIC FINDINGS

N/A

TREATMENT

N/A

MEDICATIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Severe acute inflammation usually causes neutropenia with left shift followed by neutrophilia after 3–4 days.
- Resolution of degenerative left shift suggests a more favorable prognosis.
- Disappearance of toxic changes in neutrophils suggests resolution of inflammation.
- Persistent lymphopenia suggests ongoing inflammation.
- Marked persistent lymphocytosis is associated with a guarded prognosis until lymphoma can be excluded.

MISCELLANEOUS

AGE-RELATED FACTORS

- WBC and lymphocyte counts are usually higher in younger cattle and decrease with age.
- Neutrophil counts are usually higher in neonatal calves and decrease with age.
- Eosinophil counts are usually lower in younger cattle and increase with age.

PREGNANCY

- Parturition is usually associated with neutrophilia, lymphopenia, and variable monocytosis.

ABBREVIATIONS

- BLAD = bovine leukocyte adhesion deficiency
- BLV = bovine leukemia virus

LIGHTNING STRIKE

BASICS

OVERVIEW
• A discharge of electricity occurring in association with thunderstorms, damaged power lines, or faulty wiring that results in death or injury to one or more animals.
• Sudden death in groups of animals without signs of struggle are strongly suggestive of lightning strike.
• Lightning may cause death after **direct strike** (lightning strikes animals directly), **contact** (electrical charge passing through object (tree or fence) to animal(s)), **side flash** (jumps from one object to animal), **step voltage** (lightning strikes object which allows radiation of energy in all directions including where animal(s) are standing, thereby killing animals instantly), or **blunt trauma** (lightning strike injures animal by knocking it to ground or via falling objects).

INCIDENCE/PREVALENCE
Commonly observed in specific geographic locations during the spring, summer, and early autumn months of the year.

GEOGRAPHIC DISTRIBUTION
Where thunderstorms occur

SYSTEMS AFFECTED
• Multisystemic
• Integument

PATHOPHYSIOLOGY
The massive electrical current and voltage applied to animals by lightning most commonly results in subacute cardiac and respiratory arrest. Neurologic damage in animals can be observed in or around the 4th ventricle, leading to cardiac and respiratory arrest. Survivors may develop multiple organ system dysfunction including severe burns, vascular injury (subcutaneous hemorrhages to DIC), traumatic injury to limbs (falling, blunt trauma), or nerve excitation resulting in massive muscle contraction and thermal injury to muscle. This may result in myonecrosis that may progress to renal compromise in survivors. Renal damage associated with rhabdomyolysis and myoglobinuria can also result in hyperkalemia, hypocalcemia, hyperglycemia, and acidosis. Gastrointestinal effects may be due to direct effect of electrical injury on abdominal organs leading to hemorrhage or the result of blunt trauma secondary to falling or objects striking the animal.

HISTORICAL FINDINGS
• Careful evaluation of animal(s) and immediate environment (up to 40 meters in diameter), for signs of burns, burnt or damaged trees or other objects. Useful information may include number of animals affected, number in herd, specific management practices (feeding, watering, housing), recent medical history of animals, last observation of animal and time of death (if known). History of recent severe weather, although this may confuse some cases.
• Animal(s) found dead often after severe weather storms in areas where thunderstorms are frequent. Animals may be found dead where they were standing in various postures. Single or multiple animals may be found near large trees, against fences, or near watering holes and dead or unconscious. Feed (hay, grass) may be present within the oral cavity. Burn or singe marks on the animal and damage to the environment may be present in cases; however, animals that are electrocuted secondary to charged water or earth or objects (step voltage) may not have visible signs of electrocution (burns).

SIGNALMENT
Any animal. More commonly observed in pastured animals.

PHYSICAL EXAMINATION FINDINGS
• Death is often instantaneous with little visible indication of a struggle. Singe or burn marks on animals are most commonly observed and are commonly present on medial surface of limbs, jaw, neck, and shoulders. Often, singe marks are located at one end of tree (scorch lines). Peripheral blood vessels are often distended with blood that clots poorly. Capillary damage leading to subcutaneous hemorrhage and in some instances subcutaneous gas is noted. Ruminal distension may engorge venous structures with blood from abdomen to cranial aspect of animal. This is often accompanied by blood accumulation in muscle, lymph nodes, and subcutaneous tissues of the thorax, head, and neck. The lungs are generally not compressed as in cases of severe premortem bloat. Nasal mucosal and frontal sinus congestion is observed in some cases, and linear mucosal hemorrhages of the larynx, trachea, and bronchi are present in most cases of lightning-induced death. This may lead to blood-tinged frothy fluid or ropes of clotted blood draining from mouth and nares.
• Infrequently, animals rendered unconscious by lightning strike followed by recovery may manifest neurologic signs and evidence of struggling may be present. A recent report of ocular disease in dairy cows following lightning strike indicates that electrical or blunt trauma to eyes may occur, as is observed in human victims. Swine in outdoor pens struck by lightning manifested acute hindlimb paralysis. Lesions were limited to fractures of caudal lumbar and sacral vertebrae with dorsal displacement of sacral spine and transection of the spinal cord. Bilateral femur fractures were also observed in two calves associated with lightning strike.

GENETICS
N/A

CAUSES AND RISK FACTORS
A recent review demonstrated that season of the year (spring-summer), age of the animal (>1 year), presence of tree(s), water, ruminal distension with feed present in oral cavity were associated with greater odds of lightning-associated fatalities.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Any cause of acute death in livestock. Anthrax (*Bacillus anthracis*), clostridial intoxications (*Clostridium hemolyticum*, *Cl. chauvoei*, *Cl. perfringens*, *Cl. botulinum*), *Mannheimia hemolytica, Histophilus somni* (previously haemophilus somnus), Listeria monocytogenes septicemia, organophosphate, carbamate, lead, ionophore, gossypol, toxic gases, blue-green algae intoxication, Japanese yew, nitrates, cyanogenic plants, salt poisoning, and other toxicants. Necropsy of potentially electrocuted animals is imperative.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Feed or plants consumed may also be evaluated for pesticides, herbicides, and heavy metals.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Necropsy of animal(s) is highly recommended and therefore transport to local state diagnostic laboratory or field necropsy should be performed by a veterinarian. Samples to collect would include heart, lung, liver, spleen, kidneys, gut, lymph nodes, endocrine glands (thyroid, pancreas, adrenals), rumen content, skin and subcutaneous tissues, muscle (especially from limbs), paying particular attention to lesions or abnormalities observed. Samples should be saved for histopathology (10% buffered formalin), toxicology (frozen organs such as liver, kidney, rumen content, whole eyes or ocular fluid aspirates) and microbiology (blood, brain, liver spleen, lymph nodes, kidney, and muscle, thoracic or abdominal fluids, CSF, urine). Samples for microbiology should be collected in sterile containers and stored on ice but not frozen.

TREATMENT

THERAPEUTIC APPROACH
Treatment of survivors should focus on clinical signs. Neurologic sequelae are common, and nonsteroidal and steroidal anti-inflammatory agents, hyperosmolar

LIGHTNING STRIKE (CONTINUED)

agents (mannitol, 50% dextrose, hypertonic saline) to reduce inflammation and swelling in critical locations (CNS, muscle) are recommended. Local wound care for burns and systemic antimicrobial agents. Euthanasia for more severely affected animals may be appropriate.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS
See "Treatment"

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Normally sudden death occurs with lightning strike. The prognosis in cases of survival will vary.

POSSIBLE COMPLICATIONS
Neurologic signs, fractures, paralysis

CLIENT EDUCATION
N/A

PATIENT CARE
Euthanasia is recommended in survivors with severe traumatic injury.

PREVENTION
N/A

LISTERIOSIS

BASICS

OVERVIEW
• The genus *Listeria* contains five species: *L. monocytogenes, L. ivanovii, L. innocua, L. seeligeri, and L. welshimeri*.
• *L. monocytogenes* is the only significant pathogen in this group, causing septicemia, abortion, central nervous system infection, and mastitis in ruminants.
• In ruminants, listeriosis can manifest in several ways, including CNS infection, abortion, septicemia, and mastitis.

INCIDENCE/PREVALENCE
Clinically diseased animals in a group can reach 9% but rarely exceed 1–2%.

GEOGRAPHIC DISTRIBUTION
Worldwide, particularly temperate climates

SYSTEMS AFFECTED
• Reproductive
• Nervous
• Mammary
• Ophthalmic

PATHOPHYSIOLOGY
• Typically *Listeria* causes meningoencephalitis in adults and meningitis in the young after an incubation of 2–3 weeks.
• Infection is thought to occur following injury to mucus membranes of the oral and nasal cavities, conjunctiva, or through the dental pulp when animals are cutting or losing teeth.
• *L. monocytogenes* has been proposed to invade the trigeminal nerves (CN-V) and travels centripetally along the axons to the brain, proliferates in the pons and medulla and can spread elsewhere.
• The trigeminal nerve and its neighboring CN nuclei are subject to injury as a consequence of neuritis, encephalitis, and meningitis.
• *L. monocytogenes* can invade the fetoplacental unit with or without signs of encephalitis or septicemia, typically causing late gestation abortion with or without obvious clinical signs.
• *L. monocytogenes* can also produce septicemia and focal necrosis of the liver and spleen of neonates, after incubation as short as one day. The organism is thought to invade from the GI tract after consumption of colostrum or milk from infected dams.
• Mastitis can be subclinical to severe and suppurative in cattle. Sheep tend to develop chronic inflammatory mastitis, and goats, subclinical interstitial mastitis. The organism is thought to be contracted from feces and the dairy farm environment in these cases.

HISTORICAL FINDINGS
Typically acute to subacute onset of cranial nerve dysfunction (facial paralysis and vestibular signs) in juvenile or young adult ruminants.

SIGNALMENT
• CNS infection—juvenile and adult animals
• Septicemia—common in neonates
• Abortion—reported in adult cattle and sheep
• Mastitis—reported in cattle, sheep, and goats

PHYSICAL EXAMINATION FINDINGS
• Intracranial disease commences with depression, anorexia, decreased milk production, dehydration, and inconsistent fever.
• Neurologic signs are usually asymmetric with conscious proprioceptive deficits, head pressing, obtundation, compulsive circling, and cranial nerve deficits (CNs V through XII). Deficits are described in relation to the inciting lesion location:
  ◦ CN–V—dropped jaw or asymmetric jaw closure, difficulty in prehension and mastication, facial analgesia and anesthesia.
  ◦ CN–VI—ipsilateral medial strabismus.
  ◦ CN–VIII—ptosis, loss of menace response, absent palpebral reflex, droopy ear, decreased lip tone, unilateral drooling, and exposure keratitis. In small ruminants deviation of the philtrum also occurs. Ipsilateral head tilt, nystagmus, and ataxia.
  ◦ Basal ganglia—head pressing, compulsive circling.
  ◦ CN IX and X—dysphagia, salivation, stertor.
  ◦ CN XII—paresis or paralysis of the tongue.
  ◦ Irritation of parasympathetic vagal neurons in the medulla—vomiting and bloat.
  ◦ Spinal myelitis without brainstem disease can occur in lambs, with flaccid paralysis, hemiparesis, tetraparesis, tetraplegia, paraplegia, and recumbency.
• Animals with septicemia display fever, depression, and anorexia. Diarrhea commonly occurs in small ruminants. Neurologic signs are rare. Pregnant does and ewes can abort.
• Adult cattle can develop keratitis, conjunctivitis, or uveitis due to *L. monocytogenes* with no other clinical signs.
• Abortion related to *L. monocytogenes* usually occurs in the last 2 months of gestation in cattle and during the last month in ewes and does. Clinical signs of disease are uncommon in these cases; however, fever, depression, retention of fetal membranes, or endometritis can occur.

GENETICS
N/A

CAUSES AND RISK FACTORS
• *L. monocytogenes* is widely distributed in the environment, contained in soil, vegetation, water, and the feces of different mammals.
• Resistant and persistent in the environment, able to resist high salt concentrations, to grow over a wide pH range (5–9) and temperature range (0 to 45°C). These characteristics are related to some outbreaks.
• Poorly prepared silage does not achieve appropriate acidity (pH <4) and allows the organism to multiply.
• Improper ensiling, excessive dryness of the forage, lack of fermentation caused by trench ensiling, silage inoculants, and other factors such as long fiber length, inadequate packing of forage, use of bunker rather than tower silos, absence of silo covers, and relatively slow feeding, may prevent the silage from achieving a pH <5.
• Quality of fermentation of baled silage is generally less adequate.
• In sheep and goats, pasture contamination is the most likely source in outbreaks, but it can occur in winter and spring when animals are housed indoors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• CNS signs—rabies, otitis media/interna, cranial trauma, thromboembolic meningoencephalitis (cattle), aberrant parasite migration, brainstem abscesses.
• Abortion and mastitis—see relevant chapters.
• Septicemia—salmonellosis, yersiniosis, and enterotoxemia.

CBC/BIOCHEMISTRY/URINALYSIS
• Leukocytosis, neutrophilia, and monocytosis can occur, or leukopenia, neutropenia in the septicemic form.
• Decreased water and feed intake and excessive salivation can create hemoconcentration, hyperproteinemia, metabolic acidosis and hyponatremia, hypochloremia, hypokalemia, and hypocalcemia.
• Hyperketonemia in lactating cattle due to reduced feed intake.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Analysis of CSF—increased nucleated cell count (predominantly monocytes and lymphocytes), increased microprotein. Positive culture supports the diagnosis; however, negative CSF cultures are common.
• ELISA—detects specific antibodies in the milk of animals with mastitis.

PATHOLOGIC FINDINGS
• Minimal gross anomalies. Perivascular cuffing of mononuclear cells and multifocal

LISTERIOSIS (CONTINUED)

inflammatory foci (micro-abscesses) that contain mononuclear cells and predominantly neutrophils, are observed in the brainstem.
• In aborted fetuses—gray-white foci (2 mm) are seen in liver and cotyledons; abomasal erosion has been reported in aborted lambs.

TREATMENT

THERAPEUTIC APPROACH
• Fluid and electrolyte therapy is critical to correct dehydration and severe metabolic acidosis, and can be given orally or IV.
• Manage or prevent exposure keratitis.
• Well-bedded stall with good footing.
• Appropriate antimicrobials.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Temporary rumenostomy can be considered to facilitate the administration of food, water and electrolytes to severely affected valuable animals.

MEDICATION

DRUGS OF CHOICE
• Penicillin: 20,000–40,000 IU/kg, IV, q6–8h for 7 days, then q24h for 14–21 more days.
• Oxytetracycline (100 mg/mL): 10 mg/kg, IV, q12h for 14 days.
• Treatment is usually recommended to continue for at least 1 week beyond apparent cure.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Isolation of *Listeria* spp. requires cold enrichment procedures and extended incubation times which limit timely diagnosis, and false-negative results are common.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis improves if therapy is instituted early in the disease course.
• Sheep and goats respond poorly to treatment and have a higher case fatality rate than cattle.
• Recumbent or comatose animals rarely recover and have a guarded prognosis.
• Abortion usually has a transient effect on fertility and animals tend to resist reinfection.

POSSIBLE COMPLICATIONS
• Exposure keratitis
• Pneumonia
• Myopathy

CLIENT EDUCATION
Focus on prevention measures and the zoonotic potential of this disease.

PATIENT CARE
Consider euthanasia of animals with no improvement after 2–3 days of treatment.

PREVENTION
• Use high quality, low pH silage.
• Avoid contamination of silage with soil or manure.
• Use pasteurized colostrum or milk.
• Keep bulk tank temperatures low.
• Attenuated or killed vaccines have efficacy and are available in some countries (outside of the United States).

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Exposure keratitis
• Aspiration pneumonia

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
• Listeriosis is a food-borne disease of humans, transmitted directly from contaminated meat and raw milk products, or indirectly by contaminated vegetables.
• Most commonly causes miscarriage in pregnant women; septicemia and meningitis can occur in immunodeficient adults.

PREGNANCY
Abortion can occur.

BIOSECURITY
• Aborted fetuses, placentas, and discharges must be handled wearing gloves and a facemask with proper disposal.
• During outbreaks, a high number of asymptomatic animals can shed the organism in their feces; this might have implications for animal transport or biosecurity protocols.

PRODUCTION MANAGEMENT
N/A

SYNONYMS
• Silage disease
• Circling disease

ABBREVIATIONS

LIVER ABSCESSES

BASICS

OVERVIEW

• Hepatic abscesses are a common sequela to ruminal acidosis in cattle fed highly fermentable diets.
• Neonatal calves are susceptible to ascending navel infections, which can occasionally result in hepatic abscesses.
• Foreign bodies can cause abscessation by penetrating the liver parenchyma.
• The most common bacterial species cultured from hepatic abscesses in cattle and sheep are predominantly *Fusobacterium necrophorum,* and also *Trueperella pyogenes* and *Streptococcus*, *Staphylococcus*, and *Bacteroides* spp.
• Liver abscesses represent a major economic loss to producers of feedlot cattle.
• Goats that have hepatic abscesses are usually older than 1 year of age and in poor body condition. The abscesses are usually secondary to a primary disorder and the most common bacterial species involved are *Corynebacterium pseudotuberculosis, E. coli* and other *Corynebacterium* spp.

INCIDENCE/PREVALENCE

• In general the incidence of liver abscesses is increased in ruminants fed diets high in carbohydrates and low in roughage.
• Holsteins are fed a consistently higher energy diet than beef cattle for longer periods; therefore, they have a higher incidence of liver abscesses.
• Feedlot steers have a somewhat higher incidence than heifers, believed to relate to greater feed intake.
• Cattle fed long-stem, dry, coarse hay are more prone to rumen wall penetration and abscess formation.
• Calves born into a dirty environment or that do not receive adequate colostrum are predisposed to ascending umbilical vein infections.
• Cattle in areas where liver flukes are endemic and not provided adequate prophylaxis can have abscesses form along the parasites' migratory tract.

GEOGRAPHIC DISTRIBUTION

Relates to distribution of specific management systems (feedlots) and parasites (flukes).

SYSTEMS AFFECTED

• Digestive
• Integument
• Respiratory

PATHOPHYSIOLOGY

• Liver abscessation in ruminants results from compromise to the integrity of the rumenal wall arising from ruminal acidosis and/or objects penetrating the rumen wall.
• *F. necrophorum* is isolated from 85% of liver abscesses. This organism is a commensal microbe of the rumen. Its primary energy substrate is lactate, allowing it to proliferate in an anaerobic environment that is using highly fermentable substrates to produce lactate.
• As bacteria colonize the ruminal wall, bacterial emboli shed into the vascular drainage of the rumen and enter the portal circulation. Bacteria and other foreign debris are phagocytized from the blood by Kupffer cells and leukocytes in the liver.
• The liver is highly vascular and well oxygenated. The causative anaerobic bacteria have virulence factors that allow them to establish an anaerobic microenvironment in which they can proliferate and produce an abscess.
• *F. necrophorum* has leukotoxin and endotoxic lipopolysaccharides that help defend against phagocytosis, and also promote intravascular coagulation, which results in infarcts in the parenchyma of the liver.
• As the abscess forms it becomes encapsulated with connective tissue. In time, fluid reabsorption and connective tissue infiltration result in scar tissue formation with net loss of hepatic parenchymal tissue.
• Occasionally an abscess may rupture into the venous circulation, resulting in anaphylaxis or showering of the lungs with bacterial emboli. Ruptured abscesses can also cause formation of a thrombus in the caudal vena cava, which can result in portal hypertension and lead to ascites. If an abscess continues to increase in size, it may occlude the common bile duct and prevent bile secretion into the gastrointestinal tract.
• Liver abscesses in neonates result from ascending umbilical vein infections. Neonates that have failure of passive transfer can also form liver abscesses independent of the nidus as they become bacteremic.
• Liver abscesses have also been reported in cattle infected with *Fasciola hepatica*.

HISTORICAL FINDINGS

• Weight loss.
• Reduction in feed intake.
• Decrease in feed efficiency.
• Dairy cows or dairy goats may have a decrease in milk production.

SIGNALMENT

• Liver abscesses have been identified in cows, sheep, and goats.
• In cattle and sheep abscesses are primarily associated with a highly fermentable, low roughage diet, provoking ruminal acidosis.
• Affected goats are usually older than one year and in poor body condition, with an accompanying pathologic disorder.

PHYSICAL EXAMINATION FINDINGS

• Affected animals may display fever, anorexia, stiff gait, diarrhea, and septic joints.
• Epistaxis and hemoptysis may be evident in animals with metastatic pneumonia.
• Most cases are subclinical and are not recognized until slaughter.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Rumen acidosis
• Septicemia/bacteremia
• Ascending umbilical vein infection
• Liver flukes
• Highly fermentable feeds
• Long stem, dry, coarse hay
• Dirty environments (neonates)

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Parasitism
• Malnutrition
• Poor quality feed
• Johne's disease
• Lymphosarcoma
• Traumatic reticuloperitonitis
• Hepatic lipidosis
• Polioencephalomalacia
• Septicemia

CBC/BIOCHEMISTRY/URINALYSIS

• In general, CBC and biochemistry analysis are not reliable indicators of hepatic abscessation. If alterations are observed, they usually support the diagnosis but are not specific.
• CBC may identify leukocytosis characterized by neutrophilia, and increased or decreased total protein. Anemia may be present due to chronic inflammation.
• Serum biochemistry may identify increases in liver enzyme activities (sorbitol dehydrogenase, gamma glutamyltransferase, and aspartate transaminase). If biliary obstruction occurs, direct (conjugated) bilirubin may increase in the serum and bilirubinuria might occur.

OTHER LABORATORY TESTS

Liver function tests are costly and can be challenging to interpret in ruminants.

IMAGING

• Ultrasonography is a useful tool for the diagnosis of liver abscesses, particularly in individual valuable animals. It may not be cost-effective in feedlot settings.
• Ultrasonography can also be used to evaluate the caudal vena cava and lungs of animals with hepatic abscesses.

LIVER ABSCESSES (CONTINUED)

• Radiology can be used to assess the thorax of valuable animals for accompanying pulmonary abscessation from septic emboli.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Abscesses in the liver can appear as large single lesions or as multiple irregular, granular yellow lesions randomly distributed throughout (telangiectasis).
• Abscesses may have a thin capsule and a central area of necrosis and purulent material, or may have a thick fibrous capsule, with a central cavity and little to no purulent material evident. Central mineralization of these lesions may be evident.
• Histologically, abscesses that are a result of bacterial emboli have a central area of coagulative necrosis with numerous phagocytic cells. Bacteria may be present in the center, but more often are concentrated in the periphery of the necrotic core due to the length of time lesions have been present.
• Abscesses resulting from migration of hepatic parasites include focal and multifocal coalescences of eosinophils forming granulomatous inflammation.

TREATMENT

THERAPEUTIC APPROACH
• Treatment is often unrewarding due to the diffuse nature of abscesses and limited blood supply to the heavy capsular lining. However, antibiotic treatment can be combined with supportive therapy and may be effective in some cases.
• Anti-inflammatory agents can be administered to reduce damage from inflammatory factors and to provide pain management.

SURGICAL CONSIDERATIONS AND TECHNIQUES
If the abscess is in an area where it can be accessed surgically, it can be drained. This procedure is cost prohibitive and impractical in most food animal cases.

MEDICATIONS

DRUGS OF CHOICE
• Penicillins, ampicillin, and oxytetracycline are the drugs of choice to treat animals diagnosed with liver abscesses. The drugs are usually administered at very high doses for long periods of time, to facilitate penetration of the abscess capsular lining.
• Antimicrobials used as feed additives for the prevention of abscess formation include bacitracin, oxytetracycline, tylosin, tilmicosin, and virginiamycin.
• Monensin and lasalocid are ionophores that achieve the same purpose.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Antibiotics have the potential to alter normal ruminal microflora which alters feed efficiency.
• Administering high amounts of oxytetracyclines can cause hypocalcemia in cattle.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Antibiotics or drugs that require metabolism by the liver should be used with caution if there are indications that the majority of the liver is diseased.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
The vast majority of liver abscesses are not detected until slaughter, so this is primarily a subclinical disease with major economic impact in the cattle industry.

POSSIBLE COMPLICATIONS
Liver abscesses may result in caudal vena cava thrombosis syndrome.

CLIENT EDUCATION
• Educate clients how to introduce highly fermentable feeds into the diet.
• Feed a balanced ration with enough fiber and roughage.
• Proper neonatal management to prevent failure of passive transfer of immunity and septicemia.
• Ensure the client has an adequate parasite management program to avoid liver fluke infestation.

PATIENT CARE
N/A

PREVENTION
• Prevention of ruminal acidosis by feeding adequate amounts of appropriate roughage is a key factor in reducing the incidence of liver abscesses in animals being fed highly fermentable feeds.
• Roughage increases the amount of saliva produced to buffer VFAs in the rumen. Introducing highly fermentable feeds slowly into the diets of ruminants allows adaptation of the microflora and improves absorptive capacity of the rumen, to prevent a build-up of acidic agents.
• A number of feed additives are used to decrease the incidence of ruminal acidosis and subsequently liver abscesses. These additives include ionophore antibiotics, which control the growth of Gram-positive bacteria in the rumen, and reduce the number of lactic acid producing bacteria.
• Tylosin can be added to feed to directly decrease the number of *F. necrophorum* and *T. pyogenes* bacteria in the rumen, and reduces the incidence of bacterial emboli formed in the ruminal wall that can travel to the liver.
• Regular preventive anthelmintic treatment may reduce the risk of liver flukes producing migratory tracts in the liver that can become infected and abscess.
• Proper environmental management, along with navel dipping and assuring ingestion of an adequate quantity of high-quality colostrum by neonates will help prevent ascending umbilical vein infections.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Rumen acidosis
• Bloat
• Caudal vena cava thrombosis
• Pulmonary arterial thromboembolism
• Laminitis
• Polioencephalomalacia

AGE-RELATED FACTORS
Hepatic abscesses in neonates generally relate to omphalophlebitis.

LIVER FLUKES

BASICS

OVERVIEW

• Liver flukes are Platyhelminthes (flatworms) of the class Trematoda that mainly infect domestic and wild ruminants and camelids; these species typically serve as definitive hosts.
• Three species of liver fluke commonly infect livestock: *Fasciola hepatica* (common liver fluke), *Dicrocoelium dendriticum* (lancet liver fluke), and *Fascioloides magna* (giant liver fluke). *Fasciola gigantica* is significant to ruminants in Asia and Africa.
• Flukes have a relatively long, complex life cycle that requires a snail intermediate host and, for *D. dendriticum*, also an ant intermediate host. Livestock are infected by ingesting the encysted metacercariae stage of *Fasciola* and *Fascioloides* from vegetation, or by ingesting ants containing the metacercariae of *D. dendriticum*.
• Disease arises from parasite-associated inflammation and damage to the liver, and can be exacerbated by secondary infection of the liver with bacterial organisms, particularly *Clostridium.*

INCIDENCE/PREVALENCE

• The prevalence of fluke infestation varies substantially between geographic regions, depending on intermediate host distribution and climactic factors.
• *F. hepatica* tends to be endemic in regions with favorable climactic conditions; prevalence of infection in some regions can exceed 50%.
• *D. dendriticum* infection can achieve 100% in small ruminant flocks in many European and Eastern countries.
• *F. magna* infection can exceed 15% in cattle (a dead-end host) in areas in which the definitive deer hosts are prevalent, particularly the upper Midwestern United States.

GEOGRAPHIC DISTRIBUTION

• *F. hepatica* is found worldwide where intermediate hosts and climactic conditions facilitate the life cycle of this parasite. It has been identified on all continents except Antarctica, and in more than 50 countries.
• *D. dendriticum* is found throughout Europe, the Middle East, Asia, Africa; in North and South America, and in Australia.
• *F. magna* is native to the US, where it has been identified in at least 25 states, particularly the upper Midwest. It was introduced to Europe where it has regional distribution, and it is occasionally identified in imported stock in other countries.
• *F. gigantica* is significant in ruminants in Southern Asia, Southeast Asia, and Africa

SYSTEMS AFFECTED

Digestive

PATHOPHYSIOLOGY

• Adult *Fasciola* and *Fascioloides* flukes reside in the definitive host in either the bile ducts (*Fasciola*) or in thin-walled cysts which communicate with the bile ducts (*F. magna*), and produce operculated ova, which are passed in the feces.
• The most common definitive hosts of *F. hepatica* and *F. gigantica* are cattle and sheep, and species of wild cervidae are definitive hosts for *F. magna*. Fluke eggs release free-living miracidia, which seek out and invade the tissues of the snail intermediate host (often *Lymnaea* spp. or *Galba* spp.) where asexual replication occurs to produce motile cercariae.
• Cercariae escape the snail and attach to pasture and other vegetation, where they mature to encysted metacercariae.
• After ingestion by the definitive or aberrant host, the metacercariae excyst in the bowel and migrate through the intestinal wall, peritoneal cavity, and liver parenchyma, finally taking up residence in either the bile ducts or hepatic cysts to mature to adults.
• Infection with *Fasciola* can result in clinical disease due to blood and protein loss, irritation of the biliary tree, and occasional secondary infection of damaged parenchyma with bacteria, leading to formation of abscesses. Germination of the spores of specific species of *Clostridium* in anaerobic regions of damaged liver tissue can result in severe disease related to infectious necrotic hepatitis or bacillary hemoglobinuria.
• *F. magna* generally becomes encapsulated in infected cattle with no overt clinical signs. However, in sheep, goats, and camelids, *F. magna* tends to migrate continuously; hence, small numbers of these flukes can cause substantial hepatic damage and even death in these species.
• The life cycle of *D. dendriticum* exhibits substantial differences from that of *F. hepatica* and *F. magna.* The intermediate hosts include over 90 species of land snails with broad distribution. Cercariae that leave snails subsequently infect a second intermediate host (often *Formica* spp. ants) in which they mature to metacercariae. Ants are ingested by grazing herbivores and display distinct behavior changes after infection that greatly enhance their chances of being ingested, by migrating to the tips of vegetation and waiting there for extended periods (typically at night).
• Once ingested, excysted juvenile *Dicrocoelium* flukes migrate via the biliary tree versus the hepatic parenchyma, which reduces their potential for significant tissue destruction. However, heavy burdens in small ruminants can cause biliary irritation and inflammation.

HISTORICAL FINDINGS

N/A

SIGNALMENT

• *F. hepatica* affects a range of wild and domestic ruminants, including sheep, goats, and cattle, as well as some nonruminant species. Young animals are more susceptible to infection and more likely to demonstrate clinical disease, and small ruminants are most likely to develop clinical disease. Similarly, *F. gigantica* tends to affect cattle, buffalo, sheep, and goats, again with greater pathogenicity for small ruminants.
• *D. dendriticum* infects a range of domestic and wild ruminants including sheep, goats, cattle, buffaloes, some deer, and camels, and also some nonruminant species. Higher egg counts may be identified in younger animals of grazing age, versus older animals, and small ruminants are most likely to develop clinical disease with heavy burdens.
• The definitive hosts of *F. magna* in the US are white-tailed deer, caribou, and wapiti, and there are a variety of deer hosts in Europe. Domestic ruminants including cattle, sheep, and goats, as well as alpacas and llamas can become infected, but infection is not typically patent. Cattle rarely show clinical disease with infection, but this fluke is highly pathogenic in small ruminants.

PHYSICAL EXAMINATION FINDINGS

• In general, fluke infestation in cattle is typically asymptomatic, though significant burdens, particularly with *Fasciola,* can decrease productivity and may cause poor growth, reduced fertility, weight loss, and ill thrift. Calves with heavy infections may demonstrate anemia, submandibular edema, and ascites.
• Fluke infestation in small ruminants and camelids can also be asymptomatic with light infestations; signs of anemia, anorexia, weight loss, submandibular edema, ascites, and death can occur with moderate to heavy infections of *Fasciola*. However, only one or two migrating *F. magna* flukes can cause substantial damage and death in small ruminants.
• Acute disease resembling acute haemonchosis may occur in small ruminants experiencing heavy burdens of juvenile *Fasciola*, which can occur in outbreak fashion.

(CONTINUED) LIVER FLUKES

• Infectious necrotic hepatitis (infection with *Clostridium novyi* type B) and bacillary hemoglobinuria (infection with *Clostridium haemolyticum*) can result in sudden death in affected ruminants, particularly sheep.
• In alpacas, thrombotic endocarditis inducing signs of cardiac failure including jugular distension, ventral edema, tachycardia, recumbency, and cavitary effusions has been linked to infection with *F. hepatica.*

GENETICS
N/A

CAUSES AND RISK FACTORS
• Presence of the definitive and intermediate hosts involved in the various life cycles influences the probability and prevalence of infection in domestic ruminants and camelids.
• Intermediate hosts of *F. hepatica* are typically amphibious, inhabiting shallow water sources in areas with neutral soils (pH 6–8) and poor drainage. Years with above-normal rainfall and mild temperatures (≥50°F, ≥10°C) promote increased risk of infection.
• Ruminants and camelids grazing low-lying wet pastures or pastures containing lakes or ponds in enzootic regions for *F. magna* are at increased risk.
• Calcareous or alkaline soils are most often associated with *D. dendriticum* infection, likely representing influence on the reproduction and survival of the intermediate hosts; moisture is much less of an influence for this fluke than for *Fasciola* and *Fascioloides.*
• Stress-inducing factors, such as transportation and confinement, can potentially increase egg production (*D. dendriticum*), suggesting that immunosuppression can be detrimental for these infections.
• Gender may present as a risk factor in some systems in which females are exposed to grazing at much higher rates than males or castrated males.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Gastrointestinal nematode infections, particularly *Haemonchus contortus.*
• *Taenia hydatigena* larvae in hepatic parenchyma may require distinguishing at necropsy.

CBC/BIOCHEMISTRY/URINALYSIS
• Anemia and hypoproteinemia (related to hypoalbuminemia) may be observed on CBC.
• Serum biochemistry can reveal elevations in hepatic enzyme activities, particularly GGT.

OTHER LABORATORY TESTS
• Fecal sedimentation is indicated for identification of *F. hepatica* ova, which will not float. The eggs are large, golden brown, and operculated (~140 × 80 µm in size) and should be distinguishable from the ova of the nonpathogenic rumen fluke, *Paramphistomum*. Repeated examinations can be necessary, particularly in subacute or chronic disease in cattle. A commercially available test, Flukefinder®, isolates ova by differential filtration, followed by differential sedimentation, and can identify low numbers of ova.
• Fecal flotation in solutions with a specific gravity of 1.30–1.45 is indicated for identification of the eggs of *D. dendriticum* which are small (~40 × 25 µm), thick-walled, yellowish-brown, and contain miracidium.
• The Flotac® technique is a dual chamber method gaining popularity for use as a diagnostic test to identify a wide range of parasite eggs (including trematodes) from fecal samples.
• A copro-antigen ELISA is available for the diagnosis of *F. hepatica* and an ELISA assay can detect serum antibodies to *D. dendriticum*; both of these tests can identify infection weeks before patency is established.
• PCR-based assays also exist to help distinguish *F. hepatica* from *F. gigantica*.

IMAGING
• Ultrasound can aid diagnosis after 9 weeks post-infection in sheep. Dilation of bile ducts is visible, and moving echogenic forms may be observed within the dilated bile ducts.
• In alpacas with thrombotic endocarditis, ultrasonography can detect echogenic material within the right ventricle and pleural and/or peritoneal effusion.

OTHER DIAGNOSTIC PROCEDURES
Necropsy can identify characteristic liver lesions and/or flukes, and is necessary for confirmation of *F. magna* infection in sheep, goats, and cattle which do not develop patent infections and therefore will not shed *F. magna* ova into the feces.

PATHOLOGIC FINDINGS
• Lesions of *F. hepatica* infestation often reflect chronic infection, resulting in proliferative cholangitis with bile duct dilation, thickening, and fibrosis. In cattle, calcification of bile ducts can occur ("pipe-stem" lesion). The liver may become fibrotic, firm and indurated, and adult flukes are evident within bile ducts.
• Acute disease related to exposure to large numbers of juvenile *Fasciola* can result in an enlarged liver with necrohemorrhagic tracts. The liver surface may be covered with fibrinous exudate, and serosanguineous fluid may be present in the abdominal cavity.
• Thrombotic endocarditis in alpacas is reflected by accumulation of fibrinous material in cardiac chambers (typically the right ventricle); vegetative lesions may be present on cardiac valves with peripheral edema and cavitary effusions evident.
• Heavy burdens of *D. dendriticum* can result in anemia, edema, emaciation, and eventually cirrhosis of the liver with accompanying biliary distension. The small, semi-transparent adult flukes (~10 mm length, and 2 mm wide) may be evident in the biliary tract.
• *F. magna* infection in cattle results in the production of thick-walled cysts that encapsulate the adult flukes but which do not communicate with bile ducts. In small ruminants, severe damage to liver parenchyma can be evident as a result of uncontrolled migration, with necrohemorrhagic tracts in the liver containing black hematin pigmentation.

TREATMENT

THERAPEUTIC APPROACH
• The availability of various flukicidal drugs and their respective efficacy for adults versus juvenile flukes varies between different countries. In the US, available treatments are generally only effective for adult flukes.
• Timing of treatments should be based on local patterns of transmission and is particularly critical if drugs that only reliably affect adult flukes are used.
• In areas with extended transmission seasons for *F. hepatica*, two or even three treatments may be indicated, extending from late summer through spring, to ensure maximum fluke destruction is achieved.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Only two drugs are currently available to treat liver fluke infections in the US—clorsulon (a benzenesulphonamide), and albendazole (a benzimidazole).
• Outside of the US, other drugs available to treat fluke infestations in ruminants also include triclabendazole, netobimin, closantel, thiophanate, brotianide, rafoxanide, and

L

LIVER FLUKES (CONTINUED)

oxyclozanide. Drugs such as triclabendazole have efficacy against juvenile flukes <8 weeks of age.
• No drugs have FDA label approval for treatment of *F. magna*, but it has been suggested to use albendazole at twice the recommended label dose for 2 or 3 consecutive days. Outside of the US, triclabendazole is currently the recommended agent.
• There are no approved flukicidal drugs for alpacas or llamas.
• Clorsulon dosed at 7 mg/kg PO will apparently kill 99% of *F. hepatica* adults and over 85% of flukes >8–12 weeks old. When given subcutaneously at 2 mg/kg (usually in a combination product with ivermectin), or orally at 3.5 mg/kg, clorsulon will kill most adult *F. hepatica*.
• Albendazole dosed at 10 mg/kg PO will kill >70% of adult *F. hepatica*, in addition to other parasites; withholding feed for 24 hours prior to treatment will improve efficacy. Doses of 15 and 20 mg/kg PO have been reported for treatment of *D. dendriticum*.

CONTRAINDICATIONS
• Flukicidal drugs are typically not approved for use in lactating dairy cattle.
• Albendazole should be avoided in pregnant animals.

PRECAUTIONS
• Drug resistance has been reported in *F. hepatica,* including to albendazole, clorsulon, and triclabendazole.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The prognosis for *Fasciola* or *Dicrocoelium* infection is expected to be good, particularly in cattle compared to small ruminants, with appropriate treatment. However, the prognosis is guarded for severe acute disease, particularly in calves and small ruminants.
• The prognosis for *F. magna* infection is excellent in cattle and poor to guarded in small ruminants.

POSSIBLE COMPLICATIONS
• Chronic liver failure
• Infectious necrotic hepatitis
• Bacillary hemoglobinuria

PATIENT CARE
N/A

PREVENTION
• A key management strategy can include preventing access to or proliferation of the intermediate host(s). This can include:
  ◦ Improved pasture drainage (*Fasciola, Fascioloides*).
  ◦ Fencing off natural water sources and marshy areas.
  ◦ Moving animals off suboptimal pastures during high transmission periods.
  ◦ Use of molluscicides – these can be toxic to the host species (copper-containing products in sheep) and are environmentally undesirable.
  ◦ Introduction of turkeys, chickens, geese, and ducks into small pastures (about 50 birds per hectare) to consume snails and ants.
  ◦ Avoiding grazing in the early morning or evenings to reduce the risk of infection with *Dicrocoelium*-infested ants.
• Strategic deworming in the spring or early summer may limit the degree to which snail populations become infected with immature stages of flukes and can limit amplification of infection.
• Deworming prior to introduction of livestock into low-lying pastures will have a long-term beneficial effect.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Concurrent infections with gastrointestinal nematodes is usually present in fluke-infected animals, which will exacerbate the impact of flukes on the host.
• Infectious necrotic hepatitis and bacillary hemoglobinuria can develop in affected hosts (particularly sheep) due to activation of dormant *Clostridium* spores in damaged liver tissue.

AGE-RELATED FACTORS
All ages are susceptible, but young animals are more likely to suffer severe disease.

ZOONOTIC POTENTIAL
• Metacercariae of *F. hepatica* are infective to humans, and present occasional risk through the consumption of contaminated produce such as watercress.
• Metacercariae of *D. dendriticum* are also infective to humans. The occurrence is rare and is usually the result of consumption of infected ants.
• There is no zoonotic transmission directly from animals to humans.

PREGNANCY
Albendazole is potentially teratogenic in early pregnancy.

BIOSECURITY
• *F. hepatica* can be spread between farms by infected rabbits and deer, making eradication almost impossible.
• Fencing of pastures (and ponds) with deerproof fencing should prevent *F. magna* infections in livestock in enzootic areas.

PRODUCTION MANAGEMENT
Flukes, particularly *F. hepatica*, are a significant cause of economic loss, due to morbidity and mortality, treatment expense, reduced productivity, and condemnation of affected livers at slaughter.

SYNONYMS
• *F. magna:* giant liver fluke, large American liver fluke, deer fluke
• *F. hepatica:* liver fluke, common liver fluke
• *D. dendriticum:* small liver fluke, lancet fluke, *D. lanceolatum*

ABBREVIATIONS
• FDA = Food and Drug Administration
• GGT = serum gamma glutamyltransferase activity

SEE ALSO
• Bacillary Hemoglobinuria
• Haemonchosis
• Infectious Necrotic Hepatitis

LOW-FAT MILK SYNDROME

BASICS

OVERVIEW

• Milk fat depression (MFD) is a common nutritional/metabolic condition affecting modern dairy cattle. Sometimes drop in milk fat content is related to normal seasonal changes in lactation that occurs every year; however, occasionally, MFD may be related to nutritional problems. Fat is the most variable milk solid constituent in which several nutritional factors have been related to MFD. Yeast and molds, management, forages and fiber, starch and fats are the major nutritional factors that affect the risk of MFD. Too much fat in the diet of dairy cows is a classic cause of MFD. The amount of fat fed, especially the rumen polyunsaturated fatty acid load (C18:1 + C18:2 + C18:3) or PUFA is the most important risk factor.
• Milk fat depression is also related to low fiber diet content and rumen pH. Rumen pH below 6.0 induces an undesirable biohydrogenation pathway of excessive rumen PUFA to trans-10, cis-12 18:2 fatty acid. This isomer has been strongly associated with low milk fat synthesis at the level of mammary gland. When rumen pH is normal, rumen PUFA are biohydrogenated to different isomers, mostly cis-9, trans-11 18:2 fatty acid. These isomers are not involved in the low synthesis of milk fat.
• When rumen PUFA are > 3.5% of total dry matter content of the diet trans-10, cis-12 18:2 isomers increase dramatically in the rumen. When the only source of fiber is from corn silage, trans-10 fatty acids are also higher as compared with diets based on corn silage and alfalfa hay. In addition, free fatty acids increase the risk of MFD. Conservation processes such as silage rise the levels of free fatty acids from fresh forages. This is because plant lipases are released after cutting the grass. Corn silage contaminated with yeast and molds are also at higher risk for MFD, especially when yeast counts approach 1 million cfu/g.
• A well-balanced diet for a high producing dairy cow should contain no less than 30% of total NDF, no less than 17% of ADF, no more than 44% of nonfiber carbohydrates, no less than 20% of forage NDF, no less than 17.5% crude protein or 11.6% of metabolizable protein, and no more than 6% of fat.

PATHOPHYSIOLOGY

• Milk fat is constituted by short, medium and long chain fatty acids and minor lipids. They are formed by two mechanisms. The mammary gland synthesizes short and medium chain fatty acids (C4:0 to C14:0) and part of the palmitic acid (C16:0) from acetate and butyrate. The long chain fatty acids (> C16:0 and the rest of palmitic acid) are incorporated into milk fat directly from dietary lipids and from the mobilization of adipose tissue (triglycerides) in the form of nonesterified fatty acids.
• Biohydrogenation process of RUFAL is modified in favor of trans-10, cis-12 linoleic acid (C18:2) under certain rumen environmental conditions. Risk factors for this alteration are high levels of rumen PUFA (> 3.5% of total DM), high levels of dietary starch, free fatty acids, silages, yeast and molds, low levels of effective fiber, and overall poor management.
• Trans-10, cis-12 linoleic acid is transported through the blood towards the mammary gland. At the level of parenchyma cells this isomer alters gene expression of key enzymes for the de novo fatty acid synthesis. The end result is low production of short and medium chain fatty acids with the consequent MFD.

SIGNALMENT

Holstein cows at or after peak lactation are at higher risk.

HISTORICAL FINDINGS

Fat may drop dramatically from 3.4% to 2.5%. In addition, the rumen acetate : propionate ratio may also drop from 3.1 to 1.7, but most likely due to high production of propionate and maintenance of levels of acetate.

CAUSES AND RISK FACTORS

Milk fat depression is a consequence of changes in dietary lipids as they pass through the rumen. Biohydrogenation of polyunsaturated fatty acids in the rumen leads to several isomers (18) of conjugated linoleic acid (CLA), trans-fatty acids, and saturated fatty acids. Under certain rumen negative conditions, three CLA isomers, especially trans-10, cis-12 CLA predominate over the rest. This isomer has an inhibitory effect on milk fat synthesis at the level of the mammary gland.

Risk Factors

• High dietary levels of polyunsaturated fatty acids (>3.5% of total dry matter).
• Type of oil. Fatty acids from canola oil are less dangerous than fatty acids from corn oil.
• Low-forage diets and excessive grain with large amount of rumen propionate.
• Small forage particle size (effective or forage NDF).
• Type of forages. Annual ryegrass is less likely than rye to decrease milk fat content.
• Conservation methods. Hay and silages are more harmful than fresh forages.
• Processing of grains. Overheated cotton seed is more likely to produce MFD than normal.
• High rates of starch degradability (>85%) in a 7-hour in vitro test.
• Moldy and spoiled feed and high count of yeast.
• Large amounts of dietary free-fatty acids.
• Use of ionophores.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Milk fat depression is diagnosed through milk plant fat determination and/or monthly milk fat test day records.

TREATMENT

THERAPEUTIC APPROACH

• MFD is a multifactorial problem. No single dietary factor is responsible for MFD. Interaction among various risk factors can increase the rumen production of milk fat inhibitory CLA isomers. Proper feed management and control of all risk factors should be the main objective.
• Some preventive or complementary strategies should be the addition of rumen buffers or replacement of dietary starch by rich-pectin by-products (e.g., almond hulls, whole cotton seed, soy hulls, beet or citrus pulp) to modulate rumen pH.

LUMPY SKIN DISEASE

BASICS

OVERVIEW
• Lumpy skin disease (LSD) is a viral disease related to a capripoxvirus infection of cattle.
• Disease is characterized by deep dermal skin nodules that eventually undergo central necrosis.
• Affected animals also usually have a high fever and generalized lymphadenitis.

INCIDENCE/PREVALENCE
Depending on the susceptibility of the cattle
• Channel Island breeds:
  ◦ Most susceptible
  ◦ Morbility may range from 3% to 80%
  ◦ Mortality is very low (1-3%)

GEOGRAPHIC DISTRIBUTION
Endemic throughout most of Africa and Madagascar with occasional incursions into the Middle East.

SYSTEMS AFFECTED
• Integument
• Digestive

PATHOPHYSIOLOGY
• Disease arises from systemic capripoxvirus infection that affects primarily the skin and mucus membranes of cattle.
• Animals become viremic with systemic spread to epithelial tissues throughout the body.
• The incubation period varies between 7 and 28 days with most cases observed 10–12 days after exposure.

HISTORICAL FINDINGS
Formation of skin nodules over the body approximately 48 hours after onset of fever.

SIGNALMENT
Channel Island breeds are most susceptible; calves more so than adults.

PHYSICAL EXAMINATION FINDINGS
• Fever (104–107°F, 40–42°C) is the first clinical sign and may persist up to 4 weeks.
• 1–5 cm nodules develop under the skin, usually within two days of fever onset and primarily affect the neck, muzzle, nares, eyelids, dorsum, legs, scrotum, perineum, mammary gland, teats, and tail. The oral mucosa may also become involved.
• Nodules enlarge and involve the epidermis, dermis, and subcutaneous tissues, and can involve the superficial musculature. Nodules are often painful to the touch.
• Lesions can involve the mucus membranes of the mouth, esophagus, rumen, trachea, and lungs, which may result in dysphagia, respiratory distress, and pneumonia.
• Edematous nodules eventually become necrotic and collapse centrally, leaving an umbilicated lesion with a central necrotic core covered by a scab (sitfast). These lesions heal slowly and are often complicated by secondary bacterial infection.
• Necrotic lesions may take up to 5–6 weeks to heal and nodules may remain for some time.
• In severe infections, lameness may occur due to cutaneous nodules causing swelling and inflammation in the joints, tendon sheaths, and coronary bands.
• Lymph nodes draining infected regions may become large and swollen.
• Late-term abortions can occur in infected animals, believed to relate to high fever rather than fetal infection.
• Bulls may become sterile due to fever and mechanical damage to the skin and mucosa of the prepuce and penis, or from virus-induced orchitis.

GENETICS
The virus affects cattle (*Bos taurus* and *Bos indicus*) but experimental infection has been demonstrated in giraffe and impala. Many African wildlife species have seroconverted but have not been observed with lesions.

CAUSES AND RISK FACTORS
• Transmission of LSD is believed to be mechanical, by an arthropod vector.
• *Aedes aegypti* mosquitoes can infect susceptible cattle 2–6 days after feeding on infected/viremic cattle.
• Stable flies (*Stomoxys* sp.) have been shown to maintain live LSD virus after feeding on infected cattle but have not demonstrated transmission of the disease.
• Hard ticks might possibly also transmit the virus. *Rhipicephalus* (*Boophilus*) *decoloratus* ticks display transovarian and transstadial transmission of LSD virus; *Rhipicephalus appendiculatus* and *Amblyomma hebraeum* ticks display transstadial transmission.
• Outbreaks of LSD tend to occur most commonly during rainy seasons.
• Cattle are viremic for 2 weeks; all body secretions, blood, and nodules contain virus; viral DNA can be identified in semen for up to 5 months post-exposure.
• Contact with infected scabs and fomites can also spread disease to a lesser extent. Movement of contaminated raw hides has been implicated in some outbreaks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Insect bites and associated urticaria.
• *Hypoderma bovis* infection.
• Photosensitization.
• Bovine papular stomatitis—usually affects the lips, muzzle, and oral and esophageal mucosa without fever or pain, and young animals are usually the only animals affected in the herd.
• Bovine herpes mammillitis (pseudo-LSD).
• Cowpox/pseudocowpox viruses—superficial pox-like lesions occur in the dermis of the teats and udder, and are not as deep or as extensive as in LSD.
• Dermatophilosis.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Biopsies of early lesions that have not scabbed can be used for virus isolation, histopathology, electron microscopy, PCR and ELISA testing.
• Aspirates of swollen lymph nodes should be placed in viral transport media and shipped on ice for virus isolation.
• Whole blood (heparinized or EDTA) can detect early viremia.
• Acute and convalescent sera should be obtained for serologic testing.

PATHOLOGIC FINDINGS
• Gross findings consist of generalized skin (dermal) nodules of 1–5 cm diameter composed of edema, hemorrhage, and necrotic debris. Older nodules have a central center of necrosis with a central scab present.
• Individual or coalescing pox lesions can be present in the oral cavity, nares, pharynx, esophagus, and trachea. These lesions reflect coalescing thickening of the mucosa and submucosa with some edema, hemorrhage, and necrosis.
• Lymph nodes are swollen and enlarged.
• Pox lesions may be present in the urinary bladder mucosa/submucosa and testicles.
• Fibrin may be present in joints and tendon sheaths.
• Histopathologically, early skin lesions consist of swelling of the dermis with edema and some hemorrhage.
• Variable numbers of lymphocytes, neutrophils, and macrophages are present in the dermis with some fibroblastic proliferation present. Older lesions have vasculitis and thrombosis of vessels with necrosis of the associated tissues.
• The epidermis is acanthotic with orthokeratotic and parakeratotic hyperkeratosis, ballooning degeneration of the stratum spinosum, and necrosis of keratinocytes.
• Eosinophilic intracytoplasmic inclusions are present in swollen keratinocytes in the epidermis and in macrophages, fibroblasts, and endothelial cells in the affected dermis and subcutis. In old infarcted lesions, inclusion bodies are usually absent.

(CONTINUED) LUMPY SKIN DISEASE

TREATMENT

THERAPEUTIC APPROACH
• LSD is a reportable disease in most areas of the world. Notification of state and/or federal veterinary authorities is important if there is suspicion of this disease.
• Treatment is supportive.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Antipyretic drugs (such as flunixin meglumine) can relieve fever and improve appetite.
• Antibiotics are indicated for severe secondary bacterial infections of the skin, mammary gland, joints, or tendon sheaths.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Antibiotic selection for treatment of bacterial complications should be based on antimicrobial sensitivity of the offending agent.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• In naïve animals, morbidity can reach 85–100% but mortality is usually low (<3%).
• In severe cases, lesions may persist for up to 6 months.
• Secondary bacterial infections are common.

POSSIBLE COMPLICATIONS
• Secondary bacterial infections of necrotic lesions.
• Bacterial infections of lesions of the mammary gland, joints, and penis can cause serious complications including loss of the mammary gland and loss of breeding capability in males.

CLIENT EDUCATION
Insuring that clients restrict movement of affected animals is key to preventing spread.

PATIENT CARE
• Sick animals should be monitored for secondary bacterial infections of the skin.
• Animals in regions in which old world screwworms are endemic should be kept under observation for wound myiasis.

PREVENTION
• In endemic areas, vaccination has been successful in controlling outbreaks; options include a live attenuated version of the sheeppox virus, or live attenuated Neethling virus.
• The control of insects has not proven effective at stopping spread.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Bacterial infections of necrotic lesions are common.

AGE-RELATED FACTORS
Calves are more susceptible than adults.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Late-term abortions can occur related to fever.

BIOSECURITY
Affected animals should be quarantined and movement restricted.

PRODUCTION MANAGEMENT
Infection results in economic losses due to body condition loss, reductions of milk yield, and devaluation of hides.

SYNONYM
Neethling poxvirus

LUPINE TOXICITY

BASICS

OVERVIEW

• Lupines (*Lupinus* spp.) cause two distinct forms of poisoning in livestock: lupine poisoning and lupinosis. Alkaloid-containing lupines are *Lupinus formosus* and *L. arbustus*.
• Lupine poisoning is a nervous syndrome caused by alkaloids present in bitter lupines.
• Lupinosis is a mycotic disease characterized by liver injury and jaundice.
• The genus *Lupinus* contains a large number of species. In some parts of the world they form a useful fodder crop.
• Lupines are found in climax and grassy habitats and are toxic even when dry.
• Many species of lupines contain quinolizidine or piperidine alkaloids known to be toxic or teratogenic to livestock.
• Defects caused by quinolizidine and piperidine teratogens include cleft palate and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis.
• Lupinosis affects sheep, and occasionally cattle. Horses and pigs are also susceptible.
• Cleft palate and minor front limb contractures are induced in calves by maternal ingestion of the piperidine alkaloid-containing lupines, *Lupinus formosus* and *L. arbustus.* Crooked calf disease, which includes an occasional cleft palate, is a congenital condition of widespread occurrence in cattle in the western United States and Canada. It is known to occur after maternal ingestion of certain species of *Lupinus* during specific gestational periods.

INCIDENCE/PREVALENCE

Like most toxic plants, incidence is variable. Crooked calf disease generally has been seen to affect <10% of a herd but incidence varies by year, area, and herd.

GEOGRAPHIC DISTRIBUTION

• *Lupinus* has two principal areas of distribution in the world: The first is the western North and South America, and second is the Mediterranean region.
• In North America, the genus is most abundant in the western half. Only a few species occur in the eastern half of the continent.

SYSTEMS AFFECTED

• Multisystemic
• Nervous
• Reproductive

PATHOPHYSIOLOGY

• The toxic and teratogenic effects from these plant species have distinct similarities including maternal muscular weakness and ataxia and fetal contracture-type skeletal defects and cleft palate.
• It is believed that the mechanism of action of the piperidine and quinolizidine alkaloid-induced teratogenesis is the same; however, there are some differences in incidence, susceptible gestational periods, and severity between livestock species.
• Although many lupine species contain quinolizidine alkaloids including the teratogenic alkaloid anagyrine, *L. formosus* and *L. arbustus* produce piperidine alkaloids including the reported teratogen ammodendrine. In addition to ammodendrine, *L. formosus* contains both N-acetyl hystrine and N-methyl ammodendrine, whereas *L. arbustus* contains ammodendrine, trace amounts of N-methyl ammodendrine, and no N-acetyl hystrine.

SIGNALMENT

Most common in sheep and cattle

PHYSICAL EXAMINATION FINDINGS

Lupine Poisoning

• Inappetence and dyspnea, depression, ataxia, muscle twitching, labored breathing, violent struggles, convulsions, and hyper-excitability.
• Signs are most common in sheep but all ruminants are susceptible.
• Cattle will display excess salivation, protrusion of the nictitating membrane, weakness, recumbency, and death.
• Death is due to respiratory paralysis. It may be acute or take 2–3 days.
• There is no icterus.
• Defects caused by quinolizidine and piperidine teratogens include cleft palate and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis.

Lupinosis

• Early signs in sheep and cattle may include inappetence and listlessness, blisters, erythema, edema, reluctance to move, constipation, hemoglobinuria, hepatoencephalopathy (head pressing and wandering into fences); complete anorexia and jaundice follows, and ketosis is common.
• Cattle may show lacrimation and salivation.
• Ruminants may become photosensitive. In sheep with heavy fleece, lesions occur on head and coronary band, but in shorn sheep lesions can occur on the back. Sheep can also have extensive head edema. Onset of lesions may just take hours and initially include erythema and edema followed by blisters, exudation, necrosis, and sloughing of necrotic tissue. In cattle, lesions occur on areas of the body that are nonpigmented and on the teats, udder, perineum, and nose.
• In acute outbreaks, death occurs in 2–14 days.

CAUSES AND RISK FACTORS

Lupine Poisoning

• Acute poisoning occurs when a considerable amount of the plant is eaten in a short time.
• Lupins contain a number of alkaloids; D-lupanine is the most toxic and the most widely distributed.
• The concentration of alkaloid is greatest in the seeds, and the plants are most dangerous at the seeding stage.
• The alkaloids are not destroyed by drying.
• Lupine-induced "crooked calf disease": Crooked calf disease is characterized as skeletal contracture-type malformations and occasional cleft palate in calves after maternal ingestion of lupines containing the quinolizidine alkaloid anagyrine during gestation days 40–100.
• Toxic and teratogenic effects have been linked to structural aspects of these alkaloids, and the mechanism of action is believed to be associated with an alkaloid-induced inhibition of fetal movement during specific gestational periods.

Lupinosis

• The causal fungus is *Phomopsis leptostromiformis*, a phytopathogen causing phomopsis stem blight, especially in white and yellow lupines; blue varieties are very resistant.
• The fungus is also a saprophyte and under favorable conditions grows well on dead lupine material.
• The fungus produces hepatotoxic secondary metabolites. The main one is phomopsin A.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Lupinosis

Acute aflatoxicosis

Photosensitization

• Chronic fluke damage
• Congenital porphyria
• Liver disease
• Phenothiazines
• St. John's wort
• Toxin absorption

Arthrogryposis

• BVD, IBR, bluetongue virus, akabane virus, and Cache Valley virus.
• Arthrogryposis-hydranencephaly syndrome (AHS) in lambs may be confused with spider lamb syndrome (SLS), in which there is characteristic hyperflexion of forelimbs, cranial overextension of hindlimbs, with a corkscrew deviation of the spine. In lambs with AHS, severe deformities result from primary abnormalities of the CNS and not of the skeleton. Hydranencephaly, micromyelia, hydrocephalus, and cerebellar hypoplasia are also seen with AHS.

CBC/BIOCHEMISTRY/URINALYSIS

Lupine poisoning: Elevated serum GGT, AST, LDH, and GDH concentrations

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

(CONTINUED) LUPINE TOXICITY

PATHOLOGIC FINDINGS

Lupine Poisoning

- No icterus
- No characteristic postmortem lesions

Lupinosis

- In acute disease, icterus is marked. Livers are enlarged, orange-yellow, and fatty.
- Chronic disease shows bronze- or tan-colored livers that are firm, contracted in size and fibrosed, and often likened to a boxing glove.
- Copious transudate may be found in the abdominal and the pericardial sac.

Histopathologic Findings

Lupinosis: Diffuse scattered hepatocyte necrosis with a background of mitotic figures, often appearing to be arrested in metaphase. Later in the course of the disease, diffuse fibrosis and biliary hyperplasia predominate.

TREATMENT

THERAPEUTIC APPROACH

Lupine Poisoning

Remove animals from the source.

Lupinosis

- Frequent surveillance of sheep or cattle, and of lupine fodder material for characteristic black spot fungal infestation, especially after rain.
- The utilization of lupine cultivars, bred and developed for resistance to *P. leptostromiformis*, is advocated.

MEDICATIONS

DRUGS OF CHOICE

Lupine Poisoning

None

Lupinosis

Oral doses of zinc (0.5 g of zinc or more, per day) are useful in protection from phomopsin-induced liver injury in sheep.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

With acute lupine poisoning, if the animal survives it will likely make a full recovery, because the lupine alkaloid is readily excreted in the urine.

POSSIBLE COMPLICATIONS

Lupines have a marked teratogenic effect on cattle and give rise to crooked calf disease, characterized by arthrogryposis, scoliosis, torticollis, and cleft palate.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Liver failure, respiratory failure, cleft palate, and contracture-type skeletal defects such as arthrogryposis, scoliosis, torticollis, and kyphosis.
- Cleft palate and minor front limb contractures are induced in calves by maternal ingestion (crooked calf disease).

PREGNANCY

Crooked calf disease is characterized as skeletal contracture-type malformations and occasional cleft palate in calves after maternal ingestion of lupines containing the quinolizidine alkaloid, anagyrine, during gestation days 40–100.

PRODUCTION MANAGEMENT

- Producers should be aware of the association between certain toxic plants (e.g., lupines) and angular limb deformities such as CCD.
- To reduce the incidence of crooked calf syndrome, graze lupines during their least hazardous growth period and reduce exposure of pregnant cows. Lupines are most hazardous when either young or in the mature seed stage.
- Fence off heavily infested pasture areas and use intermittent, short-term grazing of lupine pastures.

SYNONYM

Crooked calf syndrome

ABBREVIATIONS

- AHS = arthrogryposis-hydranencephaly syndrome
- AST = aspartate aminotransferase
- BVD = bovine viral diarrhea
- CNS = central nervous system
- GDH = glutamate dehydrogenase
- GGT = gamma-glutamyl transferase

LYMPHOCYTOSIS

BASICS

OVERVIEW
• Absolute number of lymphocytes greater than the reference range—bovine >7,500/μL; ovine >9,000/μL; caprine >,9000/μL; camelids >7,000/μL.
• Absolute lymphocyte counts are greater in young animals than adults.

INCIDENCE/PREVALENCE
• Pathologic lymphocytosis is uncommon in ruminants except for cattle infected with bovine leukosis virus (BLV).
• Sporadic lymphosarcoma with concurrent lymphocytosis (also known as calf or juvenile form) is extremely rare and multiple cases within the same herd are even less common.

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Hemolymphatic

PATHOPHYSIOLOGY
• Lymphocytes are produced in the bone marrow, lymph nodes, spleen, thymus, and Peyer's patches.
• Lymphocytes retain mitotic capability and can recirculate from the blood to lymphoid tissue. The number of lymphocytes in the blood represents a balance between cells leaving and entering circulation. Therefore, changes in peripheral lymphocyte counts may not necessarily indicate altered lymphopoiesis.
• Blood lymphocytes represent an assortment of lymphocyte subpopulations including B- and T-lymphocytes. B-cells are involved with humoral immunity and produce antibodies, while T-lymphocytes are responsible for cell-mediated immunity and cytokine responses involved in immune system regulation.
• Approximately 95% of all lymphocytes are B- and T-lymphocytes with T-cells predominating. The remaining lymphocytes make up a third group classified as "null" cells. Null cells consist of several subtypes including large granular lymphocytes and natural killer cells.
• In general, most lymphocyte subtypes cannot be identified on a blood film examination. However, large granular lymphocytes are occasionally observed in ruminant blood and can be recognized by the presence of small, red cytoplasmic granules.
• Infrequently, activated B-lymphocytes (i.e., immunoblasts) are identified on blood film evaluation by their large size, deep blue cytoplasm, and perinuclear clear zone.
• Ruminant lymphocytes generally have diameters equal to those of neutrophils, but can be quite irregular in size.
• Hepatosplenomegaly may occur as a result of hyperplasia or neoplasia; bone marrow may be hyperplastic; neoplastic populations of lymphocytes may rarely result in anemia and thrombocytopenia due to myelophthisis.

SIGNALMENT
• Reference values for absolute lymphocyte counts vary with ruminant species. Sheep and goats have higher mean absolute lymphocyte counts than cattle or camelids. However, alpacas and llamas generally have lower lymphocyte counts than camels.
• Sporadic lymphosarcoma (calf or juvenile form) generally affects calves 3–6 months of age, but may be observed in calves as young as 1 month or cattle as old as 3 years.
• Lymphocytic leukemia and BLV-associated lymphosarcoma affect adult ruminants >2 years of age.

PHYSICAL EXAMINATION FINDINGS
• If cause is physiologic (rare cause in ruminants), excited or fearful.
• If cause is persistent lymphocytosis associated with subclinical stage of BLV infection, affected cattle rarely exhibit clinical signs.
• If cause is pathologic (sporadic lymphosarcoma, lymphosarcoma, or lymphocytic leukemia), lymphadenopathy, anorexia, decreased milk production, poor body condition. Depending on the involvement of other organ systems, melena or diarrhea (intestinal tract), heart failure (myocardium), posterior paresis/paralysis (spinal canal), pelvic masses (uterus), and exophthalmia (retrobulbar tissue) may be observed. Anemia may result in pale mucus membranes, tachypnea, and tachycardia.

CAUSES AND RISK FACTORS
Physiologic
Epinephrine release due to excitement, pain, fear, restraint. The change occurs within minutes and usually lasts <30 minutes. Effect is usually observed in young healthy animals. Physiologic lymphocytosis is uncommon in most ruminants.

Antigenic Stimulation
Uncommon cause, but may occur occasionally with chronic viral or bacterial infections (e.g., caprine arthritis encephalitis virus, bacterial pneumonia) and within 10–14 days of vaccination.

Persistent Lymphocytosis
Subclinical BLV infection in cattle results in decreased B-cell turnover and an inverted B:T cell ratio. B cells in this condition are non-neoplastic.

Sporadic Lymphosarcoma
Cause is unknown.

Lymphosarcoma or Lymphocytic Leukemia
• Although reported in all ruminant species, lymphosarcoma with lymphocytosis and lymphocytic leukemia are rare except in cattle infected with BLV.
• Approximately 30% of BLV-infected cattle are leukemic. Lymphocytosis is primarily due to decreased cell death of B-cells.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Transient physiologic lymphocytosis typically occurs in young, healthy, and excitable animals.
• Persistent lymphocytosis (3-months duration) in cattle without clinical signs is associated with subclinical BLV infection.
• Ill cattle with absolute lymphocytosis—consider lymphosarcoma or lymphocytic leukemia; may be seropositive for BLV.

CBC/BIOCHEMISTRY/URINALYSIS
Physiologic Lymphocytosis
CBC
• Mild lymphocytosis
• Rarely, mild increases in RBC, Hgb, and PCV due to epinephrine-mediated splenic contraction
• Mild neutrophilia
• Plasma proteins typically normal
Serum Biochemistry/Urinalysis
No characteristic changes

Persistent Lymphocytosis of Cattle
CBC
• Mild to moderate lymphocytosis that persists over an interval of at least 3 months.
• Morphologically atypical and large lymphocytes may be present on blood film examination, but similar lymphocytes may occasionally be observed in normal cattle or cattle with various non-BLV-associated conditions.
Serum Biochemistry/Urinalysis
No characteristic changes

Lymphocytic Leukemia
CBC
• Marked to severe lymphocytosis with atypical lymphocytes observed in approximately 50% of the cases. (Approximately 5%–10% of BLV-infected cattle manifest with massive increases in circulating neoplastic lymphoblasts, but <2% develop lymphosarcoma.)
• Anemia (may be regenerative or nonregenerative depending on cause).
• Plasma proteins may be decreased if there is neoplastic involvement of gastrointestinal tract.
Serum Biochemistry/Urinalysis
No characteristic changes.

OTHER LABORATORY TESTS
• For cattle with persistent lymphocytosis—BLV antibody ELISA or AGID.
• Bone marrow evaluation in cases of lymphocytic leukemia often reveals a large population of infiltrating lymphoblasts.

(CONTINUED) LYMPHOCYTOSIS

IMAGING
Radiographic or ultrasonographic imaging may reveal evidence of hepatosplenomegaly.

OTHER DIAGNOSTIC PROCEDURES
• Fine-needle aspiration cytology and culture of enlarged lymph nodes is occasionally helpful in differentiating an abscess from lymphosarcoma.
• Histopathologic examination of tumor or lymph node biopsies may be more useful than cytology in confirming lymphosarcoma.

PATHOLOGIC FINDINGS
• No gross or histologic lesions with physiologic or persistent lymphocytosis.

TREATMENT

THERAPEUTIC APPROACH
Physiologic Lymphocytosis
Treatment is not warranted as lymphocyte counts typically return to normal within 30 minutes.

Lymphocytosis Due to Antigenic Stimulation
Treatment should be directed at the primary disease causing the lymphocytosis.

Lymphosarcoma and Lymphocytic Leukemia
No curative treatment for lymphosarcoma or lymphocytic leukemia exists in ruminants. Supportive or palliative therapy may be indicated to reduce discomfort.

MEDICATIONS

DRUGS OF CHOICE
• Chemotherapeutics: Case report data regarding chemotherapy are rare. A few reports summarizing unsuccessful attempts in treating lymphosarcoma and lymphocytic leukemia with dexamethasone and cylcophosphamide exist. Drug withdrawal periods must be determined and maintained.
• Fluid therapy: Rehydration with IV fluids appropriate for the primary cause (e.g., polyuric renal failure, diarrhea, etc.) and to correct any electrolyte and acid-base imbalances.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Persistent Lymphocytosis of Cattle
Precedes the onset of lymphosarcoma in approximately 65% of cases, but <5% of cows with persistent lymphocytosis develop lymphosarcoma.

Sporadic Lymphosarcoma
Rapidly progressive and usually fatal within 2–8 weeks of onset.

Lymphosarcoma or Lymphocytic Leukemia
The prognosis for patients with lymphosarcoma or lymphocytic leukemia is poor, with median survival times following diagnosis of <2–3 months.

PATIENT CARE
Restrict activity

PREVENTION
See chapters Bovine Leukemia Virus, Leukocyte Responses in Cattle, and Lymphosarcoma for control suggestions.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Persistent lymphocytosis of cattle is associated with BLV infection.

AGE-RELATED FACTORS
• Young animals—lymphocyte counts generally increase from birth to a maximum at approximately 11–12 months of age. Absolute lymphocyte counts begin to slowly decline in adult animals.
• Physiologic lymphocytosis occurs in young healthy animals.
• Sporadic lymphosarcoma occurs most commonly in 3- to 6-month-old calves.
• Lymphosarcoma and lymphocytic leukemia generally occur in adult animals >4 years.

ZOONOTIC POTENTIAL

LYMPHOSARCOMA

BASICS

OVERVIEW

• Lymphosarcoma is a lymphoid cancer caused by a single-stranded RNA retrovirus that integrates into the host cell genome.
• The cause of lymphosarcoma in cattle and sheep is believed to be bovine leukemia virus. Cattle are the natural host for BLV. However, only about 30% of BLV-positive cattle develop persistent lymphocytosis and only 5% of these develop lymphosarcoma.
• There are four forms of bovine leukemia: juvenile, thymic, cutaneous, and enzootic. The first three are considered sporadic because the animals are BLV negative for antibodies. The enzootic bovine leukemia animals are positive for BLV antibodies, have persistent lymphocytosis, and can develop lymphosarcoma.
• It can be hard to distinguish between the thymic form of BLV and lymphosarcoma.
• There are no indicators to predict which animals with persistent lymphocytosis will develop lymphosarcoma.
• BLV has not been associated with goats that develop lymphosarcoma.

INCIDENCE/PREVALENCE

• USDA NAHMS surveys estimate 39% and 89% of beef cow-calf and dairy herds, respectively, contain BLV-infected cattle.
• In the cattle industry, BLV-positive cattle are estimated to account for >285 million dollars in losses a year in the dairy industry. These losses are in the form of genetics, carcass condemnation, trade restrictions, and veterinary costs.
• Lymphosarcoma accounts for 13.5% of beef cow and 26.9% of dairy cattle condemnations at slaughter.

GEOGRAPHIC DISTRIBUTION

Widespread throughout the United States and the world

SYSTEMS AFFECTED

• Cardiovascular
• Musculoskeletal
• Digestive
• Hemolymphatic
• Ophthalmic
• Reproductive

PATHOPHYSIOLOGY

• In cattle and sheep, seroconversion occurs after exposure to the virus between 14 and 98 days. The wide temporal range of conversion is attributable to dose, route of infection, and immune status of the animal. Concurrent infection with a retro- or herpes virus may make the BLV infection more pathogenic.
• Currently it is believed that the virus is necessary only to initiate tumor development, but after initiation, the tumor self-replicates.
• Tumors can occur in every organ but primarily develop in lymph nodes.

SIGNALMENT

• Cattle are the natural host for BLV. Sheep are highly susceptible to forming lymphosarcoma once exposed to BLV. Goats tend to form tumors but do not seroconvert.
• Cattle and sheep have the highest incidence of tumor formation between the ages of 2 and 4. Goats >2 years of age tend to be identified with tumors.

GENETICS

Cattle that have been identified with the BoLA-A allele w8.1 are more resistant to BLV infections and therefore have a lower incidence of lymphosarcoma.

PHYSICAL EXAMINATION FINDINGS

• Depending on location of the developing tumor, animals will present with a wide variety of clinical signs.
• Cattle and sheep: Peripheral lymphadenopathy (prescapular, femoral, suprascapular, supramammary), weight loss, anorexia, decreased milk production, ketosis, diarrhea, ataxia, edema on ventral abdomen and udder due to blocked lymphatic drainage, exophthalmia, melena from gastrointestinal ulcers, dyspnea, cardiac dysrhythmia, pounding jugular pulse, masses in the reproductive tract, dog-sitting due to posterior paresis, and recumbent animals.
• Goats: Pyrexia, emaciation, diarrhea, and dyspnea.
• Masses may be visualized or palpated, typically associated with lymph nodes.

CAUSES AND RISK FACTORS

• Transmission of BLV occurs both horizontally and vertically.
• Horizontal transmission of BLV primarily occurs through fomites during normal cattle processing procedures. These include dehorning, rectal palpation, injections, tattoos, and surgeries. When instruments are not properly sterilized between procedures, contamination of naïve animals with the virus may occur. Body secretions from saliva, nasal discharge, broncho-alveolar fluids, and urine have all been demonstrated to seroconvert exposed ruminants. Insects have been hypothesized to be a transmitting vector, but to date, experimental infection has not been demonstrated between animals.
• Experimental vertical transmission of virus can occur through semen, ova, and embryos. It is not believed that these reproductive products are a significant source of infection. None of these products may be sold internationally if the animals are identified as having BLV. In utero, cell-free transmission of virus to offspring occurs through the placenta in 3–25% of infected dams after the third month of gestation. Colostrum and milk from BLV-positive cows are not believed capable of causing an infection in calves that ingest them if given after gut closure.
• Fomites contaminated with whole blood from an infected cow that are not cleaned and disinfected properly.
• Sheep that are comingled with infected cattle.
• Dairy cattle have more intense management and interaction than most beef cattle, which accounts for a higher incidence of transmission.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Lymphadenopathy due to systemic infection
• Fat necrosis
• Melanomas
• Carcinomas
• Internal abscesses
• Caseous lymphadenitis in goats and sheep

CBC/BIOCHEMISTRY/URINALYSIS

• Cattle
  ◦ CBC may be normal
  ◦ May see a lymphocytosis but rare
  ◦ May be anemic, due to gastrointestinal bleeding (microcytic, hypochromic)
  ◦ Can have an increase in liver enzymes if there is hepatic involvement
  ◦ Hyperglobulinemia
  ◦ Hypoalbuminemia
• Sheep and goats
  ◦ Anemia that is nonregenerative
  ◦ Hyperglobulinemia
  ◦ Hypoalbuminemia

OTHER LABORATORY TESTS

• Tests for BLV antibodies:
  ◦ *Agar gel immunodiffusion (AGID)*—this is the primary test used to screen cattle and the official test for export of cattle. Most labs that run this test are identifying antibodies to gp51 viral antigen, which appears to be more sensitive than testing for p24. Antibodies to gp51 can occur as early as 3 weeks post-exposure. A negative test indicates that the animal has not been exposed to BLV for 3–12 weeks prior to testing. A strong response to gp51 does not necessarily indicate that the animals will develop lymphosarcoma.
  ◦ *Radioimmunoassay (RIA)*—this test is more sensitive than AGID and can detect smaller amounts of antibody within the first 2 weeks of infection. It has been developed for both the detection of p24 and gp51. Both serum and milk can be used for testing.
  ◦ *Enzyme-linked immunosorbent assay (ELISA)*—sensitivity and specificity of this test are equal to RIA.
• A bone marrow aspirate and cytologic examination may reveal clonal expansion of lymphoid precursors.

(CONTINUED) LYMPHOSARCOMA

IMAGING
Can see masses on survey radiographs in the cranial thorax in ruminants that could be heart-based tumors. Ultrasonography may be used to further characterize and differentiate masses.

OTHER DIAGNOSTIC PROCEDURES
• Physical examination revealing peripheral lymphadenopathy or other masses upon careful palpation.
• Fine-needle aspirate of the mass and cytologic examination. Examination of the aspirate may reveal a large number of lymphoblasts, but it may be hard to distinguish between lymphadenopathy and systemic infections.
• Lymph node biopsy during a laparotomy.

PATHOLOGIC FINDINGS
• Grossly, tumors appear to have a heavy fibrous capsular lining with cream-colored, friable inner contents and a necrotic, soft center.
• Tumor masses can occur in one or multiple organs and lymph nodes. The most common sites for development are:
  ◦ Cardiac tumors primarily occur in the myocardium and right atrium. They are very rarely seen in the left side of the heart.
  ◦ Gastrointestinal involvement of the pylorus is common and often will result in ulcers.
  ◦ Ocular masses develop in the retrobulbar region.
  ◦ Lymphatics in the area of the cranial udder.
  ◦ Uterine masses diffusely distributed throughout the tissues.
  ◦ Ventral spinal cord masses are readily palatable rectally.
  ◦ Liver diffusely.
  ◦ Lungs diffusely but rare to find.
  ◦ Spleen diffusely.
• Histologically, the masses have a large number of lymphoblast cells.

TREATMENT

THERAPEUTIC APPROACH
None

MEDICATIONS

DRUGS OF CHOICE
None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Animals are usually culled from the herd once they present with clinical signs and are diagnosed as having lymphosarcoma.
• Ruminants with lymphosarcoma may deteriorate within a week to 2 months after clinical signs and eventually need to be humanely euthanized.

CLIENT EDUCATION
• It is important to educate clients on the modes of horizontal transmission to prevent use of contaminated equipment on BLV-negative ruminants.
• It is important to discuss the economic impact of the disease on the production goals of the farm, to determine if testing and culling of infected animals are reasonable options.
• There are a number of international shipping restrictions that prevent the sale of breeding stock and their reproductive by-products if they are BLV positive.

PATIENT CARE
• Monitor patients as their health degenerates to ensure they are humanely treated.
• Some affected animals with high genetic value may need supportive care until they can have ova or semen harvested from them. Also, pregnant animals may need nursing care until they have their offspring.
• Depending on what the animals are presenting as clinical signs, nursing care could range from soft bedding if the animal is recumbent or ataxic to slinging animals to prevent pressure necrosis.
• Limit activity to prevent further injury if the animal is ataxic or recumbent and struggling.

PREVENTION
• Identify BLV-positive animals and keep them isolated from BLV-negative animals.
• Properly clean instruments that have whole blood contamination.
• Do not reuse needles.
• Test bulls that are used for natural service for BLV and do not use them if they are BLV-positive.
• Vector control—although to date experimental transmission of BLV by vectors has not been shown to be a primary infectious route.
• Cull BLV-positive animals from the herd and maintain strict testing and biosecurity when introducing new animals to the herd.
• If the owners have BLV-positive cows, they can harvest the ova, rinse them, and implant them into a BLV-negative recipient.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Ataxia, anemia, ascites, ventral edema, bloat, choke

AGE-RELATED FACTORS
Lymphosarcoma occurs in mature ruminants, usually over the age of 4 years.

ZOONOTIC POTENTIAL
None

PREGNANCY
There is cell-free transmission of the virus after 3 months of gestation through the placenta to the fetus.

BIOSECURITY
The optimal biosecurity measures would be to test and cull BLV-positive ruminants from the herd. Culling positive animals is cost-prohibitive for most producers, so reducing the rates of transmission is a practical approach to eliminating the disease from the herd. Testing and adding only BLV-negative animals to the herd and eliminating positive animals through natural attrition and preferential selection can accomplish reducing the number of infected ruminants.

PRODUCTION MANAGEMENT
• There are several approaches to eradicating BLV from the herd. The producer is going to have to determine if the cost benefit of eradication is greater or less than having the disease present.
• Eradicating or reducing BLV from the herd begins with testing all the animals in the herd. This primarily applies to cattle and sheep. All negative animals need to be retested in 12 weeks, and calves <6 months need to be retested at 6 months of age. Once producers have this information, they have three options:
  ◦ Culling all positive animals identified can eliminate BLV from the herd in a few months. However, the economic hardship is extreme if the herd has a high rate of infection. There is also the loss of genetic material from the herd when culling.
  ◦ Segregating infected animals from negative animals and slowly eliminating them from the herd and replacing with negative animals is another option. It takes longer to eliminate BLV from the herd this way, and requires more frequent serologic testing of the herd. Segregating positive from negative animals also requires essentially two separate facilities and equipment.

LYMPHOSARCOMA (CONTINUED)

◦ Managerial practices can be altered to prevent the transmission of the disease and allow for natural attrition of infected animals. This takes a long time to eliminate BLV from the herd, and requires frequent serologic testing and a long-term commitment by the producer.

MAEDI-VISNA (OVINE PROGRESSIVE PNEUMONIA)

BASICS

OVERVIEW

• Maedi-visna (MV), known as ovine progressive pneumonia (OPP) in North America, is a multisystemic disease characterized by chronic inflammation of the lungs, mammary gland, joints, and central nervous system (CNS).
• Maedi-visna is caused by maedi-visna virus (MVV), also called ovine lentivirus (OvLV) or ovine progressive pneumonia virus (OPPV).
• Maedi-visna is an Icelandic name used for two clinical forms of the disease. Maedi (dyspnea) is a slow, nonfebrile, progressive interstitial pneumonia. Visna (wasting) is a slow progressive encephalitis of sheep.
• MVV is a member of the small ruminant lentiviruses group (SRLVs), which also includes caprine arthritis encephalitis virus (CAEV).
• SRLVs are related to other lentiviruses of domestic animals and humans.
• MVV and CAEV were considered species specific, but molecular studies show that sheep comingled with CAEV-infected goats can become infected with CAEV and vice versa.
• Susceptible animals may be infected early in life, but clinical signs manifest several years after infection.

INCIDENCE/PREVALENCE

• MV prevalence ranges from <5% to >60%. High prevalence is more common in intensively raised flocks, and in animals housed indoors.
• In the United States, the average seroprevalence is 26%, but there is a wide range between states and individual flocks. In west Texas, MVV seroprevalence is 0.5%. This difference is likely due to differences in management between regions. In Texas, most sheep are raised on open range conditions in a hot, dry climate, and lambing occurs on pasture.

GEOGRAPHIC DISTRIBUTION

MV has been reported in most sheep-producing countries with the exception of Iceland, where it was introduced but eradicated, and Australia and New Zealand.

SYSTEMS AFFECTED

• Respiratory
• Musculoskeletal
• Mammary
• Nervous
• Hemolymphatic

PATHOPHYSIOLOGY

• Maedi-visna virus is a Lentivirus in the family Retroviridae, subfamily Orthoretrovirinae.
• The genome of MVV is single-stranded RNA. After infection, the MVV genome is reverse transcribed into a double-stranded DNA copy that integrates into the host DNA. Infected sheep remain infected for life, irrespective of the presence of neutralizing antibodies and cell-mediated immunity.
• Based on phylogenetic analyses, SRLV isolates are classified into five phylogenetic clusters. Genotypes A and B are distributed throughout the world, whereas C, D and E are geographically restricted.
• Genotype A includes MVV-like strains and genotype B comprises CAEV-like isolates originally isolated from sheep and goats from across the world, respectively.
• Genotype C includes isolates that were originally detected in Norway. Isolates from Switzerland and Spain are grouped in genotype D. Italian SRLVs isolated from the Roccaverano goat breed have been designated as genotype E.
• Groups A, B, and E are subdivided into subtypes.
• Group A is heterogeneous and contains fifteen subtypes (A1–A15). Group B is less complex and contains three subtypes (B1–B3). Group E contains two subtypes (E1 and E2) which have only been found in Italy.
• SRLVs from groups B–D and most group A subtypes (A1–A6, A9, A11–A13) infect both sheep and goats. Other SRLV groups and subtypes have so far only been described either in sheep (A15), or goats (A7, A8, A10, A14, E1 and E2). Co-infection with more than one SRLV strain may occur and can result in recombination to form new MVV-CAEV strains.
• Small ruminant lentiviruses quasi-species are continuously generated through mutation, recombination, and selection pressure by the immune system.
• Routes of transmission vary depending on factors, including production purposes (dairy versus meat or wool), management (intensive versus extensive operations), housing, breed, climate, virus strain, and host genetics.
• Transmission by close contact occurs more often during periods when infected and noninfected sheep are housed close together, such as during lambing or in winter, mainly when housed in poorly ventilated pens.
• During lambing and the postpartum period, transmission may occur by contact of newborns with contaminated birth products or aerosols.
• Ingestion of infected colostrum or milk is less important in MVV transmission, but may be significant in dairy sheep raised under intensive conditions and with a high prevalence of mastitis.
• Feeding MVV- or CAEV-contaminated colostrum or milk to sheep can result in infection.
• Vertical intrauterine transmission from infected ewes to fetuses occurs in 5–10% of cases.
• Venereal transmission of MVV has not been shown to occur, but sheep experimentally infected with MVV and co-infected with *Brucella ovis* shed MVV in semen, and proviral DNA has been detected in semen.
• Seroconversion usually occurs between 2 and 8 weeks post-infection. Some sheep may remain seronegative for several months or longer in spite of being infected.

HISTORICAL FINDINGS

N/A

SIGNALMENT

• Sheep are the natural host of MVV infection.
• Phylogenetic analyses indicate that cross-species transmission of SRLVs (MVV and CAEV) occurs regularly.
• Several factors including virus strain, age, breed, genetics of the animal, route of exposure, secondary infections, and management conditions influence the outcome of MVV infection.
• There is no sex predilection.
• The percentage of seropositive sheep in a flock increases with age.
• Although MVV transmission may occur at an early age, clinical signs rarely arise before 2–3 years of age.
• Some breeds of sheep may be more susceptible to MVV infection.

PHYSICAL EXAMINATION FINDINGS

• The majority of sheep infected with MVV remain clinically healthy for life.
• In a proportion of sheep, MVV infection leads to cachexia and chronic inflammation in the lungs, lymph nodes, joints, mammary gland, and CNS.
• In North America, the most common manifestation of MV is chronic pneumonia with signs of afebrile, progressive respiratory failure in sheep 2–3 years or older. There is gradual emaciation and loss of body condition despite good appetite. Affected sheep remain behind the rest of the flock when driven and exhibit open-mouth breathing and dry cough.
• In later stages of disease, fever, purulent nasal discharge, and depression are common due to secondary bacterial infections.
• In ewes with mastitis, there is symmetrical bilateral enlargement and hardening of the udder (hardbag). Milk is normal in appearance but scant in quantity.
• Sheep with arthritis become lame and exhibit cachexia. There is weight loss and swelling of carpal and tarsal joints. Clinical signs of arthritis appear 2–3 years after infection.
• Neurologic manifestations of MV are seldom seen in the US, but are common in Europe. In this form, there is aberration of gait affecting primarily the hindquarters. There is gradual weakening, leading first to paraplegia and then quadriplegia. Affected animals lose weight, and jerking of the lips and facial muscles or blindness may be observed.
• The nervous form of MV has been diagnosed in Spain in lambs aged between 4

MAEDI-VISNA (OVINE PROGRESSIVE PNEUMONIA) (CONTINUED)

and 6 months, belonging to Assaf flocks that were managed intensively.

GENETICS
• MVV infections of sheep are influenced by host genetics and viral factors.
• Artificially produced identical twin lambs, one inoculated with a high pathogenicity MVV strain (85/34) and the co-twin inoculated with a low pathogenicity strain (84/28), developed the same degree of lymphoid interstitial pneumonia, indicating that host genetic factors are important in determining the degree of disease.
• Genetic variation in the ovine transmembrane 154 (*TMEM154*) gene associates with infection susceptibility. Distinct SRLV genetic subgroups infect sheep in association with their *TMEM154* diplotypes.

CAUSES AND RISK FACTORS
• Coexistence of chronic respiratory diseases in the flock, such as ovine pulmonary adenomatosis (Jaagsiekte) or lung parasites, seems to increase the risk of transmission.
• Larger flocks have an increased risk of infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Caseous lymphadenitis, paratuberculosis (Johne's disease), chronic parasitism, and malnutrition
• Chronic suppurative pneumonia, parasitic pneumonia, and ovine pulmonary adenomatosis (Jaagsiekte)
• Bacterial mastitis (bluebag)
• Bacterial arthritis (*Chlamydia* and *Mycoplasma*)
• Scrapie, rabies, brain abscesses, parasitic lesions, and trauma of the spinal cord

CBC/Biochemistry/Urinalysis
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Serologic screening is done with enzyme-linked immunosorbent assay (ELISA) and agar gel immunodiffusion (AGID). Western blot can be used for confirmation.
• There are several commercially available ELISA and AGID kits for detection of MVV serum antibodies.
• Competitive ELISA has high sensitivity and specificity.
• Standard PCR and real-time PCR have been developed and used mostly for research; they are currently used by only a few diagnostic laboratories.
• The sensitivity and specify of serologic tests and PCR protocols are influenced by the MVV strains circulating in a flock or region.
• A combination of ELISA and real-time PCR increases the likelihood of detecting infected animals and becomes useful in control programs and export testing.
• Serologic tests or molecular techniques with high sensitivity and specificity in Europe may have lower sensitivity and specificity in other countries, due to antigenic and genetic variability of SRLV subtypes; developing subtype-specific diagnostic tests is imperative.

PATHOLOGIC FINDINGS
• Grossly, evidence of chronic pneumonia, arthritis, and/or mastitis might be present.
• Lungs of sheep with MVV-induced chronic interstitial pneumonia do not collapse fully and have a white or gray color. Rib impression lines can occur on the costal surface of the lungs. Lungs are heavier than normal and firm. One to 2 mm or larger, gray foci may be observed throughout the lung.
Well-demarcated areas of consolidation without exudate in the airways may be found in the cranioventral lobes. Mediastinal and peribronchial lymph nodes may be five times larger than normal.
• The mammary gland in ewes affected with mastitis is symmetrically enlarged and firm.
• In sheep with arthritis, there is swelling of the carpal and tarsal joints. Other joints are less frequently affected. There is increased synovial fluid, discoloration and thickening of the synovial membrane, and erosion of the articular cartilage.
• Gross lesions are not observed in the CNS of sheep affected with the neurologic form.
• Microscopically, lymphoid interstitial pneumonia is the typical lesion in the lungs. There is thickening of the interalveolar septa due to infiltration of mononuclear cells, hyperplasia of smooth muscle, and fibrosis. Numerous lymphoid follicles with active germinal centers are found adjacent to bronchioles and small vessels.
• Ewes with mastitis have follicular lymphoid hyperplasia and interstitial infiltration of mononuclear cells.
• Joints exhibit severe infiltration with lymphocytes, plasma cells, and macrophages as well as villus proliferation of the synovium. There is degeneration of the articular cartilage, mineralization of the joint capsule, and periosteal replacement growth in more advanced cases.
• In the brain of sheep affected by the neurologic form, there is periventricular encephalitis characterized by ependymal necrosis, widespread demyelination, and prominent perivascular lymphocytic cuffing.

TREATMENT

THERAPEUTIC APPROACH
There are no treatments available.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Wide-spectrum antibiotics may be used for secondary bacterial infections.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Infected sheep remain infected for life.
• Sheep often die within 6–8 months after initial clinical signs.

POSSIBLE COMPLICATIONS
Secondary bacterial pneumonia/infections

CLIENT EDUCATION
Should focus on methods of preventing this disease within the flock

PATIENT CARE
N/A

PREVENTION
• There are no vaccines available.
• MV-free accreditation programs are in existence in some European countries.
• Serologic testing and segregation of positive reactors are used to reduce prevalence; in some cases eradication is performed.
• Retesting every 3–6 months and elimination of new positive reactors is necessary until 3–5 consecutive tests result in 100% of sheep being negative.
• Yearly testing and acquisition of replacements from MVV-free flocks are recommended.
• Reappearance of occasional positive reactors years after eradication has been documented.
• Reporting requirements for MV differ between countries.
• Lentiviruses are very susceptible to environmental factors and are destroyed by common disinfectants.

MALIGNANT CATARRHAL FEVER

BASICS

OVERVIEW

Malignant catarrhal fever (MCF) is an often lethal, acute and rarely chronic, viral infection that affects many species or the order Artiodactyla, which is caused by different members of the genus Macavirus, subfamily Gammaherpesvirinae; Ovine herpesvirus 2 and Alcelaphine herpesvirus 1. It is characterized by lymphoproliferation and inflammation of mucosas and blood vessels.

INCIDENCE/PREVALENCE

Varies according to the species. Very low morbidity and high mortality (>90%) in cattle. Variable morbidity and high mortality in bison. High morbidity and mortality within cervidae.

GEOGRAPHIC DISTRIBUTION

Worldwide distribution. OvHV-2 is found in wild and domestic sheep and goats. AlHV-1 is found in Africa and is widely distributed in zoological and wildlife parks.

SYSTEMS AFFECTED

- Multisystemic
- Digestive
- Urinary
- Hemolymphatic
- Respiratory

PATHOPHYSIOLOGY

- At least six member of the MCFv subfamily are pathogenic in natural conditions, of which AlHV-1 and OvHV-2 are the most prevalent.
- OvHV-2 is found in sheep and goats; AlHV-1 is found in wildebeest, which are well-adapted species and are able to spread the disease.
- Susceptibility varies depending on the affected species.
- Well-adapted, nonclinically susceptible reservoir hosts are capable of replicating and shedding the virus in the environment to clinically susceptible, poorly adapted hosts, which neither replicate nor shed the virus, and are considered dead-end hosts.
- The virus is shed through feces and ocular and nasal secretions into the environment.
- Nasal, ocular, and fecal contamination is common, and the virus is cell associated.
- There is serologic evidence of the infection, which should be evaluated together with clinical signs and lesions.
- Serologic evidence supports the theory that deer and cattle may become subclinically infected and the disease can be precipitated following stress or concurrent infection.
- Transmission is primarily horizontal and through direct contact. In wildebeest, transmission is vertical and horizontal.
- Long-distance transmission has been described. Traditional recommendations for spatial separation between sheep/goats/wildebeest and susceptible species are difficult to apply.
- Incubation period ranges from weeks to months, which is associated with viral dose exposure.
- CD8+ T-lymphocytes are the predominant cell associated with vascular lesions and lymphoid hyperplasia.

HISTORICAL FINDINGS

Susceptible species (cattle, bison, wild ruminants) grazing with reservoir species (sheep, goats, wildebeest). Long-distance transmission of aerosolized OvHV-2 has been described.

SIGNALMENT

- Susceptibility varies depending on the affected species.
- Wildebeest, sheep, and goats act as asymptomatic carrier species.
- AlHV-1 affects cattle and deer; OvHV-1 affects cattle deer, bison, swine, and giraffes.
- Domestic cattle, Indian gaur, Javan banteng or Balinese cattle, swamp or water buffaloes, American bison, red deer, sika deer, white-tailed deer, mule deer, axis deer, Pere David's deer, red brocket deer, rusa deer, water deer, Chinese water deer, mooses and pigs, among others.
- Frequently in animals >1 year, occasionally in 6-month-old to 1-year-old, rare in younger animals.

PHYSICAL EXAMINATION FINDINGS

- Depression and fever (1–3 days), followed by a serous to purulent oculonasal discharge.
- In all species, ulceration of the coronet, interdigital skin, teats, vulva, and perineum may occur.
- Dyspnea, open-mouth breathing; keratitis with corneal opacity and hypopion resulting in photophobia and partial blindness; upper respiratory and oral ulcers, with erosions of the buccal papillae and profuse mucopurulent nasal and conjunctival discharge; severe dysentery and diarrhea; neurologic signs may occur, with hyperesthesia, muscle fasciculation, and aggressive behavior; generalized lymphadenopathy, fever, epithelial bleeding, and ulcers.
- In highly susceptible animals, depression, separation from the herd, hematuria, diarrhea, and blood in feces.
- Sudden death can be observed, without premonitory signs.
- Disseminated intravascular coagulation is observed in different species.
- Fever, nystagmus, weakness, tremors, paralysis, lameness, vasculitis, mucopurulent nasal and conjunctival discharge, dyspnea, dysentery and diarrhea, oral and upper respiratory ulcers, hypopion, sudden death, generalized lymphadenopathy, and muzzle encrustation.

CAUSES AND RISK FACTORS

- MCF is caused by two different members of the genus Macavirus, subfamily Gammaherpesvirinae; Ovine herpesvirus 2 and Alcelaphine herpesvirus 1.
- The virus is spread from sheep, goats, and wildebeest to cattle, bison, deer, and other wild ruminants through shared grazing contact. Dissemination though aerosolized virus has also been proposed.
- Most sick animals will succumb to the disease. Cattle surviving the disease may have proliferative arteriopathy in medium-sized arteries and corneal lesions, which may evolve to perforating ulcers.
- Nasal, ocular, and fecal contamination is common and is thought to be spread by fomites.
- Direct contact of susceptible species (cattle, bison, wild ruminants) with reservoir species (sheep, goat, wildebeest).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Vesicular diseases, foot and mouth disease, rinderpest, vesicular stomatitis, BVD/mucosal disease, IBR, Bluetongue, epizootic hemorrhagic disease, East Coast tick fever (*Theileria parva*) encephalitis, shipping fever, arsenic toxicity, C naphthalene toxicity, rabies, yersiniosis, tick-borne diseases.

CBC/BIOCHEMISTRY/URINALYSIS

- CBC initially will show lymphocytosis with subsequent lymphopenia.
- When severe tissue damage is evident, neutrophilia occurs.

OTHER LABORATORY TESTS

- Polymerase chain reaction (PCR) on peripheral leukocytes in nonclotted blood samples.
- Serologic tests: Virus neutralization, immunoblotting, enzyme-linked immonosorbent assay (ELISA), competitive inhibition ELISA (current choice), immunofluorescence assay, immunoperoxidase test, and complement fixation test. Serologic results should be interpreted in context, considering the pathologic features of MCF.
- Buffy coat analysis for virus isolation.

OTHER DIAGNOSTIC PROCEDURES

- Clinical signs and typical lesions, combined with a recent history of exposure to a reservoir host, are sufficient to make a presumptive diagnosis of MCF.
- Gross and histopathologic findings.
- PCR is highly specific and is the best test for the determination of carriers in a clinically normal population, and for the postmortem diagnosis of the disease.
- Immunofluorescence is used in research settings.

PATHOLOGIC FINDINGS

- Gross findings: Corneal opacity and hypopion; muzzle crusting; mucopurulent

(CONTINUED) MALIGNANT CATARRHAL FEVER

nasal and ocular discharge; reddening of oral and nasal mucosas; multifocal to coalescing ulcers in the oral cavity, esophagus, rumen, reticulum, omasum, abomasum; ulcerative enteritis/colitis, with bloody contents; lymphadenomegaly (not a prominent feature in bison); swollen kidneys with pale focal raised areas; hemorrhagic cystitis; enlarged liver; disseminated hemorrhages.
• Histopathology: In addition to ulcerative lesions, disseminated vasculitis with fibrinoid necrosis of the vascular wall and thrombosis is common, together with multisystemic lymphoplasmacytic infiltratres (portal areas in liver, renal interstitium, myocardium, lung, brain). Lymph nodes may be hyperplastic with prominent paracortical areas (not a prominent feature in bison).

TREATMENT

THERAPEUTIC APPROACH
• No treatment is available. Cattle can recover without treatment.
• No vaccine is available.

MEDICATIONS

DRUGS OF CHOICE
Vitamins, antibiotics, corticosteroids, and antivirals have been attempted. The role of these treatments in recovery is uncertain, as animal can recover without treatment.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Disease course is generally 3–7 days; sudden death may occur.
• Prognosis is grave.
• Low morbidity and high mortality. Outbreaks with high morbidity and mortality have been described in highly susceptible species (e.g., bison).

CLIENT EDUCATION
• Physically separate susceptible species from sheep, goats, and wildebeest in known infective areas.
• Wildlife population may also spread the disease, so ensuring separation is essential to prevent disease introduction.

PREVENTION
• In areas affected by MCF, do not graze sheep, goats, and wildebeest with cattle, deer, or bison.
• Elimination of fomites, especially those contaminated with postparturient fluids, is essential. Insect control is also indicated.

MISCELLANEOUS

ZOONOTIC POTENTIAL
None

PREGNANCY
Abortion may occur in sick animals.

MANAGEMENT OF GUNSHOT WOUNDS

BASICS

OVERVIEW
• The pathology associated with gunshot wounds (GSWs) can vary dramatically with the anatomic location(s) of the injury, type of firearm, and the ballistics (shape, weight, stability in flight, and velocity) associated with the bullet.
• Radiographs or other imaging modalities are often indicated to assist in patient evaluation. GSWs may be minor and heal with little or no intervention, may require significant medical and/or surgical intervention, or may be fatal with or without treatment.
• The degree of tissue injury depends on bullet weight, velocity, and the affected tissues' expansile ability.
• Injuries from GSWs should be treated as though they are contaminated wounds.

INCIDENCE/PREVALENCE
Sporadic

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• Varies with anatomic location of injury, type of firearm, and ballistics of the bullet.
• Hemothorax and pneumothorax may occur with penetrating thoracic GSWs.
• Penetrating abdominal wounds may result in septic peritonitis secondary to disruption of hollow viscera.

HISTORICAL FINDINGS
History of GSW may or may not be known.

SIGNALMENT
All ruminant species

PHYSICAL EXAMINATION FINDINGS
Clinical signs are variable and dependent upon anatomic location of GSWs. Some animals may not show clinical signs, and GSWs may be inapparent or difficult to detect during physical examination. Evidence of hemorrhage may or may not be visible. Clinical signs may include:
• Hemodynamic instability
• Dyspnea
• Hemoptysis
• Epistaxis
• Hematuria
• Hematochezia or melena
• Lameness
• Limb fracture
• Neurologic impairment
• Nonspecific signs consistent with pain, including lethargy, depression, hypo/anorexia, and/or vocalizing. Dorsoflexion may also indicate thoracic or abdominal pain.

GENETICS
N/A

CAUSES AND RISK FACTORS
Wound severity is a function of bullet or projectile size, shape, velocity, and tissue characteristics.

Bullet Velocity
• Velocity is the most important single factor responsible for wound damage.
• Impact velocity is the speed at which the bullet meets target tissue and is important to wound characteristics.
• When impact velocities are low (non-military-civilian bullets) wounds have less tissue damage and do not exhibit explosive effect. High-velocity injuries can exhibit explosive effects.
• High-impact velocity wounds reflect maximum tissue destruction with remote injury.

Bullet Mass
• Projectile kinetic energy varies directly with the mass of the bullet.

Ballistic Shape
• Bullets of different weights, shapes, and calibers do not pass through the air in similar patterns.

Bullet Composition
• Soft-point bullets will mushroom or expand upon impact.
• Hollow-point bullets behave similarly to soft-point jacketed bullets and will mushroom or expand upon impact.

Bullet Yaw
• Yaw results from inherent asymmetry of the bullet.
• Yaw in part explains the aberrant bullet wounds seen in veterinary practice. Yaw is magnified in animal tissues.

Tissue Reaction
• Tissue retentiveness to the passing bullet contributes to its severity. Wound extent is determined by the projectile's energy upon impact and tissue energy transfer. An entering bullet's kinetic energy is transferred to the surrounding tissue when producing the wound.
• Tissue elasticity, cohesiveness, and density properties tend to oppose the bullet's inertia and slow it down.

Tissue Elasticity
• Tissues of different densities variably alter the kinetic energy transfer.
• Tissue absorption of the kinetic energy is the determinant of wound severity.

Tissue Cohesiveness
• Penetrating wounds reflect sufficient tissue resistance to cause dissipation of the bullet's kinetic energy.
• Perforating wounds reflect the difference between energy at wound entry and that remaining at exit.

Tissue Density
• Damage to bone may result from the bullet striking the long bone directly. Effects depend on the type of bone structure, the physical characteristics of the bullet, and the periosteal supporting structures.
• "Indirect fracture" occurs when a high-velocity bullet passes near a bone but does not strike it directly.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Vary with affected system(s)

CBC/BIOCHEMISTRY/URINALYSIS
• Full CBC and serum biochemistry panel may be helpful to determine extent of blood loss, presence of organ damage, and evidence of systemic infection in valuable animals.
• PCV/TP alone may be helpful to determine the extent of blood loss; serial PCV/TP may be required for monitoring of animals with uncontrolled internal or external hemorrhage.

OTHER LABORATORY TESTS
As needed

IMAGING
• Radiographs are recommended for all cases of GSW. Anatomic location of projectile(s) or fragments is important in formulating prognosis.
• Ultrasound may assist in identifying abnormal fluid accumulation(s) in cases with thoracic or abdominal cavity involvement.
• In very valuable animals, CT may also be helpful in assessing extent of internal organ involvement and bullet/pellet location.

OTHER DIAGNOSTIC PROCEDURES
History and thorough physical examination (entrance/exit wounds)

PATHOLOGIC FINDINGS
Variable and dependent upon anatomic location(s) of injury, type of firearm, and ballistics of projectile.

TREATMENT

THERAPEUTIC APPROACH
• Varies with anatomic location and extent of injury.
• Hemothorax and pneumothorax may be managed with medical treatment including thoracocentesis or thoracostomy tube, or may require surgical intervention. Ruminants with thoracic GSWs that are hemodynamically stable and eupneic generally do not require a thoracotomy.
• Penetrating abdominal wounds usually warrant exploratory laparotomy or celiotomy, to thoroughly evaluate and repair damaged viscera. GSWs to the abdomen carry a high risk of septic peritonitis.
• Antimicrobials are often indicated as GSWs are usually contaminated with dirt, hair, and skin fragments.

(CONTINUED) MANAGEMENT OF GUNSHOT WOUNDS

• Whole blood transfusion may be necessary in cases with severe or uncontrolled hemorrhage.
• Conservative treatment is often sufficient in limb wounds not associated with fractures. Wounds should be allowed to heal as open wounds, or repaired surgically after infection has been controlled.
• Extremity wounds could require tissue debridement. Thorough irrigation with physiologic saline to remove surface debris and contaminants is indicated. Excision of devitalized exposed skin, muscle, and fascia may be warranted. Foreign bodies should be removed. In severe cases, limb amputation may be warranted.
• Fracture treatment varies. Casts or splints may be sufficient in some cases, while other fractures could necessitate surgical intervention, limb amputation, or even euthanasia.
• Euthanasia may be indicated for animals with GSWs.

SURGICAL CONSIDERATIONS AND TECHNIQUES
See "Therapeutic Approach"

MEDICATION

DRUGS OF CHOICE
• Antimicrobial choice varies with location of GSW and affected species of animal. Consider drug regulations when making this selection.
• Analgesics and anti-inflammatories as needed.
• Aminocaproic acid may be helpful in controlling active hemorrhage. This drug is not labeled in food-producing animals in most countries and therefore no milk or meat withdrawal times have been established.
• Whole blood transfusions may be indicated in some animals.
• Fly repellent may be required with open wounds.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all medications administered to food-producing animals.

CONTRAINDICATIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Highly variable dependent on anatomic location of wound(s), severity of injury, type of treatment (medical vs. surgical), and degree of wound contamination.
• Limb wounds are rarely fatal.

POSSIBLE COMPLICATIONS
• Hemo- or pneumothorax from thoracic GSWs.
• Septic peritonitis from abdominal GSWs.
• Wound infection(s).
• In GSWs from a shotgun, pellets decelerate rapidly, resulting in severe damage over a wide area. Extensive devitalization of skin and/or musculature secondary to vascular disruption may occur.

CLIENT EDUCATION
N/A

PATIENT CARE
Dependent upon anatomic location of wound(s), severity of injury, and type of treatment (medical vs. surgical).

PREVENTION
Following rules regarding firearm safety may prevent accidental GSWs.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Lead toxicosis following GSWs is rare but has been reported in humans. Clinical signs could develop if one or more lead bullets or fragments remain in the animal.
• Ruminants with lead poisoning have a potentially long meat and/or milk withdrawal period; periodic blood lead testing is advisable in these cases prior to entering the food chain.

ABBREVIATIONS
• GSW = gunshot wound
• PCV = packed cell volume
• TP = total protein

MASTITIS: CAMELIDS

BASICS

OVERVIEW
• Mastitis occurs in camelids, with the dairy dromedary camel being most commonly affected.
• Different forms have been reported including clinical (severe gangrenous, acute, chronic) and subclinical.
• Various pathogens have been isolated with species, environment, housing, management, and regional differences.
• There is more focus on udder infection and raw milk quality as the camel dairy industry continues to develop as camel dairy products are sought out for health purposes.

INCIDENCE/PREVALENCE
• Low prevalence of mastitis in South American camelids. Isolated cases have been reported both in llamas and alpacas.
• In the dromedary, the prevalence of clinical mastitis ranges from 2 to 8%. The herd and quarter prevalence of subclinical mastitis in camels range from 5% to 40%. Higher prevalence of subclinical mastitis (>60%) is observed in traditionally managed dairy camels.

M

GEOGRAPHIC DISTRIBUTION
Worldwide, infectious agents vary depending on environment and management.

SYSTEMS AFFECTED
• Mammary
• Multisystemic

PATHOPHYSIOLOGY
• Mastitis is an inflammation of the mammary gland tissue, usually associated with a bacterial infection.
• Several Gram-positive and Gram-negative bacteria have been isolated from cases of clinical and subclinical mastitis.
• Infection is generally ascendant but may also result from hematogenous spread (*Corynebacterium pseudotuberculosis*, *Mycobacterium bovis*).
• Infection results in tissue damage, and decreased quality and quantity of milk production.
• Irreversible changes and loss of function may be observed with chronic infections.
• Rarely, severe acute inflammation of the mammary gland will result in systemic disease and endotoxemia.
• Mammary gland abscesses may develop in some infections (fungal infection, *C. pseudotuberculosis, M. bovis*).

HISTORICAL FINDINGS
• Poor production
• Ill-thrift or poor growth of the cria or calf
• Abnormal conformation or enlargement of the mammary gland
• Lameness or other systemic signs in acute cases

SIGNALMENT
• More common in camels (*Camelus dromedarius* and *C. bactrianus*), rarely seen in llamas and alpacas
• Camels used for traditional dairying

PHYSICAL EXAMINATION FINDINGS
• Clinical signs vary from absent to various degrees of visible changes depending on type of mastitis and etiological agent.
• Clinical mastitis: The mammary gland presents various degrees of swelling, redness, hardening, and pain upon palpation. Lameness may be seen in some cases. Severe toxic mastitis may be accompanied by fever, depression, and dehydration. The mammary gland secretions may be serous, hemorrhagic, or purulent.
• Chronic mastitis: Hardening of the gland, poor milk production, asymmetry of the quarter, abnormal shape of the gland and cisterns.
• Subclinical mastitis: There are no visible clinical signs but usually an alteration of milk color and consistency. Abscesses may be felt. Some glands may present as a blind (nonfunctional) teat or quarter.

GENETICS
Some breeds of dairy camel due to mammary gland conformation and high production

CAUSES AND RISK FACTORS
Major Pathogens
• Clinical mastitis: *Staphylococcus aureus*, coagulase-negative *Staphylococcus* spp., *E. coli*, *C. pseudotuberculosis*, *Streptococcus zooepidemicus* (alpacas and llamas).
• Subclinical mastitis: *Staphylococcus aureus*, coagulase-negative *Staphylococci*, *Streptococcus agalactiae*, *Streptococcus dysgalactiae*, *Bacillus* spp., *Proteus* spp., *E. coli.*
• Fungal mastitis (*Candida* spp., *Aspergillus* spp.) occurs sporadically in acute and chronic mastitis.
• *Corynebacterium pseudotuberculosis* causes mammary abscesses in camelids.
• *Mycobacterium tuberculosis*, *M. bovis* (camels, alpacas).
• *Klebsiella* spp. mastitis has been described in camels.
• Peracute, toxic mastitis due to *E. coli* has been described in camels.

Risk Factors
• Poor mammary gland conformation
• Increased risk with parity
• Early stages of lactation
• Poor milking hygiene
• Environmental: corral hygiene, animal density, bedding
• Tick infestation (camels)
• Association with other disease such as camel pox
• Use of soiled harness to prevent suckling by the calf (camels)

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Sepsis or endotoxemia in cases of toxic mastitis
• Other causes of mammary gland swelling: adenocarcinoma or trauma (rare)

CBC/BIOCHEMISTRY/URINALYSIS
• CBC may show toxic changes in acute and peracute mastitis.
• Serum biochemistry shows electrolyte disturbances.
• Severely depressed animals may show signs of hepatic lipidosis.

OTHER LABORATORY TESTS
• Gross examination of secretions shows changes in color (bloody or purulent) and consistency.
• Cytologic examination of milk shows increased leukocytes and causative organisms.
• Milk pH may be increased.
• Subclinical mastitis may be diagnosed by CMT (70% sensitivity and 91% specificity in camels) or SCC. SCC interpretation is difficult. Camel milk contains a large proportion of anucleated cell fragments. The use of non-DNA-specific methods such as particle counters or methylene blue staining results in overestimation of cell count.

IMAGING
Ultrasonography may be helpful in identifying mammary gland tissue changes and abscesses.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Clinical mastitis: Mammary gland tissue inflammation, focal necrosis, granulomas
• Subclinical mastitis: Damaged or sloughed alveolar epithelium

TREATMENT

THERAPEUTIC APPROACH
Dependent on type of mastitis. Acute or peracute mastitis may require intensive care and hospitalization.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Surgical drainage of abscesses may be indicated
• Mastectomy in cases of severe gangrenous or chronic suppurative mastitis

MEDICATIONS

DRUGS OF CHOICE
Treatment is indicated in cases of clinical mastitis according to the following guidelines:

• Milk stripping
• Proper systemic (IM or IV) antimicrobial therapy based on culture and sensitivity. IMM antibiotic therapy is not practical due to the anatomy of mammary gland in these species
• Anti-inflammatory drugs
• Fluid therapy in cases of endotoxemia

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Some drugs (NSAIDs and aminoglycosides) are nephrotoxic in camelids.
• Camel milk is a major source of nutrition for people in several countries. Withdrawal times for milk and meat are lacking but should be taken into consideration

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is good in subclinical mastitis
• Prognosis is guarded for severe or chronic mastitis

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
• Hygiene of milking (camels)
• Regular evaluation of the mammary gland particularly if neonate shows poor growth or signs of gastrointestinal disease (llamas and alpacas)

PATIENT CARE
N/A

PREVENTION
• Cull production animals with severe damage from known contagious agents
• Regular testing (CMT, SCC)
• Observe proper milking hygiene

MISCELLANEOUS

ZOONOTIC POTENTIAL
Many infectious agents can cause sickness also in humans, particularly with consumption of raw milk. Tuberculosis and brucellosis are major concerns.

BIOSECURITY
Testing of purchased lactating animals

ABBREVIATIONS
• CMT = California Mastitis Test
• IM = intramuscular
• IMM = intramammary
• IV = intravenous
• NSAIDs = nonsteroidal anti-inflammatory drugs
• SCC= somatic cell count

SEE ALSO
• Mastitis (by organism)
• Mastitis: Milking Procedures and Teat Disinfection (see www.fiveminutevet.com/ruminant)
• Mastitis: Pharmacology (see www.fiveminutevet.com/ruminant)

MASTITIS: COLIFORM

BASICS

OVERVIEW
Acute coliform mastitis (ACM), the most common cause of mastitis in dairy herds, is of significant importance to farm economics and welfare. *Escherichia coli, Enterobacter aerogenes, Klebsiella pneumoniae*, and *Serratia marcesans* are four common coliform bacteria that cause mastitis. Coliform bacteria are normal inhabitants of the soil, digestive tract, and manure. They accumulate and multiply in contaminated bedding. Acute coliform mastitis occurs primarily during first trimester and less commonly during the dry period. Cow-to-cow transmission has minimal impact on disease transmission. The majority (60–80%) of coliform mastitis results in intramammary infection whereas only 15–23% results in acute systemic signs.

INCIDENCE/PREVALENCE
Herd susceptibility to infection is the greatest at 2 weeks after drying off and 2 weeks prior to parturition; however, the majority of the infection during the dry period does not lead to clinical cases but is persistent and leads into acute coliform mastitis immediately after parturition. Incidence of acute coliform mastitis during lactation varies with the herd, determined by various risk factors such as husbandry practices, stage of lactation, season, age, and previous exposure. A well-managed herd has as low as 1–2 clinical mastitis cases in 100 milking cows per month, and the incidence of acute coliform mastitis is 1 –2 cases in 100 lactating cows per year. Coliform-induced acute mastitis, on the other hand, has higher rate of death and agalactia-related culling which ranges from 30% to 40% of cases, compared with other forms of mastitis.

GEOGRAPHIC DISTRIBUTION
Spatial distribution of coliform mastitis has not been established yet but temperature and precipitation are the factors affecting the incidence rate. Coliform mastitis is more common in tropical areas with high precipitation than in temperate and dry areas.

SYSTEMS AFFECTED
Mammary

PATHOPHYSIOLOGY
Infection occurs when coliform bacteria invade the mammary gland through the teat canal, most commonly immediately after milking. Bacteria multiply rapidly in the mammary gland and release the potent toxin commonly called "endotoxin." Increased level of endotoxin in the mammary gland changes the vascular permeability, resulting in acute swelling of the gland. Extravasation (diapedesis) of neutrophils in the affected quarter follows within a few hours of infection. Neutropenia and leukopenia is the immunologic response to clear the bacteria. Tissue healing starts 24 hours after the action of immunologic cells. Acute release of endotoxin leads to systemic effects such as anorexia, fever, diarrhea, and death in some cases. Local effects include changes in the color and consistency of the milk. This may lead on into the chronic form of mastitis with agalactia.

HISTORICAL FINDINGS
Increases in coliform mastitis may be seen following wet weather, changes in milking routines, worsened housing hygiene, or changes in drying-off treatment.

SIGNALMENT
- Any species of large or small, domestic or wild ruminant.
- Most prevalent and clinically relevant in high-yielding dairy cattle and goats.
- Primarily lactating cows, immediately after drying-off and a few weeks before parturition.

PHYSICAL EXAMINATION FINDINGS
- Signs vary in severity from those involving only localized changes of the mammary gland and secretion, to those involving systemic signs of peracute septicemia with a death rate of 5–15%.
- Varying levels of heat, pain, swelling, and discoloration of the infected gland(s). The majority of cases of ACM (>70%) are localized to the udder and exhibit only mild, if any, systemic signs of disease. Affected glands may be warm, firm, and swollen, often with an abnormal secretion.
- Milk closely resembles serum. Additional manifestations can include the presence of flakes, clots, or blood.
- General systemic signs can include fever, anorexia, sunken eyes, ruminal stasis, diarrhea, dehydration, and recumbency.
- Signs of septicemia can include petechiation or scleral injection, injected mucus membranes with toxic ring at gingival margins, prolonged capillary refill time, hypothermia, tachycardia, and altered mentation (depression, coma).

CAUSES AND RISK FACTORS
- Poor sanitation and environmental hygiene
- Poor milking hygiene (milking wet udders, use of communal towels to dry teats, etc.)

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Acute mastitis characterized by swelling and pain can be caused by numerous organisms in addition to coliforms. A partial list includes *S. agalactiae, S. aureus, S. dysgalactiae, S. uberis, Clostridium* spp.*, and Bacillus* spp. Common conditions that may be manifest by signs of septicemia (in addition to coliform mastitis) include metritis, peritonitis, and pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS
- CBC is variable and may include hemoconcentration, leukocytosis with neutrophilia, left shift, and leukopenia with neutropenia. Toxic changes to neutrophils may also be observed (Doehle bodies, toxic granulation, cytoplasmic vacuolization, and basophilia).
- Hyperfibrinogenemia.
- Nonspecific changes in serum biochemical parameters may include hypocalcemia, hypokalemia, hypergammaglobulinemia, and hyper- or hypoglycemia.

OTHER LABORATORY TESTS
- Milk bacterial culture.
- Blood bacterial culture. *Note:* In cows suffering severe ACM, positive blood cultures may isolate coliform organisms originating from the mammary gland or noncoliform organisms (e.g., *Bacillus* spp., *Pasteurella* spp.), which presumably originate from other organ systems (e.g., respiratory, gastrointestinal).

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
California Mastitis Test (CMT): Useful in detecting increased somatic cell count (SCC) in cases of subclinical mastitis.

PATHOLOGIC FINDINGS
Gross and histologic postmortem findings either can be confined to local mammary changes associated with inflammation or may include signs of sepsis.

TREATMENT

THERAPEUTIC APPROACH
- ACM is likely to respond to conservative therapy including frequent stripping of the affected gland, administration of anti-inflammatory agents, and oral fluid therapy (e.g., 16–24 liters of water containing 8 oz NaCl, 2 oz KCl, and 12 oz calcium propionate).
- Use of systemic antimicrobials with intravenous fluid therapy is recommended in ACM when bacteremia is suspected. IV fluid therapy will aid in flushing of endotoxin, produced by both live and dead Gram-negative bacteria, which otherwise may cause significant and irreversible organ damage.
- In severely affected cows exhibiting marked systemic signs, fluid therapy is an important consideration. Since oral administration is generally ineffective in cows with marked gastrointestinal stasis, intravenous administration is preferred. The type and volume of fluid for intravenous administration should be based on abnormalities in blood parameters and clinical interpretation. Most cows with ACM are

hypoglycemic, hypocalcemic, hypokalemic, and alkalotic.
• Administration of hypertonic saline (7.5% NaCl, 5 mL/kg or 1–2 L per adult cow) is a reasonable alternative to administration of large volume intravenous fluids. This must always be followed by adequate oral fluids (20–40 L per adult cow).

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Ceftiofur (1.1–2.2 mg/kg, IM, SC, q24h)
Note: IM administration is preferred in dehydrated patients (IV administration in cattle is prohibited in the USA based on current labeling).
• Oxytetracycline (6–10 mg/kg IV, IM, SC, q24h)
Note: IV administration is preferred in dehydrated patients. Administer slowly.
• Flunixin meglumine (1.1–2.2 mg/kg, IV, q12–24h)

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Flunixin meglumine and oxytetracycline both can cause renal toxicity in the compromised patient and therefore fluid therapy is essential when treating with these medications.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The majority of cows diagnosed with ACM resolve within 5 days of treatment and return to production.
• Cows with marked systemic signs and prolonged disease have a guarded to poor prognosis.
• Cows with marked systemic signs and concurrent bacteremia have a poor to grave prognosis.

POSSIBLE COMPLICATIONS
Possibility of persistent infections

CLIENT EDUCATION
Awareness of the client about the good animal husbandry practices and maintaining the farm hygiene dramatically reduces the incidence of ACM. Clients should be aware of using milking machine only after the drying of the teats.

PATIENT CARE
Monitor local changes to mammary gland and secretion.

PREVENTION
• Insure proper environmental hygiene.
• Insure proper premilking and milking hygiene.
• Provide fresh, palatable feeds and management conditions to help insure that cows remain standing for approximately 30 minutes after milking to allow formation of the keratin plug prior to lying.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Apart from the involvement of the mammary gland, fever and shock leading to death are associated with severe coliform mastitis cases. Agalactia is also common in acute coliform mastitis.

AGE-RELATED FACTORS
Acute coliform mastitis is common in the first three lactation periods, but repeated exposure to the coliform bacteria reduces the chances of ACM at a later age.

ZOONOTIC POTENTIAL
Coliform agents can be zoonotic.

PREGNANCY
Bacteremia develops in a substantial proportion of cows with ACM concurrently showing systemic signs and possible abortion.

BIOSECURITY
• Isolation of the infected animal from the herd
• Immediate clean-up of areas that could be a source of bacteria
• Good husbandry practices by the workers on the farm

PRODUCTION MANAGEMENT
• Avoid using fine beddings such as sawdust for 3 weeks before and after calving.
• Provide adequate space per individual.
• Avoid wet milking using excessive water and no drying before milking time.
• Avoid excessive liner slippage at the end of milking from dirty and wet teats.

ABBREVIATIONS
• ACM = acute coliform mastitis
• CMT= California Mastitis Test
• IM = intramuscular
• IV = intravenous
• KCl = potassium chloride
• NaCl = sodium chloride
• SC = subcutaneous

Consulting Editor Kaitlyn A. Lutz

MASTITIS: FUNGAL

BASICS

OVERVIEW
• Yeast and fungi are part of soil and water microflora, and opportunistic pathogens (if given the opportunity) will colonize the udder resulting in intramammary infection.
• Infections are usually sporadic, opportunistic, and limited to affected glands.
• Antimicrobials are suspected to depress host defense mechanisms and stimulate fungal growth.
• Most cases of fungal mastitis are mild and self-limiting; however, cases involving *Cryptococcus neoformans* can result in severe mastitis and permanent damage to the mammary gland.

INCIDENCE/PREVALENCE
Fungal mastitis is seen in ruminants, with low frequencies of occurrence; the true incidence is unknown.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Mammary
• Hemolymphatic

PATHOPHYSIOLOGY
Opportunistic etiologic agents include *Candida* spp. (77% of cases), *Cryptococcus* spp., and *Prototheca* spp. algae. Rare genera include *Trichosporon*, *Aspergillus*, *Torulopsis*, *Saccharomyces*, *Rhodotorula*, *Pichia*, and *Hansenula*.

HISTORICAL FINDINGS
• Sharp drop in milk yield
• Anorexia
• Positive California Mastitis Test (CMT)
• Lack of positive response to antibiotic therapy
• Subclinical cases in herd mates are common.

SIGNALMENT
Potentially, females of all species used for milk production.
Lactating animals. The likelihood of infection increases with parity and is most often seen in the second month of lactation.

PHYSICAL EXAMINATION FINDINGS
• Abnormal mammary secretions (often watery secretions containing clots and flakes)
• Inflammation of the affected gland
• Fever (often spiking at 104–106°F, 40–41°C)

GENETICS
There is no evidence of genetic predisposition.

CAUSES AND RISK FACTORS
• Yeasts and fungi often gain entrance into the mammary gland through nonhygienic administration of intramammary antibiotics for treatment of bacterial mastitis.
• Injured or damaged regions of the mammary gland can provide the opportunity for colonization by environmental yeast and fungi.
• Previous bacterial mastitis increases host susceptibility to fungal mastitis.
• Fungal mastitis is seen with milking machine malfunction and is associated with teat end damage.
• Inadequately sanitized milking units may act as fomites and result in epidemic infections.
• There is increased incidence and severity during warm, wet environmental conditions conducive to pathogen growth.
• The most common etiologic agents of fungal mastitis are *Cryptococcus neoformans* and *Candida albicans.* Others include:
  ◦ *Candida* spp.
  ◦ *Trichosporon beigelii*
  ◦ *Trichosporon cutaneum*
  ◦ *Rhodotorula* spp.
  ◦ *Hansenula holisti*
  ◦ *Hansenula polymorpha*
  ◦ *Hansenula anomala*

DIAGNOSIS

Diagnosis of fungal mastitis should be made based upon milk culture.

DIFFERENTIAL DIAGNOSES
Confusion and misidentification between protothecal mastitis and fungal mastitis is common based on colony morphology. Prototheca is an alga, which produce colonies similar to *Cryptococcus neoformans.*

CBC/BIOCHEMISTRY/URINALYSIS
• Leukocytosis and neutrophilia were found in experimental infections.
• Elevated urine ketones are possible with anorexia.

OTHER LABORATORY TESTS
Positive California Mastitis Test (CMT)

Microbiologic Laboratory Tests
• *Candida albicans:* Fermentation of various sugars
• *Cryptococcus neoformans:* Production of the enzyme urease and the assimilation of carbon substrates

Candida albicans
• *Germ tube test*: Rapid and reliable. This test utilizes media in which blastospores of *C. albicans* are suspended in serum and incubated at 37°C for 2–3 hours. The suspension must be examined between 2–3 hours for the presence of hyphal outgrowths.
• *Culture on cornmeal agar at 25°C*: Upon microscopic analysis, *C. albicans* will form chlamydospores, which are morphologically unique.

Cryptococcus neoformans
• *Direct culture*: *C. neoformans* is inhibited by cyclohexamide, but grows well on standard nonselective mycologic media. Identification is made on the presence of a capsule. Direct culture is the definitive test for identifying *C. neoformans.*
• *India ink preparation:* Upon microscopic examination, *C. neoformans* appears as a budding yeast or single cell with a clear halo surrounding it due to the presence of a polysaccharide capsule.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Direct microscopic examination of colonies or mammary secretions reveals yeast and fungi to be morphologically different from bacterial bacilli or cocci.
• The presence of hyphae or spores on direct microscopic examination of defatted milk smears renders a positive diagnosis.
• Predominant cultures on blood and/or Sabouraud's agar at 25°C or 37°C, respectively, are suggestive of a positive diagnosis.
• Both yeast and *Prototheca* are larger than bacteria, with yeast having buds and *Prototheca* being multinucleate.
• In the event of available histologic sections, Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stains highlight morphology.
• Fluorescent antibody staining can be used with sections and cultures.

TREATMENT

THERAPEUTIC APPROACH
No effective and approved treatments are available for fungal mastitis (see "Medications"). Some general recommendations are as follows:
• Stop antibiotic therapy upon diagnosing fungal mastitis.
• Milking infected animals separately, sterilizing milking units between animals, and CMT testing may reduce spread to herd mates.
• Frequent milking/stripping of affected teat(s) increases the chances of a more favorable prognosis.

MEDICATIONS

DRUGS OF CHOICE
• Fungal mastitis is usually self limiting; however, clinically recovered cows may shed yeast/fungi for up to 8 months.
• Fungal mastitis is refractory to most drug treatments and there is little evidence to support such therapy in modifying the course of disease.
• Antipyretics (flunixin meglumine 1.1–2.2 mg/kg IV, q24h) are useful to help reduce high fevers and inflammation. Follow label

directions and abide by meat and milk withdrawal periods.
• Antimycotic drugs have been used; however, there exists no substantial evidence in regard to the efficacy of antimycotic drug therapy. There are no approved antimycotic treatments for fungal mastitis in milking animals in most countries. Prudent withdrawal times should be utilized.
• Intravenous sodium iodide (66 mg/kg body weight IV once per week) and oil-based intramammary iodine solutions have been reported to be of some value.
• While resistant to most antibiotics, experimental *Prototheca* infections have been treated with limited success using tertamisole hydrochloride or levamisole hydrochloride.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Due to loss of production and persistent shedding, culling is a consideration.
• There is often irreversible tissue damage with near complete agalactia.
• Fungal mastitis does not respond well to antimicrobials.
• Tissue damage and infection are usually confined to the affected gland with rare systemic infections.

POSSIBLE COMPLICATIONS
There are rare incidences of systemic mycosis.

CLIENT EDUCATION
Unresolving cases of mastitis should be cultured rather than treated empirically.

PATIENT CARE
Monitoring temperature and milk secretions in addition to follow-up milk cultures are useful to gauge therapy effectiveness.

PREVENTION
• During the administration of antibiotics one should wear clean gloves, clean the teat end thoroughly prior to administration, and only use single-dose, sterile intramammary tubes in accordance to labeled instructions.
• Teat end hygiene is extremely important in preventing fungal contamination.
• Cull persistently infected animals.
• Use aseptic udder infusion techniques.
• Reduce environmental organic matter buildup.
• Practice aseptic milking hygiene.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Bacterial and mycoplasmal mastitis

AGE-RELATED FACTORS
Incidence of fungal mastitis increases with parity.

PREGNANCY
Sodium iodide may lead to abortion.

PRODUCTION MANAGEMENT
• Yeasts and fungi compose part of the normal makeup of the soil and environmental microflora and, if given the opportunity, will colonize the udder resulting in intramammary infection.
• Injured or damaged teat or mammary gland can provide the opportunity for the colonization of environmental yeast and fungi.
• Affected cows should be culled from the herd.

ABBREVIATIONS
• CMT = California Mastitis Test
• GMS = Gomori methenamine silver
• IV = intravenous
• PAS = periodic acid-Schiff
• USDA/FDA = United States Department of Agriculture/Food and Drug Administration

MASTITIS: MINOR BACTERIA

BASICS

OVERVIEW

• The National Mastitis Council considers the primary minor bacterial mastitis pathogens to be *Corynebacterium bovis*, *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) and *Nocardia* spp.
• Other uncommon bacterial causes of mastitis to be considered here are coagulase-negative *Staphylococcus* (CNS) spp., *Pseudomonas aeruginosa*, and *Serratia* spp.
• *Pseudomonas* spp. are found in organic bedding and water and can contaminate water sources, milking equipment, and rubber parts in hoses and the milking system.
• Sources of *Nocardia* spp. are soil, water, and udder skin.
• The reservoir for *Corynebacterium bovis* is normal teat skin and infected udders. Cases of *Corynebacterium bovis* mastitis are often associated with inadequate teat dipping or sanitizing.
• Purulent discharge from wounds, teat injuries, and abscesses are the major sources for *Trueperella pyogenes* infections.
• *Serratia* spp. are saprophytes and found in soil and plants.
• Most of the mastitis-causing CNS spp. are associated on teat skin.

INCIDENCE/PREVALENCE

Usually sporadic

GEOGRAPHIC DISTRIBUTION

Varies due to regional differences in housing, milking sanitation, intramammary treatments, teat dips, and use of pasture. "Summer mastitis" is seen with *Trueperella* infections of cows on pasture in Europe.

SYSTEMS AFFECTED

Mammary

PATHOPHYSIOLOGY

• Mastitis is inflammation of the mammary gland, usually as a result of bacterial infection. Pathogens gain entry into the gland either through ascending colonization of the streak canal (*Streptococcus* spp. and *Staphylococcus* spp.), by reverse-impaction during machine milking, or by contaminated intramammary treatments.
• Infection in the gland results in tissue damage either as the direct effect of infection in cells (e.g., *Staphylococcus* spp.) or from the immune response to the pathogen (e.g., Gram-negative bacteria).
• Inflammatory responses range from mild to severe, depending on the bacteria, the infectious dose, and the host immune function. Within the gland, the response can range from coagulation of milk or serum proteins (gargut), damage or destruction of secretory tissue, blockage of ductules with necrotic debris and purulent material, endothelial leakage of serum and blood, fibrosis, abscess formation, granulomatous lesions to gangrene.
• Extravasation (diapodesis) of white blood cells, primarily neutrophils, into the gland results from chemotactic signals by macrophages (the primary leukocyte in healthy glands).
• The leukocyte response, or SCC, is a useful measure of inflammation in the mammary gland.
• Infections from CNS and *Corynebacterium* usually result in mild to moderate inflammation and the gland returns to normal after the infection is cleared.
• Infections from *Nocardia* spp., *Trueperella pyogenes*, *Pseudomonas aeruginosa*, and *Serratia* spp. often cause serious tissue damage and can become chronic with abscesses or granuloma formation (*Nocardia*).

SIGNALMENT

• Cattle; occasionally sheep and goats.
• Adults; *Corynebacterium bovis* can affect heifers prepartum.
• There are no breed predilections.

HISTORICAL FINDINGS

• Post-milking dipping of teats with non-iodine products is commonly associated with *Corynebacterium* and *Serratia* mastitis.
• Intramammary infusions with nonsterile products.

PHYSICAL EXAMINATION FINDINGS

• Palpation of the mammary gland reveals swelling, heat, firmness, or pain. The milk secretion may have small flakes or large pieces of gargut, actual pus (in the case of *Trueperella*), or may be watery from serum leakage into the gland (with *Serratia*).
• Abscesses or granulomas may be palpable (especially with *Nocardia*).
• Fever and tachycardia are usually present in acute infections but not in chronic mastitis.
• Decreased milk production.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Contaminated intramammary infusions, bedding, or water used to sanitize teats or milking machines.
• Not employing post-milking teat dipping, improper teat dipping, or the use of ineffective teat dip preparations are associated with *Corynebacterium* and *Serratia* mastitis.
• Hyperkeratosis or damaged teat ends predispose for CNS mastitis.
• Maintaining cows with *Trueperella* or *Nocardia* mastitis with draining abscesses in the herd may also lead to infection.
• Using common medications for intramammary infusion rather than individual treatment tubes.
• Warm, moist organic bedding (*Pseudomonas* and *Serratia*).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- ◦ Subclinical cases: *Streptococcus agalactia, Corynebacterium bovis*, and minor udder pathogens.
- ◦ Corynebacteria isolates from milk samples may represent teat streak canal colonization rather than infected glands.
- ◦ Clinical cases: Coliform bacteria, mycoplasma, or environmental streptococci.
- ◦ Gangrenous mastitis with bloody secretion: Trauma to the gland.
- ◦ Acute mastitis: A partial list includes *S. agalactiae, S. aureus, S. dysgalactiae, S. uberis, Clostridium* spp., and *Bacillus* spp.
- ◦ Common conditions that may be manifest by signs of septicemia (in addition to coliform mastitis) include metritis, peritonitis, and pneumonia.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• SCC or CMT of milk from quarter or composite samples will indicate if excessive inflammation is present. SCC >200,000, CMT score of 2 or 3, or a log-linear score >4 indicates mastitis is present.
• Other indirect tests include the NAGase test (N-acetyl-β-D-glucosamidase) and electrical conductivity.
• Electrical conductivity is less sensitive due to normal variation of ions in milk.
• Microbiologic testing of an aseptically collected milk sample from the affected gland is the only way to determine the causative organism.
- ◦ Direct microbiology using suitable media is the most common method of determining the genus and often the species of bacteria involved in cases of mastitis.
- ◦ PCR techniques are becoming commercially available and are useful in determining species and subtypes of bacteria.

IMAGING

Ultrasound of the teat canal may be a helpful adjunct to diagnosis.

OTHER DIAGNOSTIC PROCEDURES

Finding inflammation in the mammary gland during physical examination or seeing abnormal milk secretion.

PATHOLOGIC FINDINGS

Gross pathology will show inflamed tissue in the affected glands, ranging from discoloration to fibrosis to severe tissue damage.

(CONTINUED) MASTITIS: MINOR BACTERIA

TREATMENT

THERAPEUTIC APPROACH

• *Corynebacterium* and CNS spp. may self-cure but treatment with commercial intramammary antibiotics is advised.
• *Serratia* spp. and *Pseudomonas* mastitis usually respond poorly to antibiotic treatment.
• *Nocardia* and *Trueperella* mastitis is often refractory to treatment due to abscessation and purulent material.

MEDICATIONS

DRUGS OF CHOICE

Commercial mastitis preparations are advised for cases of *Corynebacterium* and CNS mastitis.

CONTRAINDICATIONS

N/A

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Complete recovery of normal mammary tissue after treatment for cases of *Corynebacterium* and CNS spp. mastitis. *Corynebacterium* mastitis infections often are not associated with increased SCC.
• *Serratia*, *Nocardia*, and *Trueperella* mastitis usually become chronic.

POSSIBLE COMPLICATIONS

N/A

PATIENT CARE

Monitor for eating, drinking, reduction of inflammation in the gland, and return of normal milk secretion.

CLIENT EDUCATION

See "Causes and Risk Factors" and "Prevention"

PREVENTION

• Minimize risk factors.
• Vaccination with rough mutant Gram-negative vaccines (e.g., J-5) may reduce the severity and incidence of *Serratia* mastitis.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Nocardia spp. infections are zoonotic and cultures should be considered dangerous. Colonies should be killed with formalin before opening the plates for examination.

SYNONYMS

• "Summer mastitis" for *Trueperella pyogenes* mastitis.
• "Environmental Staphylococcus" or "other Staphylococcus" for "CNS spp."

ABBREVIATIONS

• CMT = California Mastitis Test
• CNS = coagulase-negative *Staphylococcus*
• NAGase = N-acetyl-β-D-glucosamidase
• PCR = polymerase chain reaction
• SCC = somatic cell count

SEE ALSO

Mastitis (by species and etiology)

MASTITIS: MYCOPLASMAL

BASICS

OVERVIEW
• Inflammation of the mammary gland due to infection by various *Mycoplasma* spp.
• Mycoplasmas are contagious mastitis pathogens that can cause clinical, subclinical, and chronic intramammary infections (IMI).
• Spread primarily animal to animal at milking.
• *Mycoplasma bovis* is the most important agent of outbreaks of mycoplasmal mastitis in dairy cattle, but other species may cause mastitis outbreaks clinically indistinguishable from *M. bovis.*
• *M. agalactiae* is the primary etiologic agent of mycoplasmal mastitis in small ruminants and it is reportable in the United States. *M. mycoides* subsp. *mycoides* (large-colony type), *M. capricolum* subsp. *capricolum*, and *M. putrifaciens* are goat specific.
• Unresponsive to antibiotic therapy and has the potential to cause severe losses in milk production.
• This chapter will focus on mycoplasmal mastitis in cattle, with much of the information being applicable to small ruminants. See chapter, Mastitis: Small Ruminant, for more specific information on mycoplasma in small ruminants.

INCIDENCE/PREVALENCE
• The incidence/prevalence is variable among geographic regions and among herds in a region. There is a wide variation in quarter infection rates in herds. The condition is endemic in some areas.
• Based upon culture of a single bulk tank sample, prevalence estimates for mycoplasma mastitis in US dairy herds ranges from 1% to 10%.
• Most studies report a higher prevalence in large herds (>500 cows) compared to smaller herds.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Mammary

PATHOPHYSIOLOGY
• Mycoplasmas lack a cell wall and, therefore, are not affected by antimicrobials which act via an effect on the cell wall.
• The most common source of IMI due to mycoplasmas is the udder of infected cows.
• *Mycoplasma* spp. are commonly spread from infected cows to uninfected cows at milking via milking machines or milkers' hands.
• Mycoplasmal udder infections usually persist through the current lactation and into subsequent lactations.
• Mycoplasmas are present in the respiratory and urogenital tracts of healthy cattle and may serve as a source of IMI.
• Contaminated intramammary treatments or improper teat sanitation during or at the end of lactation are also means of new infections.
• Infection results in a purulent interstitial mastitis.
• Most damage in mycoplasmal mastitis is from the cow's immune response. However, metabolic by-products and toxins from mycoplasmas also contribute to tissue damage and reduction of milk production.
• Inflammatory cells accumulate in alveoli and ducts and reduce duct lumen space. Cells in alveoli regress and fluid accumulates, with an attendant drop in milk production. In the most severe reactions, fibrous tissue replaces alveoli and ducts, resulting in a permanent loss.
• Multiple abscesses, variable in size, can be found in cases of mastitis caused by *M. bovis*. These abscesses may contain *M. bovis,* which can cause long-term shedding.
• Mycoplasmas are sensitive to heat, sunlight, and environmental pressures but can survive on teat skin and in cool, moist, and protein-rich environments for variable periods.

HISTORICAL FINDINGS
• Classically, severe clinical mastitis in multiple quarters (often in multiple cows) without systemic involvement.
• Subclinical, clinical, and/or chronic mastitis.
• Lack of response to therapy.

SIGNALMENT
• *M. bovis* is highly adapted to the bovine species, with uncommon isolations reported from buffaloes and small ruminants.
• Mycoplasmal mastitis is a common cause of contagious mastitis in dairy sheep and goats.
• All ruminant species are potentially susceptible to mycoplasmal mastitis.
• No breed, age, or lactational stage predilections exist for mycoplasmal mastitis.

PHYSICAL EXAMINATION FINDINGS
• Sudden onset of swelling of the udder.
• Grossly abnormal milk. Appearance varies, ranging from normal to watery with clots, to tan or brown with flakes. However, the majority of milk samples positive for mycoplasmas are grossly normal.
• Sharp decrease in milk production, sometimes dramatic.
• Lack of systemic signs; maintenance of appetite and thirst.
• Mild fever is often present initially but is rarely observed in clinical cases.
• Agalactia/atrophy.
• Increased somatic cell count (SCC).
• Purulent mastitis (sometimes severe) without systemic signs.
• Supramammary lymph nodes may be enlarged.
• Acute arthritis with swollen joints and lameness.
• Multiple quarter involvement; sometimes all quarters are involved.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Infection of the mammary gland with various species of mycoplasma. As few as 70 colony-forming units of *M. bovis* introduced via the teat canal can initiate mastitis.
• *M. bovis* is the most significant and common mycoplasmal agent of bovine mastitis although up to 11 species have been cultured from mastitis milk in the US including *M. alkalescens, M. arginini, M. bovigenitalium, M. bovirhinis, M. californicum, M. canadense, M. dispar,* and *M. capricolum*.
• Characteristics of mastitis produced by various *Mycoplasma* spp. are generally similar and cannot be distinguished clinically.
• *M. agalactiae* is the primary etiologic agent in dairy sheep and goats; *M. mycoides* subsp. *capri*, *M. capricolum* subsp. *Capricolum*, and *M. putrefaciens* are also commonly isolated.
• The purchase of replacement heifers and cows is frequently the origin of mycoplasmal mastitis outbreaks in previously *Mycoplasma*-free herds.
• Large herd size (>500 cows) is associated with an increased prevalence of positive mycoplasma cultures in bulk tank milk (BTM) samples.
• Outbreaks often originate in the hospital barn/string due to poor hygiene when performing intramammary treatments. Homemade mastitis treatments have also been associated with outbreaks of mycoplasmal mastitis.
• Cattle with the highest risk of infection are purchased cattle, fresh cows and heifers, and cattle that enter the treatment barn/string.
• Herds with and without mycoplasmal mastitis may contain both young and mature asymptomatic carriers.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• *Staphylococcus aureus* mastitis
• Fungal mastitis
• Caprine arthritis and encephalitis virus infection in goats
• Other causes of chronic mastitis nonresponsive to antibiotic therapy

CBC/BIOCHEMISTRY/URINALYSIS
Marked leukopenia may be present in cases of acute infection.

OTHER LABORATORY TESTS
SCC numbers markedly increase in the milk. Often, secretions contain over 20 million cells/mL.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Diagnosis is most commonly made using microbiologic procedures on aseptically

collected quarter or composite milk samples or on culture of bulk tank milk samples.
• Isolation is most commonly attempted using direct inoculation onto plates containing modified Hayflick medium. Plates are incubated in moist 10% CO_2 at 35–37°C. They are observed for growth with a microscope at intervals after plating. Plates are not called negative for growth until incubated for 7–10 days. Intermittent shedding by carriers not demonstrating symptoms may make diagnosis difficult.
• Diagnosis of infection at the herd level is usually made by isolation of mycoplasmas from BTM samples.
• In large herds, culture of partial BTM samples collected after milking each production group or the use of string sampling or milk-line sampling may be used as a method to locate groups in which cows infected with mycoplasmas exist.
• Large numbers of mycoplasmas are usually present in milk samples from cows with clinical disease.
• False-negative diagnosis may occur in BTM because dilution could mask several low-level *Mycoplasma* shedders in the herd.
• Milk samples for culture of *Mycoplasma* must be collected aseptically, kept cool during transportation to the diagnostic laboratory or storage, and plated promptly to maximize isolation.
• If delay of more than 1 day is anticipated from collection to culturing, milk samples should be frozen at –30°C or below to assure viability, or stored in liquid nitrogen.
• Mycoplasmal colonies have a fried-egg appearance on solid medium because colonies have a dense, central core that grows down into the medium.
• The polymerase chain reaction (PCR) is a highly sensitive, specific, and rapid procedure for laboratory diagnosis, but several practical problems must be solved before full-scale adoption of this diagnostic procedure.
• Mycoplasmal shedding in milk will not impact the standard plate count (SPC), preliminary incubation count (PIC), or the laboratory pasteurized count (LPC).

PATHOLOGIC FINDINGS
• The pathology in mycoplasmal mastitis is most commonly described as a purulent interstitial mastitis.
• Widespread, scattered fibrosis and granulomatous changes with pus are found in the gland. Teat sinus and ductular linings are seen as thick and rough.
• Evidence of granulomatous mastitis is seen on histopathology.

TREATMENT
There is no known effective treatment.

MEDICATIONS
DRUGS OF CHOICE
N/A

CONTRAINDICATIONS
N/A

FOLLOW-UP
EXPECTED COURSE AND PROGNOSIS
• Cows diagnosed as positively infected should be considered positive for life.
• Some cows may become agalactic and/or develop complications (e.g., arthritis, etc.), may continue in production and produce normal-appearing milk with a high SCC, may be chronically infected with abnormal milk, or may return to production, go through a dry period, and calve again, still shedding mycoplasmas.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
See "Prevention" and "Production Management"

PATIENT CARE
N/A

PREVENTION
• Mycoplasmas survive for variable, but sometimes extensive, periods of time on teat skin and multiple environmental sites.
• Isolate or quarantine new additions.
• Culture new additions using procedures described under "Other Diagnostic Procedures."
• Investigate herd of origin of any animals brought into the herd.
• If milk from animals was not cultured at purchase, milk from these animals should be cultured as they calve.
• Culture all clinical cases of mastitis and all fresh cows for mycoplasma and screen bulk tank samples for mycoplasmas.
• Workers should practice strict hygienic milking and intramammary treatment procedures.
• Avoid any use of bulk intramammary treatment.
• Effective vaccines for mycoplasmal infections are not available.

Control
• There are divergent opinions and practices with respect to management and control of mycoplasmal mastitis.
• Due to the contagious nature of *Mycoplasma* spp. and its resistance to therapy, many owners elect to cull infected animals in order to limit new infections in the herd.
• Mode of handling will vary from dairy to dairy based on the owner's attitude, facilities, number of infected animals, level of milk production, reproductive status of carrier animals, and the availability of replacements.
• Control of the disease, when present, is often based upon finding infected cows via culture of all lactating and dry cows in the herd, as well as all clinical cases and all animals at calving.
• An alternative approach is to use culture of bulk tank milk or string/group samples to identify infected groups. Alternative strategies have been proposed to deal with mycoplasmal mastitis.

Types of Approaches to Consider
If mycoplasma is diagnosed in a herd, there are two general types of approaches to be considered:
• Attempt to eliminate the organism from the herd:
  ◦ Culture all cows, identify infected animals, and cull those infected, (particularly if the number is limited).
  ◦ Culture milk from cows at dry-off, freshening, and from all clinical cases.
  ◦ Culture bulk tank milk at appropriate intervals to monitor new infections.
  ◦ Do not move cows between production groups until all cows have been cultured and classified as infected or uninfected (realizing limitations of a single culture).
• Limit spread of the disease:
  ◦ Separate mycoplasma-positive cows, and milk them last or with separate equipment.
  ◦ Cull cows with clinical mastitis or decreased production.
  ◦ Strict milking time hygiene—*M.* spp. is passed by fomites, such as the milking machine, hands, wash cloths.
  ◦ Culture milk for mycoplasmas—fresh cows, clinical mastitis cases, dry cows, bulk tanks.
  ◦ Either don't feed mastitic milk to calves or feed only after pasteurization or acidification following current recommendations.
  ◦ Back-flushing of the milking equipment.
  ◦ Strict teat dipping.

MISCELLANEOUS
ASSOCIATED CONDITIONS
• Enzootic pneumonia of calves: An infectious respiratory disease of young calves of multifactorial etiology. More common in housed dairy calves than beef calves. Feeding of unpasteurized waste milk from mastitic cows may allow transmission of *Mycoplasma* spp. to calves and result in respiratory disease characterized by dyspnea, anorexia, and depression. Mycoplasmal infections are often accompanied by head tilt secondary to otitis media/interna.
• Arthritis: The incidence of mycoplasmal arthritis is increased in herds experiencing

MASTITIS: MYCOPLASMAL (CONTINUED)

outbreaks of pneumonia or mastitis due to *Mycoplasma* spp. Lameness due to polyarthritis and/or tenosynovitis. Affected joints are warm, distended, fluctuant, and may be painful. Concurrent mycoplasmal pneumonia or mastitis is common.

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Very limited reports of human infections. Not considered a major zoonotic pathogen.

PREGNANCY
N/A

BIOSECURITY
• Since many infections are introduced into a herd by bringing replacements onto a farm, quarantine of newly introduced animals and milk culturing, as well as careful investigation into the status of the herd of origin of any introduced animals, will help limit this possibility.
• Practice strict milking time hygiene. Transmission is primarily at milking by fomites such as milking machines, milkers' hands, and wash cloths.
• The organism can also be spread when bulk mastitis treatments are administered from a contaminated vial, via a contaminated syringe, or with unsanitary treatment practices.
• Practice thorough teat dipping, iodine products preferred by some for mycoplasmal herds.
• Assure milking machine is functioning to standards.
• Use single-service towels for drying cows.
• Use gloves, disinfect between cows.
• Use single-service intramammary treatments.
• Either do not feed mastitic milk to calves or feed only after pasteurizing or acidifying using current recommendations.
• Monitor appropriate milk samples for mycoplasmas: bulk tanks, clinical mastitis cases, fresh cows, introduced cows, etc.

PRODUCTION MANAGEMENT
• Many, if not most, new mycoplasmal mastitis infections are introduced when animals are brought into a herd.
• Most cases are introduced through the teat canal but mastitis has also been proposed to occur following hematogenous spread of a respiratory infection to the mammary gland.
• Feeding of unpasteurized mastitic milk to young stock may predispose to mycoplasmal pneumonia and arthritis.
• Infected cows should be identified by culture of composite or quarter milk samples from all milking cows. Dry cows should be cultured upon calving.
• Cows diagnosed with *Mycoplasma* IMI should be considered positive for life.
• Any management plan for mycoplasmal mastitis following a whole herd culture should include segregation and/or removal of infected animals from the herd.
• Removal of infected animals from the herd to slaughter is advised when prevalence of infection is low and segregation is not practical.
• Segregation can be used when prevalence of mycoplasmal mastitis is high in the herd and culling is not economically feasible, but needs adequate facilities and management, and monitoring of the herd by repeated culturing of animals and BTM.
• Segregated cows should be milked last or with a separate milking unit from those used on uninfected cows to minimize the risk of infection for other cows.
• Mycoplasmal mastitis can be controlled with testing and discipline in the management of the disease, including the understanding by dairy personnel of the seriousness of the disease and their role to minimize its spread.
• Culture all replacements entering the herd, cows and heifers at calving, all mammary quarters with signs of clinical mastitis, cows with persistent high SCC, and BTM frequently.
• Use strict milking hygiene, including the wearing of nitrile or latex gloves by milkers, foremilking, pre- and post-milking teat disinfection with a high-quality product that covers almost the entire teat, and single use of paper or cloth towels.
• Clearly identify each infected animal by using a double identification system like leg bands and ear tags.
• Cows with blind quarters harboring mycoplasmas can spread the disease in the herd with uninformed or careless milkers and make isolation inconsistent from BTM samples.
• Avoid stresses, like the pressure effects of transportation, overcrowding, calving, and milking, particularly for the first calvers because they can be important contributors to the disease.
• A dairy's hospital pen or treatment group is usually a key area for spreading the disease when treatments are administered without following aseptic procedures, including disinfection of gloved hands between treated cows.

ABBREVIATIONS
• BTM = bulk tank milk
• IMI = intramammary infections
• LPC = laboratory pasteurized count

MASTITIS: NO GROWTH

BASICS

OVERVIEW
Mastitis yielding no bacterial growth on standard culture media.

INCIDENCE/PREVALENCE
Ten percent to 40% of clinical cases of mastitis yield no growth on culture.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Mammary

PATHOPHYSIOLOGY
• Varies depending on etiology. Most cases of no growth clinical mastitis are thought to be caused by bacteria; however, various other etiologies are possible.
• In this case, the offending organism has already been eliminated by the cow's immune system prior to sampling. Antigen-based studies indicate that Gram-negative bacteria may be a more likely cause than Gram-positive bacteria; yet there is good evidence for both occurring.

HISTORICAL FINDINGS
• Abnormal milk
• Previous treatment for mastitis

SIGNALMENT
Typically seen in lactating ruminants but also can occur during the dry period and in prepartum heifers.

PHYSICAL EXAMINATION FINDINGS
• Signs are almost always restricted to changes in the milk, such as clots or flakes.
• Systemic signs in the animal are quite rare in true no-growth cases of clinical mastitis.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Bacteriologic factors: Phagocytized bacteria (within white blood cells but alive), L-forms of *Staphylococcus aureus.*
• Sample handling: Antibiotic inhibition if sample taken post-treatment, freezer kill (*Escherichia coli* tends to be more susceptible than Gram-positive organisms), inappropriate culture medium (i.e., *Mycoplasma* and *Trueperella pyogenes* do not grow on blood agar), numbers of bacteria are too low to be detected by the quantity of milk cultured.
• Interpretation: Inaccurate assessment of the significance of culture growth reported as no growth.
• Other infectious etiologies: Caprine arthritis encephalitis virus, ovine progressive pneumonia, and maedi-visna can cause an indurative viral mastitis which is characterized by hypogalactia or agalactia.
• Noninfectious etiologies: Trauma such as bruises or contusions from environmental hazards resulting in perforations into the gland or teat.
• Risk factors are the same as other forms of mastitis. The major risk factor for trauma with subsequent clinical mastitis is a pendulous udder.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Bacteria cleared by immune system
• Bacteria alive but phagocytized
• Bacteria numbers too low to detect by standard culture methods
• L-forms (*S. aureus*)
• Viral (sheep and goats)
• Organism does not grow on standard media (*Mycoplasma,* anaerobes)
• Trauma (noninfectious)
• Antibiotic or milk product inhibition
• Storage kill
• Inaccurate interpretation of culture result

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• No additional tests need to be performed routinely on the initial or sporadic case of clinical mastitis that yields no growth, especially in herds with no history of *Mycoplasma* mastitis. However, specialized media should be utilized when multiple cases of clinical mastitis in a single cow or in a group of cows yield no growth.
• Specifically, samples should be cultured for *Mycoplasma* spp.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Aseptic milk samples may be sent to a diagnostic laboratory for further testing to include *Mycoplasma* species and differentiation of other microorganisms other than bacteria (yeast etc.).

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• No specific therapy is warranted for cows with clinical mastitis with no growth as the culture result.
• Cases are usually mild with clots or flakes in the milk with no swelling of the affected quarter(s) and no systemic effects on the cow.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• It is difficult to justify the use of antimicrobial drugs for cases of no-growth clinical mastitis.
• If treatment must be given, oxytocin, to aid milk-out should do no harm. There are no studies that document the beneficial effects of oxytocin in the treatment of clinical mastitis.
• Intramammary antibiotic therapy of clinical mastitis will usually occur prior to knowledge of culture results. This treatment does not appear to affect time to cure.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed.
• Long-term use of oxytocin may result in cows becoming dependent on oxytocin for milk letdown.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• In one study, cows with clinical mastitis were cultured and evaluated once a day for 8 days, then once a week for 1 month, then monthly until completely cured.
• The geometric mean time to clinical cure of 21 no growth cases of clinical mastitis that were not treated with anything was 4.8 days (range 1–26 days) and time until the quarter somatic cell count (SCC) was <500,000 cells/mL was 10.5 days (range 1–66 days).
• In comparison, the geometric mean time to clinical cure of 19 no growth cases of clinical mastitis that were treated with intramammary cephapirin (by label) was 5.2 days (range 2–26 days) and time until the quarter SCC was <500,000 cells/mL was 10.7 days (range 1–111).
• Providing culture results remain negative and no *Mycoplasma* is cultured, the prognosis is good.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
Clients trained to obtain culture results prior to treatment should be able to reduce drug usage, thereby decreasing the chance of antibiotic residues in bulk tank milk. Proper sample handling is important in order to minimize inaccurate culture results.

PATIENT CARE
• Any cow with clinical mastitis, especially those that are not being treated, should be

MASTITIS: NO GROWTH (CONTINUED)

evaluated on a daily basis to assess disease progression. Cows that have truly cleared the infection but are still showing clinical signs (abnormal milk) will show improvement.
• Any cow with repeated episodes of no growth clinical mastitis should be cultured for *Mycoplasma.* Cultures of cows with severe clinical mastitis that are reported as no growth should be held in suspicion.
• In one study where cows with clinical mastitis were cultured daily for 8 days, all cases of no growth were mild and did not progress to a more severe condition, whereas all cases of severe clinical mastitis yielded ample growth.

PREVENTION
• Standard mastitis control measures should always be used.
• Refer to other mastitis chapters or the National Mastitis Council's 10-point plan for a review of recommendations and a useful on-farm checklist (www.nmconline.org/docs/NMCchecklistNA.pdf).

MISCELLANEOUS

ASSOCIATIED CONDITIONS
The vast majority of cases of clinical mastitis that result in no growth are largely thought to be due to bacteria.

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
Closed herds decrease the chance of *Mycoplasma* spp. introduction.

PRODUCTION MANAGEMENT
• Any cow with clinical mastitis, especially those that are not being treated, should be evaluated on a daily basis to assess disease progression.
• Any cow with repeated episodes of no growth clinical mastitis should be cultured for *Mycoplasma* spp.

MASTITIS: SMALL RUMINANT

BASICS

OVERVIEW

While the anatomy, normophysiology, and pathology of the small ruminant mammary gland is largely comparable to cattle, a number of significant species variations exist. The normal mammary gland consists of two functionally and anatomically distinct gland-teat complexes. More milk is stored in the gland cisterns than in cattle, decreasing dependence on hormonal milk letdown. Dairy goats are typically milked for a 305-day lactation and herds in the United States average ~1,500 pounds per doe annually. Dairy sheep have a 5-month lactation, producing 650–1,000 pounds per ewe per lactation. Milk fat (3.1–6.3% caprine, 7.62% ovine) and protein (2.7–4.4% caprine, 6.21% ovine) are similar to or higher than cattle. Cytoplasmic droplets from apocrine milk secretion are normal and may be mistakenly counted as somatic cells. Caprine SCC normally increases with parity, days in milk, and estrus, as well as in response to infection; increased ovine SCC is primarily related to infection.

INCIDENCE/PREVALANCE

- Mastitis is a very common problem on small ruminant operations, affecting more than 30% of US herds and almost 3% of lactating does annually.
- The majority of subclinical infections are caused by coagulase-negative *Staphylococcus* (CNS) (78% in ewes, 71% in does).
- *S. aureus* is the most common cause of acute clinical (11–65%) and peracute gangrenous (60%) mastitis and is a common cause of subclinical mastitis (4% in ewes, 8% in does).
- *Mannheimia* spp. are a major cause of acute clinical mastitis in nursing sheep.
- *Mycoplasma* spp. are major mastitis pathogens on a global basis. *M. agalactiae* is best known as the causative agent of contagious agalactia, an uncommon and reportable disease in the US. The term "contagious agalactia" is also used loosely to refer to any mycoplasma mastitis of small ruminants.
- Lentiviral infections affect 20–40% of US flocks, with a reported prevalence of as high as 25% on an overall basis.

GEOGRAPHIC DISTRIBUTION

Bacterial mastitis is widely distributed nationally and globally. *Mycoplasma* mastitis is relatively uncommon in the US but is widespread in the Mediterranean, Asia, and North Africa. Lentivirus seroprevalence varies across geographic regions.

PATHOPHYSIOLOGY

- Up to 90% of the late lactation increase in caprine SCC can be attributable to factors other than infections.
- Intramammary infections (IMIs) may present as subclinical, acute, peracute, or chronic conditions.
- Most small ruminant IMIs are caused by contagious bacteria which are spread during the milking process, via nursing offspring, or through other fomites.
- Signs of mastitis include increased SCC, decreased milk production, abnormal milk, and inflammation of the udder parenchyma.
- Subclinical and chronic infections, which are common with CNS, *S. aureus*, and mycoplasma IMIs, present a chronic exposure risk for herd mates.
- Peracute gangrenous presentations are associated with *S. aureus*, *Mannheimia*, and coliform infections. These severe infections cause systemic illness, septicemia, and death.
- *Mycoplasma*, *Mannheimia*, and lentiviral infections are associated with other disease syndromes such as pneumonia and polyarthritis.
- Resolved natural infections do not result in any effective degree of immunity.

SYSTEMS AFFECTED

- Mammary
- Other systems depending on etiology

HISTORICAL FINDINGS

See "Signalment"

SIGNALMENT

- Heavily milking does and ewes are most susceptible to IMI during the periparturient period and at dry-off/weaning. Mastitis may be observed in dry females and males.
- A strong correlation exists between CNS infection and increased days in milk and lactation number. Affected animals may have a history of decreasing milk production and increased individual SCC or the herd may have a history of increased bulk tank SCC or bacterial counts.
- Peracute gangrenous *S. aureus* mastitis typically occurs 10–15 days postpartum but may present just prior to parturition. Chronic *S. aureus* mastitis is more prevalent with increased days in milk or lactation number.
- *Mannheimia* mastitis is most common in sheep nursing lambs that have a rapid onset of glandular and systemic signs several weeks postpartum.
- Clinical *Mycoplasma* mastitis is more common in goats. It is characterized by increased bulk tank SCC and outbreaks of mastitis in early lactation, often in association with pneumonia, conjunctivitis, and polyarthritis in young stock.
- Lentiviral mastitis presents at parturition in sexually mature animals >2 years of age.

PHYSICAL EXAMINATION FINDINGS

- Over 90% of herds rely solely on clinical signs to diagnose clinical mastitis.
- Affected animals demonstrate elevated SCCs in the affected half; this may be the only signs with subclinical CNS and *S. aureus* infections.
- Milk production is decreased.
- Milk may be thin, watery, bloody, off-color, purulent, or contain visible flakes or clots.
- Udder may be asymmetrical, enlarged, inflamed, indurated, or abscessed.
- Signs of systemic illness, including depression, anorexia, pyrexia (or subnormal temperature), dehydration, altered gait, or acute death (<24 hours) with acute clinical presentations.
- Udder gangrene ("blue bag") is a particularly severe clinical syndrome associated with *S. aureus* or *Mannheimia* infection. The udder and teat may be erythematous to cyanotic, cool, and edematous. As the case progresses, a demarcation line can be observed on the udder surface, followed by sloughing of the affected tissues. Regional lymph nodes will be enlarged, and milk secretions are serum-like, bloody, and/or gassy.
- Chronic mastitis can cause udder induration.
- Palpable internal abscesses are common with chronic *S. aureus* infections.
- Lentiviral infection causes an indurative "hard bag" mastitis. The animal presents with agalactia and a full uniformly hard udder, but the overlying skin is loose, without edema, heat, or erythema. The milk appears normal but SCC will be elevated in affected goats.

GENETICS

Some association of breed with CAEV prevalence; highest in dairy breeds and least prevalent in Angora, Cashmere, and dwarf breeds but may be confounded by management.

CAUSES AND RISK FACTORS

- Small ruminant IMIs are commonly caused by bacterial and viral pathogens and rarely by fungi, prototheca, yeast, and *Bacillus* spp.
- *S. aureus* is arguably the most important major pathogen of the mammary gland in small ruminants.
- *Staphylococcus epidermidis*, *S. caprae*, *S. warneri*, *S. simulans*, and *S. xylosus,* and other species of CNS are significant pathogens of dairy sheep and goats.
- *Mannheimia haemolytica* and *M. glucosida* infection is associated with prior viral or physical trauma to the teat followed by introduction of the pathogen to the skin or teat duct. Risk factors include pre-existing orf or papilloma infection of the teat, physical trauma to the teat end, and cross-suckling.
- Contagious agalactia is specifically associated with *Mycoplasma agalactiae,* and loosely with other *Mycoplasma* species including *M. mycoides* subsp. *mycoides* (LC), *M. putrifaciens,* and *M. capricolum* subsp. *capricolum*. Specific risk factors include introduction of new animals; poor milking hygiene practices; and dam-raising of young stock.
- Lentiviral mastitis is caused by OPP and CAE. These retroviruses are easily transmitted through milk and colostrum.

MASTITIS: SMALL RUMINANT (CONTINUED)

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- Colostrum
- Edema
- Enlarged, nonfunctional gland from prior infection
- Internal teat sealant medications
- Normophysiologic elevations in SCC
- Nutritional agalactia or water deprivation
- Precocious udder
- Teat obstruction
- Trauma

CBC/BIOCHEMISTRY/URINALYSIS

Indicated when managing severe, systemically compromised cases, as a basis for fluid therapy interventions, or to evaluate for sepsis.

OTHER LABORATORY TESTS

- Milk culture: Ensure CNS growth is reported. *S. aureus* is associated with cyclic shedding and may require multiple cultures. Mycoplasma will not grow on routine culture.
- Serology is indicated to rule out lentiviral infections; both ELISA and AGID assays are readily available in the US. OPP antigen-based AGID test has reduced sensitivity for CAE. A mycoplasma ELISA has been developed but is not available in the US.
- PCR assays are available for mycoplasma and for OPP/CAE.

IMAGING

Ultrasound can be used to evaluate the udder parenchyma and teat for abnormalities (abscesses, teat spiders, and lactoliths) or to evaluate supranumary or bifid teats.

OTHER DIAGNOSTIC PROCEDURES

The California Mastitis Test is a pen-side screening tool that detects increased SCC and decreased milk pH. While colostrum and transitional milk specificity is poor, a negative result in the first few days of lactation is reliable. Both udder halves should be compared in goats to determine if a positive result is physiologic or due to infection.

PATHOLOGIC FINDINGS

- Intra- and extracellular Gram-positive cocci and elevated neutrophils are observed with staphylococcal infections. Peracute *S. aureus* causes connective tissue proliferation, venous thrombosis, tissue necrosis, and edematous/hemorrhagic supramammary lymph nodes. Internal macro- and micro-abscesses may be observed with chronic infections.
- *Mannheimia* are Gram-negative bipolar rods. Gross findings include an enlarged gland, subcutaneous edema, sanguineous parenchymal fluid exudates, and enlarged and edematous supramammary lymph nodes.
- *Mycoplasma* infections cause an interstitial mastitis, with fibrosis and parenchymal atrophy. Additional findings may include signs of septicemia, pneumonia, arthritis with periarticular edema, hyperemic synovial membranes, hemorrhagic joint fluid, and serous to mucopurulent conjunctivitis and keratitis. The mycoplasma organism can be identified through immunohistochemical or Giemsa staining of the affected tissue.
- Lentiviral infections cause an interstitial mastitis with generalized wasting and interstitial pneumonia. Affected tissues will be firm and noncollapsing.

TREATMENT

THERAPEUTIC APPROACH

- CNS: Therapeutic objective is to clear the infection in order to improve animal and herd production metrics and reduce transmission.
- *S. aureus*: The initial treatment priority for acute/gangrenous cases may be to save the animal and preserve milking capacity through early and aggressive therapy. The overall goal should be to eliminate this contagious organism from the herd. Chronic cases and some strains of *S. aureus* may be very resistant to treatment; multiple negative cultures and consistently low SCCs are required to declare an animal clear of infection.
- *Mannheimia*: Successful treatment of peracute cases is unlikely. Early and aggressive efforts should be directed first at saving the animal's life and then the gland.
- Lentivirus: No treatment is available for OPP/CAE. Herd goals may include managing endemic disease or obtaining and maintaining a disease-free status.
- Systemic antibiotics may be indicated in cases of *S. aureus* mastitis although research is inconsistent in showing a benefit. Antibiotic choice should be based on pharmacokinetic and pharmacodynamic properties which will affect activity within the mammary gland. Tylosin and penicillin G show some clinical efficacy with limited supportive research.
- Intramammary therapy is indicted for most Gram-positive infections when the animal is not showing signs of systemic illness. Splitting mastitis tubes between udder halves increases the risk of iatrogenic infection.
- Udder halves can be chemically killed by an intramammary infusion of chlorhexidine or povidine iodine along with adjunct anti-inflammatory therapy.
- Oral or intravenous fluid therapy may be required with severe and peracute gangrenous mastitis. Avoid alkalizing solutions and correct for hypocalcemia and hypokalemia as clinically indicated.

SURGICAL CONSIDERATIONS AND TECHNIQUES

- Teat amputation can be performed just distal to Furstenberg's ring under local anesthesia.
- Ligation of the external pudendal artery and vein can be performed under sedation when the animal is not a suitable surgical candidate for mastectomy.
- Radical mastectomy and removal of the associated supramammary lymph node under general anesthesia is well described in many texts.

MEDICATIONS

DRUGS OF CHOICE

- Adjust the initial antimicrobial selection based on the culture sensitivity results if available.
- CNS: Most cattle IMM antibiotics are effective at the label dosage, e.g., cephapirin (lactating) q12–24h for 2–3 doses and penicillin-dihydrostreptomycin once at dry-off. Florfenicol (20 mg/kg IM q24h, or SC once) may be used in nondairy animals.
- *S. aureus*: Extended lactating IMM therapy regimes (e.g., cephapirin or pirlimycin for 6–8 doses) and concurrent IMM and systemic drug administration are recommended in dairy cattle. Use a product approved for *S. aureus* at dry-off. Tilmicosin (10 mg/kg SQ once, **not for use in goats**) or florfenicol may be used in nondairy animals.
- *Mannheimia haemolytica* associated pneumonias are generally responsive to long-acting oxytetracycline, sulfonamides, ceftiofur, tulathromycin, and florfenicol. Lactating therapy protocols include cephapirin q12–24h for 2–3 doses. Tulathromycin (2.5 mg/kg SQ, once) or florfenicol may be used in nondairy animals.
- *Mycoplasma*: Antibiotic therapies are generally ineffective, subject to long milk withdrawals, and induce a carrier state.
- Anti-inflammatory therapy may include flunixin meglumine (1 mg/kg IV q12–24h, up to 3 days) or dexamethasone (0.44 mg/kg IM/SQ/IV, once).

CONTRAINDICATIONS

Tilmicosin is lethal in goats.

PRECAUTIONS

Very few drugs are approved for goats and no intramammary medications (IMM) are approved for small ruminants. Follow AMDUCA guidelines for extra-label drug use; US FARAD can assist with establishing appropriate withdrawal intervals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- As many as 60% of subclinical CNS cases will self-cure over the dry period; use of dry therapy will significantly increase the number of cures.
- Acute clinical cases of *S. aureus* may become chronic and refractory to therapy. New clinical cases are most likely to respond to an

extended treatment protocol while subclinical and chronic cases, or those that have survived a dry period, are unlikely to be cured.
• Untreated gangrenous mastitis has a 30–40% case fatality rate and permanent loss of the affected gland is common. Early, aggressive, effective intervention may increase recovery rates to >90%.
• A poor prognosis for survival is associated with *Mannheimia* mastitis.
• Mycoplasma morbidity in naïve flocks can reach 30–60% of the herd. Mortality in acute, untreated cases is generally ≤20%, but may reach as high as 40–70% especially in young stock that present with septicemia. In animals that survive the acute mastitis, milk production is significantly reduced in the current lactation but they may return to production in the next lactation. Carrier animals are common. Subclinical cases and chronic mastitis are more common in endemic herds.
• Lentiviral infections that lead to clinical disease are chronic, progressive, and invariably fatal as no treatment is available. In new cases, milk quantity may transiently improve over the course of a few weeks.

POSSIBLE COMPLICATIONS

Sepsis may develop with severe Gram-negative or *S. aureus* mastitis. Animals, especially goats, with lentiviral mastitis have higher rates of concurrent bacterial IMI due to the retrovirus's immunosuppressive effects.

PATIENT CARE

Monitor for worsening clinical presentation or onset of gangrenous signs.

CLIENT EDUCATION

Educate producers on the importance of herd and milking biosecurity, best milking practices, and control of conditions that impair the innate teat defenses.

PREVENTION

• Best milking practices from the cattle dairy industry can be used on small ruminant operations to improve udder health and decrease IMI transmission. Recommendations include milking primiparous and noninfected animals first, ensuring equipment is clean and well maintained, judicious application of dry therapy, and using gloves, individual towels, and teat dips.
• Control methods for *Mannheimia* mastitis include reducing orf and papilloma teat infections, teat chapping and trauma, cross-suckling (bum lambs), and respiratory spread of *Mannheimia* pneumonia in lambs; the cattle *Mannheimia* vaccine is not efficacious in small ruminants.
• The best defense against *Mycoplasma* is to maintain a clean herd and cull infected animals. Control measures include testing new herd additions, heat-treating colostrum, pasteurizing milk, and environmental hygiene. Request a mycoplasma culture if you repeatedly encounter culture-negative mastitis, or mastitis in conjunction with polyarthritis, conjunctivitis, and pneumonia in young stock.
• Test herd additions for OPP/CAE before purchase.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• *S. aureus*: Diarrhea and pneumonia in nursing stock
• *Mannheimia*: Acute bronchopneumonia in 2-week to 2-month-old nursing stock
• *Mycoplasma*: Keratoconjunctivitis; polyarthritis and pneumonia in young stock
• Lentivirus: Chronic wasting, progressive interstitial pneumonia, arthritis, progressive inflammatory encephalomyelitis, and/or posterior paresis

AGE-RELATED FACTORS

• CNS mastitis is more common with increasing lactation number.
• Lentiviral mastitis typically presents at 2 years of age or older.

ZOONOTIC POTENTIAL

Staphylococci including *S. aureus* may present food safety or antimicrobial resistance concerns. Though less common, *E. coli* and *Salmonella* are documented causes of mastitis in small ruminants. Other pathogens such as *Listeria monocytogenes*, *Campylobacter* spp., and *Coxiella burnetii* may be shed in the milk of clinically normal animals.

PREGNANCY

Severe clinical mastitis during the pre-parturient period may cause abortion.

BIOSECURITY

Transmission of the most common and most severe mastitis organisms can be reduced through herd and milking biosecurity practices.

PRODUCTION MANAGEMENT

• Palpation of the udder at milking time is routinely performed to identify chronic cases of *S. aureus* mastitis that may otherwise serve as a source of infection for the herd.
• Follow recommended milking practices. Milk from affected animals should be pasteurized or acidified before it is fed to young stock.
• If monthly individual SCCs are available, the current month's SCC can be plotted against the previous month's SCC to monitor new, chronic, resolved, and cured IMIs.
• Bulk tank bacterial and SCCs can be rapidly reduced by selectively excluding the milk from the animals that are contributing the greatest **total** number of cells on a daily basis (cells/mL × production volume). These animals should be treated, dried off, or culled depending on the etiology.

ABBREVIATIONS

• AGID = agar gel immunodiffusion
• CAE = caprine arthritis encephalomyelitis
• CNS = coagulase-negative *Staphylococcus*
• ELISA = enzyme-linked immunosorbent assay
• IMI = intramammary infection
• IMM = intramammary medication

MASTITIS: STAPHYLOCOCCAL

BASICS

OVERVIEW

• Mastitis is inflammation of the mammary gland. The majority of mastitis is caused by microorganisms, usually bacterial, that invade the mammary gland, multiply, and produce toxins harmful to the gland.
• Mastitis in dairy cattle and milk goats produces serious economic losses.
• Mastitis is the single most common disease in adult dairy cows.
• Staphylococci are Gram-positive bacteria.
• Staphylococci organisms that cause mastitis are usually identified as *S. aureus,* CNS (coagulase-negative *Staphylococcus*), or more generally as *Staphylococcus* species.

INCIDENCE/PREVALENCE

• *S. aureus:* The 2007 National Animal Health Monitoring Dairy Study found a herd-level prevalence of 40–45% in the USA.
• CNS: Most common cause of mastitis on farms where major contagious pathogens are controlled; between 7% and 30% of quarters infected during herd surveys.

SYSTEMS AFFECTED

Mammary

M

PATHOPHYSIOLOGY

• Establishment of infection and the inflammatory response is increased by adherence factors.
• Infection causes local destruction of alveolar tissue, involution of alveoli, and occlusion of ducts by tissue debris and clots.
• Each *S. aureus* strain possesses different virulence factors to aid in avoidance of the host's immune system, impacting the course of disease and treatability. These include surface proteins, presence of a capsule, and formation of a biofilm.
• Invasion of alveoli is followed by formation of micro-abscesses, fibrosis, and nonfunctional mammary tissue.
• Production of alpha-toxins may lead to gangrenous mastitis.

HISTORICAL FINDINGS

Loss of milk production and possibly local and systemic changes.

SIGNALMENT

Cows are most susceptible to clinical mastitis during early lactation.

PHYSICAL EXAMINATION FINDINGS

• Subclinical mastitis:
  ◦ Lack of visible changes to the gland or the milk.
  ◦ Elevation of somatic cell count of the infected gland.
• Clinical mastitis:
  ◦ Changes in the gland, milk, and/or systemic signs.
  ◦ Peracute clinical mastitis:
    ▪ Gland has swelling, heat, and pain.
    ▪ Secretion is abnormal and may contain clots, flakes, discolored serum, or sometimes blood.
    ▪ Signs of systemic illness are present. These include anorexia, depression, increased pulse rate, sunken eyes, and weakness.
    ▪ Onset is rapid and mortality may be high.
  ◦ Acute, gangrenous clinical mastitis:
    ▪ Gangrenous form is due to *Staphylococcus* alpha-toxin.
    ▪ Acute systemic and local signs are due to toxemia.
    ▪ Starts with inflammation of the gland, then development of cold teats and bloody secretions.
    ▪ The gland has sharply delineated, blue discolorations.
    ▪ Mortality is generally high.
  ◦ Acute clinical mastitis:
    ▪ Similar to peracute infections but systemic signs are less severe.
  ◦ Subacute clinical mastitis:
    ▪ Mild to moderate alterations to the secretion and mammary gland.
    ▪ No systemic signs.

CAUSES AND RISK FACTORS

• *S. aureus:*
  ◦ Primary source—infected udders.
  ◦ Secondary sites include teat skin, udder skin, nose, lips, vagina, and other body sites.
  ◦ Method of spread—via transfer of bacteria-laden milk from infected to noninfected glands. The milking process is a primary means of transfer, but nursing calves, flies, and milkers' hands can also transfer the organisms.
  ◦ Often introduced into a herd by infected, purchased additions.
  ◦ Flies have been associated with infection in prepartum heifers.
• CNS:
  ◦ Normal inhabitants of bovine teat skin and can be free-living in the environment.
  ◦ Infections are more common in first lactation cows.
  ◦ Prevalence is high at parturition, then declines through the first month of lactation.
  ◦ Primary source—commonly found on teat skin and in the streak canal.
  ◦ Cow to cow spread is probably rare.
  ◦ Most infections are transient but rarely become chronic.
  ◦ May be associated with teat injuries or alteration of teat skin condition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Subclinical cases: *Streptococcus agalactia, Corynebacterium bovis,* and minor udder pathogens.
• Clinical cases: Coliform bacteria, mycoplasma, and environmental streptococci.
• Gangrenous mastitis with bloody secretion: Trauma to the gland, and *Clostridium perfringens* type A mastitis.

CBC/BIOCHEMISTRY/URINALYSIS

Usually not performed.

OTHER LABORATORY TESTS

• Microbiological identification of the causative agent is essential:
  ◦ Requires plating organisms to evaluate the colonial characteristics and hemolytic patterns on blood agar.
  ◦ The catalase test is used to differentiate staphylococci from streptococci by mixing the colony with hydrogen peroxide.
    ▪ Staphylococci are catalase-positive (produces bubbles).
    ▪ Streptococci are catalase-negative (do not produce bubbles).
  ◦ Colonies should be Gram stained.
    ▪ Gram-positive cocci that appear in clumps.
• *S. aureus*
  ◦ Large colonies that are creamy, grayish-white, or yellowish.
  ◦ Generally produce hemolysis, typically a double zone, around the colony.
  ◦ Most are coagulase positive.
• CNS (*Staph.* species):
  ◦ Large, creamy, grayish-white or yellowish.
  ◦ Generally have no hemolysis.
  ◦ Most are coagulase negative.

OTHER DIAGNOSTIC PROCEDURES

• Culture is the only method to identify the specific pathogen.
  ◦ Culture and sensitivity results may be useful in determining methicillin-resistant strains of *S. aureus*; however, are not strongly correlated with in vivo treatment outcomes.
  ◦ Strain typing for *S. aureus* is an excellent tool to determine virulence and transmissibility, both important when determining a herd-based treatment and control plan.

TREATMENT

THERAPEUTIC APPROACH

• Both intramammary and systemic therapy have been used.

• When possible, treatment should be influenced by culture and angiobiograms.
• Goal of treatment is to return the gland to production.
• Consider the economics of the treatment.
• Use only products approved for use in food-producing animals.
• Label instructions must be followed.
• Withholding times for milk and meat must be observed.
• Better response to treatment is attained during the dry period.

MEDICATIONS

DRUGS OF CHOICE

• Several commercial products for intramammary administration are available:
  ◦ Pirlimycin
  ◦ B-lactam antibiotics such as penicillin, hetacillin, and amoxicillin
  ◦ Cephapirin
  ◦ Ceftiofur HCl
  ◦ Novobiocin
• No products are labeled for systemic therapy, but injectable ampicillin (3–5 mg/lb) and oxytetracycline (5 mg/lb) have been used in conjunction with intramammary therapy with variable results. These uses are considered extra-label, and the efficacy of combined intramammary and parenteral therapy has not been supported by research.
• Extended duration therapy can be used to improve efficacy of therapy. Approved intramammary antibiotics are administered for up to 8 days into infected quarters.
  ◦ Pirsue® (pirlimycin) is labeled for treatment of clinical and subclinical mastitis associated with Staphylococcus species, including S. aureus.
  ◦ Spectramast® (ceftiofur) is labeled for clinical and subclinical mastitis associated with coagulase-negative staphylococci.
• Prepartum antibiotic therapy has been demonstrated to be efficacious in reducing IMI with coagulase-negative staphylococci and *S. aureus* at calving. Most benefits have been demonstrated in herds with a high prevalence of staphylococci IMI.
• NSAIDs are used to control pain and fever.
• Fluid therapy is essential in systemically affected animals (gangrenous *S. aureus*) as hypovolemia will predispose to kidney damage from NSAIDs and certain antimicrobials.

PRECAUTIONS

Appropriate milk and meat withholding times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Early treatment of *S. aureus* may be successful; success for chronic infections is poor.
• Response to therapy of *S. aureus* is poorer due to formation of L-forms, penicillinase production, and the formation of micro-abscesses within the udder parenchyma.
• CNS has a good prognosis but may become chronic in some cases.

POSSIBLE COMPLICATIONS

N/A

CLIENT EDUCATION

N/A

PATIENT CARE

• Infected quarters should be cultured 21–28 days after treatment to determine cure.
• In the case of *S. aureus*, three sequential cultures will significantly increase sensitivity due to cyclical shedding of the organism.

PREVENTION

• Maintain a closed herd and perform milk cultures on animals prior to purchase if this is necessary.
• See "Production Management" for prevention of transmission.

MISCELLANEOUS

AGE-RELATED FACTORS

First lactation animals have higher cure rates for *S. aureus* than multiparous animals.

ZOONOTIC POTENTIAL

S. aureus is an important zoonosis.

BIOSECURITY

Wear gloves while milking to prevent human-to-animal spread.

PRODUCTION MANAGEMENT

• Control of *S. aureus:*
  ◦ Identify infected cows and isolate or milk last.
  ◦ Cull chronically infected cows.
  ◦ Treat all cows with appropriate, FDA-approved dry cow infusion products.
  ◦ Apply an effective teat disinfectant to each teat following milking.
  ◦ Backflushing systems have been used to reduce the bacterial load in the inflations.
  ◦ Promote good milking hygiene and proper milking techniques to minimize teat end trauma.
  ◦ Vaccines are available but of limited usefulness.
• Control of CNS:
  ◦ Treat all cows with appropriate, approved dry cow infusion products.
  ◦ Apply an effective teat disinfectant to each teat following milking.

ABBREVIATIONS

• CNS = coagulase-negative *Staphylococcus*
• FDA = (US) Food and Drug Administration
• NSAIDs = nonsteroidal anti-inflammatory drugs

MASTITIS: STREPTOCOCCAL

BASICS

OVERVIEW

• Streptococcal mastitis is among the most prevalent causes of intramammary infections (IMI) on dairy farms. These include contagious as well as environmental pathogens.
• *S. agalactiae* is a contagious, Gram-positive coccus that resides in the bovine mammary gland, generally not surviving for long outside of this environment. It tends to spread aggressively.
• *S. dysgalactiae* and *S. uberis* are Gram-positive cocci that are predominantly found within the environment.
• The latter two are often diagnosed as a group in mastitis and udder health programs.

INCIDENCE/PREVALENCE

S. agalactiae

• Fifteen percent of dairy herds in the northeast United States have *Streptococcus agalactiae* infections present at any given time, while 85% are free of this eradicable organism.
• Within infected herds, prevalence of *Streptococcus agalactia* varies considerably, ranging from 1% to 77% of the herd.
• Prevalence has declined dramatically in countries with robust extension programs but remains high in countries with developing dairy industries. For example, in Brazil and Colombia prevalence is 60% and 42%, respectively.
• Prevalence of *S. agalactiae* in camel herds ranges from 3% to 30%.
• Prevalence of *S. agalactiae* in buffaloes ranges from 15% to 30%.

Other Streptococcus spp.

• Of dairy herds in the US, 96% have *S. dysgalactiae* or *S. uberis* infecting at least one cow at any given time.
• Many laboratories and commercial dairy herd mastitis control programs do not distinguish between these two types of nonagalactiae streptococci, identifying them as *Strep* sp.
• Among cows, the prevalence of *Strep* sp. is 14–16% in reports from the US and other developed countries. One large study on dairy goats found a similar prevalence (16%) for *Strep* sp.
• In one study on camels, *S. dysgalactiae* and *S. uberis* were isolated in 22.2% and 7.6% of milk samples, respectively.
• In buffaloes, *S. dysgalactiae* and *S. uberis* were isolated in 30% and 73.5% of clinical mastitis milk samples, respectively.
• In goats, *Streptococcus* spp. are isolated in 11% of subclinical mastitis cases.
• In one study on sheep, S. *uberis* was isolated from 1.7% of clinical mastitis cases.

GEOGRAPHIC DISTRIBUTION

• Worldwide depending on bacterial species and environment.
• In dairy goats, *S. agalactiae* is seen in New Zealand, India, and Brazil but is uncommon in the US.

SYSTEMS AFFECTED

Mammary

PATHOPHYSIOLOGY

• The mammary gland is generally infected via ascendant route.
• Establishment of the infection and severity of the inflammation depends on the strain.
• The presence of inflammation results in an increase in SCC.

HISTORICAL FINDINGS

Increased bulk tank SCC

SIGNALMENT

Dairy cattle, dairy camels, and less frequently dairy goats

PHYSICAL EXAMINATION FINDINGS

S. agalactiae

• There is no one classical presentation of these pathogens within dairy herds; however, in most cases, *S. agalactiae* first becomes evident within months to 1 year following purchase of infected animals.
• Three percent of heifers have infections with *S. agalactiae* at first calving, and should not be assumed to be risk-free as herd additions.
• Ninety-six percent of *S. agalactiae* cases are subclinical.
• *S. agalctiae* results in bulk tank SCC usually >400,000/mL, with a geometric mean SCC for affected quarters of 857,000. The SCC often rises steadily once the increase begins.
• Sometimes associated with high bacterial counts in milk; can be >200,000/mL SPC.
• Often high (>10%/mo) new infection rate on DHIA (or other test service) monthly reports.
• May be high level (>10%/mo) of chronic infections as well.

Other Streptococcus spp.

• *Streptococcus* sp. can be major mastitis pathogens in any herd, including herds as described above.
• However, *Streptococcus* sp. are more likely to be at high levels when tank SCC >400,000/mL.
• *Streptococcus* sp. mastitis often is subclinical but may have severe clinical signs or LS >5.0.
• Often notice many new infections on DHIA among fresh cows <60 DIM.
• *Streptococcus* sp. mastitis increases from June through September in many herds in North America.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Failure to employ standard milking time hygiene measures are risk factors for the spread of *S. agalactiae* IMI. Herds that do not use dry cow antibiotic therapy and herds that do not cull chronically high SCC cows would be at increased risk for *S. agalactiae*. There is also a suggestion that teat end hyperkeratosis increases the risk of *S. agalactiae*.
• Historically, the environmental streptococci (ES) are considered to be opportunist mastitis pathogens; however, the ES, especially *S. dysgalactiae*, may have some characteristics of contagious pathogens. A few studies have demonstrated a greater risk of ES IMI in cows with advancing age.
• Straw bedding increases the risk of cows to ES IMI. Deep-bedded straw packs tend to become contaminated with urine and feces and increase risk.
• Increased prevalence of ES was associated with poor sanitation, increased number of days dry, use of tie stalls, and lack of drying teats prior to milking. There is also a suggestion that the increased time associated with correcting liner slips increases the risk of ES IMI.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Streptococcal mastitis should be differentiated from other causes of mastitis based on epidemiology and culture

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• Bulk tank milk culture is a useful way to screen a herd or group for *S. agalactiae*.
• Sensitivity for a single bulk tank culture is 77% (across all ranges of prevalence). Three bulk tank milk culture samples should be collected approximately 3 days apart and cultured separately. This increases sensitivity to 99%.
• Bulk tank milk cultures are frequently positive for *Strep* sp., and have no practical value in monitoring for these infections.
• Culture of aseptic milk samples is the only definitive way to diagnose either type of mastitis in individual cows.
• Culture should be carried out on blood agar with incubation overnight at 37°C. Streptococci appear as small, somewhat transparent colonies with or without hemolysis at 18–24 hours.
• All mastitis-associated streptococci are catalase negative (no bubbling when a drop of hydrogen peroxide is added to a small amount of the colonies on a glass slide).
• Molecular diagnostic technique such as PCR may increase accuracy of detection and speciation.
• The three primary mastitis-associated streptococci can then be effectively differentiated from each other by a few simple tests (Table 1).

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Spontaneous cure rate for streptococcal mastitis is low (<20%) and often results in chronically high SCC.
• Timely treatment with an appropriate antibiotic is essential and usually economical.

S. agalactiae
• IMM infusion of beta-lactam antibiotic in all four quarters for three milkings in a row should be done for all infected cows as soon as culture results are available. All infected cows should be treated at the same time.
• Cure rates are approximately 90% for *S. agalactiae* cases following any single course of IMM treatment.
• Individual cows may warrant two regimens of therapy before being considered nonresponsive; many animals will cure the second time. Cows that are positive on third culture after two rounds of therapy should be strongly considered for culling.
• Culture of entire lactating herd is usually necessary to eradicate *S. agalactiae*, with resampling of the herd 3 weeks after treatment is complete, repeated until eradication is accomplished.

Other Streptococcus sp.
• Teat dipping and other classical mastitis control measures are weakly associated with control of *Strep* sp.
• The definitive control program for *Strep* sp. has not been developed.
• Environmental sanitation is critical, including dry cow and replacement heifer housing.
• Bedding cultures are often useful. Counts <100,000 cfu/g are good.
• *Streptococcus* sp. >1,000,000 cfu/g in bedding (some are billions/g) is strongly associated with higher prevalence of the infection in cows.
• Bedding cultures often convince farm management that various types of housing and bedding really are in need of increased cleanliness efforts.
• *Streptococcus* sp. control programs including bedding, housing repair, and milking clean, dry teats must be developed with managers and employees of each farm.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Penicillin-based products are the IMM drugs of choice. Several studies have found that the streptococcal species are still quite susceptible to the penicillin products.
• The initial therapeutic protocol should be an approved IMM antibiotic used according to label directions. If this therapy is not successful, there are alternatives.
• Anecdotal evidence suggests that simply switching to a different class of approved IMM antibiotic used according to label is often sufficient to obtain a bacterial cure. Another option is to extend the IMM antibiotic therapy two to three times the labeled duration. Studies with pirlimycin and ceftiofur have demonstrated increasing bacterial cures with increasing duration of treatment. However, a study with extended amoxicillin did not demonstrate any benefit over the normal labeled dosage.
• One other option is to treat both IMM and systemically. In a recent study, increased bacterial cures were obtained by using intramuscular ampicillin with IMM amoxicillin.
• For herds with a high prevalence of *S. agalactiae*, blitz treatment during lactation should be considered as it is often effective (>80%) and often proves to be economical. *Enterococcus* species tend to be considerably more resistant to successful treatment than the other streptococci.
• Camelids should be treated systemically.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals. Note that extending treatment beyond that which is labeled may increase withdrawal times.

POSSIBLE INTERACTION
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Spontaneous cure rate is around 20% for ES. The spontaneous cure rate for *S. agalactiae* is <10%.
• *S. agalactiae* remains highly susceptible to antimicrobials, with <5% of cases typically refractory to treatment.
• Extended IMM therapy has been shown to increase the bacterial cures up to 100% in some experimental studies.

PATIENT CARE
• Follow-up cultures are recommended on any treated streptococci cases.
• Recommended times to culture are 1–4 days after the milk antibiotic withdrawal (a negative culture at this time is most suggestive of the efficacy of the antibiotic) and at 28–30 days (helps to document that an actual bacterial cure did occur).
• Alternatively, a decrease in individual cow SCC to normal levels would be suggestive of a cure.

POSSIBLE COMPLICATIONS
Nonfunctional "blind" quarters in heifers

PREVENTION
• Although the significance of standard mastitis control procedures varies in importance among the streptococci, a complete mastitis control program is essential in control of the streptococci.
• Milking time hygiene will have the most effect on controlling *S. agalactiae* but will also help with control of the ES.
• Complete teat predipping with an effective germicide, which should be left in place for 30 seconds. Avoid water usage in the parlor. Teats should be dried completely with individual udder cloths or paper towels. Milking machines should be properly maintained. Avoid over- or undermilking. Quickly adjust milking units when liner slips occur. In the limited studies performed on backflushing, no benefit was found for the ES. At the end of milking, teats should be dipped up to the base of the udder with an effective germicide. Cows that have been treated and not cured should be retreated or culled to help remove the intramammary reservoir.
• The most reliable methods found to achieve a low SCC include annual milking system checks, establishing a consistent milking order, wearing gloves while milking, using automatic take-offs, and using an appropriate post-dip.
• Studies have shown that up to 50% of new streptococci infections occur during the dry period; therefore, the use of an internal teat sealant plus selective dry cow therapy is recommended. Blanket dry cow therapy is common and may be warranted based on herd dynamics.

MASTITIS: STREPTOCOCCAL (CONTINUED)

• Proper nutrition, especially in regard to appropriate levels of vitamin E and selenium, is important for mammary immune function.
• Avoid the use of straw bedding when possible, and when not possible, proper maintenance of bedding areas is essential. Inorganic bedding is preferred; however, one study found ten times more ES on the teats of cows bedded on sand than on teats of cows bedded on sawdust. Even pasture areas may be heavily contaminated with ES (e.g., common shade area). These prevention measures are less effective against *S. uberis* possibly because of its ubiquitous nature on the dairy farm (shed in the feces). Vaccines are being studied and may be available in the future. However, several studies have found that *S. uberis* strains vary considerably among dairy herds and even within dairy herds, which becomes problematic in regard to an effective vaccine.
• Refer to the National Mastitis Council's 10-point plan for a review of recommendations and a useful on-farm checklist (www.nmconline.org/docs/NMCchecklistNA.pdf).

MISCELLANEOUS

M

ASSOCIATED CONDITIONS
Loss of milk production and increased culling rates

AGE-RELATED FACTORS
Three percent of heifers have infections with *S. agalactiae* at first calving, and should not be assumed to be risk-free as herd additions.

ZOONOTIC POTENTIAL
Although relatively rare, some streptococci of bovine origin have been identified in human infections. In particular, *S. agalactiae* is one of the leading causes of human neonatal infection. However, most studies have found that the *S. agalactiae* cultured from human infants is of a different strain than that found in bovine mastitis.

MELIOIDOSIS

BASICS

OVERVIEW
• Melioidosis, a disease caused by the bacterium *Burkholderia pseudomallei*, affects a wide variety of animal species.
• Disease is most commonly seen in sheep and goats.
• The disease causes caseous abscesses of the lungs, liver, and spleen.
• In disseminated forms, lameness, arthritis, mastitis, or encephalitis may also occur.

INCIDENCE/PREVALENCE
Outbreaks and cases typically occur in endemic areas during the wet season or after heavy rainfall or flooding in areas with high humidity or temperature.

GEOGRAPHIC DISTRIBUTION
• Endemic in tropical and subtropical regions, particularly southeast Asia, northern and central Australia, the Middle East, India, China, the Caribbean, and Central America.
• Most cases occur within 20º latitude of the equator.

SYSTEMS AFFECTED
• Respiratory
• Musculoskeletal
• Nervous
• Mammary
• Hemolymphatic

PATHOPHYSIOLOGY
• *B. pseudomallei* is an aerobic, Gram-negative, facultatively intracellular motile rod that is oxidase- and catalase-positive.
• *B. pseudomallei* measures approximately 0.8 µm × 1.5 µm and exhibits bipolar ("safety-pin appearance") staining.
• It is an opportunistic pathogen that produces exotoxins.
• Strain differences exist that affect virulence.
• The organism is found in soil and water in tropical and subtropical regions.
• Exposure occurs through ingestion, inhalation, contamination of wounds, or arthropod bites. Rare cases of transplacental transmission have been described.
• Disease can develop from the exotoxins produced by the organism (acute disease) or from the survival of the organism within phagocytic cells (latent or chronic disease).
• The incubation period can be days to years following exposure.

HISTORICAL FINDINGS
Residence within a geographic area where the disease is known to occur.

SIGNALMENT
• Sheep, goats, and Old World camelids are most commonly affected.
• Cattle, buffalo, New World camelids, and deer are rarely affected.
• Malnutrition and immunosuppression can predispose to disease.

SIGNS
• Incubation is variable ranging from a few days to many years.
• Many cases are subclinical, with lesions discovered at slaughter.
• Many seropositive animals never show clinical signs.
• *Sheep*
  ◦ Acute form:
    ▪ Fever, anorexia and generalized weakness
    ▪ Respiratory distress/dyspnea
    ▪ Coughing
    ▪ Mucopurulent oculonasal discharge
    ▪ Nasal plaques
    ▪ Lameness with swollen joints
    ▪ Neurologic signs may include circling, incoordination, nystagmus, recumbency, hyperesthesia and blindness
    ▪ Death in 1–7 days
  ◦ Chronic form (much less common)
    ▪ Emaciation
    ▪ Pneumonia
    ▪ Orchitis and testicular abscesses
• *Goats*
  ◦ Acute disease is rare.
  ◦ Chronic form:
    ▪ Lameness
    ▪ Lymphadenopathy
    ▪ Mastitis
    ▪ Cough
    ▪ Emaciation
    ▪ Nasal discharge
    ▪ Salivation
    ▪ Fever
    ▪ Hindlimb paresis
    ▪ Abortion
    ▪ Sudden death
• *Camelids*
  ◦ Acute disease has been reported in an alpaca.
    ▪ Anorexia
    ▪ Dyspnea
    ▪ Froth around the mouth
    ▪ Lymphadenopathy/lymphadenitis
    ▪ Death 2 days after first signs
  ◦ Old World camelids tend toward chronic disease
    ▪ Hacking cough
    ▪ Nasal discharge
    ▪ Dyspnea
    ▪ Ataxia
    ▪ Fever
    ▪ Emaciation
• *Cattle*
  ◦ Rarely show clinical disease
  ◦ Fever
  ◦ Dyspnea
  ◦ Salivation
  ◦ Staggering
  ◦ Abscessation

GENETICS
N/A

CAUSES AND RISK FACTORS
• Transmission of *B. pseudomallei* is most commonly through contact with contaminated soil or water, via ingestion, inhalation, or by contamination of open wounds.
• Person-to-person and animal-to-person transmission can occur but is very rare.
• The primary risk factor for melioidosis is exposure to contaminated soil or water in endemic areas during the wet season or after periods of heavy rainfall in areas with high humidity and temperature.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Tuberculosis
• Caseous lymphadenitis (CLA)
• Actinobacillosis

CBC/BIOCHEMISTRY/URINALYSIS
No specific clinicopathologic changes have been noted.

OTHER LABORATORY TESTS
Submission of pus, nasal discharge, milk, or feces for culture should be considered.

IMAGING
• Pulmonary or mediastinal abscesses may be visible on radiographs.
• Ultrasound may be used to image abscesses for guided sampling of contents.
• Computed tomgraphy may be useful in valuable small ruminants.

OTHER DIAGNOSTIC PROCEDURES
• Culture of the organism from lesions confirms the diagnosis.
• Diagnosis of melioidosis is difficult but may be suspected at necropsy (see below).
• Although there are no pathognomonic lesions for the disease, isolation and identification of the organism should be attempted from swabs of nasal discharge and/or abscesses.
• Organisms may also be found in the feces or milk of infected animals.
• *B. pseudomallei* grows readily on blood agar, trypticase soy agar, chocolate agar, and MacConkey agar.
• Colonies are slow-growing, opaque brown, umbonate, and glistening. Beta hemolysis is evident on blood agar.
• The organism has a characteristic earthy or putrid odor that may be evident (although actual sniffing of plates is not recommended).
• Growth on MacConkey may be useful to distinguish *B. pseudomallei* from *B. mallei*, which will not grow on MacConkey.

MELIOIDOSIS (CONTINUED)

• Suspect *B. pseudomallei* samples should be handled in a biosafety cabinet using BSL-3 precautions.
• Serologic tests (e.g., ELISA, indirect hemagglutination (IHA), and immunofluorescence) may also be used to assist diagnosis. IHA is recommended as a screening test for use in endemic areas, while CFT has been recommended for individual animal testing.
• Serology tests may cross-react with *B. mallei* (causative agent of glanders) and other related Gram-negative organisms.
• PCR tests have been developed to distinguish *B. pseudomallei* from *B. mallei* and other *Burkholderia* species.

PATHOLOGIC FINDINGS
• On necropsy, multiple abscesses may be found in any organ, but particularly the lungs, liver, spleen, internal and external lymph nodes, subcutis, and udder.
• Purulent material from the abscesses is green-tinged or gray, thick or caseous.
• Bronchopneumonia with abscesses.
• Nodular or plaque-like coalescing lesions of the nasal septum and turbinates in sheep and goats.
• Testicular or scrotal abscesses in sheep and goats.
• Aortic aneurysms in goats.
• Nodules around joints, arthritis, and/or osteomyelitis in sheep.
• Microscopic lesions in brainstem and spinal cord of sheep and goats.

TREATMENT

THERAPEUTIC APPROACH
• Treatment is seldom attempted due to the progressive nature of the disease.
• Treatment, if attempted, is often prolonged and unsuccessful once an animal is showing clinical signs.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• In vitro susceptibility is noted to some 3rd-generation cephalosporins, tetracyclines, and potentiated beta-lactams (e.g., amoxicillin-clavulanate).
• Aminoglycoside resistance is well documented.

CONTRAINDICATIONS
N/A

PRECAUTIONS
No antimicrobial protocols have been evaluated in veterinary species.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Clinically affected animals usually die despite treatment.

POSSIBLE COMPLICATIONS
Affected animals will contaminate the environment and place naïve animals at risk.

CLIENT EDUCATION
Focus on prevention (see "Prevention")

PATIENT CARE
N/A

PREVENTION
• No vaccine exists.
• Remove animals from any contaminated source; environmental testing may be useful.
• Use chlorinated water (2–6 mg/L) at a neutral pH.
• Ensure that water drains away from where animals are kept.
• Disposal of sewage/feces away from animal housing or forage cultivation.
• Pasteurization of milk.
• Rodent control.
• In nonendemic areas, affected animals should be culled.
• Risk factors for melioidosis include brush clearing around farms, multiple animal species present, and flooding or waterlogged conditions.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Malnutrition
• Immunosuppression

AGE-RELATED FACTORS
Young animals are more likely to suffer acute septicemic melioidosis.

ZOONOTIC POTENTIAL
• Melioidosis is considered a zoonosis, but transmission to humans from animals is considered very rare.
• Most cases acquired by humans are from environmental (contaminated soil or water) infection (i.e., aerosolization or direct contact with open wounds).
• Human clinical signs vary widely based on route of exposure and most human cases occur in conjunction with underlying diseases (diabetes, alcoholism, cystic fibrosis, etc.).
• Overall human mortality rate is 20%.

PREGNANCY
• Melioidosis has been reported to cause abortion in goats.
• Rare cases of transplacental transmission have been described in several species.

BIOSECURITY
• Isolation, quarantine, and testing of new stock entering the herd or flock.
• Cull infected animals if possible.
• Hypochlorite and cresol solutions have been recommended for disinfection of premises.
• *B. pseudomallei* can survive in 0.3% chlorhexidine.

PRODUCTION MANAGEMENT
• Cull positive cases if possible.
• Environmental management is important in preventing herd infection.

SYNONYMS
• Pseudoglanders
• Whitmore disease

ABBREVIATIONS
• CFT = complement fixation test
• ELISA = enzyme-linked immunosorbent assay
• IHA = indirect hemagglutination

SEE ALSO
• Actinobacillosis: Wooden Tongue
• Caseous Lymphadenitis (CLA)
• Tuberculosis: Bovine

METALDEHYDE TOXICOSIS

BASICS

OVERVIEW

• Metaldehyde is widely used for the control of slugs and snails in the United States. In some countries, metaldehyde is also used as a solid fuel in camping stoves and lamps.
• Available formulations include pellets, granules, liquids, or wettable powder. Baits may also contain other pesticides such as insecticides. The concentration of metaldehyde in baits sold in the US is generally between 1.5% and 5%.
• Metaldehyde poisoning is characterized by the abrupt onset of severe neurologic signs.
• Poisoning in ruminants is reported infrequently but has occurred in cattle, sheep, and goats.
• The onset of clinical effects may occur as soon as 30–60 minutes after ingestion, with death as soon as 1 hour.
• The poisoning is commonly referred to as the "shake and bake syndrome" due to the development of tremors and hyperthermia.
• The oral lethal dose of metaldehyde is estimated to be 300 mg/kg body weight in sheep and 200 mg/kg in cattle.

INCIDENCE/PREVALENCE

Usually results from accidental exposure to metaldehyde so mortality depends on amount consumed. Mortality rates of 10% or greater have been reported.

GEOGRAPHIC DISTRIBUTION

Occurs where metaldehyde is used

SYSTEMS AFFECTED

Nervous

PATHOPHYSIOLOGY

• Metaldehyde toxicity results in central nervous system stimulation as a result of disruption of the GABA-ergic system; may also involve other neurotransmitters.
• After ingestion, metaldehyde undergoes partial hydrolysis in the stomach to produce acetaldehyde. Both metaldehyde and acetaldehyde are readily absorbed from the GI tract. The nature of the stomach contents and the rate of gastric emptying influence the rate of absorption and the onset of the clinical syndrome.
• After absorption, metaldehyde is rapidly metabolized. Enterohepatic circulation may prolong retention of metaldehyde in the animal, but ultimately, both metaldehyde and acetaldehyde are excreted in the urine.
• Clinical manifestations are attributed primarily to metaldehyde, although acetaldehyde does play a role in the clinical syndrome. Metaldehyde exposure alters a variety of neurotransmitter concentrations and enzyme activities.
• Metaldehyde reduces concentrations of γ-aminobutyric acid, an inhibitory neurotransmitter that causes CNS excitation. Reduced concentrations of brain serotonin (5-hydroxytryptamine) and norepinephrine decrease the threshold for convulsions.
• Monoamine oxidase activity is increased after metaldehyde exposure. Increased muscle activity and the production of acidic metaldehyde metabolites cause severe electrolyte disturbances and metabolic acidosis (shake and bake).

SIGNALMENT

• All ruminant species are susceptible to metaldehyde including cattle, sheep, goats, deer, and camelids.
• Cases in cattle, sheep, and goats are reported infrequently. Most reported cases involve dogs.

PHYSICAL EXAMINATION FINDINGS

• Signs of poisoning generally begin within 30–60 minutes of exposure.
• Initial: Salivation, tremors of the fore and hind legs, staggering, and respiratory distress.
• This is quickly followed by weakness, ataxia, hyperventilation, hyperthermia, and convulsions. In severe cases, the animals become recumbent, unconscious, and show continuous convulsions with leg paddling.
• Disseminated intravascular coagulation may occur as a result of severe hyperthermia (body temperature may reach 110°F; 43°C).
• Death may occur within 60 minutes of exposure as a result of respiratory failure.

CAUSES AND RISK FACTORS

• Geographic areas with high slug and snail populations present a greater risk due to the increased use of metaldehyde baits.
• Bran or molasses is commonly added to the bait to increase its palatability. Some baits have chemicals added to make them less likely to be ingested by species other than slugs and snails.
• Wild ruminants with access to metaldehyde baits are at risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Cyanide toxicosis—initially bright cherry-red blood, history of exposure to cyanide-containing plants.
• Nitrate toxicosis—chocolate-brown discoloration of blood, history of exposure to nitrate-containing plants.
• Lead poisoning—determination of blood lead concentration.
• Organophosphorus or carbamate insecticide exposure—GI upset and neurologic signs, evaluation of cholinesterase activity, detection of pesticides in GI contents.
• Exposure to neurotoxic plants, such as poison hemlock, water hemlock, tree tobacco, lupine—history of presence of plants in the environment; identification of plant parts and chemical analysis for plant toxins in GI contents.
• Exposure to cardiotoxic plants, such as oleander, milkweed, and azalea—chemical analysis for plant toxins in GI contents, history of presence of plants in the environment.
• Nonprotein nitrogen toxicosis—history of NPN supplements in the feed ration, detection of toxic levels of ammonia in rumen content and blood.
• Strychnine toxicosis—history of exposure to strychnine-containing bait, detection of strychnine in GI contents or liver.
• 4-Aminopyridine—history of exposure to the avicide, detection of 4-aminopyridine in GI contents.
• Neurotoxic blue-green algae toxins—peracute onset, access to pond water, detection of anatoxin-A in GI contents.
• Seizures—nontoxic etiologies (e.g., trauma, neoplasia, infection, metabolic disorder).

CBC/BIOCHEMISTRY/URINALYSIS

• No specific clinical pathologic changes occur.
• Metabolic acidosis may be present.

OTHER LABORATORY TESTS

Detection of metaldehyde in serum, urine, rumen content, or liver. Confirmation of metaldehyde in suspect material.

PATHOLOGIC FINDINGS

• No clearly distinctive changes due to the rapidity of death.
• Generalized renal, hepatic, and pulmonary congestion.
• Petechial and ecchymotic hemorrhages in the heart, lung, and GI tract.
• Metaldehyde has a characteristic odor of formaldehyde; may be present in the rumen contents along with bait material.

TREATMENT

THERAPEUTIC APPROACH

• Rapid progression of metaldehyde poisoning necessitates immediate treatment.
• Control of CNS signs and hyperthermia is essential. Decontamination with activated charcoal should be considered after initial stabilization of the poisoned animal.
• Fluid therapy should be instituted to control acidosis and dehydration.

MEDICATIONS

DRUGS OF CHOICE

• No antidote available
• Pentobarbital at 20–30 mg/kg IV or diazepam at 0.5–1.5 mg/kg IV for control of seizures

M

METALDEHYDE TOXICOSIS (CONTINUED)

• Lactated Ringer's or sodium bicarbonate solutions IV
• Activated charcoal at 2 g/kg orally

CONTRAINDICATIONS
• Pentobarbital can cause respiratory depression.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Animals poisoned with metaldehyde may be found dead.
• Poisoning progresses so rapidly that treatment is often too late. In most cases, the affected animals have a poor to grave prognosis.
• If treatment is initiated promptly after the onset of clinical signs, the prognosis is fair.

POSSIBLE COMPLICATIONS
Renal and hepatic disease may develop if poisoned animal survives the initial convulsive phase.

PATIENT CARE
Monitor progression of clinical signs.

M

PREVENTION
• Avoid metaldehyde-containing baits in areas accessible to livestock.
• Use bait according to label instructions.
• Consider the use of less-toxic alternatives to control slugs and snails.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Concurrent toxicosis from other herbicides/pesticides that may be mixed in (most commonly carbamate insecticides).

PRODUCTION MANAGEMENT
Avoid metaldehyde-containing baits in areas accessible to livestock.

ABBREVIATIONS
• CNS = central nervous system
• GABA = gamma aminobutyric acid
• GI = gastrointestinal
• IV = intravenous
• NPN = nonprotein nitrogen

METRITIS

BASICS

OVERVIEW

• Metritis is an inflammation of all layers (endometrium, myometrium, and serosa) of the uterus during the postpartum period, typically the first 7–14 days.
• Metritis is more commonly seen in dairy cattle but can affect all ruminant and camelid species.
• Affected cows have a fetid, watery, discolored genital discharge. Puerperal (toxic) metritis is distinguished by an elevation in body temperature and signs of systemic illness including anorexia, depression, and dehydration. In severe cases the condition can become septic and life threatening. In an effort to improve diagnostic, therapeutic, and prognostic precision, attempts have been made to distinguish metritic cows with and without systemic signs of disease. It should be noted that this distinction may be a temporal one as signs may have subsided at the time of the examination or they may occur later in the course of the disease. Cows with metritis are more likely to develop other postpartum disorders such as ketosis, displacement of the abomasum, endometritis, and pyometra.
• Cows with metritis usually have reduced feed intake, produce less milk, and experience a delay in days to first service, lower conception rates, and increased days open.

INCIDENCE/PREVALENCE

• The postpartum incidence of metritis varies among reports and with the definition criteria used for diagnosis.
• In North America, approximately 10–20% of dairy cows are affected with metritis. About one-half of the cows with an abnormal parturition (dystocia, RFM, twins) can be expected to develop metritis.

GEOGRAPHIC DISTRIBUTION

Worldwide; in hot climates the incidence of metritis may be higher due to the effect of heat stress.

SYSTEMS AFFECTED

• Multisystemic
• Reproductive

PATHOPHYSIOLOGY

• The vulva, vestibulovaginal sphincter, and cervix are mechanical barriers that protect the uterus from bacterial contamination. However, during parturition and shortly thereafter, these barriers break down and allow pathogenic and nonpathogenic bacteria to contaminate the uterus. Most of these bacteria are transient residents and are eliminated by the defense mechanisms of the uterus.
• The bacterial population is mixed and consists of both aerobic and anaerobic Gram-negative and Gram-positive organisms.
• Organisms frequently incriminated in bovine metritis include *Trueperella pyogenes, Escherichia coli,* and *Fusobacterium necrophorum.* Occasionally, *Clostridium* spp. infect the uterus and cause a gangrenous metritis. Depending on the species and location, a wide variety of pathogenic and opportunistic microorganisms have been isolated from cases of metritis.
• In cows with a normal parturition, the uterus resolves the bacterial infection by 4 weeks postpartum. However, in affected females the bacterial contamination becomes more severe and persistent.
• Unsanitary calving conditions and traumatic obstetric manipulation can also predispose the cow to uterine infections.
• Because of differences in husbandry practices and stress from lactation, postpartum metritis is more commonly seen in dairy cows than other ruminants.

GENETICS

Generally N/A; however, genomic testing has the potential to identify a genetic basis for many predisposing risk factors and possibly diseases themselves, including metritis.

HISTORICAL FINDINGS

Dystocia or RFM

SIGNALMENT

• More commonly seen in bovine than in caprine or ovine species.
• In camelid, metritis is observed after lengthy obstetric manipulation and in cases of fetal emphysema.
• Dairy cattle are more frequently affected than beef cattle.
• Reports are conflicting as to the effect of parity on incidence. However, most agree that the incidence is higher in primiparous than in multiparous animals.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs of metritis are influenced by the virulence of the bacteria and predisposing risk factors.
• During the first few weeks postpartum, lochia is normally expelled from the reproductive tract. Normal lochia is red to brown in color.
• Metritis occurs more commonly in those cows that experienced an abnormal parturition and these cattle should be monitored carefully during the first 2 weeks postpartum.
• Fever (>103.0°F or 39.5°C).
• Partial or complete anorexia.
• Low milk production.
• Lethargy or depression.
• Fetid serosanguineous discharge from the reproductive tract.
• Enlarged, flaccid uterus.

CAUSES AND RISK FACTORS

• Risk factors associated with metritis have been studied mainly in dairy cattle and include: RFM, dystocia, delivery of a male calf, twinning, uterine prolapse, abortion or stillbirth, hypocalcemia.
• A variety of bacteria can establish an infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Normal discharge from the uterus or lochia
• Endometritis/vaginitis/cervicitis
• Parturient trauma (often iatrogenic)

CBC/BIOCHEMISTRY/URINALYSIS

• Neutropenia with or without a degenerative left shift
• Hypocalcemia
• Hypoglycemia
• Ketonemia

OTHER LABORATORY TESTS

Bacterial culture and sensitivity may be indicated for valuable individuals.

IMAGING

Ultrasonography and vaginoscopy may be used to verify the origin of the genital discharge but are generally not necessary in cattle. They may be of more use in small ruminants and camelidae.

OTHER DIAGNOSTIC PROCEDURES

• Palpation per rectum
• Vaginoscopy
• Ultrasonography

PATHOLOGIC FINDINGS

Necropsy findings in cows that die from toxic or septic metritis: peritonitis; friable, necrotic uterus.

TREATMENT

THERAPEUTIC APPROACH

• Because of the differences in diagnostic criteria and the lack of controlled studies, treatment of this condition remains controversial among clinicians.
• Therapy generally includes antibiotics (systemic or intrauterine). The efficacy of intrauterine antibiotic is questionable.
• Supportive treatment for clinical signs and associated conditions (e.g., hypocalcemia and ketosis).
• Fluid therapy and anti-inflammatory agents are indicated for animals with systemic signs of disease.

METRITIS (CONTINUED)

• Camelidae are often treated in a manner similar to the mare. Typically this involves uterine lavage, systemic antibiotics, and supportive therapy.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Systemic administration of a broad-spectrum antibiotic is recommended for cows with metritis, particularly those that are pyretic. Follow label recommendations, maintain treatment records, and educate producers to avoid antibiotic residues in milk and meat.
  ◦ Procaine penicillin G: 22,000 IU/kg IM q24h for 3–5 days
  ◦ Ceftiofur: 2.2 mg/kg q24h IM or SubQ for 5 days
  ◦ Ampicillin: 4.4–11 mg/kg IM for 3–7 days
  ◦ Oxytetracycline: 6.6–11 mg/kg IM, SQ, or IV for up to 4 days
• Intrauterine penicillin and oxytetracycline are used by some clinicians but the efficacy is questionable.
• Sanitary procedures and avoidance of genital tract trauma are important considerations when intrauterine antibiotics are used.
• Estrogens and oxytocin have been advocated to increase uterine contractions and help evacuate uterine contents. Research is lacking that supports the use of these hormones for the treatment of metritis.
• Contractions induced by estrogen have been associated with flushing septic uterine contents into the uterine tubes, causing salpingitis or even peritonitis.
• Oxytocin causes contraction of the postpartum uterus if it is used within 6 days after calving. Doses of 20–40 IU repeated every 3–6 hours are generally used.

CONTRAINDICATIONS
• Systemic oxytetracyline is not recommended because of difficulty in reaching the minimal inhibitory concentration required for *T. pyogenes* in the uterine lumen.
• No antibiotic is approved for intrauterine use in the United States.
• Appropriate milk and meat withdrawal times must be followed.
• Veterinarians should be aware of local regulations that may restrict their choice of drugs or the method and frequency of administration.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Cows treated promptly can be expected to recover fully from metritis. However, milk production and reproductive performance are affected in the current lactation. In some cases, cows can develop uterine abscesses and pyometra.
• In camelids, prognosis for life is very good if metritis is treated promptly and adequately. Postpartum breeding should be delayed.

POSSIBLE COMPLICATIONS
• Septicemia
• Ketosis
• Displaced abomasum
• Mastitis
• Infertility
• Involuntary culling

CLIENT EDUCATION
• In dairy, clients should institute a postpartum monitoring program particular for high-risk cows.
• In camelids, females should be presented for postpartum evaluation and neonatal examination 24–36 hours after parturition.

PATIENT CARE
• In cattle, metritis patients should be monitored for development of ketosis, displaced abomasum, and mastitis.
• In camelids, metritis patients should be monitored for poor appetite and metabolic disorders. Neonates should be monitored to insure that they are getting enough milk.
• In addition, if the condition does not improve with 3 days of antibiotic treatment, an alternative antibiotic should be considered.

PREVENTION
• Effective transition cow management with special attention to adequate feed intake.
• Minimize dystocia incidence.
• Use of calving-ease bulls.
• Use of gender-enhanced semen (female) for heifers.
• Minimize abortion incidence.
• Biosecurity and quarantine procedures.
• Vaccination.
• Sanitary and atraumatic obstetric procedures.
• Sanitary maternity facilities.
• Postpartum health monitoring during the first 2 weeks postpartum should include milk production and attitude monitoring to help diagnose and treat the condition early.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Ketosis, displaced abomasum, dystocia, RFM, endometritis, infertility

AGE-RELATED FACTORS
In general, incidence of metritis is greater in primiparous than in multiparous animals.

ZOONOTIC POTENTIAL
The common bacterial agents isolated from metritis cases are rarely a zoonotic concern for healthy, immunocompetent adults. However, metritis is frequently seen following abortion or stillbirth and these conditions in ruminants are often the result of potentially zoonotic diseases (e.g., leptospirosis, brucellosis, toxoplasmosis, and Q fever). Protective clothing, sleeves, and good hygienic practices are recommended.

PREGNANCY
Metritis occurs in postpartum animals.

BIOSECURITY
Prevention of infectious diseases that may cause abortion will reduce the incidence of metritis. Testing of new arrivals, quarantine, and vaccination programs are effective methods for limiting disease introduction.

PRODUCTION MANAGEMENT
Effective herd management can reduce the incidence of metritis as well as limit the financial impact of cases when they do occur.

MILK VEIN RUPTURE

BASICS

OVERVIEW
Hemorrhage from the caudal superficial epigastric vein (milk vein)

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Cardiovascular

PATHOPHYSIOLOGY
• The milk vein is a common site for venipuncture by laypeople because it is very superficial cranial to the mammary gland on the ventral abdomen. It is an especially convenient vein for farmers and workers treating down cattle for conditions such as milk fever (hypocalcemia). The vessel is only thinly covered by skin and subcutaneous tissue.
• Perivascular hemorrhage or leakage of irritating products such as calcium, dextrose, or antimicrobials can cause small abscesses or fibrous tissue that weaken the covering over the milk vein, sometimes resulting in rupture.
• Hemorrhage also occurs due to direct trauma to the vein (e.g., lacerations, direct pressure from casting ropes).

SIGNALMENT
• Bovine species, usually adults after IV treatment.
• Predominant sex is females secondary to the propensity for hypocalcemia treatment.

HISTORICAL FINDINGS
• IV treatment in the milk vein some time prior to hemorrhage.
• Trauma.
• May see an increased incidence during times of biting flies and other insect activity due to bunching of cattle and increased leg kicking for fly avoidance.

PHYSICAL EXAMINATION FINDINGS
Bleeding from either of the caudal superficial epigastric veins.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Weakened tissue superficial to the milk vein.
• Conditions requiring IV treatments, such as hypocalcemia, ketosis, or some mastitis treatments. Farmers treating cattle IV in milking parlors without adequate restraint tend to favor the milk vein. Reusing needles is associated with local sepsis and increased tissue damage due to dull or barbed needles.
• Infrastructure in milking parlors and barns, especially metal, with exposed sharp edges.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
N/A

CBC/BIOCHEMISTRY/URINALYSIS
PCV/TP can be monitored to evaluate level of whole blood loss; however, immediate on-farm treatment should be initiated based on clinical signs.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Rupture in thin-walled area of milk vein.

TREATMENT

THERAPEUTIC APPROACH
• Suture ruptured area.
• Fluid therapy or blood transfusion may be required.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Suturing may be complicated by friable tissue. Purse-string sutures surrounding the friable area are often required.

MEDICATIONS

DRUGS OF CHOICE
• Balanced electrolytes or whole blood transfusion if pale mucus membranes or low PCV.
• Broad-spectrum antibiotics are warranted in cases with significant contamination or cases occurring secondary to improper IV administration with surrounding cellulitis.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• The rupture is often difficult to suture because of the friable tissue that resulted in the rupture.
• This is a medical emergency.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Recovery if vein successfully sutured and hypovolemia is corrected.

POSSIBLE COMPLICATIONS
Hypovolemic shock and death

PATIENT CARE
Monitor for signs of hypovolemia and sepsis.

CLIENT EDUCATION
• Advise client not to utilize the milk vein for IV treatments.
• Train dairy personnel how to manage cases of milk vein rupture until the veterinarian arrives. This includes stopping hemorrhage with a tight belly-band (e.g., duct tape, elastikon) or clamp (e.g., hemostats, binder clips, locking plyers) and keeping the animal quiet.

PREVENTION
• Do not use milk vein for IV treatments. Do not reuse needles. Fly and insect control.
• Maintain facilities well, which includes frequent walk-throughs and prompt attention to damaged infrastructure.
• Use care when casting lactating cows using the double half-hitch method as the rope puts significant pressure over the superficial epigastric veins. The Burley/Flying-W method negates this risk.

MISCELLANEOUS

AGE-RELATED FACTORS
Usually adult dairy cows.

ABBREVIATIONS
• IV = intravenous
• PCV = packed cell volume
• TP = total protein

SEE ALSO
• Fluid Therapy: Intravenous
• Fluid Therapy: Oral

MILKWEED (*ASCLEPIAS* SPP.) TOXICOSIS

BASICS

OVERVIEW

• Toxicity associated with ingestion of one of many *Asclepias* spp. (milkweed).
• Distribution of plants varies by species, however, there is at least one species present over most of North America.
• Two leaf types are present and vary in their expression of the relative amounts of toxins:
  ◦ Wide leaf varieties (i.e., *A. speciosa* and *A. syriaca*) are more commonly associated with cardiac and gastrointestinal toxicity. Toxicity is less common as they are only eaten when no other feed choices are available.
  ◦ Thin leaf (<1 cm wide) varieties (i.e., *A. fascicularis* and *A. subverticillata*), which contain higher levels of the neurotoxin and are consumed more commonly due to their more palatable nature and the animal's difficulty in selectively not consuming them in hay.
• Plants are most toxic during rapid growth but retain their toxicity even when dried in hay. Toxicity tends to decrease with maturity.
• Clinical signs develop with consumption of 0.05–2% of body weight depending on the species and toxin concentration in the plant.

INCIDENCE/PREVALENCE

Milkweed is considered to be one of the most toxic plants in North America and has been associated with mortality rates of >50% in sheep grazing milkweed for 24 hours or less.

GEOGRAPHIC DISTRIBUTION

There are over 100 species of *Asclepias* spp. growing naturally in North America and all are potentially toxic. There are few species in Canada. There are also a few species in other parts of the world.

SYSTEMS AFFECTED

• Cardiovascular
• Digestive
• Nervous

PATHOPHYSIOLOGY

• Two mechanisms of toxicity: (1) cardiovascular and gastrointestinal toxicity associated with cardenolides (cardiac glycosides) and (2) neuromuscular toxicity associated with neurotoxic pregnane glycosides.
• The cardenolides produced by the wide leaf varieties inhibit the function of the Na^+/K^+-ATPase pump and allow accumulation of Na and Ca inside the cell and depletion of intracellular K. This leads to abnormal membrane potentials and irregular action potential initiation. This results in cardiac arrhythmias and muscle weakness.
• The mechanism of action of the neurotoxin is not known.

SIGNALMENT

• Sheep are most commonly affected.
• Can occur in any ruminant species.
• Cattle require ingestion of twice as much toxin as sheep.
• Animals are consuming toxin-producing forages either green in the field or in hay.

PHYSICAL EXAMINATION FINDINGS

• Vary with the species of plant consumed (i.e., neurotoxin-producing thin leaf or cardiotoxin-producing wide leaf), amount consumed, and duration of toxicity.
• Acute death may be the only clinical sign.
• Signs generally develop within 12–18 hours of ingestion of cardiac glycosides and may be immediate or delayed (i.e., 12 hours) with ingestion of neurotoxic compounds.
• Cardiac glycoside (cardiac and gastrointestinal toxin) symptoms include depression, weakness, reluctance to stand, enteritis, bloat, labored respiration with grunt, and possibly cardiac arrhythmias.
• Neurotoxic symptoms include depression, mydriasis, ataxia, weakness, pelvic limb paresis, humped-up appearance, rabbit-like gait, seizures, opisthotonus, and death due to respiratory failure.

CAUSES AND RISK FACTORS

• Ingestion of toxin-containing *Asclepias* spp. in pastures or hay.
• Ingestion of neurotoxic compounds may be cumulative.
• Cattle on ionophore-containing diets may have an increased risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Other sources of cardiac glycosides, including dogbane, Indian hemp, lily of the valley, foxglove, and oleander.
• Other cardiotoxic plants including yew, rhododendron, and laurels.
• Other neurologic diseases including heavy metal toxicosis, buckeye toxicity, dallis grass toxicity, traumatic nerve damage (calving paralysis), spinal column lymphosarcoma, and rabies.
• Other causes of recumbency including fractures, hypocalcemia, hypomagnesemia, hypophosphatemia, and hypokalemia.
• Other causes of cardiac arrhythmias including traumatic reticulopericarditis, electrolyte disorder associated atrial fibrillation, cardiac neoplasia.

CBC/BIOCHEMISTRY/URINALYSIS

There may be an increase in serum creatinine kinase activity. However, this is not a specific indicator for milkweed toxicity.

OTHER LABORATORY TESTS

• Evaluation of the pasture or hay for evidence of milkweed contamination. Careful examination for the narrow leaf varieties must be done, as they are often hard to identify due to their similarity to grasses even when contained in large quantities in hay.
• Analysis of urine, serum, tissue, and stomach contents for cardiac glycosides is available using high-performance liquid chromatography.

IMAGING

Echocardiography would be helpful in excluding other differential diagnoses. However, it is technically challenging and requires expensive equipment and thus is not routinely done.

PATHOLOGIC FINDINGS

• Depends on the toxin consumed.
• Cardiac glycoside toxicity is associated with a hyperemia with or without hemorrhage of the abomasum and small intestine, pulmonary congestion, acute ischemia-associated glomerulopathy and tubular necrosis, and in some cases mild nonsuppurative myocardial cellular degeneration. Hemorrhage may be present on the surface of the lung, kidney, and heart.
• Ingestion of the neurotoxic compound is more difficult to determine on necropsy, but there may be evidence of external trauma; hemorrhages in the trachea, heart, and lungs; and often an empty urinary bladder.

TREATMENT

THERAPEUTIC APPROACH

• If acute ingestion of large amounts of toxin is suspected, a rumenotomy to evacuate the ingesta may be beneficial.
• Other herd mates should be isolated from the source of the toxin (i.e., pasture or hay).

MEDICATIONS

DRUGS OF CHOICE

• Orogastric intubation with activated charcoal, cathartics, or mineral oil may decrease intestinal absorption of the toxins and increase rate of excretion in feces.
• Administering balanced polyionic fluids as needed to maintain hydration and for renal diuresis may minimize effects of ischemia-induced kidney damage.
• Sedative and/or anesthesia may be helpful in patients with severe convulsions associated with neurotoxin ingestion.
• Antiarrhythmic drugs such as procainamide, lidocaine, or atropine sulfate may be used in rare cases exhibiting arrhythmias.
(Appropriate records for extra-label drug use must be maintained.)
• Appropriate drug withdrawal periods must be determined and maintained.

MILKWEED (*ASCLEPIAS* SPP.) TOXICOSIS (CONTINUED)

CONTRAINDICATIONS
Use of calcium-containing fluids is contraindicated as it may potentiate the effects of cardiac glycosides.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Varies with amount of toxin ingested, duration of exposure, and response to treatment.
- Most animals will start developing signs within 12–18 hours of ingesting toxin.
- If symptoms are severe, animals will often die within 24 hours.
- If animal develops seizures and convulsions, the prognosis is grave.
- If animals survive the first 24–36 hours, they often will remain weak for a period of time before improving.

POSSIBLE COMPLICATIONS
If the animals survive, they may develop acute to chronic renal failure.

PATIENT CARE
- Evaluation of neurologic status and monitoring for seizure activity should be done frequently.
- Frequent auscultation of the heart should be performed to assess for development of cardiac arrhythmias.
- Monitoring of urinalysis and serum chemistry for azotemia is indicated in patients that survive the acute toxicosis.

PREVENTION
Prevent animals from grazing on pasture or eating hay containing milkweed.

MOLYBDENUM TOXICITY

BASICS

OVERVIEW

• Molybdenum (Mb) is an essential micronutrient, which forms molybdenoenzymes. Dietary intake of excess Mb causes, in part, secondary hypocuprosis.
• The metabolism of copper, molybdenum, and inorganic sulfate is a complex interrelationship. Mb toxicity is directly associated with copper deficiency and has similar signs.
• Ruminants are especially susceptible to dietary molybdenum excess, leading to depressed growth, diarrhea, neurologic defects, and eventually death, if untreated.
• The ruminal interaction of molybdates and sulfides gives rise to thiomolybdates. At high levels, these compounds decrease the availability of dietary copper and, when absorbed, slow the metabolism of tissue copper and inhibit copper enzymes. This leads to signs of copper deficiency.
• Increased levels in the east and west coasts, increased in acidic, wet soil (peat bogs).
• Forage plants can accumulate Mb. Concentration is lowest in winter, increased in summer and fall.
• Seen in contamination of soils, industrial contamination, fertilizers, feeding of forages and grain. When Cu levels of feed or forages in the normal range of 8–11 ppm, cattle can be poisoned with Mb levels above 5–6 ppm and sheep on levels above 10–12 ppm.
• If Cu level is below 8–11 ppm, or sulfate level is high, even 1–2 ppm Mb may be toxic in cattle.
• High level of Cu in diet to 13–16 ppm can protect Mb poisoning up to 150 ppm dietary Mb.

INCIDENCE/PREVALENCE

Not unusual that large percentage of herd clinically affected.

GEOGRAPHIC DISTRIBUTION

Increased levels in the east and west coasts, increased in acidic, wet soil (peat bogs).

SYSTEMS AFFECTED

• Integument
• Musculoskeletal
• Nervous

PATHOPHYSIOLOGY

• In ruminants, various molybdates react with sulfides to produce thiomolybdate compounds, which react with copper to form an insoluble complex that is poorly absorbed.
• The reduced copper absorption impairs copper utilization and the synthesis of a variety of copper-dependent proteins. The reduced bioavailability of copper ultimately induces secondary copper deficiency. Causes cytochrome oxidase deficiency and limits heme synthesis.
• Excessive molybdenum intake also enhances the excretion of copper. Excessive molybdenum exposure may also impair a variety of enzymes involved in collagen and elastin maintenance and stability, which has been associated with cardiovascular disorders.
• Molybdenum exposure may reduce phospholipid synthesis in nervous tissue, resulting in demyelination and neurologic disorders clinically.

SIGNALMENT

• Ruminants tend to be more susceptible than nonruminants; cattle are more susceptible than sheep. Cattle and sheep are ~10-fold more susceptible than other species.
• Young animals have increased susceptibility.
• Calves can be poisoned by milk from cows on increased Mb.
• Lambs under 1 month of age, severely uncoordinated, ataxic, and usually blind.

PHYSICAL EXAMINATION FINDINGS

• Defects in pigmentation, keratinization, bone formation, myelination of the spinal cord, connective tissue formation, and pica.
• With chronic ingestion, osteoporosis, bone fractures, beaded ribs, and overgrowth of long bone ends are found.
• Emaciation, depressed growth.
• Liquid diarrhea full of gas bubbles, called peat scours, or teart.
• Swollen genitalia, impaired reproductive performance.
• Low-level toxicity linked to reduced fertility in cattle, result of binding to Cu.
• Anemia from decreased hematopoiesis.
• Achromotrichia (depigmentation) of the hair coat especially around the eyes, giving a "spectacled" appearance.
• In sheep, depigmentation of dark wool, loss of crimp and quality of the fine wool.
• In Australia, enzootic ataxia, in the United Kingdom "sway back" seen in the lysis of CNS white matter.
• Death is the result of starvation, exposure, or pneumonia.

CAUSES AND RISK FACTORS

The susceptibility of ruminants to a high intake of molybdenum depends on a number of factors:
• The copper contents and intake of the animal: The tolerance to molybdenum decreases as the content and intake of copper fall.
• The inorganic sulfate content of the diet: High dietary sulfate with low copper levels exacerbates the condition; low dietary sulfate causes high blood molybdenum levels due to decreased excretion.
• The chemical form of the molybdenum: Water-soluble in growing herbage is the most toxic, and curing decreases toxicity.
• The presence of certain sulfur-containing amino acids.
• The species of the animal: Cattle are less tolerant than sheep.
• The age: Young animals are more susceptible.
• The season of the year: Plants concentrate molybdenum beginning in the spring with the maximum level in the fall.
• The botanic composition of the pasture: Legumes take up more of the element than other plant species.
• In cattle forage a safe ratio of Cu : Mb is >2:1; when the ratio is <2:1, Mb poisoning occurs.

DIAGNOSIS

Made by clinical appearance, response to Cu treatment

DIFFERENTIAL DIAGNOSES

• Ca/phos/vit D metabolic imbalance
• Massive parasitism, GI parasites
• Johne's disease
• Demyelinating diseases of brain and spinal cord

CBC/BIOCHEMISTRY/URINALYSIS

• Decreased PCV, microcytic, hypochromic anemia
• Cu and Mb levels in forage and tissues
• Liver levels of Cu <10–30 ppm, Mb >5 ppm significant
• Whole blood Cu <0.6 ppm, Mb >0.1 ppm, significant
• Milk Mb up to 300 ppm significant

PATHOLOGIC FINDINGS

• Gross lesions include cardiovascular hemorrhage.
• Histologic lesions include lysis of white matter and degeneration of motor tracts of spinal cord.
• Microscopic to massive subcortical destruction.
• Neuronal degeneration and demyelination.

TREATMENT

THERAPEUTIC APPROACH

• Remove animal from feed source.
• Where Mb content of forage is <5 ppm, Cu sulfate in salt mineral mixture 1%. With higher Mb, use 2%.
• Repository Cu glycinate SQ and 60 mg for calves, 120 mg for mature cattle. May need to be repeated for a good response.
• Can use as top dressing in pasture, trace mineral mix free choice in feed.

MEDICATIONS

DRUGS OF CHOICE

Copper sulfate oral drench

MOLYBDENUM TOXICITY (CONTINUED)

CONTRAINDICATIONS
• Sheep are highly susceptible to copper drench.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
• Young animals have increased susceptibility.
• Calves can be poisoned by milk from cows on increased Mb.
• Lambs <1 month of age, severely uncoordinated, ataxic, and usually blind.

PREGNANCY
Impaired reproductive performance

MONENSIN TOXICITY

BASICS

OVERVIEW

• Monensin, a monovalent carboxylic ionophore antibiotic produced by the fungus *Streptomyces cinnamonensis,* is approved by the UnitedStates FDA for use as a feed additive in certain classes of ruminants.
• Commercially available as Rumensin and Coban, it is commonly added in feed to treat coccidiosis and to improve feed efficiency and growth by altering rumen microbial populations. It also spares dietary proteins in the rumen to prevent bloating and acidosis.
• Poisonings have been reported in cattle, sheep, goats, and camelids. Ingestion of toxic amounts of ionophores can cause effects to the cardiovascular, musculoskeletal, neuromuscular, hepatic, and renal systems.
• Toxicosis can result from overdosage and misuse. Mixing errors and ingestion of premix concentrates are the leading causes of such presentations.
• Clinical signs in affected animals may be acute, evident within a day, or subchronic, taking several weeks, depending on the concentration of monensin the animal was exposed to. Some effects may persist for months and lead to permanent damage.
• The following oral lethal doses have been reported for various ruminants on a body weight basis:
  ◦ Cattle LD_1 = 5.5 mg/kg; LD_{10} = 11 mg/kg; LD_{50} = 26.4 mg/kg
  ◦ Sheep LD_0 = 4 mg/kg; LD_{50} = 10.7–13.1 mg/kg
  ◦ Goat LD_{50} = 22.4–30.4 mg/kg
  ◦ Camelid LD_{50} = 1–2 mg/kg
• The FDA recommends 5.5–33 ppm monensin in the total diet of cattle and 22 ppm for goats.
  ◦ 100 ppm, for about 1 year, had no effect on circulatory or reproductive functions of cattle.
  ◦ 200–400 ppm monensin in feed for some days may lead to chronic toxicosis in cattle.
  ◦ Goats consuming feed with 55 ppm monensin for 3 weeks may manifest hepatotoxicity. However, no such effect is seen in goats at 11 ppm for 3 weeks, or at 8 mg/kg BW × 5 days.
• Although not approved for sheep, monensin has been purposefully added to ovine feed at levels similar to that of cattle. In lambs <1 month of age, diffuse gastrointestinal hemorrhage has been reported. Single dose of monensin at 12 mg/kg resulted in no muscular abnormality. At 2–4 mg/kg × 4 days, listlessness and feed refusal were observed; and at concentrations ≥8 mg/kg × 2 days, toxicity was observed.

INCIDENCE/PREVALENCE

The incidences are sporadic and not very prevalent because of the awareness of monensin toxicity among producers.

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

• Cardiovascular
• Musculoskeletal
• Nervous
• Urinary
• Respiratory

PATHOPHYSIOLOGY

• Following ingestion, monensin is well absorbed from GIT, undergoes hepatic metabolism by P-450s and glutathione, and is excreted in the bile. O-demethylation and hydroxylation are the primary metabolic pathways. Urinary excretion is very low.
• Ionophores differ in their cation selectivity, forming dynamically reversible $Ca^{2+}/Mg^{2+}/Na^{+}/K^{+}$-lipid soluble complexes allowing ions to be transported across membranes, down the concentration gradient.
• Monensin shows preference for Na^{+} ions, leading to increased intracellular sodium and loss of potassium from cells. Disruption of the normal cellular ionic gradient ensues, causing disturbances in cellular homeostasis (loss of osmotic pressure), metabolism (reduction in ATP production) and ion-mediated signaling events which can result in cell death.
• The loss of potential gradient across myocardial cells results in abnormal impulse transmission leading to cardiac arrhythmias and potentially congestive heart failure.
• In more chronic cases, reduction in ATP production leads to cell death or necrosis, followed by replacement with nonfunctional connective tissues such as fibroblasts.

SIGNALMENT

• Cattle, sheep, goats, and camelids have reportedly been affected. All ruminant species should be considered susceptible.
• Based on the LD_{50} values, among ruminants, the rank order of susceptibility to toxicosis is as follows: camelids > sheep > cattle = goats.
• No differentiation of toxicity on the basis of age, sex, or breed has been reported.

PHYSICAL EXAMINATION FINDINGS

Acute Effects

• Death
• Recumbency
• Arrhythmias
• Dyspnea
• Stiffness
• Ataxia and tremors due to alteration in normal impulse conduction
• Anorexia
• Edema of abdomen and legs
• Weakness
• Myoglobinuria, sometimes urinary bladder distension
• Diarrhea

Chronic Effects

• Anorexia
• Diarrhea
• Depression
• Dyspnea
• Arrhythmias
• Unthriftiness
• Exercise intolerance
• Death
• Decreased milk production
• Decreased weight gain

CAUSES AND RISK FACTORS

• Monensin toxicosis is generally a result of feeding of premix ration or other mixing errors.
• Exposure to other cardiotoxins and the absence of adequate amounts of selenium and vitamin E can result in aggravation of monensin toxicosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Selenium deficiency—evaluated by measuring selenium concentrations in blood, serum, or liver.
• Vitamin E deficiency—evaluated by measuring vitamin E in serum or liver.
• Cardiotoxic plants—identification of plant in feed, testing of rumen content for plant alkaloids.

CBC/BIOCHEMISTRY/URINALYSIS

• Hematologic parameters generally not affected; may see leukocytosis with increased PMN cells and decrease in lymphocytes.
• Muscle damage causing—increased AST, increased CPK.
• Diarrhea/rumenitis causing—hypokalemia, hyponatremia, and hypocalcemia.
• Myoglobinuria in severely affected animals.
• Myocardial damage causing—increased cardiac troponin I.

OTHER LABORATORY TESTS

• Analyze feed, GI contents, and molasses for identification and quantification of monensin. The analysis can be done using TLC, colorimetry, or the LC-MS method.
• Tissue samples (liver or heart) collected within 24 hours of intoxication can be used diagnostically for confirmation of exposure by LC-MS method.

IMAGING

Echocardiography may be used to determine the presence of myocardial damage in live, chronic cases. However, animals with acute

MONENSIN TOXICITY (CONTINUED)

exposure cannot be diagnosed with this method, as the fibrosis is not present.

OTHER DIAGNOSTIC PROCEDURES
• Prolongation of Q-T interval and the QRS complex. Absence of P wave and increased amplitude of S and T waves have been observed.
• Atrial/ventricular fibrillation, ventricular tachycardia, and intermittent and premature ventricular contractions may be evident.
• ECG abnormalities are not consistent with severity of exposure or the amount of myocardial damage.

PATHOLOGIC FINDINGS
• Findings are similar to congestive heart failure.
• Animals with acute deaths may show no significant lesions.
• Enlarged heart with hydropericardium, epicardial hemorrhages, and a tigroid appearance.
• Permanent myocardial damage appears as diffusely pale and yellow myocardium with ventricular dilatation.
• Pulmonary congestion and edema.
• Hepatic congestion. Mottling of the liver along with hepatocellular necrosis have also been reported.
• Abomasal and SI mucosal congestion.
• Ecchymotic hemorrhages around subcutaneous layer and fascia of the neck and forelimbs.
• Subcutaneous edema.
• Yellow-to-gray necrotic streaks in skeletal muscles. Cattle have about equal predilection to develop heart and skeletal muscle lesions. In animals surviving an acute exposure, scarring and pallor of certain muscle groups may be noted.
• Cattle, histologic changes—mitochondrial swelling and vacuolar degeneration of cardiac myocytes. Pallor/pale streaking in ventricular walls and the septum. Centrilobular hepatic necrosis with vacuolar degeneration and focal degeneration of active skeletal muscles may be evident.
• Sheep, histologic changes—fibrosis and hyalinization with sarcoplasmic mineralization have been reported in ewes consuming 160 ppm monensin over a period of 70 days. Mononuclear infiltration was also observed. Unlike in cattle, the skeletal muscle lesions in sheep were more severe than the cardiac lesions.

TREATMENT

THERAPEUTIC APPROACH
• There is no specific antidote for monensin intoxication.
• Remove contaminated feed immediately.
• Monitor and correct the blood electrolyte imbalances, if any.
• Fluids can be administered to maintain hydration and enhance elimination or prevent renal casting by myoglobin.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Apart from GIT decontamination and general supportive care, consider surgical evacuation of rumen contents in case of substantial exposure, followed by activated charcoal or mineral oil.

MEDICATIONS

DRUGS OF CHOICE
• No antidote
• AC/mineral oil/saline cathartics
• Vitamin E/Se to minimize secondary oxidative tissue damage

CONTRAINDICATIONS
IV fluids should not be administered in animals with cardiovascular problems.

POSSIBLE INTERACTIONS
Monensin toxicity may be potentiated by the concurrent use of tiamulin, oleandomycin, chloramphenicol, erythromycin, sulfonamides, furazolidone, and other cardiac glycosides.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Suspected animals may exhibit clinical signs within a few hours of exposure or, in some cases, may take months for the precipitation. Depending on the amount of exposure, the animals may manifest the acute or chronic effects (see "Physical Examination Findings").
• The prognosis is guarded to poor for any animal with suspected myocardial damage. These animals can be maintained, but their performance may be decreased.

POSSIBLE COMPLICATIONS
Myocardial damage may persist for a long period of time without noticeable clinical effects, predisposing the animal to succumb to factors resulting in an elevated heart rate or requiring an increase in cardiac output.

CLIENT EDUCATION
Animals surviving a toxic exposure may have permanent cardiac damage that can make the animal susceptible to sudden death following stress.

PATIENT CARE
• Stall rest and a nonstressful environment are essential to limit cardiac damage.
• A good plane of nutrition, ensuring adequate selenium and vitamin E intake.
• Restrict exercise and excitement.
• Serum chemistry, cardiac troponin I, ECGs, and echocardiography are helpful to monitor progress; however, they cannot predict the prognosis.

PREVENTION
• Proper storage of the premixes and concentrates.
• Maintain a proper feed management protocol to avoid mixing errors and possible miscalculations.
• Test feed to ensure monensin concentrations are within FDA recommended ranges (see "Overview").
• Keep animals at a good nutritional level, especially selenium and vitamin E.

MISCELLANEOUS

PREGNANCY
Ionophores have not been directly associated with reproductive problems. However, the compromised cardiovascular function may result in abortion.

BIOSECURITY
The tolerance level for monensin in edible tissues of cattle is 0.05 ppm.

PRODUCTION MANAGEMENT
• Do not feed to lactating dairy cows.
• Ensure proper mixing and final concentration within the FDA recommended ranges.

MYCOPLASMA BOVIS ASSOCIATED DISEASES

BASICS

OVERVIEW
• *Mycoplasma bovis* is a bacterial cause of mastitis, bronchopneumonia, otitis media, arthritis, and tenosynovitis in cattle and bison. Disease is common but sporadic; cattle and bison are the primary host, and infection is infrequent in other ruminants, which tend to host their own pathogenic species of *Mycoplasma.*
• Less commonly, *Mycoplasma bovis* has been associated with conjunctivitis and infection of the reproductive tract.

INCIDENCE/PREVALENCE
Mycoplasma bovis is the most pathogenic bovine mycoplasma in Europe and North America. It causes huge economic losses in cattle and milk production in both Europe and the United States. *M. bovis* is estimated to be responsible for at least a quarter or a third of losses caused by respiratory diseases in Europe. In the US, this organism causes a loss of $32 million per year as a result of the loss of weight gain and the diminished carcass value. The expenses due to *M. bovis* mastitis are estimated to be $108 million per year.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Nervous
• Respiratory
• Reproductive
• Mammary
• Musculoskeletal
• Ophthalmic

PATHOPHYSIOLOGY
• *Mycoplasma bovis* can be found in both the upper respiratory (URT) and reproductive tracts in both young and old cattle.
• The URT mucosa and the mammary gland appear to be the most important sites of persistence and shedding of *M. bovis.* Although many cattle shed *M. bovis* for a few months or less, some cattle can shed *M. bovis* intermittently for many months or years. The factors responsible for intermittent shedding have not been determined. Cattle with clinical disease usually excrete especially large numbers of *M. bovis*. Stressful events such as transportation, comingling, entry into a feedlot, and cold stress are associated with increased rates of nasal shedding of *M. bovis* and increased clinical disease.
• *M. bovis* has characteristics that enable it to colonize and persist on mucosal surfaces, to invade tissues, and to persist at sites of disease despite an aggressive immune response. Molecules involved in adherence, antigenic variation, invasion, immunomodulation, biofilm formation, and production of toxic metabolites are likely to be important in pathogenesis, but exactly how *M. bovis* interacts with the host is poorly understood.

SIGNALMENT
Cattle and bison; sheep can acquire *M. bovis* from infected cattle and may be a reservoir.

PHYSICAL EXAMINATION FINDINGS
• *Mycoplasma bovis* causes contagious mastitis in dairy cattle that can be enzootic or epizootic (outbreaks). Subclinical infection is common and contributes to persistent disease that can be difficult to eradicate.
• Cows with clinical mastitis do not usually develop severe systemic signs of disease. The mammary gland may be swollen but is not usually painful; milk may be discolored or purulent.
• *Mycoplasma bovis* is an important contributor to infectious bronchopneumonia in cattle (the "bovine respiratory disease complex" or BRDC). Co-infection with other bacterial or viral pathogens is common, though *Mycoplasma bovis* can be the sole pathogen isolated from pneumonic lungs. Experimental infections usually result in inapparent to mild signs of respiratory disease, but virulent strains have been identified that cause severe lung disease in calves.
• *Mycoplasma bovis* is a leading cause of otitis media in calves. Clinical signs include head tilt, loss of facial sensation, and loss of motor activity in the muscles of facial expression. Purulent drainage from the ear also is common. A large percentage (40–60%) of animals affected with otitis media also develop polyarthritis and tenosynovitis that causes severe chronic lameness.
• Septic arthritis and/or tenosynovitis may be caused by *Mycoplasma bovis,* with large joints in the proximal limb most often affected. Affected joints and tendon sheaths are enlarged and firm, leading to obvious lameness.
• It is common for cattle with otitis media and/or arthritis/tenosynovitis to have concurrent pneumonia due to *Mycoplasma bovis.*

CAUSES AND RISK FACTORS
• *Mycoplasma bovis* lacks a cell wall, and exposed membrane proteins form the primary interface with the host. These membrane proteins facilitate adherence to mucosal surfaces, although *M. bovis* adhesions are not yet well characterized. *M. bovis* has a large family of immunodominant variable surface lipoproteins that exhibit extensive strain variation in their coding sequences. These characteristics impart a vast capacity for antigenic variation in *M. bovis* populations that likely contributes to immune evasion and persistence and provides a challenge for vaccine development.
• Bacterial and/or viral co-infections are seen as an important co-factor for *M. bovis*-associated pneumonia and otitis media.
• The introduction of asymptomatically infected animals is thought to be the primary means by which *M. bovis*-free cattle and bison herds become infected. Transmission is delayed until, and if, shedding occurs; this delay can make it difficult to identify the source of infection and mycoplasma disease outbreaks occur in seemingly closed herds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Bovine respiratory disease bacterial agents: *Histophilus somni*, *Mannheimia hemolytica*, *Pasteurella multocida*
• Bacterial mastitis: *Staph. aureus*, *Strep. uberis*, *Strep. agalactiae*, *E. coli*
• Bacterial otitis media: *P. multocida*, *Strep* spp., *M. hemolytica*
• Bacterial polyarthritis: navel ill, *H. somni*

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Diagnosis is made by identification of *Mycoplasma bovis* from clinical specimens from animals with signs consistent with disease due to *Mycoplasma bovis*, or from materials collected at postmortem from typical lesions.
• *Mycoplasma* spp. are relatively difficult to isolate compared to other causes of mastitis or bronchopneumonia; thus diagnosis by culture requires that samples be kept cool but not frozen and submitted to the diagnostic laboratory as soon as possible. It will likely be necessary to specifically request that the laboratory carry out culture for mycoplasma, as special media and conditions are required.
• To confirm specific involvement of *Mycoplasma bovis* it will be necessary to also ask the diagnostic laboratory to identify the species of any mycoplasmas isolated; speciation is typically completed by immunofluorescence testing or PCR.
• It is possible to specifically identify *Mycoplasma bovis* by direct PCR testing of clinical materials. However, PCR alone may lack sensitivity for some samples.
• Diagnosis of mastitis at the herd level can be made by milk tank culture or PCR for *M. bovis.*

PATHOLOGIC FINDINGS
• Pneumonia, otitis media, and arthritis/tenosynovitis may be diagnosed by postmortem. In the lung, cranioventral consolidation typical of bronchopneumonia is seen, often with multiple small nodules that contain caseous material (caseous necrosis).
• Pleural effusion and/or fibrin deposition is not commonly seen in cattle with bronchopneumonia due to *Mycoplasma bovis.*
• Purulent or caseous material can be found in the tympanic bulla of animals with otitis

(CONTINUED) **MYCOPLASMA BOVIS ASSOCIATED DISEASES**

media, and in joint spaces or tendon sheaths in arthritis/tenosynovitis.

TREATMENT

THERAPEUTIC APPROACH

Mastitis

• Cows with mycoplasma mastitis respond poorly to treatment, and it appears that most if not all affected cows become permanent intermittent shedders even when clinical mastitis resolves. Thus it is recommended that cows with mycoplasma mastitis be culled from the herd.

• In herds with a high proportion of infected cows it may not be possible to cull all affected cattle; in such cases it may be advisable to maintain two milking strings, one of uninfected cows milked first, and a second string of infected cows milked second.

Bovine Respiratory Disease

• Antimicrobials most likely to be useful for treatment of bronchopneumonia due to *Mycoplasma bovis* include macrolides such as tulathromycin or gamithromycin, enrofloxacin, or florfenicol. Oxytetracycline or chlortetracycline have been used historically but resistance may be a problem; the same may be true for tilmicosin. Because mycoplasmas lack cell walls, beta-lactam antibiotics (penicillins and cephalosporins) will not be effective against these bacteria. Several antimicrobials are labeled for treatment of pneumonia due to *Mycoplasma bovis.*

Otitis and Arthritis

• Cases of otitis or arthritis/tenosynovitis are unlikely to respond to treatment with complete resolution unless treatment is initiated very early in the course of disease. Veterinarians should be attentive to the welfare of animals with chronic otitis or arthritis, and euthanasia may be the most appropriate course of action for severe, persistently infected cases.

MEDICATIONS

DRUGS OF CHOICE

Macrolides (tulathromycin or gamithromycin), enrofloxacin, or florfenicol

PRECAUTIONS

Although many drugs are labeled for treatment of pneumonia due to *Mycoplasma bovis,* cases in the field are commonly reported to respond poorly to treatment. This may be in part due the presence of lesions of caseous necrosis, which may require prolonged therapy for durations longer than indicated on the label. No evidence-based guidelines for duration of therapy for pneumonia due to *Mycoplasma bovis* are available.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• When dealing with cattle with disease due to *Mycoplasma bovis*, producers will often report failure of disease to respond as expected to antibiotic therapy. In general *Mycoplasma bovis* infection in any organ is often manifested as disease that appears subacute to chronic, with resolution being difficult to effect.

PREVENTION

• Because disease due to *Mycoplasma bovis* can be difficult or impossible to treat, preventing disease in animals at risk should be a priority.

• Mastitis should be prevented by eliminating infected cows in herds where the disease is present, by practicing biocontainment to prevent transmission within infected herds, and by preventing the introduction of infected cows to herds that are free of disease.

• Because *Mycoplasma bovis* commonly causes bronchopneumonia in conjunction with other viral or bacterial pathogens, controlling other infectious causes of bronchopneumonia may also decrease rates of bronchopneumonia due to *Mycoplasma bovis.*

• Preconditioning beef calves prior to sale can help decrease bronchopneumonia due to any cause. Preconditioning includes castration and dehorning at birth or soon after, weaning at least 45 days before sale, and vaccination to protect against common respiratory pathogens well in advance of sale, in time to allow vaccinated calves to develop an adaptive immune response to vaccination.

• Vaccines exist for *Mycoplasma bovis*; unfortunately, at this time there are few scientific reports confirming their efficacy in the field.

• Septic arthritis and tenosynovitis likely occur secondary to bacteremia in cattle with bronchopneumonia; thus preventing bronchopneumonia should help prevent these conditions.

MISCELLANEOUS

ZOONOTIC POTENTIAL

None

BIOSECURITY

Cows from herds with a history of otitis or septic arthritis in calves should be avoided.

PRODUCTION MANAGEMENT

• Because *Mycoplasma bovis* is shed intermittently, it is not possible to reliably exclude an infected cow based on milk testing. The results of bulk tank testing from the herd of origin would ideally be evaluated if possible.

• Otitis in calves is associated with feeding calves infected milk; thus, otitis can be prevented or controlled by feeding calves pasteurized milk.

ABBREVIATIONS

• PCR = polymerase chain reaction
• URT = upper respiratory tract

MYCOTOXINS

BASICS

OVERVIEW

• Mycotoxins are naturally occurring compounds produced by a variety of fungi in grains, forages, and various foods/feeds/by-products. Their occurrence worldwide appears to be increasing with climatic events and better analytic techniques. This section is focused on the more common mycotoxins in North America.
• Typically, *Fusarium* and *Claviceps* fungi act as plant pathogens on cereal crops or grasses in the field. *F. verticilliodies* and *Aspergillus flavus* produce mycotoxins on drought-stressed or senescent plants, particularly corn in the field.
• *Aspergillus* and *Penicillium* fungi occur on developing crops in the field and later proliferate in storage, especially on ensiled cereals or baled forages under higher moisture conditions.
• Fungi have been associated with grass endophytes, such as *Neotyphodium coenophialum* in tall fescue.
• Functioning ruminants are often viewed as less sensitive to mycotoxins than monogastrics because of rumen microflora metabolism to less toxic compounds. However, ruminants occupy wide agricultural niches and are exposed to diverse toxins.
• Often the moldier and highly contaminated feeds end up in beef feedlots and, in poor crop years, beef cows are often fed poor-quality feedstuffs, exposing animals to a variety of mycotoxins and sometimes atypical rations for rumen microbes to digest.
• Dairy cows appear to be more sensitive to mycotoxins, perhaps due to greater stress and increased dry-matter intake, faster rumen turnover, and decreased rumen microbial degradation time.

INCIDENCE/PREVALENCE

Varying climatic conditions in the field (drought, wet, hail damage, insect damage, overwintered grain) and in storage and transport (higher stored moisture and temperatures which vary with the particular requirements of the feed).

Aflatoxins

Group of difuranocoumarin compounds produced by *Aspergillus flavus, A. parasiticus*, and *A. nomius* that can occur pre-harvest on starchy cereal crops, cottonseeds, and peanuts or post-harvest on stored commodities. Drought, hot weather, and insect damage favor fungal growth and production of aflatoxins, including aflatoxins B1, B2, G1, and G2, with aflatoxin B1 generally found in the highest concentration and considered the most toxic and carcinogenic. Aflatoxin M1 and M2 are hydroxylated metabolites of aflatoxin B1 and B2, respectively, and can occur in contaminated feed and more importantly in tissue, milk, and dairy products. Young animals are more at risk. Ruminants fed rations with several hundred ppb aflatoxins may have reduced feed intake and growth. Sheep are considered to be the domesticated species most resistant to toxic effects of aflatoxins.

Ergot

Invasion by *Claviceps* spp. in the developing ovary of grasses and grain can cause a visible sclerotium or ergot body containing numerous ergot alkaloids. Cool, damp weather in the spring delaying pollination, no-till farming, shallow cultivation, and no crop rotation can increase ergot prevalence. Infection of tall fescue grass with an endophyte, *Neothyphodium coenophialum*, can result in production of ergot alkaloids, particularly ergopeptine alkaloids of which ergovaline predominates. Fescue toxicosis may produce syndromes of fescue foot (lameness and ischemic necrosis of hooves), summer slump (hyperthermia and ill thrift), and fat necrosis in cattle. Sheep can be affected also and develop tongue necrosis. Subacute to chronic exposures to concentrations of ergovaline at 200–600 ppb (0.2–0.6 ppm) in fescue grass pastures infected with the endophyte can result in fescue toxicosis. Extreme environmental conditions, at both cold and hot temperatures, can exacerbate thermoregulation in ergot-induced gangrene and summer slump (hyperthermia), respectively.

Fumonisins

Group of heat-stable, water-soluble mycotoxins occurring in white and yellow corn in the field produced by *Fusarium verticillioides* and *F. proliferatum*. Fumonisins can concentrate (3×) in co-products of corn ethanol production into the distiller's grains. A period of drought during the growing season followed by wet, warm conditions during pollination of corn favors development of fumonisins. Toxicity is associated with fumonisins B1 and B2, with fumonisin B2 usually occurring at about 30% of fumonisin B1 concentration. Ruminants are fairly resistant to fumonisins and generally high concentrations (>148 ppm) have been reported to depress feed intake. Dairy cows seem to be more susceptible to fumonisins, which is reflected in the FDA guidelines for feeding fumonisin-contaminated feed to ruminants (see "Follow-Up").

Ochratoxin A

Ochratoxins are potent nephrotoxins, immunosuppressants, and possible carcinogens (in humans) and teratogens produced by *Aspergillus alutaceus* var. *alutaceus* in tropical and subtropical areas and *Penicillium viridicatum* in temperate areas. These phenylalanine-dihydroisocoumarin compounds are generally produced in storage and occur on grains and various human foods. The most toxic of the ochratoxins is ochratoxin A (OTA). A functioning rumen appears to metabolize ochratoxin A to the nearly nontoxic compound, ochratoxin α; and the elimination half-life for ochratoxin in ruminants is 17.3 hours, compared with 100 hours in pigs (a sensitive species). Therefore, functioning ruminants are less at risk for toxicity. Citrinin, another nephrotoxin mycotoxin, is produced by *Pencillium* spp. and *Monascus ruber* on cereal grains at high moisture. The US has no regulatory guidelines for ochratoxins; however, the EC guidelines are a maximum of 0.25 ppm OTA in feed materials fed to animals in a daily ration.

Tremorgens

Infection of perennial ryegrass (*Lolium perenne*) with the endophyte *Neotyphodium lolii* has been associated with grass staggers in sheep and cattle. Cattle consuming Bermudagrass (*Cynodon dactylon*) invaded by *Claviceps* or endophytes can develop periodic episodes of tremors that have been associated with paspalitrem-type indole alkaloids and perhaps ergot-type alkaloids *Penicillium* spp. can synthesize indole–diterpene tremorgenic mycotoxins including penitrem A and roquefortine that have been associated with staggers in ruminants. *Aspergillus* can produce tremorgenic mycotoxins, aflatrem and verruculogen.

Trichothecenes

Fusarium molds (*F. graminearum, F. culmorum, F. poae, F. sporotrichioides, F. equiseti, F. acuminatum* and others) can produce a variety of trichothecene mycotoxins, which are sesquiterpenoid compounds with an epoxy group at C12-13 that causes toxicity. Type A trichothecenes include the more toxic compounds such as T-2 toxin, its deacetylated metabolite Ht-2 toxin, and diacetoxyscirpenol (DAS). Type B trichothecenes are common field contaminants and include vomitoxin or deoxynivalenol (DON) and its acetylated derivatives 15- and 3-acetyl DON, nivalenol and fusarenone-X (4-acetylnivalenol). Generally, *Fusarium* grows on cereal grains during wet, warm conditions at pollination and during growth of plants in the field, but also in immature crops with warm days and cool nights, following hail damage, and in overwintered grains (esp. *F. sporotrichioides* and *F. poae*). *Fusarium* can invade forages and produce toxins, in some cases T-2 toxin, HT-2, DON, and zearalenone in grasses and hays. In bad scab years, DON contamination in wheat and barley straws can be significant (>50–100 ppm).
Trichothecene exposures are usually chronic to subchronic in nature with low dietary exposures to type B mycotoxins (e.g., DON) in ruminants associated with nutritional impairment and possible reduced production

and diminished immune responses. In general, beef cattle and sheep are more tolerant of higher DON concentration than are dairy cattle. See chapter, Vomitoxin, for further information.

Zearalenone

Zearalenone is a mycoestrogen produced by *Fusarium graminearum, F. culmorum*, and *F. equiseti* on cereal grains, ear corn, wet grasses, hay, and straw during wet conditions, with warmer days and cool nights. Zearalenone has low acute toxicity in most species.

GEOGRAPHIC DISTRIBUTION

Worldwide, with fungal growth dependent on climatic conditions, feed matrices, and production/storage practices.

SYSTEMS AFFECTED

- Cardiovascular
- Gastrointestinal
- Multisystemic
- Integument
- Hemolymphatic
- Nervous
- Reproductive
- Respiratory

PATHOPHYSIOLOGY

Aflatoxins

Aflatoxins are passively absorbed from the GIT, biotransformed into aflatoxin 8,9-epoxide, and can bind to DNA, RNA, and proteins causing disruption of cellular processes and organ function. The outcome is cellular necrosis, immune suppression, mutagenesis, neoplasms, possible abortions, and death.

Ergot

Ergot alkaloids are composed of ergoline alkaloids and ergopeptide alkaloids. The latter cause vasoconstriction through inhibition of the D1 dopaminergic receptor and partial agonism of the α1-adrenergic and serotonin receptors. Constriction of small arteries can lead to ischemia and necrosis of distal extremities and possibly uterine contractions in late pregnancy (evidence of abortions vague in ruminants). Ergopeptine stimulation of the D2-dopamine receptors can lead to decreased prolactin secretion by lactotropes in the anterior pituitary and low milk production and agalactia.

Fumonisins

Fumonisins, which are aliphatic hydrocarbons with a terminal amine group and tricarboxylic acid side chains and structurally similar to sphingolipids in cellular membranes, inhibit the ceramide synthase enzyme involved in converting sphinganine to sphingosine. Fumonisins can interfere with cellular growth and differentiation, resulting in toxicity and carcinogenicity. Liver toxicity is often involved across species.

Ochratoxin A

Ochratoxins inhibit protein synthesis and can deplete humoral factors, especially immunoglobulins and decrease natural killer cell activity. The most toxic of the ochratoxins is ochratoxin A (OTA). Citrinin, another nephrotoxin mycotoxin, is produced by *Pencillium* spp. and *Monascus ruber* on cereal grains at high moisture. Both toxins target the renal proximal tubule and can result in lowered milk production, diarrhea, ill thrift, polyuria/polydipsia, and immune suppression.

Tremorgens

Neurotoxic indole-diterpene tremogens, including lolitrems (esp. lolitrem B) are thought to interfere with excitatory amino acid neurotransmitter release mechanisms, especially inhibition of gamma aminobutyric acid (GABA) receptor function.

Trichothecenes

Trichothecenes exert several effects, including inhibition of protein, RNA and DNA synthesis, alteration of membrane structure and mitochondrial function, lipid peroxidation, induction of cell apoptosis, and activation of cytokines and chemokines. Significant metabolism of trichothecenes can occur in the rumen and GIT prior to absorption. Rumen microbes, particularly protozoa, appear to be active in the deacetylation of trichothecenes. The major rumen metabolite of DON is de-epoxydeoxynivalenol (DOM-1), which is much less toxic than DON.

Zearalenone

Zearalenone is a resorcyclic acid lactone that is fairly rapidly and extensively absorbed after oral exposure. Zearalenone can undergo rumen metabolism, with reduction to α-zearalenol (increased estrogenic activity) and to a lesser amount of β-zearalenol (lower estrogenic activity). Zearalenone has affinity for the 17β-estradiol receptor and can stimulate RNA and protein synthesis and clinical signs of estrogenism.

SIGNALMENT

- All ruminants are susceptible.
- Sheep are considered the most resistant domesticated species to toxic effects of aflatoxins.
- Ruminants are fairly resistant to fumonisins and generally high concentrations (>148 ppm) have been reported to depress feed intake.
- In general, beef cattle and sheep are more tolerant of higher DON concentration than are dairy cattle.

PHYSICAL EXAMINATION FINDINGS

Aflatoxins

- Young animals are more at risk.
- In acute outbreaks, deaths occur after a short period of inappetence; other acute signs include vomiting, depression, hemorrhage, and icterus.
- Subacute outbreaks are more usual, with unthriftiness, weakness, anorexia, reduced growth and feed efficiency, and occasional sudden deaths.
- Ruminants fed rations with several hundred ppb aflatoxins may have reduced feed intake and growth.
- Chronic aflatoxicosis is associated with reduced appetite, feed efficiency, milk production, and icterus.

Ergot

- Fescue toxicosis may produce syndromes of fescue foot (lameness and ischemic necrosis of hooves), summer slump (hyperthermia and ill thrift), and fat necrosis in cattle. Symptoms include erythema and swelling of the coronary region occur, and cattle are alert but lose weight and may be seen "paddling" or weight-shifting. The back is slightly arched, and knuckling of a hind pastern may be an initial sign. There is progressive lameness, anorexia, depression, and later, dry gangrene of the distal limbs (hindlimbs first). Signs usually develop within 10–21 days after turnout into a fescue-contaminated pasture in fall. A period of frost tends to increase the incidence.
- Sheep can be affected also and develop tongue necrosis.
- Ergot alkaloids can produce gangrene of distal extremities, GIT changes, lowered milk production and feed intake.
- Extreme environmental conditions, at both cold and hot temperatures, can exacerbate thermoregulation in ergot induced gangrene and summer slump (hyperthermia), respectively.

Fumonisins

- Cattle and sheep tolerate fumonisin concentrations of 100 ppm with little effect. Dietary concentrations of 150–200 ppm cause inappetence, weight loss, and mild liver damage.
- Renal and hepatic damage have been reported in lambs fed high fumonisin diets (about 470 ppm). Dairy cows seem to be more susceptible to fumonisins,

Ochratoxin A

Citrinin, another nephrotoxin mycotoxin, is produced by *Pencillium* spp. and *Monascus ruber* on cereal grains at high moisture. Both toxins target the renal proximal tubule and can result in lowered milk production, diarrhea, ill thrift, polyuria/polydipsia, and immune suppression in cattle.

Tremorgens

- The clinical signs of perennial ryegrass staggers are ataxia, muscle rigidity, and convulsions.
- Cattle consuming Bermudagrass (*Cynodon dactylon*) invaded by *Claviceps* or endophytes can develop periodic episodes of tremors that

MYCOTOXINS (CONTINUED)

have been associated with paspalitrem-type indole alkaloids and perhaps ergot-type alkaloids. *Penicillium* spp. can synthesize indole–diterpene tremorgenic mycotoxins including penitrem A and roquefortine that have been associated with staggers in ruminants.
• *Aspergillus* can produce tremorgenic mycotoxins, aflatrem and verruculogen. The onset and duration of the "staggers" syndromes for these tremorgens can vary, but they are essentially identical to one another.

Trichothecenes

• The hallmark clinical sign of trichothecene toxicosis is feed refusal, and commonly diarrhea.
• Trichothecene exposures are usually chronic to subchronic in nature with low dietary exposures to type B mycotoxins (e.g., DON) in ruminants associated with nutritional impairment and possible reduced production and diminished immune responses. See chapter, Vomitoxin, for further information.
• Clinical effects of the more toxic type A trichothecenes include vomiting, feed refusal and weight loss, diarrhea, immunomodulation, coagulopathy, and hemorrhage.
• T-2 toxin can cross the placental barrier and cause abortions. Dairy cows appear to be more sensitive to trichothecene exposure.

Zearalenone

• Zearalenone has low acute toxicity in most species.
• Zearalenone has affinity for the 17β-estradiol receptor and can stimulate RNA and protein synthesis and clinical signs of estrogenism (swelling of vulva, increase in uterine size and sections, mammary gland hyperplasia and secretion, prolonged estrus, anestrus, pseudopregnancy, infertility, decreased libido, and secondary complications of rectal and vaginal prolapses).

CAUSES AND RISK FACTORS

Ingestion of moldy feedstuffs containing significant concentrations of a mycotoxin can lead to clinical effects. Pre-ruminants, immature animals which lack rumen microbial metabolism, and dairy cows, which are more highly stressed, are generally more at risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Aflatoxin liver damage: Plant pyrrolizidine alkaloids
• Type A trichothecenes: Radiomimetic poisoning, 4-ipomeanol pneumotoxin, *Perilla frutescens*
• Zearalenone hyperestrogenism: Phytoestrogens in alfalfa and clovers

CBC/BIOCHEMISTRY/URINALYSIS

• Aflatoxin can increase hepatic enzyme activity (ALP, AST, or ALT) and prothrombin time, and anemia can occur.
• Trichothecenes may cause leukopenia and anemia.
• Elevated BUN and creatinine levels due to ochratoxin A and citrinin.

OTHER LABORATORY TESTS

• Detection of mycotoxins in feed by liquid or gas chromatography-mass spectrometry, gas chromatography, and other reliable methods validated for the feed matrix.
• Laboratory analysis of feed for mycotoxins in tissues (milk and liver for aflatoxin M1) are the most practical assays.

PATHOLOGIC FINDINGS

Aflatoxin

• Aflatoxin-induced lesions include fatty degeneration of the liver, hepatic megalocytosis, fibrosis, necrosis, biliary hyperplasia, and possible veno-occlusive lesions and hemorrhages.
• In acute cases, there are widespread hemorrhages and icterus. The liver is the major target organ. Microscopically, the liver is enlarged and shows marked fatty accumulations and massive centrilobular necrosis and hemorrhage.
• In subacute cases, the hepatic changes are not so pronounced, but the liver is somewhat enlarged and firmer than usual. There may be edema of the gallbladder.
• Microscopically, the liver shows periportal inflammatory response and proliferation and fibrosis of the bile ductules; the hepatocytes and their nuclei (megalocytosis) are enlarged.
• The GI mucosa may show glandular atrophy and associated inflammation. Rarely, there may be tubular degeneration and regeneration in the kidneys.
• Prolonged feeding of low concentrations of aflatoxins may result in diffuse liver fibrosis (cirrhosis) and, rarely, carcinoma of the bile ducts or liver.

Ergot

• The most consistent lesions are in the skin and subcutaneous parts of the extremities. The skin is normal to the indented line, but beyond, it is cyanotic and hardened in advanced cases. Subcutaneous hemorrhage and some edema occur proximal to the necrotic area.
• In addition to gangrene of these extremities, the animals have a loss of body mass and a rough coat.

Ochratoxin

The lesions associated with ochratoxin are dilated renal tubules and fibrosis in the kidneys, thickened basement membranes, glomerular sclerosis, and fatty changes in the liver.

Trichothecenes

• Gross lesions including irritation of the skin and mucus membranes and gastroenteritis are typical signs of trichothecene toxicosis.
• Hemorrhagic diathesis can occur, and the radiomimetic injury (damage to dividing cells) is expressed as lymphopenia or pancytopenia.
• Because of the immunosuppressive action of trichothecenes, secondary bacterial, viral, or parasitic infections may mask the primary injury.
• The lymphatic organs are smaller than normal and may be difficult to find on necropsy.
• Type A trichothecenes histologic lesions include cellular necrosis of mitotically active tissues such as intestinal mucosa, skin, bone marrow, testis, and ovary.

TREATMENT

THERAPEUTIC APPROACH

• Stop feeding mycotoxin-contaminated feed or reduce exposure to concentrations associated with no clinical signs in ruminants when regulatory guidelines are available. Dilution with noncontaminated feedstuffs is one possibility, but this may not be acceptable on a regulatory basis.
• Cleaning to remove lightweight or broken grains will often substantially reduce mycotoxin concentration in remaining grain.
• Ammoniation reduces aflatoxin contamination in grain but is not currently approved by the FDA for use in food animals in the United States because of uncertainty about by-products produced.
• Provide clean feed and supportive fluids if necessary.

MEDICATIONS

DRUGS OF CHOICE

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• In many cases, low dose exposure to mycotoxins followed by a change to a clean ration will result in recovery within 3–6 weeks.
• Extensive organ damage (liver—aflatoxins, circulatory—ergot) can results in ill thrift or complications causing death.

PREVENTION

• Follow regulatory or action levels for aflatoxin in animal feed.

• In the US, the Food and Drug Administration issued action levels for **aflatoxins in feed** for cattle:
  ◦ 300 ppb for corn and peanut products intended for finishing (i.e., feedlot) beef cattle;
  ◦ 300 ppb for cottonseed meal intended for beef cattle (regardless of age or breeding status);
  ◦ 100 ppb for corn and peanut products intended for breeding beef cattle;
  ◦ 20 ppb for corn, peanut products, and other animal feeds and feed ingredients, but excluding cottonseed meal, intended for immature animals;
  ◦ 20 ppb for corn, peanut products, cottonseed meal and other animal feeds and feed ingredients intended for dairy animals, for animal species or uses not specified above, or when the intended use is not known.
  ◦ 0.5 ppb for milk (aflatoxin M1).
• The FDA guidance levels for total **fumonisins in corn and corn by-products**:
  ◦ 30 ppm (no more than 50% of diet, dry weight basis) for breeding ruminants;
  ◦ 60 ppm (no more than 50% of diet, dry weight basis) for ruminants ≥3 months old being raised for slaughter;
  ◦ 10 ppm (no more than 50% of diet) for other ruminants and immature ruminants.
• In the US, mycotoxin binders have not been approved by the Food and Drug Administration. The use of aluminosilicates and bentonite clays to bind aflatoxins is recognized as effective (based on in vivo and in vitro efficacy), but the use of other products to "bind" the varied mycotoxins in ruminants is equivocal.

MISCELLANEOUS

AGE-RELATED FACTOR

Immature, pre-ruminants are generally more susceptible than older ruminants.

ZOONOTIC POTENTIAL

Aflatoxin M1 can be transferred to milk. The US FDA action level is 0.5 ppb in milk; the EC regulatory level is 0.05 ppb in milk. Note that all of these mycotoxins can occur in foods for human consumption.

PREGNANCY

Zearalenone can cause reproductive abnormalities, possibly anestrus and abortions. Aflatoxins, type A trichothecene mycotoxins (T-2, HT-2, DAS), and ergot can cause abortions.

BIOSECURITY

Avoid feeding moldy feedstuffs. Analyze suspect feed for vomitoxin prior to use and utilize appropriate guidelines. If possible, avoid feeding screenings that contain broken grains and possibly higher concentrations of mycotoxins.

PRODUCTION MANAGEMENT

Analyze moldy feedstuffs for mycotoxins prior to use. When available, follow regulatory guidelines (see "Prevention" and chapter, Vomitoxin).

NAIROBI SHEEP DISEASE

BASICS

OVERVIEW
• Nairobi sheep disease (NSD) is a noncontagious, highly pathogenic, tick-borne viral disease of sheep and goats with very high morbidity and mortality.
• It is a reportable disease in the United States and a notifiable disease of the International Office of Epizootics (OIE).

INCIDENCE/PREVALENCE
• Limited effect on animals bred in areas in which virus is endemic due to immunity from colostral antibodies.
• High mortality seen in naïve animals exposed to virus or in animals moved from dry to wet areas where ticks are abundant. Outbreaks are also seen in high rainfall when ticks expand their range.

GEOGRAPHIC DISTRIBUTION
• Mainly East Africa and Central Africa, may also be present in Botswana and Mozambique.
• The virus has been isolated in South Asia (India and Sri Lanka), and a novel strain identified in China, but no disease has been reported in these areas.

SYSTEMS AFFECTED
• Digestive
• Hemolymphatic
• Respiratory
• Reproductive

PATHOPHYSIOLOGY
• The virus causes a viral hemorrhagic fever; however, the virus is not contagious from animal to animal without a tick vector.
• Animals develop a viremia following the feeding of infected ticks.
• The virus increases the production of cellular factor, protein disulfide isomerase (PDI) that activates integrins at the surface of various uninfected cells, including endothelial cells and platelets, leading to increased vasodilatation and coagulopathy.
• Extracellular PDI activates tissue factor (TF), inducing intravascular coagulation, which may subsequently lead to disseminated intravascular coagulation (DIC) through depletion of platelets and clotting factors, resulting in hemorrhaging.
• Finally, since ERp57 another cell protein (and probably PDI) takes part in the folding of the major histocompatibility complex (MHC) class I and therefore assists in facilitating immune surveillance and elimination of virus-infected cells, viruses, which translocate these ER chaperones from the ER may avoid adaptive immune responses, although downregulation of MHC class I has not yet been described for nairovirus-infected cells.

GENETICS
• Animals in endemic areas are usually immune, and sheep are more susceptible than goats with mortality rates up to 75% in indigenous sheep breeds, e.g., East African hair sheep and Persian fat-tailed sheep.
• Few fatal cases of NSD have been reported in duikers, *Cephalophus monticola*, and experimental infection has been achieved in the African field rat, *Arvicathus abysinicus nubilans*.

SIGNALMENT
The virus affects small ruminants, particularly sheep; there is no age or sex predilection.

PHYSICAL EXAMINATION FINDINGS
• Incubation period is 1–15 days with most infections occurring in 2–6 days.
• Animals have sudden onset of fever (105.8–107.6°F; 41–42°C) that persists for up to 7 days; leukopenia and viremia coincide with the febrile stage and many animals die during this stage of the disease. This is often followed by rapid respiration, anorexia, and profound depression, followed by fetid diarrhea watery then hemorrhagic with straining and colic, and a concomitant drop in body temperature. Many animals die during the febrile stage of the disease.
• Palpable swollen prescapular and precrural lymph nodes.
• Bloodstained mucopurulent or serosanguinous nasal discharge.
• Abortion, ± conjunctivitis, death.

CAUSES AND RISK FACTORS
• NSD is caused by NSD virus, the prototype virus of the genus Nairovirus, family Bunyaviridae. Nairovirus is a negative sense, single-stranded RNA virus. The genus is divided into seven serogroups that include Crimean-Congo hemorrhagic fever. Ganjam virus is an Asian variant of the virus.
• The brown ear tick, *Rhipicephalus appendiculatus,* is the most common vector and transmission is both trans-ovarial and trans-stadial. The virus can persist in ticks for long periods and can be transmitted by unfed adult ticks for more than 2 years after infection. The virus can also be transmitted by *Amblyomma variegatum*, African bont tick, and has been isolated in South Asia (India and Sri Lanka) from ticks, *Haemaphysalis intermedia*, *H. wellingtoni*, and *R. haemaphysaloides.*
• A novel strain of NSD virus has been isolated in China with *H. longicornis* as the main vector but no disease has been reported in South Asia or China.
• Risk factors include movement of susceptible animals/naïve animals into endemic areas, expansion of tick vector range especially after high rainfall, and inadequate tick control measures.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Heartwater, rinderpest, Rift Valley fever, anthrax, peste des petits ruminants, salmonellosis, coccidiosis, toxicosis (e.g., arsenic).

CBC/BIOCHEMISTRY/URINALYSIS
Leukopenia during the febrile stage

OTHER LABORATORY TESTS
• Detection of virus antigens during febrile stage of the disease using ELISA, virus isolation, indirect hemagglutination, IFAT.
• Serology: Indirect immunofluorescence antibody test (IFAT), agar gel immunodiffusion, complement fixation test, ELISA, and indirect hemagglutination. Fourfold or greater rise in antibody titers of paired sera samples.
• Virus isolation in BHK-21-C13 cells (baby kidney hamster cell line) from spleen and mesenteric lymph nodes.
• Inoculation of laboratory mice and sheep.

PATHOLOGIC FINDINGS
• Gross lesions include:
  ◦ Enlargement of superficial and mesenteric lymph nodes with congestion of most organs.
  ◦ Ecchymoses and petechiae on serosal surfaces of gastrointestinal tract, heart, spleen, liver, lungs, and kidney.
  ◦ Catarrhal mucoid or hemorrhagic gastroenteritis and dehydration; conjunctivitis.
  ◦ Ulceration and/or hemorrhages in abomasum, colon, cecum, distal ileum, and ileocecal valve; hemorrhages in mucosa of cecum and colon often appear as longitudinal striations (zebra striping). Hemorrhages are also present in genital tract of animals that have aborted.
  ◦ Swollen and hemorrhagic gallbladder.
  ◦ Edematous and hemorrhagic fetal membranes and hemorrhages throughout fetal organs.
• Histopathologic findings: Hyperplasia of lymphoid tissues, petechiae and ecchymoses in most organs, mucosal hemorrhages in gastrointestinal tract, myocardial degeneration, nephrosis, and coagulative necrosis of the gallbladder.

TREATMENT

THERAPEUTIC APPROACH
• No specific antivirals.
• Control of ticks by use of acaricides on unaffected animals.

• Vaccination using either modified-live virus vaccine attenuated in mouse brain, or inactivated oil adjuvant vaccine before movement of naïve susceptible animals to an endemic area.

MEDICATIONS

DRUGS OF CHOICE
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is poor for naïve animals introduced into endemic areas.
• Goats are less susceptible than sheep and thus have a better prognosis.
• Animals that recover develop life-long immunity.

PREVENTION
• Avoid movement of naïve animals into endemic areas
• Vaccination
• Control of tick vector

MISCELLANEOUS

AGE-RELATED FACTORS
Colostral antibodies confer immunity to young animals in endemic areas.

ZOONOTIC POTENTIAL
Febrile illness, headache, nausea, and vomiting

PREGNANCY
Abortion when infected

BIOSECURITY
Notifiable OIE disease and requires mandatory reporting

ABBREVIATIONS
• DIC = disseminated intravascular coagulation
• ELISA = enzyme labeled immunosorbent assay
• IFAT = indirect immunofluorescence antibody test
• MHC = major histocompatibility complex
• NSD = Nairobi sheep disease
• OIE = World Organization for Animal Health
• PDI = protein disulfide isomerase
• TF = tissue factor

NEMATODIROSIS

BASICS

OVERVIEW
• Nematodirosis related to infestation with the intestinal roundworm *Nematodirus* spp. is called nematodirosis.
• Disease can affect many ruminant species but is often most clinically relevant in sheep (lambs).

INCIDENCE/PREVALENCE
• Varies depending on management systems and climactic factors.
• Lamb mortality can reach 20% in untreated flocks in some regions (United Kingdom, New Zealand, Australia)

GEOGRAPHIC DISTRIBUTION
• Worldwide depending on species and environment
• UK, Europe, New Zealand, Australia, South Africa, North America

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• Adult *Nematodirus* spp. reside in the anterior third of the small intestine of ruminants.
• Eggs are shed in the feces and, in the case of *N. spathiger* and *N. helvetianus*, development into the third stage larvae happens within the egg in 2–4 weeks. *N. battus* and *N. filicollis* have a delayed development and require conditioning by cold over winter. These infectious larvae (L3) remain within the egg until they are stimulated to hatch with rain and they can remain viable in the soil or on vegetation for many months. They are then ingested by the host during grazing and develop into mature adults in about 3 weeks.
• If the animal survives the effects of the parasite infestation, resistance to reinfection can develop.

HISTORICAL FINDINGS
• Pasturing in an enzootic area.
• A history of previous year's lambs, calves, or kids being infected and inhabiting the same premises.
• Infection is asymptomatic in resistant animals but acute illness can occur within 3 weeks of exposure in susceptible animals.
• Young animals are more likely to be affected.
• There is lack of an adequate anthelmintic program on the premises in question.

SIGNALMENT
• Potentially all ruminant species can be infected.
• Typically clinical disease occurs in lambs 6–12 weeks of age.

PHYSICAL EXAMINATION FINDINGS
• Sudden onset of diarrhea, anorexia, and loss of condition.
• Rapid dehydration and death (can be seen within 2–3 days of onset).

GENETICS
N/A

CAUSES AND RISK FACTORS
• *Nematodirus* spp.
  ◦ Cattle—*N. helvetianus* primarily, also *N. spathiger*, *N. filicollis*, and *N. battus*.
  ◦ Sheep and goats—*N. battus* primarily, also *N. spathiger*, *N. helvetianus*, *N. abnormalis*, *N. davitiani*, *N. filicollis*, and *N. lanceolatus*
  ◦ Bighorn sheep, deer, gemsbok—*N. spathiger*
  ◦ Moufflon—*N. filicollis*
  ◦ Bison—*Nematodirus* spp.
• Feeding on infested pasture, usually early in the grazing period
• Inadequate use of anthelmintics and preventive pasturing practices

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Infestation with other gastrointestinal parasites including *Trichostrongylus* spp., *Oesophagostomum* spp., and *Cooperia* spp.

CBC/BIOCHEMISTRY/URINALYSIS
CBC and biochemistry are indicated in severely affected animals, and may reveal changes consistent with systemic inflammation and protein loss.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Identification of eggs in feces; however, clinical signs often commence during the late pre-patent period prior to maturation of female parasites, which can complicate diagnosis early in flock outbreaks of disease.
• Eggs are distinctive and easily identified. They are large (180–230 µm × 90–170 µm), smooth and elongate, tapering at both ends. They are segmented (8 cells inside) when initially passed in the feces.

PATHOLOGIC FINDINGS
• Watery, dark-green diarrhea staining the escutcheon or breech.
• Dehydration, possibly cachexia.
• Fluid mucoid content of the upper small intestine and soft or fluid feces in the colon.
• Duodenal mucosa might show hyperemia with excess mucus, but is usually normal in appearance.
• Third stage larvae reside in the deeper layers of the mucosa and crypts. Fourth or fifth stage larvae reside coiled among the villi and, in high enough numbers, result in villous atrophy.
• Worm counts reveal tangled, cottony masses of elongate, lightly coiled nematodes in heavy infestations.

TREATMENT

THERAPEUTIC APPROACH
• All animals in an affected group should be treated with an appropriate anthelmintic product to reduce exposure level.
• If possible, prevent re-infestation by moving animals to a region or premises free of the parasite.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Ivermectin, moxidectin or doramectin given at 200 µg/kg body weight.
• Other anthelmintics that may be effective include levamisole (5 mg/kg), morantel and benzimidazoles (fenbendazole, oxfendazole and albendazole). Use as directed and observe withdrawal times.

CONTRAINDICATIONS
Do not treat animals that produce milk for human consumption with macrocyclic lactone drugs.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Full recovery with resistance to re-infestation is expected if clinical disease is mild and treated early.

POSSIBLE COMPLICATIONS
Dehydration and death has been reported with high prevalence in affected lambs in the UK, New Zealand, and Australia.

CLIENT EDUCATION
Develop robust parasite prevention protocols appropriate for the specific region that rely heavily on management and monitoring techniques paired with judicious use of anthelmintic drugs.

PATIENT CARE
Supportive care, which includes adequate high-quality nutrition and ready access to fresh water.

(CONTINUED) NEMATODIROSIS

PREVENTION
• Anthelmintics can be given initially when young animals are put out to pasture in spring, and then again in 3–5 weeks.
• Repeated treatments may be needed depending on environmental conditions and the species of *Nematodirus* in the area. Single treatments can be used with a delayed spring turnout or if transfer to non-infested premises occurs.
• Protocols will vary with location, making the experience of local veterinarians essential.
• Avoid infested premises/pastures, and avoid lambing annually in the same area or pasture.
• Without re-infestation, premises should be relatively free of infective larvae or eggs after two seasons, so pasture rotation at that interval will decrease potential of exposure.
• Rotate pastures with different, nonsusceptible livestock species.
• If calves, lambs, or kids are put on the pasture, follow them with adults who are likely resistant.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Other intestinal parasites
• Diarrhea, anorexia, dehydration

AGE-RELATED FACTORS
• Clinical disease occurs primarily in lambs, also calves and kids.
• Disease is most severe in young animals, but older nonresistant animals can also be affected.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
• Isolation and quarantine of new stock entering the herd or flock.
• Treat and/or cull new animals for disease conditions prior to herd introduction.
• If possible, prevent re-infestation by moving animals to premises free of the parasite.

PRODUCTION MANAGEMENT
• Avoid infested premises and pastures.
• Without re-infestation, premises should be relatively free of infective larvae or eggs after two seasons, so pasture rotation at that interval will decrease potential of exposure, and can involve different, nonsusceptible livestock species.

NEONATAL DIARRHEA

BASICS

OVERVIEW
• Diarrhea is the most prevalent illness in ruminants during the first 28 days of life.
• The development of diarrhea in neonates can arise because of a lack of adequate passive transfer of protective maternal immunoglobulins, overwhelming exposure to enteric pathogens, environmental stressors, or a combination of these events.
• Most cases of diarrhea reflect mixed infections with more than one pathogen.
• Treatment centers on the correction of electrolyte and acid-base imbalances, and dehydration.
• Death occurs due to dehydration, metabolic derangements, and electrolyte imbalances, and occasionally sepsis.
• Prevention focuses on vaccination of dams with appropriate antigens prepartum, ensuring adequate colostrum intake by neonates, and providing a clean maternity area and neonatal environment.

INCIDENCE/PREVALENCE
• Incidence of disease is variable, influenced by management, and can be substantial when outbreak situations occur with infectious pathogens.
• Incidence is higher in neonates born to primiparous dams due to colostrum of lesser quality and volume.
• Incidence of disease is higher during conditions that favor increased pathogen survival, particularly when environmental conditions are cold and wet, resulting in neonatal stress.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Digestive
• Cardiovascular

PATHOPHYSIOLOGY
• Diarrhea results from a variety of mechanisms occurring singly or in combination.
• Secretory diarrhea arises from stimulation of intestinal cells to secrete fluid into the lumen of the intestine. Although the absorptive capacity of the intestine may remain intact, the volume of fluid secretion overwhelms absorptive capacity, resulting in diarrhea.
• *E. coli* and *Salmonella* can produce entero- or exotoxins, which stimulate the intestinal epithelium to secrete sodium, chloride, bicarbonate, and potassium, along with fluid.
• The production of prostaglandins as a result of inflammatory processes also stimulates cellular secretions.
• Malabsorptive diarrhea results from injury to the absorptive epithelium of the intestinal tract. Viral agents, including coronavirus, rotavirus, and torovirus (Breda virus) as well as parasitic agents (*Cryptosporidium* and *Coccidia*), are the main pathogenic agents that contribute to this mechanism of diarrhea.
• Injury to the intestinal epithelium results not only in the loss of absorptive capacity but also in the loss of the enzyme systems needed for the digestion of nutrients such as lactose and proteins, resulting in maldigestion.
• Osmotically active solutes result from incomplete digestion and subsequent bacterial fermentation of nondigested nutrients, and draw fluid into the intestine, overwhelming the absorptive capacity of the gut.
• Normal bacterial flora is disrupted and changed, which may contribute to the development of diarrhea.
• The severity of neonatal diarrhea is dependent on agent virulence factors as well as host factors. Some animals may remain bright and alert and only exhibit mild signs of diarrhea, while others may have profuse watery diarrhea and exhibit systemic disease, resulting in death.
• Clinical signs of disease most often relate to acid-base disturbances, electrolyte loss, and dehydration. Septic and hypovolemic shock can occur when the bowel is severely diseased or the pathogen invasive.
• Septicemia usually occurs in neonates with inadequate immunoglobulin status or that are infected with enteroinvasive *E. coli* or *Salmonella* spp.

HISTORICAL FINDINGS
• In a herd or flock situation, the number of diarrhea cases related to infectious disease typically increases with the duration of calving, lambing, or kidding season as the pathogen load builds over time.
• In systems in which neonates are hand reared, particular attention should be paid to feeding management in case of nutritional diarrhea or contagion as a result of feeding practices.

SIGNALMENT
• Neonatal diarrhea is common in cattle, kids, lambs, and crias.
• Enterotoxigenic *E. coli* usually causes disease within the first 4 days of life; this can extend to 2 weeks if viral or parasitic infections exist.
• Enteroinvasive *E. coli* tends to cause septicemic disease during the first week of life; joint infections may develop during the first 2 weeks of life.
• Enteropathogenic and enterohemorrhagic *E. coli* affect neonates typically in the second and third weeks of life (range 4–28 days).
• *Salmonella* can affect any age group, and tends to be very uncommon in camelids.
• Coronavirus typically creates disease in neonates 5–28 days of age.
• Rotavirus typically creates disease in neonates 5–14 days of age.
• Cryptosporidiosis afflicts animals 7–28 days of age.
• Coccidiosis usually causes clinical disease in animals 16 days of age and older.

PHYSICAL EXAMINATION FINDINGS
• Soiled perineal region and tail.
• Dehydration is suggested by increased skin tent time, sunken eyes, and tacky mucus membranes.
• Fever may be present. Body temperature may be subnormal in animals that are significantly dehydrated and in shock.
• Tachycardia is often present as a result of hypovolemia; however, bradycardia or irregular cardiac rhythm can occur due to hyperkalemia, hypothermia, and/or hypoglycemia.
• Respiratory rate can be elevated in animals with metabolic acidosis. Neonatal calves with diarrhea often have concurrent pneumonia which will influence respiratory rate and pattern.
• The abdomen may appear poorly filled if the animal is anorexic, or may appear distended, particularly on the right side, due to ileus and collection of fluid within the intestines.
• The umbilicus may be enlarged, suggesting omphalitis which is often associated with failure of passive transfer.
• Scleral injection and hypopyon may be observed in septicemic neonates.
• Animals may be recumbent and unable to rise as a result of severe hypovolemia, metabolic acidosis, hypoglycemia, septicemia, or severe electrolyte disturbances.

GENETICS
N/A

CAUSES AND RISK FACTORS
• A wide variety of viral, bacterial and parasitic agents can cause diarrhea in neonatal ruminants and camelids, as listed below (some species differences exist).
• Although infectious agents are by far the most frequent cause of neonatal diarrhea, other possible etiologies include nutritional mismanagement, toxicities, and nutritional deficiencies.
• Infectious agents:
  ◦ Rotavirus
  ◦ Enterotoxigenic *E. coli*
  ◦ *Cryptosporidium parvum, C. bovis, C. ryanae* and *C. andersoni*
  ◦ Coronavirus
  ◦ Enteropathogenic and enterohemorrhagic *E. coli*
  ◦ Enteroinvasive *E. coli*
  ◦ *Salmonella* spp.
  ◦ *Clostridium perfringens* type A, B, C, and D
  ◦ *Eimeria* spp.
  ◦ Bovine viral diarrhea virus (BVDV)
  ◦ Bovine torovirus (Breda virus)
  ◦ Calici virus
  ◦ Astro virus
  ◦ Parvovirus
  ◦ *Campylobacter coli* and *C. jejuni*
• Inadequate passive transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia is a major risk

factor in neonatal diarrhea, and can occur due to factors that influence the neonate's access to and intake of colostrum in an appropriate time window, or that adversely affect the quality of the dam's colostrum. These factors include dystocia, prematurity, dam health and parity, and separation of dam and neonate without adequate colostrum substitution.
• Maternity areas that are contaminated with fecal material containing pathogenic agents are also a risk, due to enhanced ingestion of pathogens by the neonate from dirty udders, overcrowded maternity areas, and where there is lack of adequate cleaning and replacement of dirty bedding between birthing dams.
• Inadequate or improper nutrition is a risk, including improper reconstitution of milk replacers, poor quality milk replacers, once daily feeding, provision of bacterially contaminated colostrum or milk from mastitic quarters, or milk/milk replacer containing antibiotics.
• Dirty and crowded neonatal housing increases the risk of high pathogen loads and transmission.
• Cold, wet, and/or drafty environments contribute to immunosuppression and enhance survival of some pathogens.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• The gross characteristics of neonatal diarrheic feces are not diagnostic, although the presence of blood and mucus usually suggests large intestine involvement.
• Bloody diarrhea suggests *Salmonella*, coronavirus, enterohemorrhagic *E. coli*, BVDV, and *Coccidia.*
• Diarrhea with mucus can suggest *Salmonella*, coronavirus, enteropathogenic *E. coli*, enterohemorrhagic *E. coli*, and *Coccidia.*
• The presence of milk curds in the feces indicates a malabsorptive or maldigestive condition, often associated with viral agents.
• If fever is evident, *Salmonella*, enteropathogenic and enterohemorrhagic *E. coli*, and *Coccidia* should be considered.
• Tenesmus can also occur with coccidiosis in calves.
• Nutritional diarrhea.

CBC/BIOCHEMISTRY/URINALYSIS
• CBC can demonstrate hemoconcentration, with increased PCV and total protein concentrations. A left shift may be observed in animals in which the infectious agent invades the mucosa, produces toxins, or causes significant mucosal damage.
• Serum chemistry often reveals hypoglycemia, metabolic acidosis, and prerenal azotemia. Serum sodium and chloride might be low or normal. Hyperkalemia is often observed if metabolic acidosis is present despite a whole body potassium deficit.

OTHER LABORATORY TESTS
• Determination of immunoglobulin status during the first five days of life can be performed by a variety of methods:
  ◦ Plasma protein concentration determined by refractometry can provide an indirect measure; <5 mg/dL suggests of failure of passive transfer. However, the impact of dehydration and other plasma solutes on the plasma protein reading must be considered.
  ◦ Zinc sulfate or sodium sulfite turbidity tests can be performed to estimate immunoglobulin status.
  ◦ Single radial immmunodiffusion testing is accurately quantitative but takes 24 hours for results.
• Fecal floatation for observation of *Coccidia* and *Cryptosporidium* oocysts.
• Estimation of base deficit by evaluating serum or plasma total CO_2 concentration (which is 1–2 units higher than serum or plasma bicarbonate concentration).

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Necropsy
• Fecal culture
• Electron microscopy to detect viral agents

PATHOLOGIC FINDINGS
• At necropsy the intestines are filled with fluid and the mucosa may be congested, but gross lesions are often fairly minimal with most of the common causes of neonatal diarrhea.
• Hemorrhagic enteritis is associated with *Clostridium perfringens* type C infection.
• Fibrinonecrotic enteritis is associated with salmonellosis.
• Mucosal ulceration is associated with BVDV infection.
• Disruption of the mucosa and petechial hemorrhages may be observed in animals infected with *Salmonella* or *Coccidia*.
• Congestion of the lungs, liver, and spleen and petechial hemorrhages of the epicardium and serosal surfaces of organs are often observed in animals with septicemia resulting from *Salmonella* or enteroinvasive *E. coli* infection.
• Histopathologic findings vary. Colonization of the intestinal epithelium by enterotoxigenic *E. coli* may be evident, or adherence and effacement of epithelial cells by enteropathogenic and enterohemorrhagic *E. coli*.
• Developmental stages of *Cryptosporidium* and *Coccidia* can be observed within the small and large intestines.
• Desquamation of epithelial cells, villus shortening, and degrees of villus fusion are observed with viral infections.

TREATMENT

THERAPEUTIC APPROACH
• Fluid therapy is typically the foundation of treatment to correct dehydration, circulatory impairment, and electrolyte and acid-base imbalances. Fluid may be administered orally or intravenously depending on how severely diseased the neonate is.
• Commercial oral electrolyte solutions containing glucose and a nonbicarbonate alkalinizing agent are recommended if the neonate is still nursing.
• Neonates without a suckle response should receive IV fluids, such as physiologic saline with the addition of bicarbonate and glucose as needed. After establishment of rehydration, lactated Ringer's solution may be used for maintenance.
• With severe acidosis, isotonic sodium bicarbonate solution (1.3%, 13 g of sodium bicarbonate to 1 litre of distilled water) may be used.
• Dextrose solutions (2.5–5%) are indicated if hypoglycemia is present.
• With hypoglycemia and unknown electrolyte and acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.
• Neonates with a suckle response should be left with the dam and allowed to nurse. Animals being artificially reared should remain on their diet or be switched to whole milk or colostrum. If the diarrhea becomes worse or the neonate becomes depressed, removal from the dam or milk is warranted for 24 hours.
• In hand-reared neonates that are depressed with no suckle, or neonates refusing to nurse the dam, a high-energy electrolyte solution can be administered at 10% of body weight (minimum) divided into a minimum of four feedings. Once neonates are suckling, feed milk at 5% of body weight divided into 4 feedings per day, increasing the amount per feeding gradually to full volume over 2–3 days.
• Neonates should not be denied milk for longer than 24 hours.
• Oral electrolytes containing an alkalinizing agent, other than acetate, should not be fed when neonates are receiving the dam's milk or whole milk, as milk digestion may be disrupted.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

NEONATAL DIARRHEA (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE
• Many causes of diarrhea in neonates are self-limiting and antibiotics are not indicated. However, approximately 30% of neonates with diarrhea will have bacteremia in which antimicrobial therapy may be beneficial.
  ◦ Oral amoxicillin trihydrate (10 mg/kg PO q12h) for nonruminating calves.
  ◦ Amoxicillin trihydrate-clavulanate potassium (12.5 mg combined drug/kg PO q12h for 3 days).
• Flunixin meglumine (1.1 mg/kg IV or 2.2 mg/kg IM) has been shown to decrease secretion induced by *E. coli* enterotoxins and to reduce days of morbidity in calves with fecal blood.
• Plasma transfusion is indicated in neonates with failure of passive transfer and sepsis if the value of the animal warrants the expense.

CONTRAINDICATIONS
Do not use kaolin and pectin in diarrheic neonates, as this may increase electrolyte loss.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Most cases of neonatal diarrhea are self-limiting and resolve over 2–3 days, depending on the cause.
• Diarrhea is more severe in animals in which multiple disease agents are present, such as viral diarrhea with secondary bacterial infection.
• Time to recovery is often proportional to the amount of mucosal damage the animal experiences.
• Prognosis is directly related to the ability of the animal to maintain hydration and its immunoglobulin status.
• Animals that are hypogammaglobulinemic or that are septicemic are at increased risk of mortality.

POSSIBLE COMPLICATIONS
• Sepsis
• Hypovolemic shock
• Septic arthritis

CLIENT EDUCATION
Focus on biosecurity measures and nutritional management

PATIENT CARE
• Monitor attitude, suckling response and appetite, fecal color and consistency, and hydration status.
• Monitor age cohorts for signs of diarrhea.

PREVENTION
• Ensure adequate colostrum quality through management and vaccination of dams, and monitoring of neonates for access and intake.
• Maternity areas should be kept clean and disinfected periodically as appropriate.
• Remove the dam and neonate from the birthing area into a clean environment as soon as safe and feasible.
• Dip neonatal navels in appropriate antiseptic agents.
• Eliminate access of neonates to areas of fecal buildup.
• Dams can be administered vaccines containing enterotoxigenic *E. coli*, rotavirus and coronavirus antigens, and autogenous *Salmonella* prepartum.
• Neonates should be kept dry and in a draft-free environment.
• Equipment used to treat or feed neonates should be cleaned and disinfected between animals.
• Diarrheic animals should be isolated from healthy animals since they are sources of a large numbers of pathogens.
• Caregivers should wash hands between animals and keep clothing free of fecal material.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Septic arthritis
• Omphalitis
• Meningitis

AGE-RELATED FACTORS
Diarrhea is a very common neonatal disease.

ZOONOTIC POTENTIAL
• All diarrheic animals should be handled as though zoonotic potential is present.
• *Salmonella*, *Cryptosporidium*, *Campylobacter,* and some *E. coli* are potentially transmissible and pathogenic to humans.

PREGNANCY
N/A

BIOSECURITY
• Equipment used to treat or feed neonates should be cleaned and disinfected between animals.
• Handle and feed the youngest animals first, then handle in order of increasing age.
• Diarrheic animals should be isolated from healthy animals as they are sources for large numbers of pathogens, and they should be fed and handled last.
• Caregivers should wash hands between animals and keep clothing free of fecal material.

PRODUCTION MANAGEMENT
Neonatal diarrhea is a significant cause of economic loss, and preventive measures are critical in controlling the incidence and prevalence within herds and flocks.

SYNONYM
Scours

ABBREVIATION
BVDV = bovine viral diarrhea virus

SEE ALSO
• Coronavirus
• Cryptosporidiosis
• Diarrheal Diseases: Bovine
• Diarrheal Diseases: Camelid
• Diarrheal Diseases: Small Ruminant

NEONATAL SEPTIC ARTHRITIS

BASICS

OVERVIEW
• An inflammatory disease confined to the synovial membrane and articular surfaces as a result of sequestered bacteria.
• Route of infection is hematogenous as a result of bacteremia, which often originates from an umbilical infection or the GI tract.
• Often, this occurs in multiple joints ± physeal involvement.

INCIDENCE/PREVALENCE
• Incidence is not well described.
• Usually sporadic.
• Outbreaks in herds with endemic organisms or poor management.

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
• Musculoskeletal
• Nervous

PATHOPHYSIOLOGY
• Bacterial infections of newborn ruminants occur largely as a result of hypogammaglobulinemia (from FPT or depletion of immunoglobulins in the face of an overwhelming sepsis).
• Neonates become bacteremic or septicemic from an infection that often originates from the umbilical cord or via oral ingestion.
• Bacteria then sequester in the joint and cause inflammation of the synovial membrane.
• Multiple joints are often affected.
• Synovitis causes distention of the joint capsule with fluid.
• Arthritis may be suppurative or serofibrinous.
• Erosion of articular cartilage, infection of subchondral bone, and osteomyelitis can be sequelae.
• Synthesis of inflammatory mediators that can degrade cartilage.

HISTORICAL FINDINGS
• Unhygienic calving environment
• History of inadequate colostral intake
• Small, weak calves that remain recumbent for some hours
• Beef cows that reject their calves

SIGNALMENT
• All ruminants, but more common in dairy calves than beef calves
• Neonatal ruminants <4 weeks of age
• Usually evident within 2–3 days post-birth

PHYSICAL EXAMINATION FINDINGS
• Lameness is acute and severe.
• Joint effusion.
• Pain.
• Fever.
• Lethargy/Inappetence.
• Recumbency.
• Palpation and flexion of joint(s) reveal(s) heat and pain.
• Tachycardia and dehydration may be evident.
• Umbilicus may be moist and painful with purulent discharge.
• Nervous symptoms associated with meningitis may be present.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Enterics are most common (Gram-negative)—*Trueperella pyogenes*, *Escherichia coli*, *Salmonella* spp.
• Skin commensals (Gram-positive cocci)—*Streptococcus dysgalactiae*, *Lactococcus lactis* (lambs)
• Respiratory tract commensals—*Histophilus somni*, *Mycoplasma bovis*
• *Chlamydia psittaci* (lambs)
• *Erysipelothrix rhusiopathiae* (lambs)
Risk factors include:
• Hypogammaglobulinemia as a result of inadequate colostral intake.
• Dystocia.
• Mismothering/abandonment.
• Hypothermia.
• Raw milk/fermented dairy products (source of Gram-positive pathogens).
• Poor-quality colostrums (source of Gram-positive pathogens).
• Environmental contamination—unhygienic or overcrowded calving area, fecal contamination of dam's hocks and tail (source of Gram-negative pathogens).
• Calves born to first-lactation cows tend to have lower immunoglobulin concentrations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Primary infection arthritis: Penetration of joint by foreign body
• Extension of infection from surrounding tissues such as decubital lesions
• Idiopathic arthritis
• Myositis
• Degenerative myopathy
• Trauma
• Diseases of the nervous system that may cause recumbency or lameness
• Osteomyelitis
• Articular fracture
• Ligament injury
• Osteochondrosis

CBC/BIOCHEMISTRY/URINALYSIS
Elevated white blood cell counts

OTHER LABORATORY TESTS
• The neonate should be assessed for FPT.
• Blood culture improves the chance of finding bacteria in a febrile calf (use an ARD if the animal has received antibiotics prior to culture).
• Specific testing for *Mycoplasma* spp. (esp. if the umbilicus is normal and routine culture is negative).

IMAGING
• Radiology may only reveal soft tissue swelling in early stages, with destruction of articular cartilage and bone evident in advanced cases.
• Radiographic lesions more lytic with less new bone formation deposited at the joint periphery vs. older animals.
• Ultrasound joint (soft tissue swelling/effusion/fibrin) and umbilical structures.

OTHER DIAGNOSTIC PROCEDURES
• Joint aspiration may reveal purulent synovial fluid.
• Synovial fluid cytologic examination to evaluate TP and TNCC.
• Synovial fluid with TNCC >25,000 cells/μL, PMN count >20,000 cells/μL or >80% PMN cells should be considered septic.
• Total leukocyte counts range 50,000–100,000 cells/μL.
• Leukocytes are usually >90% neutrophils.
• Synovial fluid has elevated protein content (>4 g/dL).
• Joint culture is recommended, but is often unrewarding.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Systemic antibiotic therapy should be initiated and maintained for 10 days to 3 weeks.
• Treatment of FPT should be considered (plasma/whole blood).
• Short-term analgesic therapy (24–48 hours) in the form of NSAIDs (flunixin meglumine, ketoprofen, or meloxicam) may be used to reduce pain.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Joint lavage using a "through-and-through" technique with two 18- to 14-gauge needles placed on either side of the joint (very effective in acute cases).
• Sterile, warmed isotonic fluid should be flushed through the joint to remove debris (1 liter if possible).
• A light dressing should be applied to the joint for 24–48 hours post-lavage.
• IA antibiotics provide concentrations above MIC for a long period of time.
• RLP (IV administration under tourniquet).
• Arthroscopy, arthrotomy, the use of AIPMMA, and arthrodesis are further options to consider if response to initial treatment is unsuccessful or the animal is highly valuable.

NEONATAL SEPTIC ARTHRITIS (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE

• Selection of antibiotic may be determined by results of joint culture and sensitivity.
• Empirically treat with broad-spectrum antibiotics while awaiting culture results. In neonates with septic arthritis, antimicrobials should also be effective against mycoplasma, especially if concurrent pneumonia or otitis.
• Florfenicol (reports of successful use in IA and RLP as well as systemically).
• Macrolides.
• Potentiated sulfonamides (trimethoprim sulfadiazine).
• Oxytetracycline (good joint penetration).
No mycoplasma coverage:
• Ampicillin/Penicillin (good joint penetration and do not cause chemical synovitis if IA).
• Ceftiofur (effective at increased dosage IV and in RLP; however now illegal to use extra-label in US).

CONTRAINDICATIONS

Do not use antibiotics not approved for food animals.

PRECAUTIONS

• If NSAID therapy is prolonged, neonates should be monitored/treated for abomasal/C3 ulcers.
• When treating via IA or RLP routes withdrawal times will differ, thus recommendations should be made based on available pharmacokinetic and pharmacodynamic data. FARAD is a useful resource for acquiring such information. All drugs are considered extra-label for the indication of septic arthritis in food animals in the US.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Prognosis is dependent on level of FPT and chronicity.
• Prognosis is poor if multiple joints or meningitis are evident.
• Rapid intervention after clinical signs increases the chance for recovery; delay in initial treatment will cause the prognosis to be poor.
• Cases involving a single joint that are treated early have a reasonably good prognosis (up to 80% of calves may recover).

POSSIBLE COMPLICATIONS

• Chronic arthritis may result in severe degenerative joint disease.
• Recurrence of infection may occur if source of infection is not eliminated.
• Osteomyelitis.
• Meningitis may occur in neonates with septicemia.

CLIENT EDUCATION

• Predisposing causes should be discussed and eliminated.
• Evaluate colostral management and calving area hygiene.
• Warn client of need for long-term antibiotics and guarded prognosis.
• Educate clients on the importance of hygiene in calf health as well as zoonoses prevention—wear gloves (assisting birth), clean animal and calving equipment when assisting delivery, promptly remove placentas, rebed maternity pen.

PATIENT CARE

• Calf may need to be assisted to stand and nurse if appropriate (beef cattle).
• Physiotherapy by gentle flexion and extension or regular exercise may improve return to function.

PREVENTION

• Insure adequate colostral intake
• Appropriate umbilical hygiene

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Omphalophlebitis
• FPT
• Septicemia
• Meningitis

ZOONOTIC POTENTIAL

Salmonella spp., *E. coli* can have a zoonotic potential.

BIOSECURITY

Hygiene of calving area will aid in prevention.

SYNONYMS

• Joint ill
• Infectious arthritis
• Polyarthritis

BASICS

OVERVIEW
• The neonatal period in cattle goes from 0 to 30 days of age.
• During the neonatal period the calf is subjected to physiologic and environmental changes and challenges that increase the risk of morbidity and mortality.

INCIDENCE/PREVALENCE
• Approximately 3% of anatomically normal beef calves can die in association with difficult calving (dystocia).
• Neonatal mortality in beef calves is in the range 4–10%, with approximately 50–70% of neonatal mortality occurring during the first 3 days after birth.

SYSTEMS AFFECTED
Multisystemic

HISTORICAL FINDINGS
• Failure in the transfer of passive immunity is the most common risk factor for morbidity and mortality in beef calves. Low IgG1 levels in calf's serum at 24–72 h after birth are significantly associated with higher morbidity and mortality rates and lower ADG in pre-weaned beef calves. Infectious diseases such as septicemia, diarrhea, and pneumonia are a common consequence of FPT in calves.
• Dystocia, premature delivery, inadequate colostral intake.
• Unable or no interest to stand and nurse/weakness.
• Depression.
• Diarrhea.

SIGNALMENT
Beef breed calves <4 weeks of age

PHYSICAL EXAMINATION FINDINGS
• Weakness/depression—hypoxic/ischemic encephalopathy leading to dummy calf syndrome; metabolic acidosis; hypoglycemia
• Dehydration
• Hypothermia
• Fever (may or may not be present)
• Nasal discharge of various types (serous to mucopurulent)
• Crackles and wheezes uni or bilaterally—meconium aspiration; inadequate surfactant in premature calves or those delivered via C section
• Heart murmurs—ventricular septal defect is the most common in cattle
• Enlarged joints—often seen with septic arthritis in septicemic calves
• Enlarged umbilical structures—umbilical hernias and abscesses
• Diarrhea—the most common disease manifestation in neonates
• Seizures—often associated with meningitis in septicemic calves
• Congenital abnormalities (e.g., cleft palate, arthrogryposis, hydrocephalus)

GENETICS
Some neonatal conditions are genetic (e.g., epitheliogenesis imperfecta in shorthorn and Angus; arthrogryposis multiplex in Angus).

CAUSES AND RISK FACTORS
Congenital
Numerous congenital defects that may affect calves linked to genetic, infectious, and toxic causes

Immune
Inadequate colostrum intake

Infectious
• Bacterial, viral, and fungal agents can cause infections in neonatal calves.
• Neonatal diarrhea and pneumonia are consistently the most common causes of beef calf morbidity and mortality in cow-calf operations.

Risk Factors
• Dystocia is one of the most important risk factors for beef calf morbidity and mortality.
• Calves born from a dystocic delivery have a higher risk of cerebral hypoxia and FPT.
• Calving first-calf heifers and adult cows in the same pasture/pen.
• FPT ranges from 9% to 32% in beef calves.
• Calves born in the winter months and calves from first-calf heifers.
• High infection pressure in the calving pasture/pen.
• Housing calves with adult cows and older calves.
• Poor quality nutrition and body condition score prepartum are associated with lower IgG1 levels in colostrum of beef cows.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Septicemia: *E. coli*, *Trueperella pyogenes*, *Staphylococcus aureus*, *Streptococcus* spp.
• Diarrhea: *E. coli*, Rotavirus, Coronavirus, *Cryptosporidium parvum*, *Salmonella* spp.
• Omphalitis: *Trueperella pyogenes*, *E. coli*, *Proteus*, *Enterococcus* spp.
• Pre-weaned calf pneumonia: *Pasteurella multocida*, *Mannheimia haemolytica* and *Mycoplasma* spp.
• Congenital defects
• Lameness: Septic arthritis, trauma (fracture)

CBC/BIOCHEMISTRY/URINALYSIS
• Leukocytosis/Leukopenia with left shift
• Hyperfibrinogenemia
• Hypoglycemia
• Hyponatremia
• Hyperkalemia/Hypokalemia
• Hypochloremia
• Metabolic acidosis
• Increased liver enzymes (SDH, AST, GGT)

OTHER LABORATORY TESTS
• FPT: Serum IgG or total protein at 24 hours of life <10 g/L or <5.5 g/dL, respectively
• Blood culture
• Fecal culture
• Fecal EM, ELISA or PCR for viral pathogens
• Fecal flotation

IMAGING
• Thoracic radiographs
• Ultrasonography of the heart and umbilical structures

PATHOLOGIC FINDINGS
Varies depending on disease condition

TREATMENT
Depends on specific disease or condition.

THERAPEUTIC APPROACH
• Maternal colostrum or colostrum replacers if within 24 hours of life.
• Plasma or whole blood transfusion (10–20 mL/kg).
• Fluid therapy to correct dehydration and metabolic acidosis. Oral solutions should contain 50–80 mmol/L of alkalinizing agent (acetate, lactate, citrate, gluconate, or bicarbonate), 90–120 mmol/L of sodium, and glucose. Acetate solutions provide best results for nursing calves.
• Supplemental oxygen.
• Antibiotic and anti-inflammatory medications as needed depending on condition.
• Keep recumbent neonates in sternal recumbency, if possible.
• Provide heat source to correct hypothermia.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Infection of the umbilical structures or umbilical hernias may need surgical repair.

MEDICATIONS

DRUGS OF CHOICE
Varies depending on disease condition and antimicrobial susceptibility.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Prolonged use of antibiotics may alter intestinal microbiota and lead to diarrhea.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

PREVENTION
• Ensure nursing (colostrum intake) during the first 2 hours of life.

NEONATOLOGY: BEEF (CONTINUED)

• Any calf that has not nursed during the first 6 hours of life should receive a colostrum replacer product or frozen colostrum from a dairy source.
• Minimal amount of total IgG mass present in colostrum replacers given to newborn beef calves should be 100 g or, ideally, 150 g.
• Calve first-calf heifers and adult cows separately. First-calf heifers should calve early in the season 3–4 weeks before adult cows.
• Clean, dry, and hygienic calving pastures and pens are essential (adequate drainage and low stocking density).
• Vaccinate cows against common enteric pathogens before the calving season with a final booster 2–3 weeks before the first calving.

MISCELLANEOUS

ZOONOTIC POTENTIAL

Some neonatal diseases have zoonotic potential: *Salmonella, Cryptosporidium parvum*, *E. coli.*

BIOSECURITY

• Isolate pairs of sick calves and their dams to prevent disease spread.
• Maintain a closed herd and avoid introduction of pregnant cows/heifers or steers of unknown health status into the herd.
• If new animals are to be introduced into the herd, adequate quarantine and testing should be followed before introduction. Pregnant animals should be maintained isolated until calving and their offspring should be tested (persistent infection with BVDV) before herd introduction.

PRODUCTION MANAGEMENT

• Vaccination of cows during the prepartum will increase deposition of specific antibodies against common calf enteric and respiratory pathogens in colostrum and might decrease fecal shedding at calving as well as prevent clinical disease in neonatal calves.
• Adequate management of calving pasture/pen to decrease infection pressure to newborn calves is essential.

ABBREVIATIONS

• ADG = average daily gain
• AST = aspartate aminotransferase
• BVDV = bovine viral diarrhea virus
• ELISA = enzyme-linked immunosorbent assay
• EM = electron microscopy
• FPT = failure of transfer of passive immunity
• GGT = gamma glutamyltransferase
• IgG1 = immunoglobulin G
• PCR = polymerase chain reaction
• SDH = sorbitol dehydrogenase

NEONATOLOGY: CAMELID

BASICS

OVERVIEW
• Neonatal (<3 weeks of age) camelid problem management is more similar to the equine than to other ruminants.
• Camelid pregnancy and parturition physiology has unique features that affect camelid neonatology.
• Prematurity is a neonatal emergency.

INCIDENCE/PREVALENCE
• Neonatal losses are significant in camelid production systems.
• Losses may reach 50%.

GEOGRAPHIC DISTRIBUTION
Worldwide with a significant regional variation in incidence of specific disorders

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• Transition to extrauterine life requires fetal maturity and excellent peripartum conditions.
• The rapid nature of parturition and the type of placentation predisposes to hypoxia.
• Camelids are born agammaglobulinemic. FPT is one of the major predisposing factors to septicemia.
• SAC are notorious for a high incidence of congenital abnormalities.

HISTORICAL FINDINGS
• Dystocia
• Premature birth
• Unattended birthing
• Prepartum conditions in the dam

SIGNALMENT
• Young less than 3 weeks of age.
• More than 50% are in the first week of life.

PHYSICAL EXAMINATION FINDINGS
• Assessment of the dam and placenta should be done first.
• Behavioral: Inactive, weak, recumbent, sleepy. "Wall baby"—unable to discern mother from physical environment or "dummy cria"—neonatal maladjustment syndrome; may be due to hypoxia. These crias can respond positively within a week or less with supportive care.
• Neurologic: Most crias will stand within 30 minutes after delivery and walk within 1 hour
• Ophthalmic: Cataracts, hyphema, hypopyon
• Cardiovascular
  ◦ Normal neonate heart rate is 80–120 bpm immediately after birth and 60–100 bpm after several hours.
  ◦ Perinatal murmurs are common and disappear after the first few days of life.
  ◦ Congenital cardiac abnormalities are relatively common.
• Respiratory
  ◦ The normal respiratory rate is 20–40 breaths per minute.
  ◦ Choanal atresia can occur with subsequent open-mouth breathing with severe dyspnea when nursing.
• Gastrointestinal
  ◦ Crias have brief and frequent suckle, this is not a sign of poor milk production.
  ◦ Defection should be observed within the first 12 hours.
  ◦ Colic, distension, straining, and gaunt are signs of GI disorders.
• Urogenital
  ◦ Urination should be observed within the first 12 hours.
  ◦ Lack of urination or straining warrant further evaluation.
• Prematurity: Low birth weight, silky hair coat, firmly attached epidermal membrane, floppy ears, tendon laxity, unerupted incisors, domed skull.
• Congenital defects: CA, atresia ani, atresia vulvi/fused labia, polydactyly, syndactyly, cleft palate, wry face.
• Medical emergency care is required if:
  ◦ Hypothermia (temp <90°F, 32.2°C, normal temperature is 99–101°F, 37.2–38.3°C for cria)
  ◦ Respiratory distress
  ◦ Hypotension
  ◦ Cyanosis
  ◦ Blood loss
  ◦ Blunt trauma to skull.

GENETICS
Several congenital defects are hereditary

CAUSES AND RISK FACTORS
Genetics, dystocia, abnormal gestation, parturition conditions, and FPT exposure to the environment contribute to neonatal diseases and loss.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Common neonatal problems
  ◦ Failure of passive transfer (FPT) of immunoglobulins
  ◦ Septicemia
  ◦ Prematurity, hypoglycemic neonate
  ◦ Hypoxia/hypothermia
  ◦ Constipation: check for atresia ani, meconium impaction
  ◦ Patent urachus and omphalitis/omphalophlebitis
  ◦ Postpartum failure to stand and/or angular limb deformities
  ◦ Aspiration distress and subsequent pneumonia
  ◦ Choanal atresia
  ◦ Cleft palate
  ◦ Cataracts
  ◦ Wry face/parrot jaw
• Neonatal concerns, first 24 hours
  ◦ Premature neonate: hypothermia, acidosis, hypoglycemia, and hypoxia
  ◦ Meconium retention: digital palpation and subsequent warm water enema
  ◦ Dysuria: check for congenital problem or lack of nursing
  ◦ Oral/nasal/respiratory complications: evaluation (manual or endoscopy) generally requires sedation with IV butorphanol at 0.05 mg/kg. CA can be diagnosed by passing of a small rubber catheter through the nostril. If CA exists, the catheter will not advance beyond the medial canthus of the eye. May be unilateral or bilateral
  ◦ Blindness secondary to FPT
  ◦ Umbilical hernia
• Neonatal concerns, after 24 hours
  ◦ FPT/speticemia
  ◦ Diarrhea: heavy milking dam, coliform bacteria, *Salmonella* spp., *Cryptosporidium* spp., rotaviral infection
  ◦ Neonatal diseases are many times multisystemic in nature

CBC/BIOCHEMISTRY/URINALYSIS
Important in critically ill neonates. Abnormalities vary with condition.

OTHER LABORATORY TESTS
• IgG level evaluation
  ◦ Evaluated after 15 hours post delivery
  ◦ TSS in the field: <4.5 g/dL is evidence of FPT, 5–6 some transfer, >6 adequate.
  ◦ Camelid specific immunoglobulin assay (serum radial immunodiffusion assay) is the gold standard: Inadequate <400 mg/dL; suspect 400–1,000 mg/dL; adequate >1,000 mg/dL. Healthy crias consuming good quality colostrum often have serum IgG >2,000 mg/dL at 24 hours of age.
• Parasitology, bacteriology (aerobic and anaerobic blood cultures).

IMAGING
Radiographs and ultrasonography

OTHER DIAGNOSTIC PROCEDURES
Depends on condition

PATHOLOGIC FINDINGS
Depends on condition

TREATMENT

THERAPEUTIC APPROACH
• Catheter placement: 18- to 20-gauge catheter in jugular vein.
• Failure of passive transfer: Plasma transfusion 15–25 mL/kg body weight IV or IP. Whole blood transfusions can be used if plasma is not available (>500 mL of whole blood in acid-citrate-dextrose administered over 2 hours).
• Fluid care and maintenance
  ◦ Maintenance rate should begin at 2 mL/kg/h.
  ◦ Hypoglycemia: 2.5% dextrose in half-strength saline IV. Regular monitoring of blood glucose is recommended.

NEONATOLOGY: CAMELID (CONTINUED)

• Thermal support: Maintain in sternal recumbency. Heating lamps, hot water units, and blankets (available commercially) all work well.
• Nutritional support
  ◦ Tube or bottle-feed cria.
  ◦ Parenteral nutrition if a poor suckle reflex.
  ◦ It is important to monitor blood and urine glucose.
  ◦ Repeated orogastric tube placement may be stressful to the cria. Indwelling nasogastric tubes may be better tolerated. Stallion catheters work well as orogastric tubes. The 18–22 French generally are the right size for smaller crias and 24–30 French stallion catheters should be used for larger crias.
• Respiratory support
  ◦ Arterial blood gas from the medial saphenous artery.
  ◦ Thoracic radiographs/ultrasonography may be indicated with compromised patients.
  ◦ Hypoxemia is common in the critical neonate. Support with 100% humidified oxygen intranasally at a starting rate of 5 L/minute. Adjust according to the pO_2 and the oxygen tension should be at 80 mmHg.
• Pharmaceutical support
  ◦ Antibiotic use should reflect culture and sensitivity results.
  ◦ Commonly camelids have a Gram-negative or "mixed bag" culture and *Clostridium perfringens* A and C is not uncommon.
  ◦ Ceftiofur is a good initial antibiotic choice in the cria while awaiting culture/sensitivity results.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgery may be considered in some situations (umbilical hernia, angular limb deformities).

MEDICATIONS

DRUGS OF CHOICE
Antibiotics should be selected based on safety and sensitivity results.

CONTRAINDICATIONS
Aminoglycoside are nephrotoxic and should be avoided.

PRECAUTIONS
Many drugs are used off-label.

POSSIBLE INTERACTIONS
Drug interactions are not well-studied in camelids.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is good for FPT and septicemia if diagnosis and implementation of critical care is early.
• Crias with severe congenital abnormalities should be humanely euthanized.

POSSIBLE COMPLICATIONS
Stunted growth, ill thrift

CLIENT EDUCATION
• Proper management of pregnant females and parturition.
• Recognize the normal newborn behavior and when to call the veterinarian.
• Prepare a source of colostrum replacement.

PATIENT CARE
• Prevent hypothermia and provide supportive (nutritional) care.

PREVENTION
• FPT can be prevented by providing an alternate colostrum source. Ovine or caprine colostrum is a good choice. Bovine colostrum is a last choice due to potential transmission of Johne's disease.
• For camels, a stock of good-quality camel colostrum is the best choice.
• Camelid plasma may also be administered orally if colostrum is unavailable.
• Colostrum requirements: 10% of the body weight fed q2h over 12 hours.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Berserk male syndrome can occur in camelids who form a human bond during the neonatal period.
• FPT may be associated with lactational problems (mastitis, agalactia, udder edema/mastitis, inadequate mothering behavior).

AGE-RELATED FACTORS
Neonates

ZOONOTIC POTENTIAL
Salmonella spp. and *Cryptosporidium* spp.

PREGNANCY
Proper nutrition and immunization during pregnancy insures colostral quality and good lactation.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Diet requirements throughout pregnancy
• Milk replacer: 6–8 ounces of goat milk replacer plus 2–3 ounces of live culture yogurt. It is essential that the milk/milk replacer contains no antibiotics as scours will result.

SYNONYMS
N/A

ABBREVIATIONS
• CA = choanal atresia
• FPT = failure of passive transfer
• IgG = immunoglobulin G
• IM = intramuscular
• IP = intraperitoneal
• IV = intravenous
• SAC = South American camelids

Client Education Handout available online

BASICS

OVERVIEW
Common diseases found in goats from birth to 1 week of age. Management factors and environmental conditions play a very large part in the disease process of the neonate.

INCIDENCE/PREVALENCE
Dependent on specific disease process

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Multisystemic

HISTORICAL FINDINGS
- Premature delivery
- Failure of passive transfer
- Diarrhea
- Anorexia

SIGNALMENT
Birth to 1 week of age

PHYSICAL EXAMINATION FINDINGS
- Congenital defects (e.g., cleft palate, contracted tendons, VSD)
- Dehydration
- Hypothermia
- Depression
- Weakness

GENETICS
Some conditions in neonates have a genetic predisposition.

CAUSES AND RISK FACTORS
Causes include:
- Congenital defects
- Failure of passive transfer
- Dehydration
- Hypothermia
- Hypoxia
- Hypoglycemia
- Nutritional deficiency in doe or kid
- Trauma

Risk factors include:
- Poor body condition or underlying disease in doe
- Failure of passive transfer
- Premature delivery
- Poor environmental conditions

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
- Septicemia
- Floppy kid syndrome
- Hypothermia
- Starvation
- Meconium impaction
- Neuromusculoskeletal diseases: tetanus, white muscle disease, trauma
- Congenital defects
  - Cleft palate
  - Contracted tendons
  - Umbilical hernia
  - Patent urachus
  - Cardiac (i.e., VSD)
- Diarrhea
  - *E. coli*
  - *Salmonella* spp.
  - Adenovirus
  - Coronavirus
  - Rotavirus
  - *Cryptosporidium* spp.
  - *Giardia* spp.
  - Clostridial enterotoxemia type B
- Respiratory disease: Aspiration pneumonia, *Mannheimia haemolytica*, rib fractures

CBC/BIOCHEMISTRY/URINALYSIS
- Hypoglycemia
- Hypoproteinemia
- Hyperfibrinogenemia
- Left shift in leukogram with neutropenia (toxic bands)
- Metabolic acidosis

OTHER LABORATORY TESTS
- IgG <400 mg/dL or TP <5.0 g/dL
- *Salmonella* positive on fecal culture
- Electron microscopy for viruses
- Fecal IFA for *Cryptosporidium* and *Giardia*
- Bacteremia on blood culture
- Hypoxemia on blood gas
- Decreased serum vitamin E
- Decreased EDTA or heparin whole blood selenium

IMAGING
Radiography if suspect fractures or aspiration pneumonia

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
Varies based on disease condition and the environment

SURGICAL CONSIDERATIONS AND TECHNIQUES
- Stabilize patient before beginning any surgical procedures.
- Congenital defects and/or traumatic injuries may need surgical correction.
- Neonates in many instances are not good surgical candidates.

MEDICATIONS

DRUGS OF CHOICE
- Antibiotics based on suspected problem and/or culture and sensitivity.
- NSAIDS may be indicated. Care should be used in selection and hydration status of the neonate. Some NSAIDs are contraindicated in the neonate.
- Intravenous plasma, oral plasma, or oral colostrum.
- Antidiarrheal medications.

CONTRAINDICATIONS
Avoid using drugs prohibited or not labeled for use in food-producing animals (e.g., aminoglycosides, metronidazole). Follow drug withdrawal periods for meat and milk.

PRECAUTIONS
Beware of drugs that may affect growing tissues.

POSSIBLE INTERACTIONS
N/A

ALTERNATIVE DRUGS
Probiotics may be indicated.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Varies based on disease(s) encountered

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
Correct any deficiencies in husbandry or breeding selection.

PATIENT CARE
- Warming neonate
- Oxygen supplementation
- Oral or intravenous fluids (correct electrolyte and acid-base disturbances)
- Meet caloric needs via PO or IV nutrition (i.e., oral sugar/syrup or IV dextrose for hypoglycemia)
- Enema for meconium impaction (warm soapy water)
- Activity
  - Passive range of motion
  - Rolling from side to side
  - Maintain sternal recumbency
- Diet
  - Proper nutrition of the prepartum doe
  - Important to feed the kids a balanced diet that meets their caloric and nutritional requirements.

PREVENTION
- Correct management deficiencies.
- Avoid poor husbandry and/or breeding selection.
- Ensure colostral quality.
- Ensure adequate amount of colostrum is administered within the first 24 hours after birth.
- Adequate nutrition and vaccination of prepartum does.

NEONATOLOGY: CAPRINE (CONTINUED)

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Some diseases of small ruminants may have zoonotic potential (e.g., *Salmonella* spp., *E. coli*, *Campylobacter* spp., *Cryptosporidium* spp., *Giardia* spp.).

PREGNANCY
N/A

BIOSECURITY
- Biosecurity measures may help to decrease the severity and course of neonatal diseases and may improve the prognosis.
- Can decrease transmission among other neonates, adult goats, and humans.
- Isolation and quarantine of new stock entering the herd or flock.
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT
- A good environment is vital to neonatal health.
- Management of pregnant does is important to neonatal health and viability.
- Proper husbandry and breeding practices are crucial in selecting for healthy neonates.

Colostrum
- Does should be stripped after kidding to ensure functional teats and milk production.
- Kids should consume 2.5 ounces/lb (160 g/kg) BW of colostrum in the first 24 hours. Colostrum may be bottle fed or tubed using a red rubber catheter if the kid is weak or the dam will not allow nursing. The first feeding should take place within an hour after birth and subsequent volume should be given over four feedings. Stored colostrum should be refrigerated and re-warmed to 38–39°C (100–102°F) by immersing in warm water prior to feeding. Extra colostrum can be frozen and saved for instances of triplets or low production.
- If the farm tests and manages for Johne's, CAE and CL, kids should be given colostrum and milk from negative dams.

Umbilicus
The umbilicus should be dipped or thoroughly sprayed with 7% tincture of iodine immediately after birth. This may be repeated in 12–24 hours.

Housing
- Clean, dry bedding is essential to prevent infectious disease and aid in neonatal thermoregulation.
- Good ventilation is imperative to decrease risk of pneumonia and transfer of disease.
- Heat lamps may be used in particularly cold climates but caution should be observed as they present a fire hazard, especially with straw bedding. Kids must always have room to move away from the heat source to prevent hyperthermia.
- A creep feeding area should be set up to allow groups of kids a safe haven away from does as well as access to feed (grass hay and/or grain). Kids begin consumption of feed as early as 1 week of age and ruminal digestive function is complete by 2 months of age.

Disbudding
If clients plan on disbudding, arrangements should be made to perform by 1–2 weeks of age. If performed later, the procedure is much more difficult and stressful on the kid.

Vaccination
- Ideally, dams are vaccinated with CDT one month prior to kidding in order to enhance colostral antibody production. If adequate colostrum is consumed thereafter then kids will be adequately protected during the high-risk neonatal period.
- Vaccination with CDT (followed by booster vaccination according to label directions) should be administered by 30 days of age. If dams are unvaccinated or colostrum is not consumed, then earlier vaccination is warranted. Vaccine response may not be optimal due to developing immune system earlier than 1 month of age and therefore the above vaccination program may still be warranted.
- Other vaccinations (e.g., rabies) may be necessary based on location and herd management.

SYNONYMS
N/A

ABBREVIATIONS
- CDT = *Clostridium perfringens* type C & D plus tetanus vaccine
- CL = caseous lymphadenitis (CLA)
- EDTA = ethylene diamine tetraacetic acid
- IFA = immunofluorescence assay
- IgG = immunoglobulin G
- IM = intramuscular
- IV = intravenous
- NSAIDs = nonsteroidal anti-inflammatory drugs
- PO = per os, by mouth
- TP = total protein
- VSD = ventricular septal defect

SEE ALSO

NEOSPOROSIS

BASICS

OVERVIEW

• *Neospora caninum,* an obligate intracellular coccidian parasite of ruminants, is the causative agent of late-term abortions or birth of congenitally infected, weak, or unthrifty calves in cattle.
• There are sporadic reports of abortion in sheep and goats due to infection with *Neospora caninum*.
• *N. caninum* has been reported as a cause of abortion in camelids.

INCIDENCE/PREVALENCE

• *Neospora caninum* infects 10–20% of all cattle worldwide and is incriminated in up to 20% of diagnosed bovine abortions.
• Seroprevalence studies have documented specific antibody responses in cattle, canids, and a multitude of likely intermediate hosts.
• Successful isolation of viable parasites has been limited to cattle, sheep, water buffalo, bison, white-tailed deer, and dogs.

GEOGRAPHIC DISTRIBUTION

• *Neospora caninum* infection has been detected in cattle populations and other ruminant and camelid species worldwide

SYSTEMS AFFECTED

• Reproductive
• Nervous

PATHOPHYSIOLOGY

• *N. caninum* has a heteroxenous life cycle highlighted by three infectious stages:
  ◦ Tachyzoites
  ◦ Tissue cysts
  ◦ Oocysts
• Dogs (*Canis familiaris*) and coyotes (*Canis latrans*) are the only recognized definitive hosts for *Neospora* sp.
• Cattle and a wide range of warm-blooded animals act as intermediate hosts.
• A sylvatic cycle including white-tailed deer and coyotes is important in maintaining a reservoir of infection.
• In cattle, *N. caninum* transmission may occur efficiently by both horizontal and vertical routes.
  ◦ Horizontal transmission occurs when cattle ingest sporulated *N. caninum* oocysts present due to fecal contamination from definitive hosts present in feed sources.
  ◦ Transplacental vertical transmission results in infection of a fetus carried by an acutely or persistently infected dam and can result in either abortion, birth of a weak, compromised neonate, or birth of a subclinically infected, apparently normal neonate.
• Abortions occur most commonly at 5–6 months of gestation, associated with chronic infection of the placenta and fetus.
• Abortion may be triggered either as a result of a recent primary maternal infection or following recrudescence of a persistent infection during pregnancy.
• Infected mature cows are asymptomatic but may abort or continually produce congenitally infected calves following transplacental transmission.
• A similar pathophysiology with abortion occurring in the second half of pregnancy has been reported in llamas and alpacas.
• Abortion, stillbirth, and neonatal mortality due to *N. caninum* infection has been reported in goats. Experimental infection at 40 days of pregnancy resulted in abortion. Infection at 90 days produced abortion and stillbirth while infection at 120 days of gestation resulted in birth of congenitally infected kids. Abortion occurred 17–21 days after infection. There were fewer placental lesions in small ruminants than in cattle.

HISTORICAL FINDINGS

• Abortion
• Birth of weak neonate with neurologic symptoms

SIGNALMENT

• Both beef and dairy cattle may be infected. Abortions due to *Neospora* are more common in dairy cattle.
• Both nulliparous and multiparous cattle may abort.
• Abortions are nonseasonal and may be seen in all months of the year.
• Bulls may be infected but there is no evidence that *N. caninum* is spread venereally or via artificial insemination.

PHYSICAL EXAMINATION FINDINGS

• Abortion is the main clinical manifestation of bovine neosporosis in dairy and beef cattle.
• Epidemic and endemic abortion outbreaks may occur.
• Fetuses dying in utero are generally expelled but mummification may occur.
• Postnatally infected cattle are unlikely to abort due to *Neospora* or to transmit the infection transplacentally more than once.
• 95% of congenitally infected calves appear normal at birth.
• Occasionally congenitally infected neonates exhibit neurologic deficits at birth or within the first 4 weeks of life. Neurologic signs include ataxia, weakness, decreased patellar reflexes, and loss of conscious proprioception.
• *Neospora* may occasionally cause birth defects of hydrocephalus, narrowing of the spinal cord, and arthrogryposis.
• Data on clinical and pathologic findings in sheep, goats, and camelids are scarce.

CAUSES AND RISK FACTORS

• *Neospora caninum*
• Presence of canids on farm

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Any pathogen that may cause mid to late term abortion
• Protozoal: *Toxoplasma gondii* and *Sarcocystis cruzi*
• Viral: Bovine viral diarrhea virus, infectious bovine rhinotracheitis, bluetongue
• Bacterial: *Leptospira*, *Salmonella*, *Histophilus*
• Miscellaneous: Foothill abortion, mycotic abortion
• Causes of weak and unthrifty calves: Persistent infection with BVDV, selenium deficiency, iodine deficiency, congenital bluetongue virus, failure of passive transfer, or neonatal septicemia

CBC/BIOCHEMSTRY/URINALYSIS

Often unrewarding from cows that have aborted or congenitally affected calves, as results are unremarkable and nondiagnostic.

OTHER LABORATORY TESTS

• CSF obtained from neurologically abnormal congenitally infected neonates may demonstrate mild pleocytosis.
• Congenitally infected calves may be at increased risk of failure of passive transfer due to weakness.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

• Laboratory submissions should include sera from aborting dams, fetal fluids, and tissues including placenta if available.
• Histopathology
  ◦ Gold standard for diagnosis of *Neospora.*
  ◦ Degenerative to inflammatory lesions may be found through fetal tissues but most commonly in central nervous system, heart, and liver.
  ◦ Tachyzoites in tissues are demonstrated with special stains.
• Gross pathology
  ◦ Aborted fetus, commonly autolyzed or mummified.
  ◦ Gross lesions, uncommon but may be present.
  ◦ Pale white foci may be observed in the heart or skeletal muscle.
  ◦ Very small, pale to dark necrotic foci may be observed in brain.
• Serology
  ◦ ELISA and IFAT serologic assays that detect specific antibodies allowing for confirmation of *Neospora* antibodies.
  ◦ Positive serology from an aborting cow is only indicative of exposure to *N. caninum* and diagnosis should be paired with histopathology.
  ◦ In contrast, a negative result on fetal submissions does not rule out *Neospora*, because of autolysis, immature fetal

NEOSPOROSIS (CONTINUED)

immunocompetence, or short interval between infection and death.
• Molecular techniques: PCR-based assays are available to detect *Neospora* in fetal tissues, amniotic fluid, milk, semen, or dog feces.

PATHOLOGIC FINDINGS
• Lesions most commonly observed in brain, spinal cord, heart, and liver, but may be present in other tissue.
• Most characteristic lesions are multifocal encephalitis, myocarditis, and periportal hepatitis associated with tachyzoites demonstrable by IHC.

TREATMENT

THERAPEUTIC APPROACH
• No pharmaceuticals are approved for treatment of bovine neosporosis.
• Experimental treatment of congenitally infected newborn calves with toltrazuril was shown to eliminate infection.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

N

DRUGS OF CHOICE
There are no approved medications.

CONTRAINDICATIONS

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Infected cows will often return to normal heath and conceive.
• There is an increased risk for abortion in subsequent pregnancies.

POSSIBLE COMPLICATIONS
• Milk production loss
• Other complications associated with abortion (retained fetal membranes, metritis, infertility)

CLIENT EDUCATION
• Role of canids in transmission
• Importance of biosecurity measures

PATIENT CARE
Farm biosecurity is important in controlling bovine neosporosis, with maintenance of a closed herd the best way to avoid introducing parasites.

PREVENTION
• Farm biosecurity is important in controlling bovine neosporosis, with maintenance of a closed herd the best way to avoid introducing parasites.
• Access of dogs and other canids to stored feeds should be minimized.
• No vaccine is currently commercially available.
• Determining the serostatus of each animal at birth and culling those congenitally infected.
• Embryo transfer to seronegative recipients can be used preserve the genetics of valuable seropositive animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS

NIGHTSHADE (*SOLANUM* SPP.) TOXICOSIS

BASICS

OVERVIEW
• Member of Solanaceae family; *Solanum* spp. (nightshade) has the largest number of species (>1,500 worldwide).
• Weeds, herbs, shrubs, small trees; erect stems or vines; annual or perennial; berry-like fruit.
• Present in pastures, gardens, waste areas, and cultivated crops.
• Common species of *Solanum* in North America include *S. nigrum* (black nightshade), *S. dulcamara* (bittersweet), *S. carolinense* (horse nettle), *S. elaeagnifolium* (silverleaf nightshade), *S. physalifolium* (hairy nightshade), *S. rostratum* (buffalo bur), *S. tuberosum* (potato), *S. ptychanthum* (eastern black nightshade).
• Related genera include *Lycopersicum* (tomato), *Datura* (jimsonweed or angel's trumpet), *Capsicum* (pepper), *Nicotiana* (tobacco).
• Depending on genera and species, gastrointestinal (GI) irritation, nervous system dysfunction, and teratogenicity are possible.

INCIDENCE/PREVALENCE
• Ruminants tend to be resistant, especially to the toxins solanine and solanidine
• Toxicosis with large ingestions

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Cardiovascular
• Digestive
• Nervous
• Reproductive

PATHOPHYSIOLOGY
• Toxins are concentrated in the green (unripe) fruits, leaves, sprouts, and green potato tubers.
• Steroidal alkaloids solanidine and solanine are primary toxins; many other toxins including solasonine, solamargine, chaconine; cause saponin-like effects with GI mucosal irritation and necrosis.
• Related genera contain tropane alkaloids (scopolamine, hyoscyamine, others), capsaicinoids, pyridine alkaloids (nicotine), other toxins; affects the autonomic nervous system. Activity of anticholinesterase is blocked, allowing accumulation of acetylcholine resulting in more severe GI, nervous, and cardiac effects.

SIGNALMENT
• All ruminant species can be affected
• All ages, both genders

PHYSICAL EXAMINATION FINDINGS
• Salivation, abdominal pain, vomiting, abdominal pain, diarrhea, or constipation from direct GI irritation.
• Decreased salivation, mydriasis, decreased GI motility, and increased heart rate may result from anticholinergic effects.
• Depression, incoordination, tremors, weakness, seizures.
• Rarely teratogenic effects.

CAUSES AND RISK FACTORS
• Lack of available food sources
• Season of year—consumed fresh in summer/fall; fed throughout the year in hay or silage

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Many other plants and chemicals produce similar signs of gastroenteritis or nervous dysfunction.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

OTHER DIAGNOSTIC PROCEDURES
• History of ingestion
• Clinical signs
• Presence of plant material in rumen or stomach

PATHOLOGIC FINDINGS
• Gastroenteritis, possibly severe with hemorrhage and necrosis
• Hyperemia of intestinal mucosa
• Increased peritoneal fluid, especially in calves
• Purkinje cell swelling and/or loss

TREATMENT

THERAPEUTIC APPROACH
• No antidote
• Symptomatic and supportive

SURGICAL CONSIDERATIONS AND TECHNIQUES
Rumenotomy and evacuation of contents may be useful early in the course of intoxication.

MEDICATIONS

DRUGS OF CHOICE
• Activated charcoal 1–5 g/kg PO as slurry; may repeat charcoal but add cathartic (magnesium or magnesium sulfate, sorbitol) × 1 dose only.
• Physostigmine 0.04–0.08 mg/kg IV (extra-label); use very cautiously and only if anticholinergic signs are severe.
• Atropine sulfate 0.1–0.5 mg/kg SC, IM, IV for severe cholinergic signs.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• May have a latent period of hours to days before signs develop
• Variable, generally good with adequate treatment

PREVENTION
• Prevent further access to toxins
• Maintain good source of nutrition

MISCELLANEOUS

PREGNANCY
Teratogenic effects such as craniofacial malformations have been reported in laboratory animals.

ABBREVIATIONS
• GI = gastrointestinal
• IM = intramuscular
• IV = intravenous
• PO = by mouth
• SQ = subcutaneous

NITRATE AND NITRITE TOXICOSIS

BASICS

OVERVIEW
• Toxicity most commonly results from ingestion of nitrate-accumulating forages or noxious weeds.
• Methemoglobin (MHb) formation gives the blood a chocolate-brown color and results in tissue hypoxia/anoxia giving rise to the observed clinical signs.
• Clinical signs develop acutely and include dyspnea, weakness, and sudden death.
• IV administration of methylene blue is the treatment of choice for affected animals.
• Many factors affect nitrate uptake by plants, and it is difficult to predict when problems may arise.

INCIDENCE/PREVALENCE
Generally unpredictable, but more likely to occur in times of drought and during the winter months.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Cardiovascular
• Multisystemic

PATHOPHYSIOLOGY
• Nitrate (NO_3) is converted to nitrite (NO_2) by the rumen microflora.
• NO_2 is ten times more toxic than NO_3.
• NO_2, once absorbed systemically, converts hemoglobin (Fe^{2+}) to MHb (Fe^{3+}).
• MHb is incapable of oxygen transport and tissue anoxia results in the clinical signs observed.

SIGNALMENT
• All ruminant species can be affected.
• Adults are more susceptible due to conversion of NO_3 to NO_2 in the rumen. Functional ruminants are ten times more susceptible to toxicity than pre-ruminants.

PHYSICAL EXAMINATION FINDINGS
• Abrupt onset of dyspnea and weakness.
• Muscle tremors, stumbling, or recumbency.
• Salivation.
• Pale, cyanotic, or brown mucus membranes.
• MHb formation imparts a chocolate-brown color to the blood. This color will disappear within a few hours postmortem.
• Sudden death, with or without terminal convulsions.
• Abortion in pregnant animals follows acute signs by several days to a few weeks. The developing fetus is highly susceptible to anoxia, and abortion may occur in cattle with minimal signs of acute nitrate/nitrite toxicity.

CAUSES AND RISK FACTORS
• An acute oral lethal dose is approximately 0.5 g nitrate/kg body weight.
• Many forages and cereal grains have been associated with nitrate accumulation including sorghum, alfalfa, oats, corn, barley, wheat and rye.
• Noxious weeds that are recognized as important accumulators of nitrate include pigweed (*Amaranthus* spp.), lambs quarter (*Chenopodium* spp.), Canada thistle (*Cirsium arvense*), and fireweed (*Kochia scoparia*) (See Table 1). Such plants may be consumed directly from pasture or can easily invade hay fields and be incorporated in dried harvested forages. This risk is especially true for the thistles that are likely to be sprayed with herbicides, some of which, for example, 2,4-D, cause the plants to accumulate higher levels of nitrates for a few days.
• Water can be the source of poisoning, but this is uncommon. Gross contamination of the water source and/or environment with nitrogen-containing fertilizers or use of tanks that once transported nitrogen-containing fertilizers as water troughs can be a risk. Nitrate levels <200 ppm are generally considered safe, and most animals can tolerate much higher levels (1,000–1,500 ppm).
• Animals that are more dominant, in an energy deficit, or debilitated with a pre-existing disease, may be more susceptible.
• Clinical signs in animals and death occur abruptly, despite feeding the same diet for days or weeks. This is not a cumulative or chronic problem. The sporadic nature of illness is directly related to the nonhomogeneous distribution of nitrate in the feed and lack of rumen adaptation.
• Once the animal's rumen has become "acclimated" to nitrate, the animal can tolerate much higher dietary levels.
• Any environmental stressors that limit photosynthesis but allow the plant to continue to take up nitrogen from the soil will result in increased nitrate accumulation. Examples of such stressors include frost, drought, pesticide application, and low light levels.
• Stunted plant growth results in nitrate accumulation in the lower part of the plant; this is clinically important when making silage from corn or other cereal grains.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Chlorate, copper, and *Mercurialis* toxicities are capable of causing methemoglobinemia.
• Other causes of "abrupt" onset of similar signs and death include anthrax, clostridial infection, cyanobacteria, lightning strike, and toxicities caused by *Cicuta* (water hemlock), *Taxus* (yew), *Zigadenus* (death camas), oleander, organophosphate and carbamate insecticides, ionophores, and nonprotein nitrogen.

CBC/BIOCHEMISTRY/URINALYSIS
No remarkable abnormalities are observed, other than the blood appearing "chocolate" brown.

OTHER DIAGNOSTIC PROCEDURES
• Muddy-colored mucus membranes, "chocolate brown" blood, and clinical signs suggestive of oxygen deprivation are consistent with nitrate/nitrite toxicosis.
• Due to the instability of MHb and the need for phosphate buffers for storage of blood samples, determination of MHb concentrations is rarely performed.
• Diphenylamine kits or nitrate/nitrite qualitative or semiquantitative strip tests can be used on feed and water to confirm high nitrate levels.
• Suspect forages can be tested using diphenylamine to semiquantitatively estimate the nitrate concentration, and ion chromatography can be used to quantitatively analyze for nitrate and nitrite in suspect forages and water.
• NO_3 concentrations can be measured in most biological fluids including refrigerated blood, serum or plasma, peritoneal, and pericardial fluids or urine along with feed or water using ion chromatography. Concentrations >15 ppm are suggestive, and concentrations >20–30 ppm are diagnostic of excessive exposure to nitrates; levels >50 ppm are consistent with NO_3 poisoning.
• Ocular fluid (aqueous humor) nitrate concentrations can be determined, using diphenylamine (semiquantitative) or ion chromatography (quantitative), for up to 72 hours postmortem or up to a week after death in refrigerated samples. Concentrations >10 ppm nitrate in ocular fluid are suggestive, and concentrations >20 ppm are diagnostic of exposure to excessive nitrates.
• Since neonatal calves normally have ocular fluid nitrate concentrations approximating 20 ppm during the first day of life, nitrate concentrations >30 ppm are generally more consistent with nitrate/nitrite toxicosis in these animals.
• Rumen contents are not useful diagnostically because of postmortem instability associated with the activity of microorganisms.

PATHOLOGIC FINDINGS
Postmortem changes are nonspecific. General vascular congestion may be observed. The blood is dark and may clot poorly.

TREATMENT

THERAPEUTIC APPROACH
• Stress associated with handling must be minimized in severely hypoxic animals.
• Exposure to the identified source of the excessive nitrates should be discontinued.

(CONTINUED) NITRATE AND NITRITE TOXICOSIS

• Rumen lavage with cold water and oral penicillin may slow the continuous reduction of nitrate to nitrite in the rumen.
• Methylene blue is a specific antidote for nitrate/nitrite toxicosis. Administer 5–15 mg/kg body weight IV as a 1% solution in physiologic saline.
• Additional, lower doses of the antidote can be administered to animals still exhibiting signs.
• Mild to moderately affected animals may recover spontaneously if left untreated.

MEDICATIONS

DRUGS OF CHOICE
1% Methylene blue, 5–15 mg/kg IV, slow. Response should be immediate.

CONTRAINDICATIONS
The use of methylene blue is off-label. Consult FARAD for recommended withdrawal times.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The course of the disease is relatively short, generally lasting within one feeding period.
• The prognosis is heavily dependent on the exposure dose within a short time frame, and levels of methemoglobinemia (blood levels >80% are typically fatal).
• Pregnant animals may abort several days to a few weeks after the toxic insult, due to fetal hypoxia.

PATIENT CARE
No long-term problems have been documented other than abortions. Animals can completely recover, with or without treatment (depending on exposure dose), within a few hours.

PREVENTION
• Knowledge of the high-risk nitrate-accumulating plants and ability to recognize in the field or hay will minimize the risk.
• Knowledge of the risk factors predisposing high nitrates in the feed (e.g., fertilization, irrigation, soil conditions, environmental conditions) can lead one to be proactive in testing forages during the growing season and pre- and postharvest.
• Suspect forages or crops known to accumulate nitrate should be tested for nitrate concentrations prior to inclusion in the diet of ruminants, especially cattle.
• Forages containing <5,000 ppm nitrate are generally safe for consumption by ruminants.
• High-nitrate-containing forages can be diluted with low-nitrate-containing forages prior to feeding to ruminants, or suspect forages can be divided into two feedings to prevent rapid intake.
• Forages of high or questionable NO_3 content should not be fed to pregnant cattle; open cattle or growing calves may prove more resistant to toxicity.
• The harvest of forages or crops grown under conditions conducive to nitrate accumulation should be delayed until conditions improve to allow nitrate levels in stalks to drop.
• If the harvest of forages or crops grown under conditions conducive to nitrate accumulation cannot be delayed, then the harvesting cutter-bar should be raised to 18 inches to leave the lower portions of the stems or stalks in the field.
• Gradual adaptation of ruminants to high-nitrate-containing forages can be performed over a period of 7–10 days.
• Feeding readily fermentable carbohydrate sources in conjunction with high-nitrate-containing forages will promote a denitrifying environment within the rumen.

MISCELLANEOUS

AGE-RELATED FACTORS
• Younger animals with nonfunctional rumens are resistant to nitrate/nitrite toxicosis.
• The fetus has higher oxygen demands and is reported to be more susceptible to the adverse effects of methemoglobinemia.

PREGNANCY
• Abortions may occur several days to a few weeks after the initial toxic insult in those animals that survive.
• Abortion is a common sequela in pregnant cattle consuming forages containing excessive nitrates (>0.5% or 5,000 ppm).

Table 1

Genera and Species of Weeds that are Nitrate Accumulators

Amaranthus spp.	pigweed
Ambrosia spp.	ragweeds
Carduus nutans	musk thistle
Chenopodium spp.	lambs quarter
Cirsium arvense	Canada thistle (to 4.8% NO_3)
Gnaphalium spp.	cudweeds
Helianthus annuus	annual sunflower
Heliomeris spp. (= *Viguiera*)	goldeneyes
Lygodesmia spp.	skeleton plants
Kochia scoparia	fireweed
Silybum marianum	milk thistle (to 10% NO_3)

Source: Adapted from Burrows, George E., Tyrl, Ronald J. Toxic Plants of North America (p. 151). Wiley. Kindle Edition.

PRODUCTION MANAGEMENT
Avoid feeding exceptionally weedy feeds, particularly avoiding those weeds that are well-recognized nitrate accumulators.

NUTRITION AND METABOLIC DISEASES: BEEF

BASICS

OVERVIEW
• Nutrition and metabolism of the ruminant is a balance between meeting the nutrient needs of the host's microbial population and the host itself.
• Common diseases associated with nutrition and metabolism in beef cattle include bloat (ruminal tympany), ruminal acidosis, founder/laminitis, ketosis, atypical interstitial pneumonia, and numerous diseases associated with specific nutrient deficiencies, toxicities, and interactions (energy, protein, mineral, vitamin, water).
• Aberrations in ruminant nutrition and metabolism are frequently associated with nutrient excess, deficiency, or inappropriate timing for the needs of the microbial population and host.
• Proper nutrient analysis of feedstuffs, determining the nutrient requirements of the animal, and providing the right quantity, quality, and timing of nutrients are key areas of focus.
• Nutrient requirements of beef cattle vary based on factors such as body weight, stage of production, breed, and age.
• The nutrient quality and availability of feed can vary considerably over the course of a year and season, which can dramatically impact the nutrients available to the animal.
• Nutrient delivery, and subsequent nutrient intake, varies by production system; from feedlot systems where all nutrients are fed in a TMR to a grazing system where animals obtain nutrients provided by the environment.

INCIDENCE/PREVALENCE
• Feedlot Closeout digestive death loss prevalence can range from 0.1% to 0.5%, with bloat accounting for 20–40% of all feedlot mortalities. Digestive death loss in feedlot and backgrounded cattle occurs more commonly in the spring months in the northern hemisphere.
• Atypical interstitial pneumonia death loss prevalence ranges from 0.03% to 0.15%, with peak mortality occurring in the hottest and driest months of the year and more commonly in heifers.

GEOGRAPHIC DISTRIBUTION
• Worldwide
• Areas where cereal grains are fed to livestock are commonly associated with certain diseases
• Geographical areas with soil nutrient deficiencies or excesses which manifest in the feedstuffs

SYSTEMS AFFECTED
• Digestive
• Musculoskeletal
• Nervous
• Cardiovascular
• Reproductive
• Respiratory
• Integument

PATHOPHYSIOLOGY
• Abnormal ruminal fermentation can result in microbial metabolites that are harmful to the host (e.g., lactic acid, H_2S gas).
• Nutrients may be limited or in excess to a point where ruminal microbial populations experience an undergrowth or overgrowth. In either case, ruminal and postruminal nutrient metabolism are altered.

HISTORICAL FINDINGS
• Sudden death
• Poor growth
• Low body condition score
• Chronic morbidity

SIGNALMENT
N/A

PHYSICAL EXAMINATION FINDINGS
Dependent on specific nutritional and/or metabolic disease state

GENETICS
Genetic lines of cattle selected for greater growth and carcass traits are at a greater risk of certain nutrition and metabolic-related disease. This is primarily due to an increased nutrient requirement to meet maintenance and growth needs and a propensity for higher feed intake.

CAUSES AND RISK FACTORS
• Cattle with increased nutrient requirements based on stage of production (growth, lactation) may be at a greater risk.
• Seasonally or during abnormal weather patterns (e.g., drought) when feedstuff quality or quantity is altered.
• Abrupt changes to the diet resulting in unfavorable shifts in ruminal microbial population.
• Cereal grains that are rapidly fermentable; which is dependent on grain type, variety, and processing method utilized. More intensively processed grains increase surface area and starch availability, which can predispose cattle to metabolic diseases such as ruminal acidosis and bloat.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Rule out infectious causes of lameness, gastrointestinal upset, pneumonia, and down animals.

CBC/BIOCHEMISTRY/URINALYSIS
Abnormalities dependent on underlying cause of disease—refer to specific chapters.

OTHER LABORATORY TESTS
• Ruminal fluid collection and analysis (pH and protozoal activity)
• Liver biopsy (assessment of trace mineral levels)
• Feed ingredient or pasture sampling and analysis (nutrient composition and processing efficacy, particle size, etc.)

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Presumptive diagnosis based on collection of historical information, which includes feed records, ration composition, feed analysis, water analysis, and epidemiologic patterns.

PATHOLOGIC FINDINGS
• Gross necropsy should be performed on mortalities suspected from disease associated with nutritional and metabolic causes.
• Sample collection of primary organs and fluid (blood, rumen fluid, urine, cerebrospinal) can aid in diagnosis in more complicated cases lacking obvious gross necropsy signs.

TREATMENT

N/A

MEDICATIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
Metabolic disease may result from a variety of nutritional issues including improper feed formulation, lack of available feed, decreased intake due to palatability or competition, or underlying disease processes inhibiting proper digestion and/or absorption (e.g., Johne's disease, subacute ruminal acidosis).

CLIENT EDUCATION
• The importance of proper nutrition throughout various life and production stages must be emphasized to all owners, managers, and workers. Nutritional requirements will vary depending on all of the factors described above and therefore unique feed formulation, delivery, and monitoring protocols will need to be developed with each client.
• Emphasis should also be placed on proper feed storage and pasture management in order to improve feed quality.

PATIENT CARE
N/A

PREVENTION
• For cattle provided nutrients solely as a TMR, diet formulation, mixing, delivery, and consumption are all areas to monitor closely.

Errors can happen in any of these steps, resulting in nutritional and metabolic disease.
• Diet changes should be as gradual as possible. Diet transition should consist of 2- to 3-week periods with multiple intermediate steps in diet composition progressing towards the final diet.
• Diet formulation should be adjusted when a change in feedstuff usage is expected, if feedstuff nutrient composition changes, or when the nutrient requirements change.
• Water testing should be conducted on an annual basis or when a change in water source occurs.
• Water consumption should be monitored closely, especially with cattle that are not familiar with certain water sources (e.g., automatic waterers). Floats can be set to overflow waterers and encourage consumption.
• Young calves may have difficulty reaching water tank heights designed for mature cattle.
• During the winter, if tank heaters are used, stray voltage is a possibility and water intake will be inhibited.

MISCELLANEOUS

AGE-RELATED FACTORS

Young and old are likely more susceptible to nutritional and metabolic disturbances, especially around weaning and the periparturient period.

PREGNANCY

Pregnancy increases nutrient requirements and associated hormone changes can alter nutrient metabolism.

BIOSECURITY

Sound biosecurity practices will help rule out infectious causes of cattle disease and help maintain an overall low disease prevalence in the herd.

PRODUCTION MANAGEMENT

A production management plan that focuses on frequent cattle observation, routine feed and water sampling, and monitoring of cattle health and disease occurrence will minimize impacts of potential nutritional and metabolic diseases.

NUTRITION AND METABOLIC DISEASES: CERVIDAE

BASICS

OVERVIEW
• For deer of temperate origin, considerable seasonal fluctuations and variation in food availability result in observable changes in body weight, fatness, and food intake.
• Voluntary feed intake (VFI) in grazing cervid species is influenced by photoperiod, the feed value of the forage, and the stage of the reproductive cycle.
• Deer are generally considered to be "concentrate selectors" because of their tendency to choose the richest parts of consumed plant species, although some may be classified as intermediate.
• Optimizing pasture conditions and nutritional supplements can lead to improved growth rate in weanlings and improved reproductive performance in female cervids.
• Monitoring body condition score (BCS), especially during periods of nutritional stress, is the most effective way to monitor the status of a nutritional program and determine if any changes are necessary.

INCIDENCE/PREVALENCE
In one study on captive fallow deer, 28% of mortality was due to nutritional disease.

GEOGRAPHIC DISTRIBUTION
Worldwide where captive cervid are raised

N

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• A basic understanding of the annual appetite cycle is crucial for making appropriate nutritional management decisions in captive populations.
• Cervid species of temperate origin undergo seasonal changes in body condition, with a large proportion of fat being stored during late summer to be later mobilized by males during autumnal rut or by females throughout the winter.
• Changes in body condition are modulated through variations in VFI, which is partially regulated by photoperiod.
• At mid-summer, VFI peaks and increased day length causes the hypothalamus to become resistant to leptin, enabling fat deposition.
• As day length decreases (autumn and winter), VFI declines (~20%) and the hypothalamus becomes more sensitive to leptin, allowing fat mobilization to occur.
• In autumn and winter, reduced appetite helps to avoid energy expenditure from unproductive searching for scarce or poor-quality food sources and is compensated for by improved efficiency of nutrient absorption, especially crude protein.
• Female cervids mobilize fat reserves gradually, allowing for maintenance of an appropriate body condition during the first two trimesters of pregnancy in winter and early spring when nutritional resources are limited.
• Nutritional and/or mineral deprivation can negatively affect fetal development and mammary tissue development in most cervid species.
• In red deer, a variable gestation length has been reported, and it is speculated that this allows the fetus to obtain a critical mass before parturition can occur.
• Male cervids mobilize fat reserves rapidly during autumnal rut, devoting the majority of their energy expenditure to roaming and breeding.
• Weanlings (~3–4 months) also experience a decline in VFI in the autumn and winter months with maximal weight gain occurring in the following spring and summer months.
• If nutritional programs are poorly managed, malnourishment and premature depletion of fat stores may occur and result in clinical ketosis if animals must derive energy from stored fat and protein.

HISTORICAL FINDINGS
Poor BCS in the herd (especially outside of the breeding season), poor conception rates, and sudden death may be suggestive of malnourishment.

SIGNALMENT
All species and ages of cervidae

PHYSICAL EXAMINATION FINDINGS
• Seasonal variation in BCS should be considered.
• Dull/rough hair and sunken eyes might be noticeable.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Males are most at risk for malnutrition during breeding season if summer nutrition was inadequate.
• Though rare in cervids, late-pregnant females may be at risk for pregnancy toxemia if overweight and carrying triplets/quadruplets.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Debilitating disease (e.g., Johne's disease and chronic wasting disease) should be ruled out as a cause of poor BCS.

CBC/BIOCHEMSTRY/URINALYSIS
• Depend on the condition.
• Ketosis (urine/blood ketones) and hypoglycemia detectable in malnourished animals.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Necropsy of malnourished animals may show lack of fat in subcutaneous, visceral, and bone marrow locations with diffuse muscular atrophy; GI organs may be empty/shrunken with rumen ulcerations.

TREATMENT

THERAPEUTIC APPROACH
• Supplemental feeding with pelleted formulated feeds may be required during high risk periods.
• Monitor BCS closely in the herd and make appropriate changes as needed.
• Animals diagnosed with severe ketosis may need to be managed with oral propylene glycol or IV fluids/dextrose if possible.

SURGICAL CONSIDERATION AND TECHNIQUES
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Good prognosis if appropriate changes to nutritional management programs are made.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
N/A

PATIENT CARE
N/A

PREVENTION
Pasture Considerations
• Cervids are considered "concentrate selectors" because of their behavioral tendency to select plants with better nutritive value when browsing.
• Most cervid feeding programs emphasize the feeding of good-quality legume/grass hay or pasture with grain (oats, corn, barley) as a supplemental energy source and a mineral supplement in deficient areas.
• Research has shown that grazing on red clover (*Trifolium pretense*) or chicory (*Chicorium intybus*) increased red deer weanling growth during autumn by 26–47% and during spring by 10–14% compared to traditional perennial ryegrass (*Lolium perenne*)/white clover (*Trifolium repens*) pasture (0.8/0.2). Additionally, pre-weaning growth during lactation was increased by ~20%.

• Grazing on the legume, sulla (*Hedysarum coronarium*), in autumn and spring has also been shown to improve growth rate of weanling deer by 33% and 10%, respectively, compared to other pasture-fed deer.
• Reduced parasitism has been reported in animals grazing chicory versus perennial ryegrass/white clover, likely due to the plant morphology and/or presence of secondary compounds (sesquiterpene lactones) which inhibit the motility of L1 and L3 lungworm and GI nematode larvae.

Energy and Protein Requirements

• Most grass hay feeding programs require additional protein, mineral, and vitamin supplementation. Commercial pellet supplements designed for cervids or sheep generally work quite well.
• Weanlings and stags feed ratio: 6:3:1, hay : concentrate : nutritional supplement.
• Pregnant females feed ratio: 8:1.5:0.5, hay : concentrate : nutritional supplement.
• Daily energy requirements can increase by as much as 2.5 times maintenance during the 3rd trimester of pregnancy and peak lactation.
• Dietary protein requirements vary by life stages:
  ◦ Fawns (growth): 14–18%
  ◦ Adults (maintenance): 6–10%
  ◦ Females (late pregnancy): 11–15%
  ◦ Females (lactation): 14–22%
  ◦ Males (antler development): 15–16%

Trace Mineral Requirements

• General purpose mineral and trace element supplements should always be available.
• Copper (Cu) deficiency can have a significant impact on deer health and performance and usually manifests as clinical disease (enzootic ataxia and osteochondrosis).
  ◦ Cu supplementation strategies can consist of Cu-EDTA injections, Cu oxide needles, or direct application of Cu to pasture.
  ◦ Chicory contains higher concentrations of copper and cobalt than perennial ryegrass/white clover and may be included in mineral-deficient areas.
• Selenium and iodine deficiencies may also negatively impact reproductive performance if not managed appropriately.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Ruminants on pasture or being supplemented with concentrates should always be monitored for bloat, though this is less common in cervids compared to other ruminants.

AGE-RELATED FACTORS

Feeding weanlings during the fall; it is imperative to prepare them for the winter feeding pattern. Required body weights, BCS, and gains are important early in the season.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

• About 65% of a breeding hind's adult life is associated with pregnancy.
• The 3rd trimester of pregnancy, when the conceptus gains >70% of its ultimate mass, is when nutritional stress is most likely to occur, especially in years with prolonged winters. This can be overcome in captive herds with appropriate nutritional supplementation.
• Nutrition deprivation in the last trimester of pregnancy can hinder fetal development.

BIOSECURITY

N/A

PRODUCTION MANAGEMENT

• Flushing, the practice of heavy concentrate feeding immediately before the breeding season, has been found to induce an earlier first estrus and higher initial ovulation rates in the first cycle in cervids.
• The opportunity to increase live weight gain (LWG) in fawns/calves during late lactation can be improved by increasing metabolizable energy with dietary supplementation. LWG can be further maximized by feeding these supplements to the fawns/calves during weaning in early autumn.
• It is important to have multiple feeding supplementation stations. More aggressive animals can dominate a supplement program, leaving more submissive/subordinate animals without needed nutrients.
• Summer pastures should contain a mixture of grasses as well as legumes. These pastures should be tested annually for nutrient content and deficiencies supplemented on an as-needed basis.
• Concentrate or pelleted supplements may be fed to increase the diet's energy content, but they should not exceed 50% of the ration on an as-fed basis.
• Monitoring a nutrition management program requires regular live weight monitoring and body condition scoring. Setting individual animal and herd target weights allows nutritional and management program evaluation. Target weights should be evaluated on a per-farm basis.

SYNONYMS

N/A

ABBREVIATIONS

• BCS = body condition score
• LWG = live weight gain
• VFI = voluntary feed intake

NUTRITION AND METABOLIC DISEASES: DAIRY

BASICS

OVERVIEW
Metabolic diseases are very important conditions affecting dairy cattle because they play a role in compromising milk production, fertility, and overall health. The majority of these diseases affecting milk production, fertility, and general health have a nutritional component, either as a primary cause or as a risk factor. The most significant metabolic diseases described in the dairy cow are hypocalcemia, hypomagnesemia, ketosis, and fatty liver.

INCIDENCE/PREVALENCE
See chapters on specific metabolic and nutritional disease.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEM AFFECTED:
- Mammary
- Musculoskeletal
- Digestive
- Nervous
- Multisystemic

PATHOPHYSIOLOGY
- In general, metabolic diseases are produced because an imbalance between inputs and outputs of a particular metabolite occurs within the body. Nutrition plays a key role in the pathophysiology of metabolic diseases by providing the necessary input to maintain balance of a metabolite within the body.
- Hypocalcemia arises because the entire Ca^{2+} homeostasis is altered during the transition period. Ca^{2+} intake is low around parturition and the output is high, because of lactational demands. In addition, Ca^{2+} intestinal absorption and Ca^{2+} bone resorption are depressed during this period.
- Hypomagnesemia primarily occurs in animals grazing lush pastures that are rich in potassium and nitrogen. For this reason, hypomagnesemia can often precipitate independent of a normal Mg^{+} content within the pasture grasses. In this case, excessive amounts of nitrogen and potassium affect Mg^{+} bioavailability by substantially decreasing the absorption of this mineral in the digestive tract.
- Ketosis and fatty liver are two metabolic diseases that are interrelated. In dairy cows, the energy demands for milk production after calving trigger the mobilization of nonesterified fatty acids (NEFA) from the adipose tissue. This mobilization is more severe in obese cows. The end result is the uptake of a large amount of NEFA by the liver. Inside the hepatocyte, NEFA are either oxidized or re-esterified to triglycerides. If NEFA are extremely high, the re-esterification to triglycerides dominates over the normal mitochondrial oxidation process. This subsequently leads to pathologic fat accumulation (hepatic lipidosis). Often at the same time as NEFA mobilization, the blood glucose can become very low due to the high metabolic demands during lactation. In the case of the postpartum dairy cow, a temporary state of insulin resistance can even develop. Blood glucose concentrations determine the synthesis of oxaloacetate inside the hepatic mitochondria. A low blood glucose concentration reduces oxaloacetate production within the hepatic mitochondria and subsequently shuts down the Krebs cycle. As a result, acetyl-coA coming from the oxidation of NEFA cannot continue into the normal oxidative pathway of the tricarboxylic acid cycle; therefore, the acetyl-coA is redirected to the pathway of ketogenesis.

HISTORICAL FINDINGS
- The appearance of clinical signs related to metabolic disease are often correlated with a poor nutritional program and inadequate attention to cow comfort.
- In the case of hypocalcemia and hypomagnesemia, neuromuscular dysfunction is common.
- An increase in the incidence of other conditions such as retained fetal membranes, metritis, mastitis and displacement of the abomasum may also occur.

SIGNALMENT
- Bovine, dairy cows. Nutritional and feeding management related to dairy operations are essential.
- Older and high production animals are more likely to develop metabolic diseases. An efficient nutritional management strategy is required.

PHYSICAL EXAMINATION FINDINGS
Refer to individual chapters for unique physical examination findings.

GENETICS
- Some of these diseases may have a genetic component.
- High producing dairy cows (Holstein) are more likely to experience ketosis/fatty liver problems.
- The Jersey breed is more likely to develop hypocalcemia.

CAUSES AND RISK FACTORS
- Unbalanced diets which do not meet the requirements of the lactating dairy cow, overall poor feeding management such as improper mixing of the ingredients, insufficient bunk space, improper frequency of feeding, poor water quality, inadequate cow comfort, and poor environment management.
- Risk factors include genetic level, breed, days in milk, parity, milk production, environment, and nutrition.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
N/A

CBC/BIOCHEMISTRY/URINALYSIS
- CBC analysis is generally not indicated unless concurrent infectious disease is being investigated.
- Biochemistry panels can be useful to assess the mineral and protein profile within a herd, especially in herds with a high incidence of down cows and postpartum disease during the transition period.
- Urinalysis findings are very useful in the assessment and management of metabolic disease and transition cow rations specifically. Prepartum, urine pH should be assessed on a routine basis in herds managed on a DCAD system to control hypocalcemia (see chapter, Hypocalcemia: Bovine). Postpartum, blood or urine ketone assessment of cows between 4 and 11 DIM aids in ketosis detection and management (see chapter, Ketosis: Bovine).

OTHER LABORATORY TESTS
The Dairy Herd Improvement Association (DHIA) tests for milk production, SCC, milk solids, and MUN. This service offers invaluable information that can reflect changes in nutrition and metabolic status of the herd. Ration analysis is also important when investigating metabolic disease issues.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Liver biopsy will aid in diagnosis of mineral deficiencies (e.g., copper) and hepatic lipidosis.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
Individual animal treatment should be instituted while the underlying cause of disease (i.e., management and nutritional factors) is determined and corrected.

N/A

CLIENT EDUCATION
A proper nutrition and feeding management program, especially during the transition period, is fundamental to reach a low incidence of metabolic diseases and related disorders, maximize milk production, and achieve outstanding fertility. In order to accomplish these goals the following items must be addressed:
- Implement an efficient diet formulation.
- Optimize dry matter intake in all the steps of the production cycle.
- Feed balance diets in term of energy, protein, fiber, mineral, vitamins, and water.
- Maintain macromineral homeostasis, especially when considering the relationships between potassium, magnesium, calcium, and phosphorus.
- Consider animal grouping strategies to obtain a proper BCS and minimize the presence of excessively fat or thin cows (no more than 10% of the herd).
- Minimize stress and provide adequate cow comfort.
- Consider sufficient feed bunk and watering space.
- Minimize group changes and overcrowding.
- Institute an appropriate monitoring system to evaluate prepartum and postpartum health status and disease risk assessment.

PREVENTION
- Proper feed management and balanced diet
- Good overall management
- Health monitoring protocols

MISCELLANEOUS

AGE-RELATED FACTORS
Metabolic diseases are seen most commonly in lactating dairy cows and are uncommon in heifers.

PRODUCTION MANAGEMENT
Metabolic diseases continue to be a problem in the dairy cow that is managed and fed for high milk production standards. This trend is related to progressive genetic improvement for milk yields and solids. Consequently, dairy cows must adapt properly to the tremendous metabolic and physiologic changes that modern genetics imposes on them. Nutrition and feed management must evolve at the same level in order to succeed.

ABBREVIATIONS
- BCS = body condition score
- BHBA = beta-hydroxybutyrate
- DCAD = dietary cation anion difference
- DHIA = Dairy Herd Improvement Association
- DIM = days in milk
- MUN = milk urea nitrogen
- NEFA = nonesterified fatty acid
- SCC = somatic cell count

NUTRITION AND METABOLIC DISEASES: SMALL RUMINANT

BASICS

OVERVIEW
• Nutrition is a critical component of metabolic diseases of small ruminants.
• Key metabolic diseases in adult small ruminants include pregnancy toxemia, ketosis, milk fever, grass staggers, and transit tetany (low blood calcium and/or magnesium in transported small ruminants).
• The most important metabolic diseases in young small ruminants are drunken lamb and floppy kid syndromes, which are forms of acidosis without dehydration.

INCIDENCE/PREVALENCE
• Pregnancy toxemia has a low incidence (2–5%).
• Milk fever and grass tetany are less common in small ruminants than in cattle.
• Floppy kid and drunken lamb syndromes have been reported as affecting >10% of lamb/kid drops in the United Kingdom. Client education and earlier treatment with oral antacids have reduced recent incidence rates.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Multisystemic

N

PATHOPHYSIOLOGY
• Stress is often a trigger for metabolic diseases (e.g., dog worry, extreme weather).
• In late pregnancy multiple fetuses drain energy from the dam. In addition, the fetuses take up abdominal space, limiting feed intake. This can be further restricted if there are large amounts of abdominal fat. Goats lay down fat internally, rather than subcutaneously.
• When blood glucose levels drop, fat reserves are utilized, ketone bodies are released, and the liver becomes fatty.
• Glucose is the main energy source needed for both the fetus and the brain. Nervous signs occur as the brain no longer has enough glucose to function properly.
• In milk fever, there is a sudden increase in calcium demands due to colostrum or milk production around parturition.
• Magnesium is absorbed in the rumen and reticulum but excreted in the saliva. Absorption is reduced if there are high potassium levels.

HISTORICAL FINDINGS
Dependent on underlying cause

SIGNALMENT
• Milking sheep and dairy goats
• Females of breeding age for adult metabolic diseases; drunken lamb syndrome, 1–4 weeks; floppy kid syndrome, 3–10 days

PHYSICAL EXAMINATION FINDINGS
• For pregnancy toxemia, ketosis, and milk fever, there is reduced appetite progressing to anorexia, depression, and swollen lower limbs (from fetlock down). There is often teeth grinding and inability to rise. In the terminal stages there can be additional nervous signs, e.g., blindness, twitching of facial muscles, or lack of response to stimuli. The affected ewes or does are generally emaciated or over-conditioned and in late gestation.
• Signs of milk fever include constipation, dragging foot/feet, ataxia, weak uterine contractions, trembling, and recumbency. Signs may be very subdued in goats.
• Signs of grass tetany vary according to whether acute (excited, tremors, facial twitching, convulsions, death), subacute (inappetence, reduced yield, apprehension), or chronic (dullness, poor milk production, poor growth rate of young).
• In lambs and kids the signs of metabolic acidosis syndromes are ataxia, recumbency, and lethargy.
• Lambs and kids with metabolic acidosis syndromes are not hypothermic nor dehydrated, yet have the above signs.

GENETICS
• Heavy milking lines and breeds with multiple young are more likely to be affected.

CAUSES AND RISK FACTORS
• Very low or high body condition scores in late pregnancy or early lactation.
• Does with 3 or more fetuses are 40 times more likely to get pregnancy toxemia than those with only 1 or 2.
• Small ruminants grazing lush heavily fertilized pastures and low-sodium pastures are at high risk for grass tetany.
• In drunken lamb syndrome, smaller lambs are more likely to be affected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Any illness that causes anorexia can result in a secondary pregnancy toxemia.
• Ruminal acidosis is a differential diagnosis for milk fever.

CBC/BIOCHEMISTRY/URINALYSIS
• Low blood calcium levels for milk fever.
• In drunken lamb and floppy kid syndromes, the levels of D-lactate are very high and there is a severe acidosis (pH 7).

OTHER LABORATORY TESTS
• Animals with pregnancy toxemia would have ketones in the urine identified by urine test strips of values above 1.5 mmol/L as well as ketones in the blood. Blood glucose, serum 3-OH butyrate concentrations (>3 mmol/L) or blood β-hydroxybutyrate (>0.8 mmol/L) can be used for a diagnosis of pregnancy toxemia and ketosis.
• Handheld devices (as used in human medicine) can diagnose high levels of β-hydroxybutyrate and low glucose levels in ewes with pregnancy toxemia.

IMAGING
For pregnancy toxemia, ultrasound is useful to confirm if fetuses are still alive by observing movements.

OTHER DIAGNOSTIC PROCEDURES
Response to treatment will confirm a diagnosis of milk fever, grass tetany, or transit tetany.

PATHOLOGIC FINDINGS
• For pregnancy toxemia, ketosis, and milk fever, the main pathophysiology is a pale or yellow/orange, greasy and friable liver. Adrenal glands may be enlarged.
• Aqueous humor levels of 3-OH butyrate >2.5 mmol/L is also seen in the above diseases.

TREATMENT

THERAPEUTIC APPROACH
Dairy goats or ewes should not be milked for 24 hours after being treated for milk fever.

SURGICAL CONSIDERATIONS AND TECHNIQUES
An emergency cesarean may be necessary in advanced cases of pregnancy toxemia, where death of the ewe/doe is likely to occur before induction would take effect. If dam is unlikely to survive, use local blocks, recover the young, then euthanize the dam.

MEDICATIONS

DRUGS OF CHOICE
• Treatment for pregnancy toxemia involves drenching with an energy source, e.g., 60–200 mL propylene glycol (higher dose initially then reduce) or 60 mL of glycerin q12h plus NSAID such as flunixin meglumine (2.5 mg/kg).
• The best treatment for pregnancy toxemia is induction of parturition. If the due date is known, then dexamethasone can be given at day 143; parturition should occur in the next 48–96 hours. In the doe, where the corpus luteum is the sole source of progesterone, prostaglandin can be given after day 144 (when the kids' lungs would have matured enough to survive).
• Ketosis is treated with drenching with energy sources as per pregnancy toxemia plus an injection of dexamethasone (2–6 mg) to stimulate appetite and glucogenesis.
• Milk fever is treated with 80–100 mL 20% warm calcium borogluconate solution or ideally a commercial combined product with Ca, Mg, and P either slow IV or SC, or half

(CONTINUED) NUTRITION AND METABOLIC DISEASES: SMALL RUMINANT

IV and the rest SC. Grass tetany and transit tetany are treated with the combined commercial product given SC.
• Drunken lamb syndrome has been successfully treated with 50 mmol sodium bicarbonate as an 8.4% solution given orally plus parenteral antibiotics. Stomach tube as young cannot suckle and keep warm.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Ca, Mg, and P solutions should be given slowly IV, while monitoring the heart, and SC doses spilt across 2 sites.

POSSIBLE INTERACTIONS
Sodium bicarbonate should not be added to fluids containing calcium.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Pregnancy toxemia has a high mortality rate (80%) for both dam and offspring.
• Grass tetany cases can often relapse.

POSSIBLE COMPLICATIONS
Lower lactation yields

CLIENT EDUCATION
• Increase quality and quantity of feed in the last 6 weeks of gestation and first few weeks of lactation to meet animals' needs.
• Early oral treatment with antacids for metabolic acidosis of lambs and kids.

PATIENT CARE
Appropriate management of recumbent animals is essential and includes clean, dry bedding, shelter, and availability of feed and water.

PREVENTION
• Exercise may be useful for preventing dairy does and pet sheep from becoming over-conditioned, and in preventing pregnancy toxemia in general. Data loggers confirm that does that spend more time lying down are at higher risk for pregnancy toxemia or ketosis after kidding.
• Reducing calcium intake in the last few weeks before parturition, so that animals start using bone stores of calcium as recommended for cattle, is **not** recommended for small ruminants. Instead the cation/anion balance of the diet should be adjusted by adding more anionic salts to prevent milk fever. Magnesium levels should also be checked.
• High-quality fiber should be used in the periparturient period.
• Providing ½ oz/day of magnesium oxide has stopped outbreaks of grass tetany in ewes. It can be sprayed onto hay or grain as a suspension (can also add molasses to improve palatability). If strip grazing, dust pastures with 10-gram magnesium oxide per day per small ruminant. Alternatively add supplements to livestock water supplies, i.e., 500 g Epsom salts or 420 g magnesium chloride per 100 L water. Rumen boluses have been used. Salt and Mg licks are available but intakes by individuals are variable.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Ketoacidosis should be suspected in pregnancy toxemia cases with nervous signs, and sodium bicarbonate given.

PREGNANCY
Pregnancy toxemia occurs in the last weeks of gestation.

SYNONYMS
• Twin lamb disease or hyperketonemia for pregnancy toxemia
• Hypocalcaemia, parturient paresis, and lambing sickness for milk fever
• Hypomagnesemia and grass staggers for grass tetany
• Lamb D-lactic acidosis syndrome for drunken lamb syndrome

ABBREVIATIONS
• IV = intravenous
• NSAID = nonsteroidal anti-inflammatory drug
• SC = subcutaneous

NUTRITION AND METABOLIC DISEASES: WATER BUFFALO

BASICS

OVERVIEW
• Buffalo need more feed and grasses than cattle on a body weight basis.
• Buffalo generally graze during the day time but, in high ambient temperatures, grazing takes place in the morning and afternoon and sometimes during the night.
• Newborn buffalo calves suckle their mothers within 2 hours of birth and start to nibble grass at 3–4 weeks of age.
• Natural weaning of calves usually takes place within a year or before its mother's next calving.
• Buffalo are more efficient in converting highly fibrous low-grade foods than domestic cattle.
• Buffalo have a larger gut with a slower passage of digesta and a higher rate of crude fiber digestion.
• The rumen in buffalo is well adapted to utilize cellulose material.
• They are better converters of nonprotein nitrogenous (NPN) compounds into protein than domestic cattle. This gives an opportunity to improve poor-quality roughage with various NPN compounds.
• Metabolic diseases are important for high-producing dairy water buffalo.
• Ketosis, milk fever, fatty cow syndrome, hypomagnesemia, and down cow syndrome are major metabolic diseases of water buffalo.
• Correcting the diet and proper management during pregnancy and the lactation period reduce the incidence of such diseases.

INCIDENCE/PREVALENCE
High among high-producing dairy water buffalo

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Digestive
• Musculoskeletal
• Reproductive

PATHOPHYSIOLOGY
The pathophysiology of metabolic disorders and nutritional deficiency syndromes is similar to that of cattle.

HISTORICAL FINDINGS
Depends on complaint.
Nutritional deficiencies result in a wide variation of presentation ranging from poor fertility to increased predisposition to disease.

SIGNALMENTS
• Nutritional disorders are mainly seen in growing animals.
• In adult animals, production and reproduction may suffer due to nutrition restrictions.

PHYSICAL EXAMINATION FINDINGS
• Varies depending on the complaint.
• Poor weight gain and poor body condition score.

GENETICS
N/A

CAUSES AND RISK FACTORS
• *Parturient paresis (milk fever)*—generally occurs in high-yielding dairy buffalo within 72 hours of calving due to decreased blood calcium level (<6 mg/dL), calcium borogluconate 400–800 mL IV is the preparation of choice to treat clinical cases. Dietary management during prepartum period, calcium gel containing calcium chloride dosing (24 hours before and 10–14 hours after calving), administration of vitamin D_3 and its metabolite can help prevent milk fever.
• *Ketosis*—blood glucose levels are decreased from the normal of 50 mg/dL to 20–40 mg/dL and increased ketone bodies in blood from normal (up to 10 mg/dL) to 10–100 mg/dL. Ketonuria and ketogalactia are the evidence of ketosis in buffalo.
• *Down cow syndrome*—generally occurs after milk fever cases, leg injuries, and other metabolic conditions. Creeper cow syndrome is the principal sign; animal is bright and alert but cannot rise. Injection of calcium, magnesium, phosphate salts, vitamin E and Se, proper bedding, frequent turning of buffalo side to side will be useful in such animals.
• *Hypomagnesemic tetany*—occurs due to decreased serum magnesium level, i.e., below 1 mg/dL compared with the normal level of about 1.7–3 mg/dL. For treatment calcium and magnesium preparation, e.g., 500 mL of solution containing 25% calcium borogluconate and 5% magnesium hypophosphite IV followed by SC injection of magnesium salt can be used. Similarly 200–300 mL of 20% magnesium sulfate solution may be injected intravenously.
• *Postparturient hemoglobinuria*—occurs after several weeks after calving in high-yielding dairy buffalo and cow. Low phosphorus diet and the feeding of cruciferous are considered the common cause of this disease. Transfusion of large quantity of whole blood (minimum 5 liters of blood for a 500 kg buffalo) and administration of 60 g of sodium acid phosphate in 300 mL distilled water SC repeated 24-hourly same dose SC will protect the severely affected animal.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Differential diagnoses of the cause of poor production or poor growth require a thorough evaluation of the feeding system, feed analysis, and ration calculation.
• Trace mineral deficiencies may present in various clinical forms. Laboratory analysis of feed and blood may help refine the diagnosis.
• Metabolic disorders are often the result of poor feeding management.

CBC/BIOCHEMESTRY/URINALYSIS
Alterations in CBC, serum biochemistry, and urinalysis are similar to those described for cattle for various metabolic disorders.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Similar to those described for cattle

TREATMENT

THERAPEUTIC APPROACH
Therapeutic approach for the major metabolic disorders is similar to that used in cattle.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Similar to cattle; dosage needs to be adjusted (see "Causes and Risk Factors")

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
The prognosis for malnutrition is relatively good if ration is corrected before onset of severe disorders.

POSSIBLE COMPLICATIONS
Poor conception rate, abortion birth of weak calves

CLIENT EDUCATION
Importance of nutrition and mineral supplementation, particularly in high-producing dairy animals.

(CONTINUED) NUTRITION AND METABOLIC DISEASES: WATER BUFFALO

PATIENT CARE
Varies depending on the disorder.

PREVENTION
Prevention of metabolic and nutritional disorders is based on a solid preventive (vaccination, parasite control) program as well as adequate ration formulation for different ages and stages of production.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Malnutrition can predispose animals to infertility, pregnancy loss, and poor immunity (increased risk for infectious diseases).

AGE RELATED FACTORS
Adult buffalos above 3–4 calvings are more susceptible to metabolic diseases.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Nutritional requirement should be adjusted based on stage of gestation.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT

Feeding from Birth to Weaning
• Buffalo calves should take milk about 10% of their body weight.
• It is better to introduce a mash starter from 2 weeks of age and offer good-quality berseem leaves ad libitum after 3 week of age.
• Water buffalo are superior to cows in lignin turnover.
• TDN output/input ratio varied from 6% to 30% and protein output/input ratio from 5% to 40%, indicating that buffalo fed on straw and a grain-based diet were more efficient than cows.
• Maintenance and production requirements are higher in Murrah buffalo than in cows, indicating that cows are more efficient in utilizing ME for milk production than buffalo.
• To achieve ADG of 0.7–0.8 kg a highly palatable starter ration with 70–75% TDN and 15–17% DCP is essential for growing male calves.
• The concentrate to roughage ratio ranges between 50:60 and 60:40 on a DM basis, with good-quality berseem hay making up at least half of the roughage.
• A report in Egypt compared fattening from 200 kg to 350 kg over a short fattening period of about 4 months, and fattening from 250 kg to about 500 kg over a relatively longer period of 10–11 months; the first practice produces relatively juicier meat but the second is popular because of its high dressing percentage. The overall ADG during fattening is usually 800–900 g/d, depending on the level of concentrates. ADG was 800–1,000 g when the concentrate fraction was 75% and when 1 kg concentrate was offered for each 50 kg body weight.

Feeding of Growing and Pregnant Heifers
• Raising a good buffalo heifer is a prerequisite for achieving a high-yielding buffalo cow. In Egypt a good buffalo heifer is characterized as weighing 350–370 kg at 16–18 months of age when the heifer reaches sexual maturity.
• From weaning to about 180 kg, heifers require the same special attention as described for feeding males.
• About 2 kg/100 kg body weight of the pellet starter is required to achieve about 700 g ADG.
• A typical ration during this growing phase (average weight 125 kg) is composed of 2.5 kg starter concentrate and 1 kg each of berseem hay and rice straw.
• Calculated intakes of nutrients in this ration are as follows: DM 4.1 kg, DM % of body weight 3.2, TDN 2.5 kg, DP 0.455 kg, ME 229 kcal/kg $W^{0.75}$.
• ME requirement for maintaining buffalo heifers as 188 kcal/kg $W^{0.75}$; others reported a value of 206 kcal/kg $W^{0.75}$ for maintenance and growth. Late-pregnant buffalo heifers need an extra 0.5 kg of corn per day.

Feeding Lactating Buffalo Cows
• A standard water buffalo cow weighing 500 kg, in her 3rd lactation, producing 7 kg/d milk for 300 days with average 7% fat requires 2 kg TDN and 400 g DCP for maintenance plus 750 g TDN and 80 g DP per kg milk produced.
• Common concentrates include cereal grains, cane molasses, cottonseed cake, wheat bran, rice (polish), horse bean, soybean meal, linseed meal, and sunflower seed.
• Common roughages include teosinte, sudan grass, bajra, berseem hay; rice, wheat and barley straw; wheat and rice brans; rice hulls and silage. The main green forages in winter are berseem (*Trifolium alexandrinum*), vetch, and oat.
• In practice, a mixture of concentrates (60% TDN, 14% DP) is prepared in a cube form and comprises yellow corn 23–25%, undecorticated cottonseed cakes 25–40%, wheat bran 10–15%, rice bran 10–15%, sugar cane molasses 3–6%, and common salt plus limestone 1.5–2.5%.
• In winter, the feeding system for dairy buffalo depends on green berseem and rice straw for dry, nonpregnant, or early-pregnant buffalo cows.
• The level of roughage in rations for lactating buffalo has been generally accepted as 50% of total DM.
• Research on the use of cheaper sources of nitrogen indicated that urea can replace up to 50% of total nitrogen in rations for lactating buffalo with no adverse effect on milk or fat yield.
• Supplementary minerals and vitamins when required.

SYNONYMS
N/A

ABBREVIATIONS
• ADG = average daily gain
• DCP = digestible crude protein
• DM = dry matter
• DP = digestible protein

OAK (*QUERCUS* SPP.) TOXICITY

BASICS

OVERVIEW

• Renal damage and gastroenteritis can occur in ruminants following ingestion of leaves, buds, and acorns from oak trees.
• Cases involving other species such as horses, goats, sheep, and camelids are rare. Pigs and deer are resistant.
• Tannins are the toxic principle, and high concentrations are found in oak leaves, buds, and acorns. Tannins cause direct damage to epithelial cells in the GI tract, causing oral, esophageal, and ruminal ulceration. Protein-bound tannins can be refractory to ruminal hydrolysis and once they reach the abomasum are released, creating further GI ulceration in the abomasum and intestine.
• Animals that survive acute renal insults often develop chronic renal disease and demonstrate poor weight gains compared with their cohorts.

INCIDENCE/PREVALENCE

• Approximately 90 species of oak are found in North America, and while many are reported to be toxic, differences exist in the amount of toxin present.
• Case fatality rate is high, often >80%.

GEOGRAPHIC DISTRIBUTION

• Oak or acorn poisoning has been reported worldwide.
• Most oak species found in Europe and North America are considered toxic.

SYSTEMS AFFECTED

• Digestive
• Urinary

PATHOPHYSIOLOGY

• Tannins are the toxic principle, from which pyrogallol, gallotannins, polyhydroxyphenolic compounds, and other phenolic metabolites are produced by microbial hydrolysis in the rumen.
• Gallic acid and pyrogallols bind and precipitate proteins, which are extremely toxic to renal tubules, causing acute renal tubular necrosis. Acute tubular necrosis leads to severe azotemia, anuria, electrolyte imbalances, and uremia, which results in GI and renal dysfunction.
• Hydrolyzed tannins can also be absorbed and become bound to plasma proteins and endothelial proteins, which leads to hemorrhage and fluid loss from blood vessels resulting in edema.
• Severity of renal damage depends on the duration of exposure to oak and the amount ingested.

SIGNALMENT

• Cattle are the species most commonly affected. Young cattle often appear to be more severely affected than adult cattle.
• Oak poisoning has been reported in sheep, goats, and camelids.

HISTORICAL FINDINGS

A history of ingestion for 2–14 days (average of 1 week) usually precedes clinical signs; however, some reports describe disease occurring 21 days after removal from oak exposure.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs usually occur within 3–7 days after consumption of green oak leaves or acorns.
• In peracute poisoning, cattle may be found dead. If observed closely, affected cattle may be recumbent, weak, and listless.
• Clinical signs include anorexia, depression, and ruminal stasis. Affected ruminants develop constipation, which is often followed by hemorrhagic diarrhea. Edema is observed in the ventral abdomen, perineum, vulva, submandibular area, and brisket, and can be severe.
• Anuria is present in peracute disease; however, polyuria and hematuria may also be observed.
• Secondary complications including bronchopneumonia and GI perforation with abscessation may occur.

CAUSE AND RISK FACTORS

• Immature leaves, stems, acorns, and buds are the most toxic and the most palatable.
• Oak poisoning is associated with ingestion of leaves and buds in the spring and with ingestion of acorns in the fall months.
• Toxicosis may occur when adequate forage is available but more commonly is associated with drought or other circumstances that lead to poor grazing.
• Cases may also be seen following wind or rain storms that drop leaves, acorns, or branches into pastures where cattle are grazing. Early spring snowstorms can cause oak branches containing oak buds and/or young leaves to break, making them accessible to grazing animals.
• Some animals develop a craving for acorns, occasionally to the exclusion of other available forage, and this may explain why individuals with the same access to oaks may remain unaffected.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Diagnosis of oak poisoning is made on history of exposure and characteristic clinical signs or necropsy findings.
• Primary differentials include diseases that cause sudden death, GI ulceration, and acute or chronic renal failure in ruminants.
• Pigweed (*Amaranthus retroflexus*) poisoning, obstructive urolithiasis, clostridial diseases, heavy metal poisoning, leptospirosis, and renal injury due to nephrotoxic antibacterial drugs should be considered.
• Other differentials include diseases that cause GI ulceration: Infectious bovine rhinotracheitis, bovine viral diarrhea, foot and mouth disease, and bluetongue.

CBC/BIOCHEMISTRY/URINALYSIS

• Azotemia (elevated serum urea nitrogen and creatinine), hyponatremia, hyperkalemia, hyperphosphatemia, and/or hypocalcemia are present on serum biochemistry profiles. Mild metabolic acidosis with a high anion gap may be observed. Elevations in liver enzymes may also be observed.
• The animal may be anuric, or the urine may be isosthenuric with proteinuria, hematuria, and/or glucosuria.
• Granular or proteinaceous casts are often found on urinalysis.
• In chronic cases, elevated serum urea nitrogen, creatinine, and anion gap in addition to variable electrolyte imbalances may be seen.
• Elevated white blood cell counts usually indicate chronic GI ulceration or abscessation.
• Chronic inflammation may lead to a normocytic normochromic anemia. Serum protein levels may be abnormally low due to GI and renal losses.

OTHER LABORATORY TESTS

Serum and urine may be evaluated for concentrations of pyrogallol; however, detectable levels of pyrogallol in urine and serum usually precede clinical signs.

PATHOLOGIC FINDINGS

• Subcutaneous edema, ascites, hydrothorax, and hydropericardium are observed in peracute and acute cases.
• Tubular necrosis and perirenal edema are prominent. Grossly, the kidneys are pale, enlarged, and may contain multifocal hemorrhages.
• Multifocal ulcerative lesions are found in the mouth, esophagus and throughout the GI tract. Perforation and associated inflammation may be observed.
• Histopathologic examination reveals coagulation necrosis of the cortical tubular epithelium. Tubules are dilated and devoid of epithelium but with intact basement membranes. Many tubules contain granular, hyaline, or cellular casts. Necropsy findings after 3–6 weeks of disease may show GI abscessation associated with perforated ulcers, and secondary bacterial pneumonia. Some tubular regeneration may also be seen.

TREATMENT

THERAPEUTIC APPROACH

• Immediately remove affected and unaffected animals from oak trees and provide fresh hay and water.

OAK (*QUERCUS* SPP.) TOXICITY (CONTINUED)

• Intravenous fluid therapy to promote diuresis, establish urine production, and correct acid-base and electrolyte abnormalities is critical. Oral fluid therapy can be used in some cases, but is less effective.
• Antibiotic therapy should be initiated to treat secondary pneumonia and GI abscessation.
• Transfaunation is beneficial to restore rumen motility.
• Adding calcium hydroxide into feed as a 10% concentration has been shown to be effective in decreasing the incidence of intoxication and mortality rates.

MEDICATIONS

DRUGS OF CHOICE
• There is no specific antidote for oak poisoning.
• Calcium hydroxide, activated charcoal, ruminatorics, and purgatives (such as mineral oil [1 L/500 kg], sodium sulfate [1 kg/400 kg], or magnesium sulfate [450 g/400 kg]) may be effective antidotes if administered early in the course of disease.
• Polyethylene glycol (1 g/kg/day) administered in the feed or water will bind tannins and reduce tissue damage.

CONTRAINDICATIONS
Nephrotoxic antibiotics should be avoided.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Clinical recovery usually occurs within 60 days but is rare if renal dysfunction is severe.

PATIENT CARE
Monitoring kidney function is essential for animals recovering from oak poisoning.

PREVENTION
• Improved range management to limit grazing in immature oak stands will prevent development of the syndrome.
• Consumption of a pelleted ration supplement (1 kg/head/day) containing 10–15% calcium hydroxide plus access to more palatable feeds may be used as a preventive measure if exposure to acorns or oak leaves cannot be avoided.

MISCELLANEOUS

PREGNANCY
Ingestion of large numbers of acorns in the second trimester of pregnancy can result in congenitally malformed calves. "Acorn calves" seem to be a result of poor nutrition and ingestion of acorns.

SYNONYMS
• Acorn calves
• Acorn toxicity

ABBREVIATION
• GI = gastrointestinal

OESTRUS OVIS INFESTATION

BASICS

OVERVIEW
• Infestation of the nasal cavity and/or sinuses with larval stages (bots or maggots) of *Oestrus ovis.*
• Infestation can produce a chronic rhinitis and sinusitis, most commonly associated with a mucopurulent nasal discharge.

INCIDENCE/PREVALENCE
The incidence/prevalence is variable among geographic regions and within flocks in a given region. The condition is endemic in some areas.

GEOGRAPHIC DISTRIBUTION
The parasite is found worldwide. Various sources report it as widely distributed in Africa, Australia, Europe, countries of the Mediterranean basin, South Africa, some countries in South America, countries of the former USSR, and the United States.

SYSTEMS AFFECTED
• Respiratory
• Nervous

PATHOPHYSIOLOGY
• *Oestrus ovis* is a dipteran fly in the same family as the warble fly of cattle.
• The adult fly is dark gray and is approximately 1 cm long with rudimentary or vestigial mouthparts. It cannot feed.
• Female flies deposit larvae (larviposit or oviposit) in and around the nostrils of the ruminant host.
• Adult *Oestrus ovis* live 2–28 days and each female produces up to several hundred larvae.
• The parasite can "overwinter" as first-stage larvae in the nasal cavities of hosts and/or as pupae in the ground.
• The first-stage larvae, or instars, initially less than 2 mm long, enter the nasal cavity and feed upon mucus and exfoliated epithelial cells.
• The first-stage instars migrate in the nasal passages and undergo maturation to second-stage larvae in the frontal and maxillary sinuses. Further maturation leads to third-stage instars. After a total larval period of weeks to several months, the fully developed third-stage larvae migrate back to the nostrils, are sneezed out, and pupate in the ground.
• The pupal period is 3–9 weeks.
• Adult flies arise after a period of approximately 4 weeks in summer but require much longer in cooler weather.
• Mechanical damage and trauma occur to the nasal mucosa due in part to attachment by the oral hooks and cuticular spines of the larvae.
• Hypersensitivity has been proposed to play a role in the pathophysiology. In the sinuses, dead larvae may produce an allergic and inflammatory response.
• Larvae and/or their products may produce inflammatory reactions in the lung.

HISTORICAL FINDINGS
The female adult flies bother sheep, causing one or more of the following signs: head shaking, sneezing, rubbing the nose on the ground or on other sheep, foot stomping, circling with nose to the ground, blowing, and interference with grazing.

SIGNALMENT
• Most common in sheep, reported less commonly in goats.
• Has been reported in bighorn sheep (*Ovis canadensis*) and the European ibex (*Capra ibex*), some deer, elk, camels and camelids, dogs, and humans.
• All ages and breeds of sheep are affected.
• Larval burdens have been reported by some sources as being higher in younger animals.

PHYSICAL EXAMINATION FINDINGS
• Rhinitis with nasal discharge (initially clear and mucoid; later mucopurulent and often with blood), sneezing, and stertorous (snoring) respiration.
• Chronic sinusitis, secondary bacterial pneumonia is possible in some cases.
• Very uncommonly, larvae may enter the brain from the sinuses or there can be the spread of purulent inflammation from the sinuses to the brain.

CAUSES AND RISK FACTORS
Infestation of the nasal cavity/sinuses with larvae or bots of *O. ovis.*
• Environmental factors may play a major role in influencing the frequency of infestation.
• In North America, the adult fly is seen from spring to summer or autumn.
• The fly is particularly active in warm weather. In warm climates, the fly can be active over a greater portion of the year.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Foreign bodies (visualization of foreign body in nasal cavity), nasal adenocarcinoma (visualization of tissue and/or biopsy), pneumonia (characteristic clinical signs, evidence of pulmonary pathology), sinusitis (clinical signs, lack of evidence of oestrosis), trauma (history), and others depending upon specific symptoms.
• When the brain is involved (rare), signs of incoordination and a high-stepping gait may simulate signs of gid, a parasitic invasion of the CNS due to larval stages of a canine tapeworm (*Coenurus cerebralis*) and related species (*Taenia multiceps*).

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Serologic techniques such as an enzyme-linked immunosorbent assay (ELISA) test have been developed.

IMAGING
Techniques such as endoscopy may be used to visualize the parasite in the nasal cavity.

OTHER DIAGNOSTIC PROCEDURES
Diagnosis is usually based upon clinical signs; it can be confirmed by necropsy or visualization of the larvae in the sinuses (e.g., endoscopy) antemortem.

PATHOLOGIC FINDINGS
• Up to 20 or more larvae at different developmental stages may be found in the sinuses.
• Sinuses with live larvae may be seen as normal; sinuses with dead larvae may demonstrate edematous and thickened membranes and cavities with exudates.

TREATMENT

THERAPEUTIC APPROACH
• Treatment may be administered at various times during the year, based upon climatic factors and occurrence of infestations.
• In temperate climates, treatment in autumn has been recommended. The majority of larvae are small during this time period.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
These recommendations refer to treatment of the disease in the US in sheep.
• Some anthelmintics used in control/treatment programs for GI parasites may be effective in maintaining control of *O. ovis.*
• Ivermectin at 0.2 mg/kg (200 µg/kg) PO kills all instars and is reported as highly effective. A controlled-release form of ivermectin is available in some countries and has been shown to be effective over an extended period of time.
• It has been recommended in temperate zones to treat in autumn when the majority of larvae are small.
• Closantel, moxidectin, ruelene, rafoxanide, trichlorfon, and other systemic products have been reported in the literature.
• Some authors have recommended various treatments applied directly into the nostrils.

O

OESTRUS OVIS INFESTATION (CONTINUED)

CONTRAINDICATIONS
Ivermectin is not recommended for use in dairy animals due to its extended milk withdrawal time.

PRECAUTIONS
• Obtain current and complete information on any drugs used.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
Check drug label and follow all regulations within individual country.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Treatment at the appropriate life cycle stage with an effective drug should produce high cure rates.

POSSIBLE COMPLICATIONS
• Calcified or septic sinusitis with possible extension to the brain (rare) with presence of dead larvae
• Interstitial pneumonia and lung abscesses
• Killing mature larvae may result in marked reactions in the membranes of the sinuses.

CLIENT EDUCATION
Strategic treatment may interrupt life cycle before the parasite becomes widely established.

PREVENTION
Prevention is difficult. Attempts to minimize the effects of adult flies have been made by utilizing insecticides and by providing shelter or access to cool areas where flies are less active.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Chronic sinusitis and secondary bacterial pneumonia are possible.

AGE-RELATED FACTORS
Young animals may experience greater larval burdens.

ZOONOTIC POTENTIAL
• *Oestrus ovis* is a zoonosis.
• It most commonly causes ocular myiasis or ophthalmomyiasis, primarily among individuals with close contact with sheep or infested animals (e.g., shepherds).
• Affected individuals most commonly report the sensation of being struck in the eye by an insect or foreign body, followed by pain and inflammation in the ocular conjunctiva.

BIOSECURITY
Spread of the parasite may be promoted by importation of infested animals.

PRODUCTION MANAGEMENT
• Moderate numbers of larvae cause little harm; heavy infestations may produce effects such as decreased grazing and feeding times.
• Heavy infestations may interfere with feeding and lead to loss of condition and a significant decline in production of milk or a decrease in weight gains.

SYNONYMS
• Head bot/grub
• Nasal bots
• Nostril fly
• Oestrosis
• Sheep nasal fly
• False gid

OLEANDER AND CARDIOTOXIC PLANT TOXICITY

BASICS

OVERVIEW

• Toxicosis caused by exposure to cardiotoxic plants.
• Major toxins are cardiac glycosides, which are found in a number of unrelated plants, such as oleander (*Nerium oleander*), summer pheasant's eye (*Adonis aestivalis*), foxglove (*Digitalis purpurea*), lily-of-the-valley (*Convallaria majalis*), dogbane (*Apocynum* spp.), and some species of milkweed (*Asclepias* spp.).
• Oleander is cultivated widely in the southern United States and is most commonly associated with plant poisonings in livestock. Therefore, oleander is discussed in detail as a representative of plants containing cardiac glycosides.
• Other cardiotoxic plants that have resulted in poisoning of cattle include yew (*Taxus* spp.), grayanotoxin-containing plants, avocado (*Persea* spp.) and death camas (*Zigadenus* spp.)
• Sudden death is often the primary reported finding.
• In camelids, oleander poisoning may present as renal failure that develops several days post-exposure.

INCIDENCE/PREVALENCE

• Oleander poisoning is relatively common in camelids and cattle and is especially reported in California, Arizona, and Texas. Most cases of oleander poisoning are a result of ingestion of dried oleander clippings or oleander contamination in hay.
• Not all animals in a herd may be affected. Oleander contamination of hay may be uneven.
• Yew, death camas, and avocado poisoning are relatively uncommon in ruminants. Poisonings should be suspected if plants are identified in the environment of the animal or found in hay or burn piles (e.g., yew).
• Grayanotoxin poisoning is usually reported in goats due to browsing azaleas and rhododendrons.

GEOGRAPHIC DISTRIBUTION

• Cardiotoxic plants have specific distribution in the US.
• Oleander is commonly found across the southern US.
• Grayanotoxins are found in several members of the Ericaceae (Heath) family and are widely distributed in the US. They are often found along coastal regions as well as in mountain areas.
• Avocado is extensively cultivated in California and Florida, but can also be found as an ornamental in Gulf coast areas.
• Many species of death camas occur across the US and are seasonal with the greatest abundance being in the spring.

SYSTEMS AFFECTED

Cardiovascular

PATHOPHYSIOLOGY

• Oleander contains cardiac glycosides or cardenolide glycosides that are composed of a steroid core, an unsaturated lactone ring, and a sugar moiety. Cardiac glycosides such as oleandrin, digitoxin, and digoxin inhibit Na^+/K^+-ATPase with similar efficacy to their respective aglycones. The addition of sugar moieties to the steroid core is not essential for the Na^+/K^+-ATPase inhibition, but affects the pharmacodynamics and pharmacokinetics of cardenolide glycosides. Inhibition of the Na^+/K^+-ATPase on myocardial and other cells leads to intracellular retention of Na^+, followed by increased intracellular Ca^{2+} concentrations through the reverse operation of the Na^+-Ca^{2+} exchanger. Elevated intracellular Ca^{2+} concentrations promote inotropy. Other signaling pathways involving NF-κB, TNF-α, and Na^+-dependent amino acid transport have also been identified as targets of cardenolides. The toxic effects are primarily attributable to cardiac conduction alterations and other electrical activity changes. Atrioventricular block is one of the most common manifestations of toxicity, and death is typically due to ventricular fibrillation.
• Yews contain taxine alkaloids (major alkaloids are taxine A and taxine B) that are rapidly absorbed, metabolized, conjugated in the liver, and eliminated in urine as conjugated benzoic acid (hippuric acid). Taxine alkaloids can cause an increase in cytoplasmic calcium by interfering with both calcium and sodium ion channel conductance across myocardial cells. This results in depression of cardiac depolarization and conduction of the heart.
• Grayanotoxins are diterpenes that bind to sodium channels in excitable cell membranes, resulting in increased membrane permeability to sodium ions and maintaining excitable cells in a state of depolarization. Accumulation of intracellular sodium results in an exchange with extracellular calcium, and plays an important role in the control of transmitter release. The membrane effects caused by grayanotoxins account for the observed responses of skeletal and myocardial muscle, nerves, and central nervous system.
• The toxic compound of avocado is called persin. While the exact mechanism of action remains unclear, persin and its analogs arrest the cell cycle.
• Death camas contains steroidal alkaloids, such as zygacine and zygadenine. The alkaloids decrease blood pressure, slow the heart rate, and lead to respiratory depression.

SIGNALMENT

• All ruminant species are susceptible to oleander. Oleander poisoning has been reported in cattle, sheep, goats, and camelids.
• Goats are particularly sensitive to the mammary effects caused by avocados.
• No breed, age, or sex predilections.

PHYSICAL EXAMINATION FINDINGS

• Animals exposed to cardiotoxic plants are often found dead.
• Clinical signs of abdominal pain are often seen within hours of exposure.
• Progression of disease is rapid and animals develop weakness, tremors, excessive salivation, incoordination, dyspnea, and sometimes convulsions.
• In cardiac glycoside poisonings, animals often have an irregular fast pulse with tachycardia, ventricular arrhythmias, or gallop rhythms.
• Clinical signs of *Taxus* poisoning in cattle include incoordination, nervousness, difficulty in breathing, bradycardia, diarrhea, and convulsions, but sudden death is often all that is seen.
• Grayanotoxin poisoning can lead to depression, severe salivation, abdominal pain, and vomiting. In severe cases, animals may then become laterally recumbent, and develop seizures, tachycardia, tachypnea, and pyrexia.

CAUSES AND RISK FACTORS

• Cardiotoxic plants most commonly associated with acute poisoning are oleander and yew. The toxic principles are glycosidic cardenolides and/or cardiotoxic glycosides.
• All parts of oleander are extremely toxic, whether the plant is fresh or dried. Ingestion of dried oleander clippings is a common source of poisoning. Five medium-sized oleander leaves can cause illness and death in an adult cow or camelid.
• All parts of the yew, green or dried, with the exception of the red fleshy part surrounding the seed (aril portion), are toxic. Ingestion of yew clippings is most often the cause of poisonings. All species of *Taxus*, including *T. baccata* (English yew), *T. cuspidata* (Japanese yew) and *T. brevifolia* (Pacific or Western yew), are considered toxic.
• Grayanotoxin poisoning usually occurs when animals are offered plant trimmings or stray into wooded areas where little else is available to eat. The leaves of the plants are considered the greatest risk.
• Avocado leaves are especially toxic, but ingestion of fruit and seeds can also result in poisoning.
• Death camas leaves during the early stages of growth pose the greatest risk for poisoning. Seeds and fruits as well as the dried plant in hay are also toxic.
• Fresh plant material of cardiotoxic plants is often considered to be of low palatability, so animals are most likely to ingest dried plant material.
• Plant trimmings present the most common source for oleander and yew poisoning.
• Contamination of hay or hay cubes with oleander is of great risk.

OLEANDER AND CARDIOTOXIC PLANT TOXICITY (CONTINUED)

• The Guatemalan strain of avocados and its hybrid ("Fuerte") are reportedly toxic, while the Mexican strain has low toxicity.
• Many species of death camas occur across the US and are seasonal with the greatest abundance being in the spring.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Ionophore antibiotics—history of ionophores (e.g., monensin) in the feed ration, detection of toxic concentrations of ionophores in the feed, histologic lesions.
• Cyanide poisoning—mucus membranes are initially bright cherry red, evidence of exposure to cyanogenic plants, chemical analysis for cyanide in gastrointestinal contents, liver or muscle.
• Organophosphorus or carbamate insecticide exposure—commonly associated with gastrointestinal irritation and neurologic signs, evaluation of cholinesterase activity, detection of pesticides in gastrointestinal contents.
• Exposure to neurotoxic plants, such as poison hemlock, water hemlock, tree tobacco, lupine—chemical analysis for plant toxins in gastrointestinal contents, history of presence of plants in the environment.
• Myocarditis—murmurs are usually present, differentiate echocardiographically.
• Endocarditis—fever, differentiate echocardiographically.

O

CBC/BIOCHEMISTRY/URINALYSIS

• Changes are limited in acute poisonings.
• BUN and CREA may be elevated in camelids several days after exposure.
• Myocardial damage may result in hyperkalemia, elevated LDH, CK and AST activities, and elevated cardiac troponin I.

OTHER LABORATORY TESTS

• Detection of oleandrin, gitoxin, digitoxin, grayanotoxins, strophanthidin, or other cardiac glycosides or aglycones in serum, stomach, cecal, or colon contents, and liver.
• Detection of taxine alkaloids in stomach contents.
• Visual and microscopic examination of stomach or intestinal contents for plant fragments. Direct microscopic examination of water and gastrointestinal contents.

OTHER DIAGNOSTIC PROCEDURES

ECG disturbances are supportive—atrioventricular conduction blocks and ventricular arrhythmias.

PATHOLOGIC FINDINGS

• In peracute cases, no lesions are found.
• Postmortem lesions are generally nonspecific in animals that died of exposure to cardiotoxic plants. Lesions include reddening of the mucosa of the gastrointestinal tract and congestion of organs.
• Ruminants with oleander poisoning have evidence of fluid in the pericardium and body cavities, endocardial hemorrhages, and multifocal myocardial degeneration and necrosis. Mural thrombi and hemorrhage under the epicardial surface may be seen.
• *Taxus* poisoning is associated with mild to moderate endocardial hemorrhages in both ventricles, acute multifocal contraction band necrosis of the ventricular wall and the papillary muscles, and occasional neutrophilic and lymphocytic infiltrates in the interstitium of the myocardium.
• There are no or very few lesions in cases of grayanotoxin and death camas poisoning.
• Avocado poisoning can result in fluid accumulation in the pericardial sac and in the thoracic and abdominal cavities. Edema of the gallbladder and perirenal tissues and a flabby, pale heart has been observed. In lactating animals, mammary glands are edematous and reddened.

TREATMENT

THERAPEUTIC APPROACH

• Treatment of animals exposed to cardiotoxic plants is primarily supportive and symptomatic. Supportive therapy should include administration of intravenous fluids, antiarrhythmics, and antibiotics if indicated.
• Prevention of further exposure to the cardiotoxic plant is essential.
• Adsorption of toxins with activated charcoal (AC) has been suggested. Multi-dose AC is beneficial in oleander intoxications.
• Any possible stress or trauma should be avoided.
• Atropine should be considered in cases of severe bradycardia.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Rumenotomy or a rumen lavage may be considered in valuable animals.

MEDICATIONS

DRUGS OF CHOICE

• No antidote is available.
• Antiarrhythmics according to cardiac function (e.g., ECG).
• Atropine (0.01–0.02 mg/kg IV) to treat bradyarrhythmias.
• AC (2–5 g/kg PO in a watery slurry [1 g of AC in 5 mL of water]) via nasogastric tube
• Recommended IV fluid administration in oleander poisonings is 0.9% NaCl with 2.5% dextrose.
• Anticardiac glycoside Fab antibodies have been used in humans and small animals but their usefulness in the treatment of cardiac glycoside-poisoned ruminants has not been evaluated.

CONTRAINDICATIONS

• Do not administer potassium in fluids if hyperkalemia is present.
• Avoid calcium-containing solutions and quinidine.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Animals poisoned with cardiotoxic plants are often found dead.
• Cardiotoxic plant exposure progresses so rapidly that treatment is often too late. In oleander and yew intoxications, the prognosis is poor.
• If treatment is initiated promptly after the onset of clinical signs, the prognosis is fair.
• Animals that survive the acute poisoning may suffer from myocardial damage and may be more prone to stress.
• Camelids that survive 24–72 hours after exposure may develop renal failure.

CLIENT EDUCATION

• Recognize cardiotoxic plants of concern in the geographic location and prevent access by ruminants.
• Provide adequate forage to limit ingestion of toxic plants.

PATIENT CARE

Monitor progression of clinical signs and evaluate ECG.

PREVENTION

• Ruminants should be denied access to landscaped yards and discarded clippings.
• Suspect forage should be inspected for the presence of cardiotoxic plants before allowing access.
• Hay should be inspected carefully for weeds, as many cardiotoxic plants remain toxic when dried (oleander, death camas, yew).

MISCELLANEOUS

PREGNANCY

None

ABBREVIATIONS

• AC = activated charcoal
• AST = aspartate aminotransferase

ORAL DISORDERS

BASICS

OVERVIEW
• Disorders of the oral cavity and esophagus often provoke decreased feed intake, weight loss, and reduced production.
• The lips of cattle are relatively immobile and insensitive, which may contribute to indiscriminate eating habits.
• The lips of small ruminants and camelids are much more mobile and allow superior prehension compared with cattle. In cattle and goats, the upper lip is complete; sheep and camelids have a dividing philtrum, enhancing mobility.
• Dental formula of cattle, sheep, and goats
  ◦ Deciduous: 2 (incisors 0/4, premolars 3/3) = 20
  ◦ Permanent: 2 (incisors 0/4, premolars 3/3, molars 3/3) = 32
• Dental formula of camelids
  ◦ Deciduous: 2 (incisors 1–2/3, canine 1/1, premolars 2–3/1–2) = 18–22
  ◦ Permanent: 2 (incisors 1/3, canine 1/1, premolars 1–2/1–2, molars 3/3) = 30–32
  ◦ The upper incisor is caudal to the last lower incisor. Adult canine and upper incisor teeth are the "fighting teeth," which are larger in males.
• The parotid, mandibular, and sublingual glands are the three largest salivary glands.

INCIDENCE/PREVALENCE
Oral disorders are normally sporadic unless a contagious pathogen (typically viral) is involved.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• The lips and tongue of cattle are relatively insensitive, which contributes to oral trauma and ingestion of foreign bodies.
• Lip lesions are more often clinically significant in camelids and small ruminants; tongue lesions are more likely to adversely affect feeding of cattle.
• Grazing short grass and sandy soil can predispose to abnormal dental wear, dental injuries, decay, and dental loosening.
• The feeding of abrasive materials may predispose to the development of actinomycosis, actinobacillosis, and necrotic stomatitis through mucus membrane trauma.

HISTORICAL FINDINGS
• Anorexia or abnormal feeding activity, often accompanied by weight loss or reduced production, is common.

SIGNALMENT
N/A

PHYSICAL EXAMINATION FINDINGS
• Poor condition
• Fever (variable)
• Lesions on gums, dental pad, hard palate, or tongue
• Protruding tongue
• Abnormal odor
• Quidding
• Ptyalism
• Milk/feed from nostrils
• Swellings or tracts of maxilla or mandible
• Facial deformity
• Swelling of the throat or neck
• Extended head and neck
• Coughing
• Lymphadenopathy

GENETICS
N/A

CAUSES AND RISK FACTORS
• Causes of oral ulcers, erosions, or vesicles include trauma, foreign body penetration (e.g., foxtails), and viral infections—bluetongue, orf, bovine papular stomatitis, BVDV, VS, MCF, and FMD.
• Bacterial infections associated with erosions include *F. necrophorum* (necrotic stomatitis/laryngitis), and *Actinobacillus lignieresii* (wooden tongue). *Actinobacillus* spp. have been reported to cause stomatitis in camelids.
• Oral neoplasias include fibropapillomas (lip, mucosa, esophagus), squamous cell carcinoma, hemangioma, or hamartoma.
• Ptyalism or dysphagia can reflect retropharyngeal trauma/abscessation, foreign bodies, necrotic laryngitis, actinobacillosis, choke, megaesophagus, esophagitis, cleft palate, toxicity (slaframine, grayanotoxin, lead) and neurologic disorders (rabies, tetanus, botulism, listeriosis, and otitis media/interna).
• Mandibular/maxillary masses, swellings, or draining tracts can arise from tooth root abscesses, fractures, sequestrae, actinomycosis (lumpy jaw; *A. bovis*) sialocele, sialoadenitis, abscesses (*F. necrophorum*, *T. pyogenes*, *C. pseudotuberculosis*), cryptococcomas, or neoplasia (odontogenic, osteoma, fibroma, fibrosarcoma, lymphosarcoma).
• Quidding or abnormal regurgitation can reflect dental attrition, malocclusion, periodontal disease, retention of deciduous teeth, retropharyngeal trauma or infection, or choke, megaesophagus, and esophagitis.
• Respiratory distress can reflect retropharyngeal trauma/abscess, necrotic laryngitis, obstruction to the respiratory tract by feed material or masses, and aspiration pneumonia secondary to dysphagia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Vary with signalment and clinical signs.
• Oral disorders can be associated with disease of other body systems, complicating diagnosis (e.g., concurrent respiratory signs, lameness).

CBC/BIOCHEMISTRY/URINALYSIS
• Hemoconcentration.
• Increased WBC count and fibrinogen with bacterial infection or inflammatory conditions.
• Lymphopenia reflects stress or viral infections.
• Metabolic acidosis may arise with ptyalism or dysphagia (salivary bicarbonate loss).

OTHER LABORATORY TESTS
• Bacterial culture
• Biopsy and histopathology assist confirmation of actinomycosis, actinobacillosis, neoplasia, cryptococcoma, and viral mucosal infections.
• Serology, PCR, or virus identification procedures are indicated to confirm the etiology of viral mucosal infections.

IMAGING
• Radiography: Mandibular or maxillary fractures, infections or neoplasia, sequestrae, tooth root abscesses, tooth fracture, retropharyngeal trauma, and metallic foreign bodies. Addition of contrast is useful for megaesophagus.
• Endoscopy: Cleft palate, necrotic laryngitis, retropharyngeal trauma, choke, megaesophagus, esophagitis, and neoplasms.
• Ultrasound: Retropharyngeal abscess, cellulitis, sialocele, sialoadenitis, and neoplasia.
• Computed tomography provides excellent imaging of the skull and dental structures; soft tissue anomalies are enhanced by IV contrast administration.

OTHER DIAGNOSTIC PROCEDURES
• Observe animals eating and swallowing different types of feeds.
• Complete oral examination requires physical restraint ± sedation, and an oral speculum used in concert with a good light source to visualize and palpate the oral cavity and pharynx if possible.

PATHOLOGIC FINDINGS
Vary with specific disorders.

TREATMENT

THERAPEUTIC APPROACH
• Medical management is often beneficial depending on the disorder.
• Antibiotics are indicated for bacterial infections or secondary complications such as pneumonia.
• For animals with severe and noncorrectable dental anomalies, a presoaked well-balanced pelleted diet may be fed as a mash.
• Abscessed teeth may require extraction and antimicrobials.

• Nutritional support may be necessary in animals that are dysphagic, via eosphagostomy, rumenostomy, ororuminal intubation, or parenteral nutrition.
• IV fluids may be necessary in dehydrated animals that cannot swallow and should target the animal's acid-base and electrolyte disturbances.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• Emergency tracheostomy may be necessary in animals with respiratory distress related to upper airway obstructions.
• Retropharyngeal abscessation or other abscesses of the head and neck may require surgical drainage into the mouth or externally, and debridement of the affected areas.

MEDICATIONS

DRUGS OF CHOICE

• Antibiotic recommendations are made in chapters on specific conditions.
• NSAIDs are often indicated to assist pain and inflammation; flunixin meglumine is often used (1.1 mg/kg q12–24h).

CONTRAINDICATIONS

NSAIDs should not be used in dehydrated, azotemic animals.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

The prognosis is good in acute and transient infectious conditions such as orf, and guarded for severe and chronic diseases of soft tissue and bone such as actinomycosis.

POSSIBLE COMPLICATIONS

• Azotemia/renal insufficiency
• Aspiration pneumonia
• Secondary bacterial infections
• Dental loss

CLIENT EDUCATION

Focus on provision of high-quality, palatable feedstuffs and regular assessment of body condition score.

PATIENT CARE

• Response to treatments should be monitored closely, and treatment course modified accordingly.
• Monitor hydration status, electrolyte abnormalities, and acid-base status in patients that are anorexic and/or dysphagic.

PREVENTION

• Specific viral disorders can be prevented by vaccination.
• Dental care is commonly needed in aged small ruminants with dental attrition. Excessive enamel points that cause oral discomfort and ulceration, and hooks or wave mouths can be managed by floating the arcades.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Aspiration pneumonia

AGE-RELATED FACTORS

Some disorders such as orf and necrotic stomatitis are much more common in young animals.

ZOONOTIC POTENTIAL

Contagious ecthyma can be transmitted to humans via contact with infected animals, fomites, or during vaccination procedures.

PREGNANCY

N/A

BIOSECURITY

• Viral mucosal diseases are contagious and appropriate biosecurity methods should be employed within herds and flocks diagnosed with one of those conditions.
• Mucosal diseases such as BVD, bluetongue, MCF, and VS require differentiation from foreign animal diseases (e.g., FMD) that threaten livestock in the United States. Consultation with regulatory veterinarians is imperative when these diseases are identified.

PRODUCTION MANAGEMENT

ORCHITIS AND EPIDIDYMITIS

BASICS

OVERVIEW
• Inflammation of the testes and epididymides may occur separately but often occur concurrently and frequently have the same etiology.
• The inflammation is most often the result of infection or trauma but can also have an autoimmune component.

INCIDENCE/PREVALENCE
• The incidence and prevalence are variable with local disease conditions. Where brucellosis and tuberculosis have been eradicated or controlled, the conditions are sporadic and relatively uncommon.
• Incidence of contagious epididymitis due to *Brucella ovis* in rams may be very high in some regions.

GEOGRAPHICAL DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Hematogenous spread of bacteria is the most common route of infection. Extension from other parts of the genitourinary tract is also an important route of infection.
• Periorchitis, an inflammation of the tunica vaginalis testis within the scrotum, may be directly related to orchitis or occur as an extension of peritonitis or penetrating trauma.
• Unilateral disease is more common but bilateral disease may also occur.
• In unilateral cases, local swelling and inflammation often disrupt scrotal thermoregulation, leading to problems with spermatogenesis and eventually degenerative changes in the unaffected testis.
• In most cases, epididymitis is the more common initial disease with either an extension of the infection to the testis (orchitis) or subsequent testicular degeneration.

HISTORICAL FINDINGS
• Male infertility
• Poor libido
• Observed testicular or epididymal swelling
• Incidental finding during BSE

SIGNALMENT
• All males at any age but especially those that are sexually mature.
• A form of contagious epididymitis has been described in ram lambs and may be caused by a variety of organisms including *Actinobacillus seminis.*

PHYSICAL EXAMINATION FINDINGS
• Warm, painful swelling of the entire testis or one or more segments of the epididymis is the most common sign of acute disease.
• Epididymitis most frequently involves the tail segment (cauda epididymis).
• Some cases of *Brucella ovis* epididymitis in rams are subclinical and cannot be detected by palpation alone.
• Painful animals may refuse to mate or may be reluctant to move. Frequently they walk with a stilted gait.
• Chronic disease of these organs may not be accompanied by either heat or pain. Swelling of the head, body, or tail of the epididymis may be the only clinical sign of chronic epididymitis.
• Transient testicular degeneration usually occurs subsequent to inflammation of either the testis or epididymis. Severe inflammation of one or both testes may lead to irreversible atrophy.
• Blood and/or pus may be seen in the ejaculate. In some cases, abscessation and liquefaction of the testicular parenchyma may occur with subsequent eruption and drainage through the scrotum. This is especially evident with cases of brucellosis in bulls and caseous lymphadenitis in goats.

GENETICS
N/A

CAUSES AND RISK FACTORS
Infectious
• *Brucella abortus* (bulls, camelids)
• *Brucella melitensis* (bucks, camelids)
• *Brucella ovis* (sexually mature rams)
• Epivag virus (bulls, only in Africa)
• Caseous lymphadenitis (CLA) (*Corynebacterium pseudotuberculosis*) (bucks, rams, camels)
• Tuberculosis (*Mycobacterium tuberculosis/bovis*) (bulls and camels, but scrotal lesions are uncommon)
• *Trueperella pyogenes* (bulls and rams)
• *Hemophilus* spp. (bulls, young rams)
• *Mycoplasma* spp. (ram)
• Herpesvirus III (IBR-IPV) (bulls)
• A variety of nonspecific bacteria, protozoa, and parasites have been isolated from or identified in sporadic cases of ruminant orchitis and epididymitis. Of special note are those that cause orchitis or epididymitis in rams and are differentials for *B. ovis* (i.e., *Actinobacillus seminis, Histophilus ovis, Haemophilus* spp., *Corynebacterium pseudotuberculosis ovis, Chlamydophila abortus,* and *B. melitensis*).

Traumatic
Management practices that predispose to male-male aggression can lead to problems with scrotal trauma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Inguinal hernia
• Scrotal hydrocele or hematocele
• Sperm granulomas secondary to trauma or obstructive lesions
• Metastatic mesothelioma
• Lymphoma

CBC/BIOCHEMISTRY/URINALYSIS
Hematuria or pyuria

OTHER LABORATORY TESTS
• Hematospermia or pyospermia
• Immunologic or molecular-based tests for specific infectious agents (e.g., *B. ovis*)

IMAGING
• Ultrasonography may help differentiate hernia, hydrocele, etc. It will also localize the swelling to the epididymis or testis.
• Thermography may also localize inflammation.

OTHER DIAGNOSTIC PROCEDURES
• Scrotal palpation
• Semen collection and evaluation
• Semen culture
• Aseptic aspiration of scrotal fluid for culture/cytology
• Testicular fine-needle aspiration or biopsy
• *Brucella Brucellosis ovis* serologic test—complement fixation test

PATHOLOGIC FINDINGS
• Local infiltration of inflammatory cells, edema with disruption of normal histology
• Transient testicular degeneration
• Testicular atrophy
• Occluded seminiferous tubules, rete testes, vas deferens, or epididymis

TREATMENT

THERAPEUTIC APPROACH
• Unilateral castration can be effective in preserving fertility if the disease is unilateral.
• Systemic antibiotic therapy for 7–14 days or longer, combined with anti-inflammatory treatment, may resolve cases of acute bacterial orchitis. Culture and sensitivity of the organism is indicated if a bacterial etiology is suspected.
• Treatment is reportedly less effective for cases of epididymitis which is not unexpected given epididymal anatomy, as any significant occlusion of the duct can result in a spermatocele.
• Cool water hydrotherapy 30 minutes q12h for 7–10 days.
• Sexual rest.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Unilateral castration should be considered if infection is not due to a contagious or reportable disease.

(CONTINUED) ORCHITIS AND EPIDIDYMITIS

MEDICATIONS

DRUGS OF CHOICE
• Antibiotic selection based on culture and sensitivity testing
• Flunixin meglumine or meloxicam to reduce inflammation and for pain relief

CONTRAINDICATIONS
• Appropriate meat withdrawal times must be followed.
• Animals suspected or confirmed to have reportable or regulated diseases should not be treated with the intention of returning them to the breeding population.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Poor prognosis for return to fertility for the affected testis/epididymis.
• Good to guarded prognosis for normal fertility in cases where medical or surgical treatment is successful.

POSSIBLE COMPLICATIONS
Reduced fertility or sterility

CLIENT EDUCATION
• Report any detected testicular abnormalities to a veterinarian.
• Perform BSE on all males before the breeding season.

PATIENT CARE
• Frequent monitoring during therapy is recommended to evaluate the effectiveness. If no improvement is seen, unilateral castration should be considered along with a change in antibiotic.
• Re-evaluate the scrotum and testes for adhesions or atrophy 1 month after the end of therapy.
• Re-evaluate semen quality a minimum of 60 days after the end of the insult or removal of the affected testicle.

PREVENTION
• Vaccination (*Brucella ovis, Corynebacterium pseudotuberculosis*)
• Test and quarantine of herd or flock additions

MISCELLANEOUS

ASSOCIATED CONDITIONS
Seminal vesiculitis

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Brucella abortus and *B. melitensis* are significant zoonotic concerns.

PREGNANCY
N/A

BIOSECURITY
• Report and appropriately dispose of animals infected with *Brucella* spp.
• Routine screening for scrotal disease is recommended for sheep flocks and affected animals should be tested and culled.

PRODUCTION MANAGEMENT
N/A

ABBREVIATION
• BSE = breeding soundness examination

ORF (CONTAGIOUS ECTHYMA)

BASICS

OVERVIEW
• Orf is a highly contagious, zoonotic viral disease characterized by the development of ulcerative, pustulo-proliferative, or wart-like lesions of the skin of sheep, goats, camelids, and a variety of wild ruminants.
• Although rarely fatal, orf is an economically important disease that has resulted in severe economic losses due to international trade barriers.
• Orf can cause growth retardation and loss of body condition in young lambs and kids, and predisposes to secondary infections.

INCIDENCE/PREVALENCE
• Orf virus (ORFV) is a ubiquitous pathogen with high prevalence worldwide
• Morbidity often reaches 60–80% in a susceptible group; mortality rarely exceeds 1%.

GEOGRAPHIC DISTRIBUTION
• Worldwide in regions where sheep and goats are raised.

SYSTEMS AFFECTED
• Integument
• Digestive

PATHOPHYSIOLOGY
• Caused by the double-stranded DNA orf virus of the Parapoxvirus genus.
• ORFV can be transmitted by close contact between infected and susceptible animals, and through contact with contaminated fomites and dirt.
• ORFV does not cause latent infections; however, clinically healthy animals can act as mechanical carriers.
• ORFV is environmentally resistant and has been found to survive for up to 17 years in wool and contaminated material in dry climates.

HISTORICAL FINDINGS
Flocks or herds may be endemically affected, allowing the virus to infect vulnerable individuals; individual animals may be exposed during transport or with introduction of infected animals into groups.

SIGNALMENT
• Young kids and lambs are most often affected.
• Does and ewes may develop teat lesions while nursing affected offspring.

PHYSICAL EXAMINATION FINDINGS
• Skin lesions consist of macules, papules, vesicles, pustules, crusts, scabs, and papillomatous wart-like growths that usually start at the commissures of the lips and spread around the lip margins to the muzzle. Lesions can occasionally occur at earmarking or tail docking sites.
• In more severe cases, the skin of other areas, such as the eyes, feet, vulva, or udder may be affected.
• Occasionally, lesions may develop in the oral cavity and skin of the interdigital space, and animals may be reluctant to suckle, eat, or walk. Esophageal lesions can occur.
• A generalized persistent form of orf, characterized by severe, multifocal, proliferative dermatitis, occurs in sheep and goats. In these cases, secondary bacterial infections or maggot infestation of affected areas may occur.
• Animals that have recovered or that have been vaccinated can develop lesions that are usually less severe with a shorter clinical course.
• Outbreaks usually last 6–8 weeks.

GENETICS
N/A

CAUSES AND RISK FACTORS
Orf primarily affects young animals, and is enhanced by comingling and stress.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Other ulcerative vesicular or proliferative dermatitis disorders, including capripox and sheep poxviruses, bluetongue virus, foot and mouth disease, or pearmouth (dermatitis of lips and muzzle caused by ingestion of prickly pear cactus).

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Real-time PCR from scab material is replacing electron microscopy (EM). Unfixed scabs should be submitted at room temperature or refrigerated in a double container.
• EM relies on the identification of typical ovoid-shaped parapoxvirus virions. Other parapoxviruses, including bovine papular stomatitis virus and pseudocowpox virus, are indistinguishable by EM.
• Virus isolation is often unsuccessful but can be attempted using primary cell cultures.
• Serologic tests including serum neutralization, agar gel immunodiffusion, and complement fixation have limited diagnostic value.
• Demonstration of typical microscopic lesions (proliferative and erosive dermatitis with intracytoplasmic inclusions in keratinocytes) can aid in the diagnosis.

PATHOLOGIC FINDINGS
• Macroscopically lesions consist of ulcers, crusting, and papillomatous wart-like growths on the skin of the lips and muzzle, ranging from a few millimeters to several centimeters in size.
• Macules, papules, vesicles, and pustules can be observed. In the majority of cases, these lesions are transient and rapidly progress to crusting lesions. Within 3–4 weeks the scabs drop off, and the lesions heal.
• Orf lesions can occur in the oral cavity, and rarely extend to the esophagus and forestomachs.
• Lymph nodes draining affected areas of skin may be enlarged.
• Histologically orf lesions are characterized by papillated, hyperplastic dermatitis with a mixture of epidermal and dermal proliferation with hyperkeratosis and parakeratosis.
• Eosinophilic intracytoplasmic viral inclusions may be found in the stratum spongiosum. Subcorneal vesicles and pustules may be present throughout the epidermis.
• Ulcers covered by serocellular crust containing bacterial colonies or foreign debris can occur.

TREATMENT

THERAPEUTIC APPROACH
• No specific treatments in animals.
• When possible, affected animals should be isolated in shaded pens and provided with clean water and good-quality feed.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Broad-spectrum antibiotics and topical insecticides should be used in animals with secondary bacterial infections or maggot infestation, respectively.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Common zoonotic disease.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• In the majority of cases, lesions heal spontaneously within 3–4 weeks.
• Disseminated persistent orf occurs in some animals. In these cases, lesions can be severe and can extend to other areas including the face, ears, feet, vulva, teats, and scrotum. In these cases, lesions can persist for weeks or months, with the risk of death from secondary bacterial infections.

POSSIBLE COMPLICATIONS
• Secondary bacterial infections or maggot infestation of ulcerated surfaces are common in animals with disseminated persistent orf.
• Foot lesions co-infected with *Dermatophilus congolensis* may result in "strawberry foot rot."
• Lesions on the udder can provoke abandonment of offspring by dams.

CLIENT EDUCATION
Ensure clients understand this is a zoonotic disease that can be contracted via handling of infected animals or the orf vaccine.

PATIENT CARE
N/A

PREVENTION
• Live ORFV vaccines, prepared by sheep skin passage or attenuated virus in cell culture, are commonly used to control the disease, but perpetuate the infection in the environment.
• The vaccine should not be used in locations where the disease has never been diagnosed.
• When animals in a flock/herd are vaccinated for the first time, all susceptible animals on the premises should be vaccinated to avoid vaccine-induced orf in nonvaccinated animals.
• On premises where orf is endemic, all lambs and goat kids should be vaccinated at 6–8 weeks of age. In subsequent years, only new lambs or kids and newly acquired animals need to be vaccinated.
• Vaccines contain live virus and can induce disease in naïve animals and humans.
• During vaccination, an area of the skin of the animal to be vaccinated is scarified, most commonly the medial aspect of the thigh, and the vaccine is brushed onto the site. The appearance of a localized lesion at the site 2–3 days later indicates successful vaccination.
• Vaccinated animals or those that recover from natural infection are susceptible to re-infection which tends to be milder and more transient.
• Sheep and goat ORFVs are essentially the same, but phylogenetic analyses have shown that ORFV has co-evolved with the species. A higher degree of protection is achieved in each species when vaccines are prepared with ORFV from the homologous species.
• Gloves should be worn during physical examination and vaccination of ruminants.
• Disinfection of surfaces and areas potentially contaminated with ORFV can be achieved using detergents, hypochlorite, alkalis, glutaraldehyde or multifaceted products (e.g., Virkon®).

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Orf primarily affects young animals.

ZOONOTIC POTENTIAL
• Orf is more common among farmers, sheep shearers, and veterinarians due to exposure to small ruminants. Slaughterhouse workers, butchers, and meat handlers are sometimes infected from carcasses.
• Orf infection in humans manifests as one or several localized pustules and scabby lesions on the hands, face, or ears. The lesions form painful nodules that heal in 4–6 weeks.
• Multifocal, widespread skin lesions can occur in immunocompromised people.

PREGNANCY
N/A

BIOSECURITY
• New animals should be acquired from orf-free flocks or herds.
• The purchase of new animals from sale barns should be avoided.
• Visitors should wear clean boots and coveralls, and gloves if handling small ruminants.

PRODUCTION MANAGEMENT
N/A

SYNONYMS
• Contagious ecthyma
• Soremouth
• Cutaneous or contagious pustular dermatitis or stomatitis
• Infectious labial dermatitis
• Scabby mouth
• Ecthyma contagiosum

ABBREVIATIONS
• EM = electron microscopy
• ORFV = orf virus
• PCR = polymerase chain reaction

ORGANOPHOSPHATE TOXICITY

BASICS

OVERVIEW
• Organophosphates are anticholinesterase agents commonly found in crop and animal insecticides.
• The binding of organophosphates is irreversible.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Nervous
• Digestive
• Respiratory
• Musculoskeletal
• Cardiovascular

PATHOPHYSIOLOGY
• Anticholinesterase insecticides bind with and inhibit acetylcholinesterase, the enzyme that breaks down the neurotransmitter acetylcholine.
• These compounds cause acetylcholine to accumulate at nerve junctions and cause excessive synaptic activity.
• The effects are in the parasympathetic nervous system and at neuromuscular sites. Nicotinic and muscarinic receptors are activated.

SIGNALMENT
Any species can be exposed to toxic levels of organophosphate insecticides.

PHYSICAL EXAMINATION FINDINGS
Muscarinic Symptoms
Result from stimulation of the parasympathetic nervous system and are described by the acronym SLUD:
• Salivation
• Lacrimation
• Urination
• Defecation

Other Possible Muscarinic Signs
• Vomiting
• Myosis
• Bradycardia
• Dyspnea
• Bloating
• Transient diarrhea

Nicotinic (Neuromuscular) Signs
• Muscle tremors
• Hyperthermia
• Ataxia
• Progressive paresis to paralysis

Central Nervous System (CNS) Signs
• Depression
• Seizures
• Behavioral changes

CAUSES AND RISK FACTORS
• Domestic animals are usually exposed to organophosphate insecticides due to accidental ingestion, or improper treatment by owners. Organophosphate insecticides are used primarily on crops and other plants but can be used as topical insecticides on animals. They were previously commonly used for ectoparasite control.
• Organophosphates are anticholinesterase agents commonly found in insecticides.
• Acute toxicity of organophosphates depends strongly on kinetics of absorption:
  ◦ LD50 for parathion in mice is 5 mg/kg orally.
  ◦ 10–40 mg/kg can be lethal in calves exposed to coumaphos.
  ◦ A dermal dose of 8 mg/kg has caused death in sheep when using coumaphos.
  ◦ Malathion causes clinical signs at 10–20 mg/kg in calves and 50–100 mg/kg in adult cattle when applied externally.
  ◦ Toxic dose of malathion in sheep is 50–100 mg/kg dermally.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Gastrointestinal causes of diarrhea
• Metabolic disturbances such as nervous ketosis
• Nonprotein nitrogen toxicosis
• Pesticides including carbamates, rodenticides
• Plant toxicities that cause tremor or ataxia
• Rabies
• Toxins such as strychnine or lead

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

OTHER DIAGNOSTIC PROCEDURES
• Diagnosis is often based on known exposure to organophosphate and response to treatment with atropine.
• Cholinesterase activity will be inhibited with exposure to an organophosphate.
• Cholinesterase activity in whole blood, retina, or brain that is 25–50% of normal for the species being tested indicates cholinesterase inhibitor toxicosis. If less than 25% of normal, clinical correlation of symptoms is required for diagnosis.
• Check with the laboratory before submitting blood samples because some testing methods may require serum instead of whole blood samples.
• Half of the brain should be submitted for homogenization, as cholinesterase activity varies in different brain regions.

PATHOLOGIC FINDINGS
None

TREATMENT

THERAPEUTIC APPROACH
• Provide supportive care for SLUD or secondary clinical signs such as dehydration.
• Wash the animal with soap and water if dermal exposure occurs, to decrease absorption. Clipping may be advisable in long-haired animals.
• Administer activated charcoal at a dose of 1–2 lb PO per 500 kg animal.
• Atropine should be given at a dose of 0.5–1.0 mg/kg to competitively bind acetylcholine. Give one-fourth of the initial dose IV (watch the pupils and see if they start to return to normal) and the rest subcutaneously or intramuscularly. Dosage can be repeated in 6 hours if clinical signs recur.

MEDICATIONS

DRUGS OF CHOICE
• Activated charcoal
• Atropine
• Oximes such as pralidoxime chloride (2-PAM) that are used to release the acetylcholinesterase-organophosphate bond can **not** be used due to the irreversible nature of organophosphate binding to acetylcholinesterase.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Good prognosis if treated promptly

POSSIBLE COMPLICATIONS
Bloating, inhalation pneumonia

PATIENT CARE
• Heart rate
• Respiration
• Fluid and feed intake

PREVENTION
• Closely follow instructions for dilution and application found on organophosphate insecticide label.
• Premises should be washed and contaminated soil removed. Runoff can poison fish and aquatic animals.

• Avoid use of organophosphate insecticides for ectoparasite control, especially on sick or debilitated animals.

MISCELLANEOUS

ZOONOTIC POTENTIAL

• Organophosphate toxicity is not a transmissible disease; however, humans are also susceptible to toxic exposures.
• Follow labeled instructions and precautions when handling organophosphate insecticides.
• Use caution when washing poisoned animals.

ABBREVIATIONS

• 2-PAM = pralidoxime chloride
• LD50 = estimated dose at which 50% of the population is expected to die
• SLUD = salivation, lacrimation, urination, defecation

SEE ALSO

• Ketosis: Dairy Cattle
• Lead Toxicosis
• Metaldehyde Toxicosis
• Rabies
• Rodenticide Toxicity
• Strychnine Poisoning

OSTEOCHONDROSIS

BASICS

OVERVIEW
Osteochondrosis (OCD) results from defective endochondral ossification. The defect may cause dissection cartilage flaps (osteochondrosis dessicans), subchondral bone cysts, or physitis. "Dyschondroplasia" and "chondrodysplasia" are other terms used for osteochondrosis.

INCIDENCE/PREVALENCE
True incidence is unknown. It appears most commonly among registered beef bulls and male and female show cattle of both beef and, to a lesser extent, dairy breeds because these animals are fed diets supporting maximum growth for extended periods of time. Among commercial beef and dairy replacements, the condition is rare because these animals are fed to support relatively slow growth. Although lesions are common in feedlot cattle, these animals rarely show clinical disease because they attain market weight before clinical signs become severe.

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Musculoskeletal

PATHOPHYSIOLOGY
• In osteochondrosis, cartilage cells fail to differentiate normally and calcification fails to occur; however, the cartilage cells continue to grow, resulting in a zone of hypertrophied cartilage cells.
• Synovial fluid provides nutrition to the immature joint cartilage. A thicker zone of cartilage results in decreased nutrition to the basal layer of the cartilage cells. This results in degeneration and necrosis of the cartilage cells. The necrotic area can form the basis of a fissure that can lead to dissecting flaps, which present as osteochondrosis dissecans.
• Direct trauma has also been cited as a source of necrosis and eventual fragmentation.
• Subchondral bone cysts may result from thickened cartilage that infolds into subchondral bone of weight-bearing surfaces. Studies suggest that subchondral bone cysts may develop from defective connective tissue or cartilage rather than endochondral ossification. This theory suggests that the cartilage cracks following mechanical trauma, creates an opening, and synovial fluid pumps through the defect into subchondral bone during weight bearing.
• Physitis is associated with thickening and weakening of the growth plate cartilage.

HISTORICAL FINDINGS
Animals often have a post-legged conformation with abnormally straight stifle and tarsus joints.

SIGNALMENT
• There is no specific breed predilection in cattle, pigs, and goats. Hereditary dyschondroplasia ("spider lamb syndrome") in Suffolk and Suffolk crossbred lambs has been recognized.
• Reported in animals as young as 5–7 months, but overt clinical signs usually are observed in cattle between 12 and 24 months of age.
• More common in males and among males, bulls.

PHYSICAL EXAMINATION FINDINGS
• The primary clinical sign in cattle is lameness and joint effusion. Joint effusion is thought to be associated with joint capsule proliferation and synovial fluid production due to inflammation. The most commonly affected joints include stifle, tarsus, carpus, and shoulder, and multiple joint involvement is common.
• Affected cattle are usually reluctant to move and walk with a short-strided gait with minimal flexion of the stifle and hock.

GENETICS
May reflect the effects of genetic selection for rapid growth

CAUSES AND RISK FACTORS
• The exact cause of osteochondrosis is unknown.
• The most important risk factor for OCD is rapid weight gain during a young animal's period of cartilage maturation, prior to 2 years of age.
• High-energy and protein diets producing rapid growth have been implicated.
• The disease is more common among registered or valuable animals; however, this apparent predisposition probably reflects superimposed effects of genetic selection for rapid growth, diets composed to support maximum growth, and the increased likelihood of more definitive diagnostics in valuable animals.
• Mineral imbalances including calcium, phosphorus, copper, and zinc are thought to contribute to the development of osteochondrosis.
• Cattle raised on concrete floors with limited exercise are thought to be more predisposed.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Differential diagnoses include disease conditions causing either polyarthritis or multiple limb lameness. Thus, diseases such as mycoplasmosis, *Histophilus somni* infections, and bacterial endocarditis are likely differentials. Mycoplasmosis and *Histophilus* infection are usually associated with respiratory signs. *Histophilus* can also result in encephalitis. Joint fluid analysis with both mycoplasmosis and *Histophilus somni* infections are associated with marked increase in white cell count and protein. PCR on joint fluid can be used to identify *Mycoplasma.* Signs of right-sided heart failure and presence of a systolic murmur are characteristic in endocarditis.
• Septic physitis, a common sequela to salmonellosis, may appear as a lameness involving multiple limbs and multiple swollen joints; however, joint distention is usually absent in this condition and examination will reveal that the swelling is localized to the physis, rather than joints.
• Laminitis should be considered as a differential. Cattle with chronic laminitis will have altered hoof growth. Laminitis will be confirmed by close examination and trimming of the hooves. Joint distention will be absent in cattle with laminitis.

OTHER LABORATORY TESTS
Joint fluid analysis reveals a nonseptic inflammation with mild to moderate increase in leukocyte count and protein.

IMAGING
Radiology
• Definitive diagnosis of osteochondrosis is confirmed by radiographic findings.
• Lesions are either the appearance of subchondral bone irregularity with bone fragmentation referred to as osteochondrosis dessicans or subchondral bone cysts characterized by periarticular focal areas of subchondral bone lucency.
• The stifle joint is the most commonly affected joint followed by the tarsal joint.
• Bilateral radiographs should be considered although clinical signs of bilateral disease might not occur.
• Osteochondrosis can lead to degenerative joint disease.

Arthroscopy
• Arthroscopy can be an effective technique for the diagnosis and treatment of osteochondrosis in cattle, sheep, goats, and camelids.
• Equipment costs and subsequent surgery may be prohibitive for most individuals.

TREATMENT

THERAPEUTIC APPROACH
• Conservative therapy includes stall rest for 1–3 months.
• Deep bedding and dirt-floored or pasture housing are recommended.
• Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be dramatically decreased to limit the patient's rate of gain.

• Nonsteroidal anti-inflammatory drugs may be considered for short-term palliative therapy.
• In feedlots, therapy should not be attempted and affected cattle should be marketed immediately.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Surgical treatment involving removal of the osteochondral fragment and debridement of the fragment bed or debridement of the cyst in cases of subchondral bone cyst may be considered in valuable animals; however, no controlled clinical trials have examined the efficacy of these procedures in cattle.

MEDICATIONS

DRUGS OF CHOICE

• Meloxicam: 0.5 mg/kg SQ or IV, 1 mg/kg PO q24h (cattle), 2 mg/kg loading dose then 1mg/kg q24h (goats and sheep)
• Flunixin meglumine: 1.1–2.2 mg/kg IV q12–24h
• Ketoprofen: 2–4 mg/kg IV or IM q24h (cattle and sheep); 3 mg/kg IV or IM q24h (goats)
• Phenylbutazone: 10–20 mg/kg orally as loading dose then 5–10 mg/kg q48h. In the United States, use is discouraged in food-producing animals and prohibited for use in female dairy cattle 20 months of age or older.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Cases with signs of lameness and secondary degenerative joint disease have a poor prognosis. May improve with surgical intervention.

POSSIBLE COMPLICATIONS

• Degenerative joint disease
• Decreased production

CLIENT EDUCATION

Breeding stock with clinical disease will likely have a shortened productive lifespan due to the anticipated development of degenerative joint disease and culling should be considered.

PATIENT CARE

• Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be dramatically decreased and the patient's rate of gain limited.
• Activity should be restricted.

PREVENTION

• The diet and housing of herd mates of affected animals should be examined.
• Rations should be balanced with respect to mineral micronutrients. Energy content of the diet should be decreased to the level needed to support economically relevant rates of gain.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Degenerative joint disease

AGE-RELATED FACTORS

Osteochondrosis has been reported in animals as young as 5–7 months, but overt clinical signs usually are observed in cattle 12–24 months of age.

PRODUCTION MANAGEMENT

OSTERTAGIASIS

BASICS

OVERVIEW

• *Ostertagia* is a nematode parasite of the gastric glands and lumen of the abomasum of cattle.
• The subfamily Ostertaginae is divided into several morphologically distinguishable but biologically similar genera that are somewhat host specific.
• *Teladorsagia* and *Marshallagia* of sheep and goats, *Camelostrongylus* and other genera of ostertagids in cameloids, cervids, and antelope may cause a similar syndrome in their hosts.

INCIDENCE/PREVALENCE

• All animals in a pasture are exposed to infection but younger animals are more likely to show clinical signs of disease.
• Older cattle become resistant to the parasite but still may have economically important infection, presumably due to anorexia and decreased milk production.
• Clinical disease has decreased tremendously in the past 30–40 years but economic losses still appear to be prevalent where cattle are grazed in high rainfall or irrigated pastures.

GEOGRAPHIC DISTRIBUTION

• *Ostertagia ostertagi* is the most economically important nematode parasite of cattle in temperate regions and *Teladorsagia circumcincta* and *Marshallagia marshalli* are among the most important parasites of small ruminants in temperate and Mediterranean climates.
• Transmission occurs in cool temperate climates following the onset of spring grazing.
• Transmission in Mediterranean climates begins after the onset of rains and persists until the warm dry season.

SYSTEMS AFFECTED

• Digestive
• Cardiovascular

PATHOPHYSIOLOGY

• The disease is associated with the emergence of larvae from the gastric glands, causing cellular hyperplasia leading to increased abomasal pH, lowered serum protein, and anorexia. The number of larval worms emerging from gastric glands determines the severity of disease.
• Because of increased pH, pepsinogen is not converted into pepsin and protein is not denatured.
• Abomasal hyperplasia may be associated with leakage of fluid, leading to hypoproteinemia and diarrhea.
• Anorexia causing failure to gain weight and/or produce milk is the most common observation with this infection. The animals eat less and lie around more.
• The infection/disease may be manifest at different times of the year depending on the emergence of larvae from the gastric glands.
• *Ostertagia* causes a nonspecific suppression of immunity by the host.
• Hypersensivity reactions occur with infections, which may be deleterious to both host and parasite.

HISTORICAL FINDINGS

• Anorexia manifest by lying around rather than grazing is the reason for economic loss.
• Most cattle do not exhibit signs of disease but fail to gain weight at their genetic potential.

SIGNALMENT

• All ages may become infected but young are more at risk for disease.
• Stressed animals such as first calf heifers or those which have not been previously exposed to the parasite are more likely to show signs of disease.
• Breeds that evolved in cool moist environments are more likely to possess traits making them able to become resistant to infection.

PHYSICAL EXAMINATION FINDINGS

• Weight loss and diarrhea are the most common clinical signs.
• Hypoalbuminemia and dehydration may be seen in individual animals.
• The disease is seasonal and manifest in different ways depending on the epidemiology in a geographic region.
• Type I ostertagiasis occurs following exposure to larvae on pasture during the transmission season. Emergence from the glands begins approximately 2 weeks following infection.
• Pretype II infection occurs later in the transmission season as larvae acquired on pasture enter hypobiosis (arrest). No signs are observed.
• Type II ostertagiasis occurs when the previously arrested (hypobiotic) larvae resume development. This tends to occur near the onset of the transmission season. Because large numbers of larvae emerge simultaneously, there is a much higher likelihood of clinical signs.
• Watery diarrhea with the color depending on the forage consumed.
• Submandibular edema (bottle jaw), anemia, and dehydration with a dull hair coat may be seen.

GENETICS

Zebu cattle and zebu crosses are more likely to exhibit signs of disease than European breeds of cattle.

CAUSES AND RISK FACTORS

• Ostertagids are transmitted during cool, moist grazing conditions.
• Young animals and those in early lactation are at greatest risk.
• Heavily stocked and overgrazed pastures.
• Animals on low protein diets.
• Breeds that evolved in arid or moist tropical conditions.
• When animals are producing at their genetic maximum they are at greater risk of parasitic disease because they are immunologically and nutritionally challenged.
• Hypobiosis, or arrested development within the host's abomasum during the early 4th stage. These larvae are in a state of inactivity and are not affected by the host's immune system. They survive until conditions in the environment are more favorable for resuming their life cycle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Malnutrition, especially a protein-deficient diet
• Diarrhea due to intestinal parasitism
• Hypoproteinemia due to haemonchosis or fasciolosis
• Enteric viral or bacterial diseases

CBC/BIOCHEMISTRY/URINALYSIS

• Anemia with low packed cell volume but not clinically apparent.
• Hypoproteinemia, especially low serum albumin levels.
• Elevated serum pepsinogen levels >3.0 IU tyrosine, cattle or >2.0 sheep.

OTHER LABORATORY TESTS

• Fecal flotation egg counts are usually elevated but the level may not be high as individual ostertagids do not produce as many eggs as some other nematodes, and there may be dilution due to diarrhea.
• Eggs are not diagnostic as other genera of gastrointestinal nematodes produce identical thin-shelled segmented eggs.
• Culturing larval nematodes to the infective L3 stage will enable a differential identification of worms at the generic level.
• Species-specific PCR will detect eggs in feces.

OTHER DIAGNOSTIC PROCEDURES

• History of grazing permanent cool season pastures
• Age and source of animals with clinical signs
• Weight loss, diarrhea, and no fever
• Elevated serum pepsinogen and low serum protein

PATHOLOGIC FINDINGS

Gross findings include
• Edematous roughened (Morocco leather) abomasal folds
• Enlarged regional lymph nodes
• Raised umbilicated nodules on surface of abomasum
• May be sloughing of mucosa
• Elevated abomasal pH

• Adult worms (reddish brown and about 1 cm long) may be seen on surface of abomasum; easily overlooked if not fresh and moving.

Histopathologic findings include:

• Distended gastric glands containing developing worms.
• Cells lining glands are undifferentiated with a scarcity of acid-producing cells.
• Reactive regional lymph nodes.
• Edema and inflammatory cells in submucosa.

TREATMENT

See "Medications" and "Production Management"

MEDICATIONS

DRUGS OF CHOICE

• Broad-spectrum anthelmintics approved for use in food-producing animals are the primary means of treatment and control. Withholding periods (meat and milk) should be observed.
• Virtually all of the available anthelmintics should be effective against adult and metabolically active larvae.
• Benzimidazoles and macrocyclic lactones are effective against some populations of arrested larvae. Levamisole is only effective against adult worms.
• Macrocyclic lactones have a residual effect against incoming larvae, killing them before they can enter gastric glands. This residual period (weeks to months) varies with the chemical and carrier. Residual activity may be a selection mechanism for resistance or may eradicate the worm from the facility until reintroduced by infected cattle.
• Strategic deworming selects for anthelmintic-resistant worms but also has a greater impact on total worm populations, lowering numbers below the economic threshold for a longer time than other approaches.
• Not treating all the animals in a herd or flock will allow the parasites in the untreated population to survive and become the refugia (a population of worms not selected for resistance). Worms in the refugia will presumably mate with survivors of the treatment and preserve the usefulness of the anthelmintic used for a longer time.
• Schemes that recognize that some animals are much more at risk than others and strive to assure that the at-risk population is exposed to fewer worms or, if exposed, treated have a chance of success.
• Providing refugia by not treating all the animals in a population may preserve the value of anthelmintics longer than treating all the animals in a herd. Treating bulls, first and second calf cows but not older cows or treating mother cows but not suckling calves may be approaches to provide refugia.

CONTRAINDICATIONS

• The currently available anthelmintics have a wide safety margin. However, levamisole, when injected, can cause nervous signs such as salivation, lacrimation, urination, and defecation.
• Albendazole in early pregnancy in small ruminants can cause loss of the embryo or act as a teratogen.

Enhancement of Anthelmintics

• The effectiveness of benzimidazoles may be enhanced by dividing the dose over several days or by fasting overnight in a dry lot prior to treatment.
• Drug choice for each individual farm should be based on what has the highest efficacy on that farm.
• Strategic treatment with a product effective against arrested larvae in the late autumn/winter in cool climates or spring/summer dosing in the warm climates when the pasture larvae die out.

Rotation of Anthelmintics

• Slow rotation (yearly) is thought to slow onset of resistance in comparison to continual rotation.
• See chapter, Anthelmintic Resistance.

PRECAUTIONS

• Anthelmintic resistance is common in some geographic areas in *Teladorsagia* in sheep and goats but rare in *Ostertagia* in cattle, probably due to the frequency with which anthelmintics are used in the livestock populations.
• See chapter, Anthelmintic Resistance.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Good when appropriate management strategies and effective anthelmintics are used in combination.

POSSIBLE COMPLICATIONS

Economic loss due to decreased production (weight gains)

CLIENT EDUCATION

It is important to educate clients on the proper administration of anthelmintics and alternative management practices in order to decrease resistance.

PATIENT CARE

• Providing sufficient protein is vital with ostertagiasis. During the periparturient period, increased protein will lessen egg production by gastrointestinal nematodes.
• A high protein diet may mask some signs of disease and may also aid in the immune response of the host against the parasite.

PREVENTION

• See "Production Management."
• Vaccination is an approach likely to be successful. Commercial vaccines have not been produced although experimental vaccines have shown promise.

MISCELLANEOUS

AGE-RELATED FACTORS

• Livestock develop resistance to infection following repeated exposure to larvae. However, the resistance is not complete and parasites can occur in any age animal.
• Older cattle may become infected but are more resistant to effects of the worms and can be used to clear larvae from a pasture.

PRODUCTION MANAGEMENT

• Management systems that lower the exposure of hosts to parasites can be devised. These systems may not optimize the value of forages but they result in healthier livestock.
• Utilizing pastures that have been used for cropping, especially in the last half of the grazing season, results in grazing parasite-free pastures and by the following year any larvae deposited on the cropland will not survive until the next grazing.
• Alternate or co-grazing with other species or classes of livestock may harvest larvae from the pasture. The Ostertaginae in sheep and goats do not infect cattle, and vice versa. Horses do not share *Ostertagia* and can be safely grazed in areas dangerous to ruminants.
• Warm season transmission: Autumn/winter treatment and move young animals into barns or dry lots.
• Cool season transmission: Late spring/summer treatment and move young animals to pastures with low numbers of parasitic larvae.
• Pastures in which plants high in condensed tannins are grazed may be helpful as some of the incoming larvae are adversely affected.
• The physical structure of browse plants is a challenge for larvae to ascend, so the animals' chance of acquiring larvae diminishes as the distance from the ground increases.
• Predacious fungi have been evaluated as agents which kill larvae in pastures. One species, *Duddingtonia flagrans*, is able to traverse the digestive tract and is present in the fecal pat when the larvae hatch. Feeding spores or incorporating them in ruminal boluses has the capacity to lower pasture contamination.

OTITIS MEDIA/INTERNA

BASICS

OVERVIEW
Inflammation of the middle ear (otitis media) or inner ear (otitis interna) usually associated with respiratory infections caused by viruses, bacteria, and *Mycoplasma* spp.

INCIDENCE/PREVALENCE
• True prevalence unknown but likely underestimated
• Incidence varies from year to year, even on the same premises
• More frequently encountered during the fall and winter months

GEOGRAPHIC DISTRUBTION
Worldwide

PATHOPHYSIOLOGY
• Otitis media/interna most commonly results from ascending viral or bacterial infection from the nasopharynx into the middle or inner ear via the eustachian tube.
• Progression from the external ear into the middle ear is uncommon but may occur secondary to ectoparasites or foreign bodies.

SYSTEMS AFFECTED
Nervous

SIGNALMENT
• All domestic ruminant species (cattle, sheep, goats, camelids).
• There is no apparent breed or sex predisposition.
• Animals of all ages are susceptible; however, pre- and post-weaned stock seem to be predisposed. Calves and lambs <1 month of age and calves 6–9 months of age are at greatest risk of disease.

PHYSICAL EXAMINATION FINDINGS
• The most common and prominent clinical signs are neurologic in origin and related to cranial nerve (CN) VII dysfunction. Drooping of the ear is often the first sign noted and occurs ipsilateral to the lesion. Ipsilateral ptosis and lip droop may be present in some cases. Deviation of the muzzle opposite the lesion may be seen in small ruminants and camelids but will not be detected in cattle.
• Signs consistent with dysfunction of CN VIII are also common and are usually manifested as head tilt and circling towards the lesion. Nystagmus and strabismus may occur but are generally uncommon.
• Concurrent bronchopneumonia is common and clinical signs consistent with respiratory disease (lethargy, anorexia, fever, increased respiratory rate and effort, nasal discharge, crackles) may also be seen.
• If associated with *Mycoplasma bovis,* polyarthritis and conjunctivitis may be encountered in affected animals or their herd mates.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Progression from the external ear into the middle ear is uncommon but may occur secondary to infestation with ectoparasites (*Otobius megnini, Raillietia auris, Psoroptes cuniculi*) or damage from foreign bodies (e.g., foxtail awns).
• Feeding of contaminated waste milk has been implicated as a source of *Mycoplasma bovis* in outbreaks of otitis on dairies.
• Respiratory pathogens such as *Mannheimia haemolytica, Pasteurella multocida, Mycoplasma* spp., and *Histophilus somni* can frequently be isolated from animals with otitis. Of the aforementioned pathogens, *Mycoplasma* spp. is the organism most frequently associated with clinical disease and has the most impact on the design of treatment regimens.
• *Trueperella pyogenes* can be frequently isolated from animals with chronic otitis and isolation of this organism should not be considered significant.
• Numerous environmental organisms (*Bacillus* spp., *Staphylococcus* spp., *E. coli*) have been isolated from affected individuals.

Risk Factors
• Factors that increase the risk of respiratory disease within a population greatly increase the occurrence of otitis.
• Overcrowding, failure of passive transfer, co-mingling, long distance transport, excessive weight loss during transport (shrink), adverse environmental conditions, feeding of raw, unpasteurized waste milk, and poor herd health management programs are likely to contribute to the development of disease within both individual animals and populations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Although signs of peripheral vestibular disease predominate in ruminants with otitis media/interna, differentiation from central vestibular disease is important to establish a list of differential diagnoses. With peripheral vestibular disease animals are bright, alert, and aware of their surroundings and have no evidence of conscious proprioceptive deficits. If nystagmus is detected in animals with peripheral disease, it is consistently horizontal. Animals affected with central vestibular disease are obtunded and show evidence of marked conscious proprioceptive deficits. If nystagmus is detected in animals with central vestibular disease it will vary in direction.
• Common differential diagnoses include listeriosis, brainstem abscesses, and thromboembolic meningoencephalitis (TEME) caused by *Histophilus somni.*

CBC/BIOCHEMISTRY/URINALYSIS
N/A

IMAGING
• Radiographs have been used to identify lesions in the tympanic bullae. Lateral and lateral oblique projections are needed to optimize diagnostic utility. With the advent of digital equipment the practicality of using radiographs as a diagnostic tool in a field setting is improved. Very specific but insensitive diagnostic modality.
• Ultrasound using a lateral approach caudal to the ramus of the mandible, and ventral to the base of the ear, provides visualization of the tympanic bullae and surrounding structures. Ultrasound is well tolerated by most ruminants and requires minimal restraint.
• Computed tomography (CT) is considered the gold standard in diagnosing otitis media. For many cattle producers, CT would not be an economically feasible option. However, for more valuable individuals, CT has the potential to increase the amount of information available to clinicians managing cases. Access to this form of diagnostic imaging would only be available at referral facilities and institutions.

OTHER DIAGNOSTIC PROCEDURES

Ancillary Diagnostic Tests
• Rarely needed to establish a specific diagnosis.
• A necropsy should be performed on all dead or moribund animals, especially when multiple animals in a group are affected.
• Analysis of cerebrospinal fluid (CSF) in calves with meningitis.
• Cultures of brain and lung tissue should be performed. When necropsy specimens are not available, specific efforts should be made to characterize the source and etiology of ongoing herd respiratory disease.
• Transtracheal wash or bronchoalveolar lavage cytology and culture may permit identification of the offending pathogens.
• *Mycoplasma* spp. are laborious and difficult to culture and some laboratories will use PCR to identify *Mycoplasma* spp.
• Cerebrospinal fluid analysis may be helpful in differentiating causes of asymmetric brainstem disease in feedlot cattle. Otitis will cause either a normal CSF composition, or alternatively, a CSF with increased concentrations of protein and neutrophils.
• Thromboembolic meningoencephalitis will typically result in a CSF which has a high cell count, a high protein concentration, a visible yellow color, and a preponderance of neutrophils.
• Listeriosis will generally cause milder increases in CSF cell counts and protein concentrations, with the predominant cell type being mononuclear cells. Likewise culture of the CSF may support specific

OTITIS MEDIA/INTERNA (CONTINUED)

differential diagnoses; however, negative CSF cultures are common.
• In those animals with polyarthritis in concert with middle ear infections, arthrocentesis with culture and cytology may be useful in determination of the specific etiology.
• Septicemia and TEME tend to cause more dramatic changes in joint fluid composition and the predominant cell type is the neutrophil with both agents.

Herd Diagnostic Procedures

• In dairy herds, the recognition of otitis should encourage practitioners to re-evaluate the herd status with regard to *Mycoplasma bovis* mastitis, particularly if the herd has practiced feeding waste milk to calves.
• Bulk tank cultures performed on three sequential days are reasonable, low-cost strategies to screen herds for *Mycoplasma* spp. mastitis.
• When multiple cases of otitis are recognized in calves <1 month of age on a dairy, practitioners should establish the effectiveness of colostrum administration practices. Serum protein concentration should be determined on all calves <10 days of age. Calves with serum protein concentrations <5.2 g/dL should be classified as having inadequate passive transfer.
• If >20% of calves have less than adequate passive transfer status, immediately targeted intervention should be undertaken to correct deficiencies.

O

TREATMENT

THERAPEUTIC APPROACH

• Antimicrobials are usually used in affected animals. Unfortunately, no antimicrobials are labeled for the treatment of otitis media/interna in food-producing animals. Any antimicrobials used for treatment should follow extra-label guidelines, and those that are strictly prohibited should not be administered.
• Antimicrobial treatment designed to target pathogens associated with respiratory disease for calves that have concurrent infections should be considered.
• Due to the role that *Mycoplasma* spp. play in the disease process, antimicrobials with a spectrum of activity against this pathogen should be considered first-line agents.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Tympanic bulla osteotomy is a surgical option to treat otitis media/interna in valuable individuals and has been used with some success in small ruminants and camelids.

MEDICATIONS

DRUGS OF CHOICE

• Reasonable antimicrobial choices include florfenicol, tulathromycin, and gamithromycin since they have documented efficacy against *Mycoplasma bovis*.
• In animals with respiratory disease, enrofloxacin would be a reasonable antimicrobial choice. However, extra-label use of fluoroquinolones in food-producing animals in the United States is strictly prohibited and their use in animals without respiratory disease is considered illegal.
• Anti-inflammatory drugs (flunixin meglumine 1.1–2.2 mg/kg IV q12–24h, meloxicam 1 mg/kg PO q24h) are indicated to provide pain relief.

CONTRAINDICATIONS

• No antimicrobials are currently labeled specifically for the treatment of food-producing animals with otitis media/interna. Guidelines for extra-label drug use as defined by the Animal Medicinal Drug Use Clarification Act (AMDUCA), or similar organization guidelines in other countries, should be followed.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE/PROGNOSIS

Prognosis for recovery is fair to good with long-term antimicrobial therapy, with 50–75% of treated animals demonstrating partial to complete improvement in clinical signs. Animals with chronic disease or meningitis have a poor prognosis.

POSSIBLE COMPLICATIONS

Extension of infection into the central nervous system and subsequent development of meningitis is possible, particularly in cases with a prolonged course.

PATIENT CARE

Affected animals should be examined regularly with examinations focused on evaluating improvement in clinical signs related to the vestibular system. In animals that fail to respond or that worsen, complicating factors should be considered. See "Possible Complications" and Expected Course and Prognosis."

PREVENTION

See "Age-Related Factors" and "Biosecurity."

MISCELLANEOUS

ASSOCIATED CONDITIONS

Pneumonia. See "Causes and Risk Factors."

AGE-RELATED FACTORS

• Among older calves 6–9 months of age, factors which increase the incidence of respiratory disease will likely increase the incidence of otitis media/interna. In neonatal calves, group housing, inadequate passive transfer of colostral immunoglobulins and feeding raw milk, particularly waste milk on dairies with endemic *Mycoplasma bovis* mastitis, are important additional risk factors.
• When multiple cases of otitis are recognized in calves <1 month of age on a dairy, practitioners should establish the effectiveness of colostrum administration practices.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

BIOSECURITY

Avoid buying stock from co-mingled groupings (e.g., sale barns). Quarantine of newly arriving stock for a minimum of 3 weeks and testing each arrival for persistent infection with bovine viral diarrhea virus (BVDV) can be helpful in the diagnosis and prevention of the disease. Screen any purchased lactating animals for mastitis or test newly purchased heifers or dry cows upon initiation of lactation.

PRODUCTION MANAGEMENT

• Inadequate vaccination against respiratory disease, mixing animals from multiple sources, and inadequate preconditioning programs should all be considered risk factors.
• In a feedlot setting, adequate preconditioning programs including single sourcing of pen lots, immunization programs for respiratory viruses, and *M. haemolytica* and bunk adjustment are important factors.
• On dairy farms, efforts should focus on adequacy of passive transfer in calves, elimination of group housing for young calves (if disease present or at high risk), and avoiding feeding of unpasteurized or nonacidified waste milk.

OVARIAN CYSTIC DEGENERATION

BASICS

OVERVIEW
• Ovarian cystic degeneration (OCD) is an anovular condition that occurs most commonly in dairy cattle and goats but can affect any ruminant species.
• Affected females may or may not display estrus. The core pathology is a failure of the dominant follicle to ovulate.
• Anovulatory follicles are a common finding in camelids that are not mated. It is sometimes referred to as cystic ovarian disease. However, it does not have the same physiopathology as OCD in cattle.

INCIDENCE/PREVALENCE
• Highly variable among herds and species.
• 10–20% in lactating dairy cows.
• The apparent incidence in dairy cattle is greatly influenced by the timing of postpartum examinations as many cows will develop OCD and then spontaneously recover before the end of the voluntary waiting period.
• Anovulatory follicles are common in camelids that are not mated (5–8% alpacas, 10–20% llamas, 30–40% camels).

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Ovulation failure, associated with follicular growth to the point of deviation and beyond, appears to be related to inadequate LH pulses for follicular development or the absence of an LH surge sufficient to cause ovulation.
• Large follicular cysts (greater than normal ovulatory size) may represent a lack of a positive feedback effect of estrogen on the hypothalamic-pituitary axis, resulting in the absence of the LH surge necessary for ovulation and luteinization of the follicle.
• There are two types of cyst described. Follicular cysts are thin-walled structures that produce varying amounts of estradiol but they do not produce progesterone. Luteal cysts have a thicker wall and represent a degree of luteinization occurring without ovulation. Luteal cysts produce variable amounts of progesterone.
• Cysts are generally larger than normal follicular and luteal structures but this is not a necessary condition. OCD occurs when the cysts are steroidogenically active and interrupt normal ovulatory cycles. Cysts may occasionally be diagnosed in cycling or pregnant animals but these are presumed to be steroidogenically inactive and of no clinical consequence.
• In small ruminants, OCD diagnosis is complicated by seasonal factors (ewes and does).
• In camelids, in a large proportion of non-mated cycling females the follicle continues to grow, forming a large anovulatory follicle which loses its ability to ovulate after mating. These follicles may become hemorrhagic or even luteinize. They do not seem to affect follicular wave dynamics in all cases.

HISTORICAL FINDINGS
Complaint of anestrus or erratic estrus cycles

SIGNALMENT
• All ruminants but principally dairy cattle.
• Reported more commonly in Holstein cattle, related to the predominance of this breed throughout the world and affinity for high milk production.
• In dairy cattle, OCD is more common in the 2nd–5th lactations.

PHYSICAL EXAMINATION FINDINGS
• Anestrus is the common presenting complaint.
• Occasional animals may display erratic, prolonged, or persistent estrus behavior or even masculine behavior.

GENETICS
• A genetic predisposition has been implicated in dairy cows.
• In camelids, some females seem to be more predisposed to development of anovulatory hemorrhagic follicles in absence of mating.

CAUSES AND RISK FACTORS
• Genetic predisposition
• Dystocia
• Retained placenta and uterine infection (metritis/endometritis)
• High milk production, metabolic disease, and negative energy balance
• Stressful conditions (e.g., lameness, heat, severe overcrowding)
• Repeated MOET procedures in beef and dairy cattle
• Exogenous estrogen treatment and possibly phytoestrogens or estrogenic toxins in feed
• The causes and risk factors for anovulatory follicles in camelids are not known.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Normal ovarian structures: Preovulatory follicle, cystic corpus luteum
• Paraovarian cysts
• Ovarian abscess
• Ovarian tumors (especially GCT)

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Milk or blood progesterone concentration may help distinguish a luteal from a follicular cyst.

IMAGING
Use of ultrasonography to evaluate ovarian structures increases the diagnostic accuracy.

DIAGNOSTIC PROCEDURES
Palpation or ultrasonography per rectum to assess uterine character and ovarian structures is usually sufficient to make the diagnosis in the absence of a corpus luteum.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Successful treatment of OCD is generally directed at re-establishment of normal ovulatory cycles rather than targeting the cystic structure. An exception is the use of ultrasound-guided aspiration or ablation of follicular cysts. The reported success of this approach, in contrast to the lack of success with manual rupture of cysts, must be interpreted with caution due to the lack of untreated controls.
• Prophylactic treatment with GnRH during the voluntary waiting period decreases the incidence of anovular conditions at the onset of the breeding period, as does exogenous progesterone therapy.
• Any significant predisposing disease or management condition should also be addressed.

SURGICAL CONSIDERATIONS AND TECHNQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Gonadotropin releasing hormone (GnRH) (100 μg IM in cattle and camels; 10–50 μg IM in SAC and small ruminants) or hCG (human chorionic gonadotropin) (3,000–5,000 IU IV in cattle and camels; 500–1,000 IU IV in SAC and small ruminants) may luteinize a follicular cyst but more commonly causes the ovulation of a responsive follicle present on the ovary.
• $PGF2_{\alpha}$ at the luteolytic dose (cattle and camels 25 mg IM) or cloprostenol (cattle and camels 500 μg IM; 250 μg for SAC) is an effective treatment for luteal cysts as well as follicular cysts that have responded to GnRH with partial luteinization.
• Progesterone (PRID) for 7–14 days may initiate normal ovarian cyclic activity.
• Perhaps the most effective treatment for OCD in dairy cattle is an ovulation synchronization program as follows
  ◦ Day 0, inject GnRH and insert a PRID.

- Day 7, remove the PRID and inject $PGF2_{\alpha}$.
- Inject GnRH again, 56 hours after PRID removal, and inseminate 16–20 hours later. It should be noted that this treatment regimen eliminates the need to distinguish between follicular cysts and luteal cysts as the basis for OCD.

CONTRAINDICATIONS
- Estrogenic compounds
- Appropriate milk and meat withdrawal times must be followed.
- $PGF2_{\alpha}$ should never be used in pregnant animals unless pregnancy termination is desired.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- About 60% of cows with OCD early in the voluntary waiting period will spontaneously resume normal cycles by the time they enter the breeding period.
- Most cows affected with ovarian cystic degeneration respond favorably to treatment in terms of resumption of cyclicity; however, fertility may be compromised.

POSSIBLE COMPLICATIONS
- Animals with OCD have more days to first service, lower conception rates, longer days open, and a greater risk of being culled than do unaffected herd mates.
- Poor response to superovulation is observed in embryo donor camelids with anovulatory follicles.

PATIENT CARE
Careful observation for estrus is imperative following treatment in order to inseminate the cow in a timely manner or re-treat refractory cases as soon as possible.

PREVENTION
Reduce stressful condition on dairy farms.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Anestrus

AGE-RELATED FACTORS
A higher incidence has been observed in multiparous cows.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
- OCD will delay pregnancy and even prevent it in chronic, refractory cases.
- Pregnant cows will occasionally be diagnosed with follicular cysts. No treatment is necessary for these cows.
- IVF programs may offer a way to propagate valuable animals with chronic or refractory OCD.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Sound nutrition, health, and reproductive management practices can minimize the economic impact of OCD.

ABBREVIATIONS
- GCT = granulosa cell tumor
- GnRH = gonadotropin releasing hormone
- hCG = human chorionic gonadotropin
- IM = intramuscular
- IV = intravenous
- IVF = in vitro fertilization
- LH = luteinizing hormone
- MOET = multiple ovulation and embryo transfer

OVARIAN HYPOPLASIA, BURSAL DISEASE, SALPINGITIS

BASICS

OVERVIEW
• Ovarian hypoplasia: An incomplete development of the ovary characterized by lack of follicles; less severe than aplasia
• Bursal disease: Diseases associated with the ovarian bursa
• Salpingitis: Inflammation of the uterine tube (oviduct)

INCIDENCE/PREVALENCE
• Ovarian hypoplasia is rare in common breeds of cattle but was found in nearly 17% of infertile camelids at postmortem examination.
• A 10% incidence of bursal/oviductal disorders was reported in cattle with about one quarter being bilateral.
• Bursal disease and salpingitis may occur together.
• A high incidence of ovariobursal adhesions with hydrobursitis has been reported in infertile or subfertile camels.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
Ovarian Hypoplasia
• Occurs as an autosomal recessive trait in Swedish Highland cattle; the condition can be partial or complete, unilateral or bilateral.
• The condition is also associated with intersex conditions (e.g., freemartinism, XO monosomy, etc.) or may be acquired in cases of severe, chronic disease (e.g., tumor cachexia, lameness, starvation, etc.).
• In alpacas, ovarian hypoplasia has been associated with several chromosomal abnormalities (XX/XY, XO, XXX, minute chromosome).

Bursal Disease
• Causes include trauma, aggressive per-rectal palpation of the reproductive tract, developmental defects such as paraovarian cysts, and inflammation associated with metritis or perimetritis.
• Bursal adhesions and abscesses are a rare complication of transvaginal, ultrasound-guided oocyte aspiration (OPU) in bovine IVF programs.
• In camelids ovariobursal adhesions and hydrobursitis may be due to rupture of large hemorrhagic follicles. *Chlamydophila abortus* infection has been suspected to cause this condition.

Salpingitis
• Causes include ascending infection from the uterus, perimetritis, peritonitis, and ineffective treatments for retained fetal membranes and metritis.
• Inflammation may lead to adhesions and fluid accumulation (cysts) or in some cases abscess formation.
• A variety of bacterial and viral agents have been implicated.
• Factors that interfere with ova transport in the bursa and uterine tube or obstruct the uterotubal junction are a cause of repeat breeding.

HISTORICAL FINDINGS
Infertility, repeat breeding

SIGNALMENT
• Potentially all ruminant and camelid species may be affected.
• Ovarian hypoplasia: Swedish Highland cattle, shorthorn cattle.
• Ovarian hypoplasia is one of the most common congenital defects of the reproductive tract in alpacas.
• Salpingitis has been reported with a much higher incidence in water buffalo than in domestic cattle.

PHYSICAL EXAMINATION FINDINGS
Anestrus and infertility

GENETICS
• Ovarian hypoplasia has been attributed to a single recessive autosomal gene with incomplete penetration in some cattle breeds.
• Future expansion of genomic testing for economically important food and fiber species, coupled with careful disease definition and good record systems, will provide an opportunity to reduce or eliminate diseases with a heritable component.

CAUSES AND RISK FACTORS
• Causes and risk factors for ovarian hypoplasia include inheritance, female intersex conditions, and chronic, severe systemic disorders.
• For salpingitis and bursal disease, infectious conditions are most common and associated with a variety of nonspecific organisms (e.g., *Trueperella pyogenes, Streptococcus* spp., *Staphylococcus* spp., *Campylobacter* spp., *Mycoplasma* spp., *Histophilus somni,* and *Mycobacterium tuberculosis*) as well as specific genital infectious agents (e.g., *C. fetus* subsp. *venerealis*). Infectious agents usually ascend from the uterus and are often associated with abortion or metritis. Traumatic ovarian palpation or CL enucleation may cause inflammation and adhesions. Rarely, adhesions and abscesses may occur after OPU procedures in bovine IVF programs.
• The cause of the high incidence of ovariobursal adhesions with accumulation of fluid (hydrobursitis) in camels is not yet well understood.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other causes of repeat breeding such as infectious diseases (endometritis) and deficiencies in reproductive management
• Other causes of anestrus:
  ◦ Pregnancy
  ◦ Inadequate estrus detection
  ◦ Freemartinism
  ◦ Heat stress
  ◦ Ovarian cystic degeneration
  ◦ Starvation
  ◦ Lactational anestrus in beef cattle
  ◦ Seasonal anestrus in ewes and does
  ◦ Pyometra
  ◦ Mummified fetus

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Culture and sensitivity may be helpful to rule out bacterial causes and select appropriate therapy.

IMAGING
Ultrasonographic imaging of the reproductive tract may help to increase diagnostic accuracy. Endoscopy is particularly useful for diagnosis of subtle lesions of the bursae and oviducts.

OTHER DIAGNOSTIC PROCEDURES
• Palpation per rectum and transrectal ultrasonography are most commonly employed for cattle and camelids.
• Endoscopy or laparoscopy are often required for antemortem diagnosis of small ruminants or more subtle lesions in all species.
• Oviductal blockage is most reliably confirmed by repeated failure to obtain embryos from animals that respond well to superstimulation protocols.

Ovarian Hypoplasia
Hypoplastic ovaries are small, thin, narrow, and firm. It may be difficult to find them by palpation or ultrasonography.

Bursal Disease
In cases of adhesion, the ovary is difficult to palpate per rectum. Fluid accumulation associated with bursal disease may develop due to adhesions of the fimbriae to the ovary.

Salpingitis
• *Tubo-ovarian cysts*—in cases of salpingitis, clear fluid accumulates in the proximal portion to reflux into the bursa. The cranial portions of the uterine tube distend in a cystic manner.
• Per-rectum palpation and ultrasonographic imaging of the reproductive tract are mandatory. The use of a dye test or embryo flush technique to diagnose the distended tube or oviductal blockage can be helpful. It allows differentiation of a unilateral or bilateral condition.

(CONTINUED) OVARIAN HYPOPLASIA, BURSAL DISEASE, SALPINGITIS

PATHOLOGIC FINDINGS

Ovarian Hypoplasia

• Hypoplastic ovaries are small, thin, narrow, and firm; the ovary may be so small that it is difficult to locate.
• In severe cases, only a cordlike thickening of the cranial border of the ovarian ligament may be evident. On palpation it may resemble a pea- or kidney-bean-like structure in partial hypoplasia or as a shrunken structure in total ovarian hypoplasia.

Bursal Disease

Pathologic lesions may range from mild adhesions of a few fibrous threads between the bursa and the ovary to extensive ovariobursal lesions. The lesions include narrow, shallow, or closed bursa, roughness of the internal wall of the bursa, and cysts of the bursa.

Salpingitis

• Hydrosalpinx—secondary to segmental aplasia or uterine/oviductal blockage due to adhesions distally, proximally, or at both ends of oviduct.
• Pyosalpinx—accumulation of pus in the oviduct following extensive uterine infection.
• The oviduct usually distends to a diameter of 0.5–2.0 cm (depending on species) containing clear mucus or pus; it is elongated, coiled, and thin-walled on palpation.

TREATMENT

THERAPEUTIC APPROACH

• There is no treatment for congenital ovarian hypoplasia.
• Medical treatment of acquired bursal and oviductal disorders is often unrewarding. Acute inflammatory disease may respond to antibiotics and anti-inflammatory drugs but these disorders are seldom diagnosed early. Elective culling is the most common outcome but extremely valuable animals may be candidates for IVF or even cloning.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Ovariectomy may be justified for valuable animals with unilateral localized lesions.

MEDICATIONS

DRUGS OF CHOICE

If an acute infectious condition is suspected, appropriate antibiotic and anti-inflammatory treatment may be considered.

CONTRANDICATIONS

Appropriate milk and meat withholding times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Prognosis—guarded to poor, especially if bilaterally affected

POSSIBLE COMPLICATIONS

Infertility or sterility is the most common complication of these disorders. Peritonitis and gastrointestinal problems are rare.

CLIENT EDUCATION

• Importance of pre-breeding evaluation of maiden females, particularly in camelids
• Importance of submission of females that fail to become pregnant to examination
• Cost associated with examination procedures

PATIENT CARE

N/A

PREVENTION

• For heritable conditions, culling of the affected animal may help reduce the incidence.
• Measures to reduce the incidence of infectious diseases that may lead to bursal and oviductal problems include farm biosecurity, sound vaccination and nutrition programs, and hygienic and appropriate interventions for dystocia and postpartum uterine infections.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Infertility, repeat breeding
• Anestrus

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Not a concern where tuberculosis and brucellosis are well-controlled or eradicated but should be considered in areas where this is not the case.

OVINE ENCEPHALOMYELITIS (LOUPING ILL)

BASICS

OVERVIEW
• Louping ill refers to an acute, tick-transmitted encephalomyelitis that mainly affects sheep, but which can occur in other vertebrates including humans.
• Louping ill virus (LIV) is a single-stranded, neurotropic, RNA virus in the genus *Flavivirus* (family Flaviviridae). The virus has four subtypes and belongs to a subgroup of related viruses known as the tick-borne encephalitis complex.
• Small mammals and birds such as hares, red grouse, and ptarmigan can carry and amplify the virus.

INCIDENCE/PREVALENCE
• Yearling sheep are the most susceptible to clinical disease after waning of maternal protection occurs and they encounter ticks on pasture. Mortality rates in young sheep can reach 60%.
• Prevalence of infection may be as high as 60% in adult sheep, but the incidence of clinical disease is low unless the sheep are new to an endemic area; mortality rarely exceeds 15% in adults.
• The disease is most prevalent during spring, late summer, and fall during periods of heightened tick activity.

GEOGRAPHIC DISTRIBUTION
• Louping ill occurs in the British Isles and Norway, and has also been reported in sheep in Bulgaria, Turkey, and the Basque region of Spain.
• Outbreaks typically occur in swampy areas where dense populations of infected ticks overlap with wild animals.

SYSTEMS AFFECTED
• Nervous
• Respiratory
• Digestive

PATHOPHYSIOLOGY
• Louping ill is transmitted by a tick vector, *Ixodes ricinus*. Other tick species including *Rhipicephalus appendiculatus, Ixodes persulcatus*, and *Haemaphysalis anatolicum* can also carry the virus but appear less important.
• The larva, nymph, and adult tick contract the virus by feeding on a viremic host. Transmission between life stages of the tick appears to be transstadial, wherein the pathogen persists between life stages. The virus survives in the salivary glands of infected ticks.
• Infection can also occur via transmission on needles or in blood products. Ptarmigan may be infected by ingesting ticks.
• After susceptible sheep contract the virus, it migrates to regional lymph nodes and the spleen to replicate. Animals become viremic 6–20 days later. Those capable of generating a rapid antibody response may recover with minimal clinical effects. In others, viral replication in the brain can induce nonsuppurative inflammation and cell death, resulting in neurologic disease.
• Concurrent infection with *Anaplasma phagocytophilum* (the agent of tick-borne fever) results in increased viremia and mortality of LIV infected sheep.
• LIV can be transmitted in unpasteurized sheep and goat milk. Lactating goats can shed significant amounts of virus creating fatal infection in neonatal kids.

HISTORICAL FINDINGS
Rapid onset of suggestive clinical signs in young sheep weeks or months after introduction to a pasture environment in a region in which louping ill is possible.

SIGNALMENT
Sheep, cattle, goats, and deer can be affected. Young animals are typically most vulnerable once maternal protection wanes.

PHYSICAL EXAMINATION FINDINGS
• Initial signs of infection include high fever (42°C, 107.6°F), lethargy, hypophagia, and generalized muscle tremors.
• As disease progresses with CNS invasion, affected animals develop gait abnormalities including ataxia, conscious proprioceptive deficits, and severe hypermetria. Some animals develop a characteristic bunny hopping gait, responsible for the name louping (leaping) ill.
• Head tremors, hyperexcitability, head pressing, opisthotonus, jaw champing, hyperesthesia, recumbency, and seizures can develop in advanced disease prior to death, which occurs after 3–12 days.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Grazing pastures containing infected ticks is the most common way to acquire infection.
• Concurrent infection with *Anaplasma phagocytophilum*, spread by the same tick species, can exacerbate the clinical course of louping ill, possibly via immunosuppression.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• In small ruminants, other infectious disorders should be considered (scrapie, maedi-visna, tetanus, listeriosis, rabies, and hydatid disease) as well as metabolic or nutritional disorders (pregnancy toxemia, polioencephalomalacia, hypocalcemia, copper deficiency); and toxic disorders (heavy metal toxicity, plant toxicities, strychnine poisoning).
• In cattle, consider other infectious disorders with similar signs (tetanus, malignant catarrhal fever, listeriosis, pseudorabies, rabies, hydatid disease, and bovine spongiform encephalopathy); metabolic or nutritional disorders (hepatic lipidosis, hypomagnesemia, hypocalcemia); and toxic disorders (heavy metal toxicity, strychnine and plant toxicities).

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Virus isolation from blood during the febrile stage prior to onset of neurologic signs, or from the brain or spinal cord of deceased animals. Sterile unfixed tissue should be placed in 50% glycerol and normal saline or frozen on dry ice.
• Virus isolation has been largely superseded by RT-PCR on brainstem tissue; immunohistochemistry (monoclonal antibody) can also be performed.
• Hemagglutination inhibition testing can detect specific serum IgM, which suggests recent infection (<10 days).
• Serum neutralization, ELISA, and complement fixation tests are also available. Cross-reaction with other flaviviruses is possible.

PATHOLOGIC FINDINGS
• Gross lesions are typically minimal; however, congested meningeal vessels and secondary pneumonia may be observed.
• Microscopically, there is nonsuppurative (mononuclear) polio- and meningoencephalomyelitis with gliosis, perivascular infiltration, and neuronal degeneration. Lesions are primarily located in the brainstem and cerebellum, as well as in the ventral horn of the spinal cord.

TREATMENT

THERAPEUTIC APPROACH
There are no specific treatments.

SURGICAL CONSIDERATIONS AND TECHNIQUES

CONTRAINDICATIONS
N/A

PRECAUTIONS
N/A

(CONTINUED) # OVINE ENCEPHALOMYELITIS (LOUPING ILL)

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Approximately 50% of animals with clinical signs succumb after 1–12 days. Those that survive clinical disease typically have residual deficits.
• Animals infected with LIV are immune for life.

POSSIBLE COMPLICATIONS
Animals that survive clinical disease often have residual central nervous system deficits of variable severity.

CLIENT EDUCATION
• Educate clients about tick control and vaccination protocols to prevent infection.
• Inform clients this is a zoonotic disease which can be transmitted via skin wounds or unpasteurized milk.

PATIENT CARE
• Recovering animals should be provided with basic supportive care and sedation if needed to prevent convulsions stimulated by noise or touch. Cattle may fare well with basic nursing care, compared to sheep.
• Affected animals may require hand feeding for adequate nutrition.

PREVENTION
• An inactivated, tissue-culture-propagated vaccine is available for sheep, cattle, and goats. One subcutaneous injection will provide protection for >2 years. All animals kept for breeding should be vaccinated at 6–12 months of age, and pregnant ewes can be vaccinated in the last trimester to optimize maternal antibodies.
• Pour-on insecticides should be used to reduce tick exposure.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Where the disease is endemic, it usually afflicts animals <2 years of age; adults are immune due to previous infection, and lambs are protected by maternal antibodies.

ZOONOTIC POTENTIAL
• LIV may infect humans through tick bites, skin wounds, and potentially aerosol exposure.
• Ingestion of unpasteurized sheep or goat's milk may also result in infection.
• Infected humans may develop an illness that resembles influenza, polio, biphasic encephalitis, or a hemorrhagic fever.

PREGNANCY
N/A

BIOSECURITY
Louping ill is exotic to the United States, but is listed as a reportable disease. Any suspicion of this disease should therefore be reported to state and federal authorities.

PRODUCTION MANAGEMENT
Appropriate herd vaccination procedures are indicated in areas where the disease is endemic.

SYNONYMS
• Infectious encephalomyelitis of sheep
• Trembling ill

ABBREVIATIONS

O

OVINE PULMONARY ADENOCARCINOMA

BASICS

OVERVIEW
• A beta retrovirus called jaagsiekte sheep retrovirus (JSRV) causes a contagious disease characterized by the formation of pulmonary tumors in sheep.
• The disease is known as ovine pulmonary adenocarcinoma (OPA); however, it is also referred to as ovine pulmonary adenomatosis, jaagsiekte, and sheep pulmonary adenocarcinoma.

INCIDENCE/PREVALENCE
• Accurate information on the prevalence of OPA is difficult to obtain because OPA is not a notifiable disease and therefore very few countries collate data regarding the number of cases diagnosed.
• In the United Kingdom where JRSV is endemic, approximately 0.2–0.65% of sheep per year submitted to diagnostic laboratories for postmortem examination between 1975 and 2008 were diagnosed with OPA.

GEOGRAPHIC DISTRIBUTION
• OPA is found in sheep populations throughout the world; however, disease does not occur in Australia and New Zealand, and Iceland has successfully eradicated OPA.
• OPA is a significant problem in sheep-raising countries where it is enzootic. OPA is an economically important disease in Scotland, South Africa, and Peru; it is a minor disease in Canada and the United States.

SYSTEMS AFFECTED
• Hemolymphatic
• Respiratory

PATHOPHYSIOLOGY
• JSRV infection initiates OPA. The majority of tumor cells express markers of type II pneumocytes or Clara cells. However, the presence of undifferentiated cells makes likely that bronchioloalveolar stem cells (BASCs) are the also a target.
• Once JSRV has infected its target cell in the lung, it is able to promote neoplastic transformation of that cell. The JSRV Env glycoprotein functions as a viral oncoprotein to stimulate cellular transformation directly, in addition to its primary role in cellular entry.
• Following the initial activation of signaling pathways by JSRV Env, additional genetic mutations are needed for OPA to develop. This would be consistent with the long incubation period of natural OPA. Multiple events are generally required for other retrovirus-induced tumors such as the activation of additional cellular oncogenes or inactivation of tumor suppressors.
• JSRV has the ability to evade the immune system, allowing infection and tumors to progress.
• By the stage at which clinical OPA is apparent, a large proportion of the lung is commonly taken over by tumor and multiple lobes of the lung may be affected. Tumors may metastasize to thoracic lymph nodes and occasionally to other tissues.
• The reduction in functional lung parenchyma and the increased production of lung fluid cause respiratory difficulties, and the resultant coughing or spilling out of fluid via the nose promotes transmission of JSRV through aerosol production and contamination of the environment.
• Frequently, a bacterial infection appears to be the cause of death in the OPA-affected animal.

SIGNALMENT
• Sheep most susceptible.
• Goats: The disease has been experimentally transmitted from sheep to goats. Goats have a low susceptibility to infection. The disease appears to occur naturally at a low prevalence in goats.
• Some breeds appear to be more susceptible to OPA.
• The incubation period ranges from 3 weeks in lambs to several years in older animals.
• Average duration of clinical signs is 2 months (range of a few days to 6 months).
• The normal course of overt disease occurs in adult sheep 2–4 years of age; lambs are more susceptible to infection if exposed prior to 10 weeks of age.
• The peak incidence of OPA after natural infection is thought to be 3–4 years.

GENETICS
• There appears to be some breed predilection.
• There is some evidence that the presence of endogenous viral sequences in ovine genomes may increase the OPA susceptibility in sheep. Polymorphisms in MHC are linked to progression of disease.

PHYSICAL EXAMINATION FINDINGS
• Marked dyspnea, sporadic coughing, and copious watery nasal exudate
• Weight loss and increased secretion from the lungs

CAUSES AND RISK FACTORS
• Jaagsiekte sheep retrovirus (JSRV), a beta retrovirus, is the cause. It is in the same family as mouse mammary tumor virus but only distantly related to maedi-visna virus which is a retrovirus but a member of the lentivirus group.
• Transmission occurs by aerosol and, experimentally, by contact. OPA is highly contagious and susceptibility is age dependent.
• Detection of subclinical infection is difficult. Field diagnosis relies on identifying overt animals within a flock with typical clinical and postmortem symptoms.
• The presence of the disease may not be recognized in flocks containing a predominance of animals <4 years of age.
• When purchasing new stock, the infection status of individual animals depends on the disease status of the originating flock.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Epithelial hyperplasia, a sequela to chronic infections of sheep
• Maedi-visna virus
• Bacterial pneumonia
• Verminous pneumonia

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Detection of infected sheep prior to development of clinical disease may be extremely difficult.
• Sheep do not develop detectable antibody responses to JRSV so standard serologic methods are not applicable.
• A blood PCR test for JSRV has been developed but is not commercially available. It is more accurate for herd-level diagnosis because it is not sensitive for infection at early stages.
• JSRV antigen can be detected in tumors and lung fluids using immunohistochemistry, PCR, immunoblotting, or interspecies competition radioimmunoassay. The JRSV 26-kD antigen cross-reacts with a primate-derived type D retrovirus.

IMAGING
Transthoracic ultrasound may be used to detect animals with overt tumors; however, a normal thoracic ultrasound does not rule out the potential for JSRV infection.

PATHOLOGIC FINDINGS
• On gross examination a large percentage of the lungs is taken over by the tumors and multiple lung lobes are involved. The tumor mass is frequently necrotic at the center.
• Metastases are found most commonly in the bronchial or mediastinal lymph nodes in 10–50% of cases.
• Histologically, pulmonary tissue pathologic changes occur as multiple, well-circumscribed nodules of transformed secretory epithelial cells, multifocal nodules of neoplastic cuboidal epithelial cells in acinar or papillary patterns, peribronchiolar and interstitial lymphoid hyperplasia, type II pneumocytes and nonciliated bronchiolar (Clara) cells, and fibromuscular proliferation.
• Virus replicates actively in the transformed epithelial cells of the lung, and viral DNA and RNA have been detected in lymphoid tissues.
• Electron microscopically, cells have microvilli, tight junctions, and cytoplasmic lamellar bodies reflecting alveolar type II cells.

TREATMENT

THERAPEUTIC APPROACH
Not effective. Humane euthanasia is indicated where infection is suspected.

MEDICATIONS

DRUGS OF CHOICE
None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Grave; 95% of all clinical cases die. Surviving animals spread the disease.

PREVENTION
• Due to the long preclinical incubation period, OPA may disseminate widely in a flock prior to disease recognition.
• Lung fluids from affected sheep contain large numbers of virus particles and can survive in the environment for many days, so decontamination and rotation of grazing areas is recommended if clinical cases are identified.

MISCELLANEOUS

AGE-RELATED FACTORS
Adult sheep between 1 and 4 years of age with 4 years of age being the norm; lambs are more susceptible to infection if exposed prior to 10 weeks of age.

ZOONOTIC POTENTIAL
None

PREGNANCY
OPA has not been detected in embryos or uterine fluids. However, during the later stages of disease, exposure of embryos, ova, and semen to virus may be possible.

BIOSECURITY
• Restrict movement of sheep from known infected flocks.
• Purchase replacement stock from known disease-free farms and ranches.

PRODUCTION MANAGEMENT
Economic losses can arise from mortalities, the cost of eradication programs, and control measures.

SYNONYMS
• Jaagsiekte
• Jaagsiekte sheep retrovirus (JSRV)
• Ovine pulmonary carcinoma
• Ovine pulmonary adenomatosis
• Sheep pulmonary adenocarcinoma

OXALATE TOXICITY

BASICS

OVERVIEW

• Due to ingestion of plants containing large amounts of soluble potassium and sodium oxalate salts that, when absorbed, form insoluble calcium and magnesium oxalate salts.
• Associated with ingestion of a number of different plant species; the most commonly seen include *Halogeton glomeratus* (halogeton), *Sarcobatus vermiculatus* (greaseweed, black greaseweed), and *Oxalis* (shamrock, soursob, sorrel).
• Many other plants contain oxalates but are less commonly associated with toxicity including, but not limited to, *Amaranthus* (red-pig root), *Chenopodium* (lamb's quarters), *Rheum rhaponticum* (rhubarb), *Panicum* spp. (elephant grass), and *Alocasia* (elephant's ear).
• Concentration of the oxalates depends on season, stage of plant growth, weather, soil, geographic area, and variation between plant species.
• Ruminants are able to detoxify oxalates in the rumen by bacterial degradation and this accounts for decreased toxicity in ruminants compared to some other species.
• Rapid absorption of oxalates and formation of insoluble calcium and magnesium salts yields a rapid decline in serum calcium and magnesium levels. Acutely, these animals may present with signs commonly seen with hypocalcemia due to impaired cellular membrane function.
• More chronic ingestion will yield formation of oxalate-containing urinary stones and oxalate nephrosis (due to precipitation of these salts in the tubules).
• Toxicity most commonly occurs when unadapted sheep or cattle are placed in or move through areas containing large stands of these plants.
• Local oxalate crystal formation in the rumen wall may induce a rumenitis or more severe gastroenteritis.

INCIDENCE/PREVALENCE

• Depends on season, stage of plant growth, weather, soil, geographic area, and variation between plant species.
• Host factors affecting the toxicity following ingestion include the amount and rate of ingestion, previous adaptation to the plant in allowing increased bacterial degradation (can occur over 2–3 days), and volume of other nontoxic plants in rumen.

GEOGRAPHIC DISTRIBUTION

• Worldwide
• These plants grow throughout continental North America; however, those most commonly associated with toxicity (halogeton and greaseweed) are found mainly in the western areas of the continent.

SYSTEMS AFFECTED

• Digestive
• Nervous
• Urinary

PATHOPHYSIOLOGY

• When a ruminant consumes an oxalate-containing plant, the oxalate is metabolized in four possible ways. Three of the pathways render oxalate nontoxic to the animals.
• Only when Ca is low in the diet and/or large quantities of dietary oxalate is consumed, are the conditions right for oxalate toxicosis. Oxalate remains soluble in the liquid portion of the intestine contents and is readily absorbed from the intestine into the bloodstream.
• If the oxalate ion concentration becomes very high in the blood being filtered by the kidney, it may combine with Ca^{2+} or Mg^{2+} to form insoluble oxalate crystals that may block urine flow and cause kidney failure.
• The acute toxicosis is the result of low serum Ca^{2+}.

SIGNALMENT

• All ruminant species and swine can be affected, but the disease is seen more commonly in sheep.
• Acute exposure to the plant in unadapted animals is important in toxicity.

PHYSICAL EXAMINATION FINDINGS

• Acute toxicity present with signs of hypocalcemia.
• Signs occur within several hours and death can occur within 12 hours.
• First signs may include dullness, anorexia, belligerence (mainly cattle), stiffness, weakness, muscle tremors, tetany, and recumbency. As disease progresses without treatment, coma and death may occur.
• Rumenitis, rumen stasis, and gastroenteritis.
• If animal lives through acute stages, then azotemia and kidney failure ensue.
• Azotemia may be associated with increased depression, anorexia, and death.

CAUSES AND RISK FACTORS

• Ingestion of plants containing high levels of soluble oxalate salts.
• Most commonly halogeton or greaseweed.
• Ingestion of large amounts rapidly is a risk factor.
• Increased rumen fill by nontoxic forage is protective.
• Slow adaptation to oxalate plants over a period of 4 days can increase the rumen's ability to degrade the oxalates by up to 30%.
• Diets high in calcium may be protective due to formation of insoluble calcium oxalate salts in the GI tract.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Hypocalcemia of other causes, including lactational hypocalcemia (cattle) and gestational hypocalcemia (sheep and goats).
• Hypomagnesemia of other causes including grass tetany, lactation tetany, wheat pasture tetany, transport tetany, and grass staggers.
• Other causes of acute renal failure—ischemia, heavy metal toxicosis (arsenic, mercury, lead), drug-related nephropathies, *Quercus* (oak toxicity), pigment nephropathies (hemoglobin, myoglobin), and monensin toxicity.
• Other urinary tract disease—pyelonephritis, urolithiasis (struvite and silicates, calcium carbonate), and amyloidosis.
• History of exposure to oxalate-containing plants is helpful in differentiating oxalate toxicity from other processes.

CBC/BIOCHEMISTRY/URINALYSIS

• Oxalate crystals in urine (may not be present in acute cases).
• With chronic toxicity, an azotemia would be consistent with but not diagnostic of oxalate toxicity.

OTHER LABORATORY TESTS

Quantification of oxalate levels in suspect forage

IMAGING

Transabdominal or transrectal ultrasound of the kidneys may demonstrate perirenal edema (especially if pigweed is the plant involved) or cortical hyperechogenicity due to deposition of crystals in tissue.

PATHOLOGIC FINDINGS

• Depends on the severity, chronicity, and plant of oxalate origin.
• Ingestion of *Amaranthus* spp. (pigweed) often leads to perirenal edema in pig and cattle.
• Acute cases may have enlarged edematous, red kidneys, while more chronic cases may have smaller kidneys with histopathologic evidence of renal tubular nephrosis and oxalate crystal formation.
• Rumen wall may be hemorrhagic due to oxalates in the wall.
• Histopathology may demonstrate oxalate crystals in rumen wall.

TREATMENT

THERAPEUTIC APPROACH

• Evaluate rest of the herd for early evidence of disease.

• Consider relocating rest of herd to a new area without plants or try to slowly introduce oxalate-containing forage and maintain intake with additional nontoxic forage to dilute the oxalates.
• Adaptation to oxalate forage should be done by cautiously allowing animals to graze for increasing periods of time over a minimum of 4 days.
• Add supplemental dicalcium phosphate to the diet to bind oxalates in the GI tract in the form of dicalcium phosphate–containing salts of alfalfa pellets.
• Hospitalization and fluid therapy to actively diurese the patient may slow down renal crystaluria and subsequent nephrosis.

MEDICATIONS

DRUGS OF CHOICE
• Hypocalcemic or hypomagnesemic patients should receive a slow IV infusion of 23% calcium gluconate or a commercially available mixture of calcium, magnesium, and glucose.
• IV fluid for diuresis is indicated.

PRECAUTIONS
• Infusion of IV calcium should be done slowly and the heart rate and rhythm monitored. Calcium infusion should be discontinued if any abnormalities are observed.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Severely affected animals often succumb to renal failure if they survive the acute disease process.
• Early treatment of less severely affected cases may be successful.
• Aggressive fluid therapy and diuresis may improve the prognosis in animals with renal involvement.

POSSIBLE COMPLICATIONS
Chronic renal failure

PATIENT CARE
• Cases with renal involvement should have repeated serum chemistries and urinalysis to monitor renal function, evaluate efficacy of diuresis, and determine when fluids can be safely discontinued.
• Electrolytes, PCV, acid-base status, and albumin should be monitored in cases that survive severe renal compromise, as alterations in these values may continue after treatment.

PREVENTION
• If possible, avoid grazing oxalate-containing forages.
• Cautiously and slowly introduce oxalate forages over a period of 4 or more days.
• Increase calcium diphosphate in the diet (this may have an effect on DCAD balance and induce other metabolic syndromes if done long term).

MISCELLANEOUS

PREGNANCY

PARAINFLUENZA-3 VIRUS

BASICS

OVERVIEW
• Parainfluenza-3 (PI-3) is an RNA virus in the Paramyxoviridae family.
• Infection is very common and found in cattle populations worldwide.
• Uncomplicated infections are generally associated with subclinical or mild disease.
• Viral infection can predispose to secondary bacterial infection and bovine respiratory disease complex (BRDC).

INCIDENCE/PREVALENCE
• Infection is considered nearly ubiquitous in cattle populations.
• Seroprevalence in sheep is also widespread; prevalence in goats is likely similar to rates seen in sheep.

GEOGRAPHIC DISTRIBUTION
• The virus is found worldwide.
• Large differences in geographic distribution of the three genotypes has been noted. Genotype A is found worldwide; genotype B is found primarily in Australia; and genotype C has been found primarily in Southeast Asia.
• Recent surveys have found the presence of all three genotypes in American livestock.

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• Virus spread is primarily through large droplet transmission.
• PI-3 is absorbed across the respiratory epithelium.
• Viral infection antagonizes innate immune responses, including interferon production and function of the mucociliary apparatus.
• PI-3 replicates readily in pulmonary alveolar macrophages, resulting in decreased phagocytic activity and bacterial killing.
• Depression of immune responses predisposes to secondary bacterial invasion.

SIGNALMENT
• Infection is considered widespread in all domestic ruminant species; exotic species are also susceptible to PI-3 infection.
• Infection seen most commonly in young animals following the waning of maternal immunity (2–6 months of age).

PHYSICAL EXAMINATION FINDINGS
• Most infections are subclinical with no detectable signs. Seroconversion follows infection.
• Mild fever develops 2–3 days following infection.
• Harsh coughing is often the first observed sign in outbreaks.
• Serous to mucopurulent discharge.
• Uncomplicated infections generally resolve within 7–10 days.

CAUSES AND RISK FACTORS
• Infection results from exposure of susceptible animals to the PI-3 virus.
• Aerosol and direct contact are the means of viral spread.
• Close contact, inadequate ventilation, and stress increase likelihood of spread.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Other mild, uncomplicated viral respiratory infections:
• IBR
• BRSV
• BVDV
• Bovine adenovirus
• Bovine respiratory coronavirus

CBC/BIOCHEMISTRY/URINALYSIS
No specific changes observed.

OTHER LABORATORY TESTS
• Virus isolation
• Serology
• RT-PCR
• Positive results may not indicate the primary cause of disease since infection with PI-3 is very widespread. Testing for other viral respiratory pathogens should be performed concurrently.

OTHER DIAGNOSTIC PROCEDURES
• Nasal or laryngeal swabs are most commonly obtained for viral detection assays. A transtracheal wash could also be performed.
• Lung tissue or airway swabs can be obtained for postmortem testing.

PATHOLOGIC FINDINGS
• Gross lesions may be absent in uncomplicated cases.
• Rhinitis with mucopurulent nasal discharge.
• Atelectasis and consolidation of the anterior-ventral lung lobes.
• Thoracic lymphadenopathy.
• Histologic lesions include acute necrotizing bronchitis and bronchiolitis, infiltration by a mixed population of inflammatory cells, and intracytoplasmic eosinophilic inclusion bodies.

TREATMENT

THERAPEUTIC APPROACH
• Uncomplicated infections are generally mild and self-limiting.
• Treat as undifferentiated bovine respiratory disease.
• Broad-spectrum antibiotics may be warranted to prevent secondary bacterial infection.

MEDICATIONS

DRUGS OF CHOICE
Broad-spectrum antibiotics labeled for the control of BRDC

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Spontaneous recovery following mild course of illness is likely in uncomplicated viral infection.
• Prognosis for bacterial pneumonia depends on the severity of clinical signs and progression of the disease before diagnosis and treatment.

POSSIBLE COMPLICATIONS
PI-3 infection can predispose to secondary bacterial pneumonia (BRDC).

PATIENT CARE
Worsening of clinical signs may indicate BRDC.

PREVENTION
• Vaccination
  ◦ Both killed and modified live (MLV) parenteral vaccines are commercially available. Typically, PI-3 is included with other viral respiratory antigens in a multivalent vaccine.
  ◦ A vaccine for intranasal administration containing temperature-sensitive, MLV strains of PI-3 and IBR is commercially available.
• Nonspecific prevention measures include adequate colostral intake, limiting nose-to-nose contact of housed dairy calves, and providing suitable ventilation for animals housed indoors.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• BRDC may follow PI-3 infection.
• BRSV also belongs to the Paramyxoviridae family but is generally characterized by more severe respiratory disease.

AGE-RELATED FACTORS
• Infection is more common in young (age 2–6 months) animals.
• Maternal immunity is short-lived and disease is often seen shortly after weaning as passive immunity wanes.

ZOONOTIC POTENTIAL
None

BIOSECURITY

Virus is ubiquitous in most ruminant populations. Thus, specific biosecurity measures are often not employed.

PRODUCTION MANAGEMENT

Uncomplicated PI-3 infection is not a significant production concern. However, predisposition to BRDC is noteworthy. PI-3 infection should be addressed as part of the overall program to prevent and control BRDC.

ABBREVIATIONS

- BRDC = bovine respiratory disease complex
- BRSV = bovine respiratory syncytial virus
- BVDV = bovine viral diarrhea virus
- IBR = infectious bovine rhinotracheitis (bovine herpesvirus-1)
- MLV = modified live virus
- PI-3 = parainfluenza-3
- RT-PCR = reverse transcription-polymerase chain reaction

PARASITE CONTROL PROGRAMS: BEEF

BASICS

OVERVIEW

• Parasite control programs are designed to limit clinical as well as subclinical disease within the beef herd. Effective programs incorporate appropriate management strategies to limit exposure along with tailored protocols to properly treat infected animals.
• The majority of internal parasites undergo part of their life cycle on grassland, making cow-calf and pastured stocker cattle at highest risk. Finishing animals and others within a drylot or feedlot system are more likely to perpetuate external parasites due to close proximity.
• Young cattle and immunosuppressed animals (e.g., pregnant) are at higher risk of internal parasitism due to lack of developed/effective immunity.
• Adults generally develop immunity to nematodes and coccidia if exposed over their lifetime; however, highly contaminated pastures and pens may still lead to clinical infection of adults.
• Subclinical losses due to parasitism may be greater than acknowledged and come in the form of decreased milk production leading to decreased average daily gain and weaning weights, delayed puberty, decreased fertility, and in general, reduced feed efficiency.

INCIDENCE/PREVALENCE

Nematode parasitism is common whenever cattle are pastured.

GEOGRAPHIC DISTRIBUTION

Worldwide, with parasitic species varying based on region.

SYSTEMS AFFECTED

• Integument
• Digestive
• Respiratory

SIGNALMENT

• Bovine species.
• Younger cattle are more susceptible to endoparasites, with the exception of liver flukes and *Neospora*.

CAUSES AND RISK FACTORS

• Nematodes infecting cattle include: *Haemonchus, Ostertagia, Trichostrongylus,* and *Nematodirus.* The nematode that has historically caused the greatest pathology and economic loss in cattle is *Ostertagia*; however, the NAHMS survey in 2008 found *Cooperia* spp. as the most prevalent nematode in beef cow-calf operations in the United States. This change is speculated to be due to the widespread use of avermectins, whose efficacy is questionable for *Cooperia* spp.
• The most common protozoa in cattle include *Isospora, Eimeria*, *Cryptosporidium parvum,* and *Neospora caninum*.
• The cattle liver fluke, *Fasciola hepatica,* thrives in wet environments and needs a snail intermediate host to complete the life cycle. Due to these requirements, flukes are regionally specific and at-risk animals can be determined based on herd of origin.
• The cattle lungworm is *Dictyocaulus viviparus*, which is found worldwide.
• Tapeworms affecting cattle most commonly are *Moniezia* spp. Their significance relating to production is not well documented.
• The most important ectoparasites of beef cattle include lice (sucking and biting) and various fly species.

Risk Factors

• Cattle grazing pasture are at risk of nematode infection, with management practices (i.e., stocking rate and pasture length) and climactic factors (i.e., rainfall, temperature, and season) greatly influencing the degree of risk.
• Calves 1–4 weeks of age are at highest risk for cryptosporidiosis.
• Young cattle >1 month of age and in a confinement system are at risk for coccidiosis. Poor sanitation is a major risk factor due to fecal-oral transmission.
• The definitive host for *N. caninum* is the canine and therefore free-roaming dogs defecating on pasture or in feed areas are a major risk factor.
• Liver fluke infestation depends on a wet environment and the presence of the snail intermediate host.
• *Moniezia* spp. require an intermediate host, the oribatid mite, which lives in soil and litter. Pastured animals are at highest risk.
• Lice infestations generally occur in the winter months, in closely confined animals with thick hair coats. Underlying immunosuppressive disease is also a risk factor.
• Flies are closely associated with environmental conditions and poor manure management.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

• Eosinophilia may exist in highly parasitized cattle.
• Anemia may be present with haemonchosis, heavy infestations of sucking lice and liver flukes, or any chronic parasitism (anemia of chronic disease).

OTHER LABORATORY TESTS

• Fecal egg counts are used to diagnose nematode infestation; however, sensitivity and specificity will vary based on technique and season. Hypobiotic larvae may present a large worm burden during very cold or very hot weather, leading to underestimates of the true worm burden.
• Quantitative PCR is available in some areas to discern nematode species present in fecal samples. Eggs can also be speciated by culture and identification.
• Lungworms are diagnosed using the Baermann technique.
• Fecal sedimentation and ELISA serology (*F. hepatica*) can diagnose liver flukes.
• Coccidia can be seen on fecal flotation.
• Cryptosporidia are diagnosed by using acid-fast staining of fecal smears.
• Serology can be used to diagnose cows infected with *Neospora*, but confirmation of abortion requires either necropsy of the fetus or case control studies using serology.
• Lice can be easily identified as either sucking or biting types based on the shape of their head and mouthparts grossly or, more easily, under a microscope. Lice can be sampled directly from the hair coat of the affected animal.

OTHER DIAGNOSTIC PROCEDURES

Necropsy examination is the most definitive method of diagnosing internal parasites in cattle. Histochemistry can be used along with gross examination.

TREATMENT

THERAPEUTIC APPROACH

• Nematodes: Anthelmintic treatment should be targeted around times when worm burden is most significant. Specifically, the late winter/early spring when hypobiotic nematode larvae will start to become active again and grass growth, rainfall, and moderate temperatures will allow for reinfection. At this time, a class of drug effective against arrested larvae should be used, such as the macrocyclic lactones (MLs), which include the avermectins and moxidectin. Treatment is often repeated at the end of the grazing season (i.e., after the first frost of the late autumn/early winter) to "clean" animals and decrease the number of larvae that will overwinter within the GI tract. In warmer climates, larvae are arrested during the hot, dry summer months rather than during the winter.
• Lungworms: Various classes of anthelmintics are effective including MLs, benzomidazoles, and levamisole.
• Liver flukes: Clorsulon and albendazole are effective against adult liver flukes.
• Coccidiosis: Calves with clinical coccidiosis should be treated with sulfamethazine or amprolium. Amprolium is easily dosed in the water and is therefore convenient for large groups of calves.
• Cryptosporidiosis: Supportive care with oral or parenteral fluids and anti-inflammatories as

there is no specific treatment. Quarantine and good hygiene are important to prevent spread.
• Lice: Treatment is usually only necessary during the winter months and only in herds with clinically relevant lice infestation (pruritus and hair loss). MLs are effective against sucking lice (injectable or pour-on). Biting lice may be treated with pour-on MLs but efficacy may be higher with permethrin pour-on or dust treatments. Treatment should be repeated in 2 weeks.

MEDICATIONS

DRUGS OF CHOICE
• The appropriate anthelmintic to use should be primarily based on the parasite(s) being targeted and the season (see "Therapeutic Approach"). Other factors to consider include processing facilities, availability, and withdrawal times. The facilities may impact whether oral, injectable, or pour-on products are feasible. Oral products are less likely to perpetuate resistance whereas more resistance (or treatment failure) has been shown with the use of pour-on products. Pour-on products are generally considered less appropriate for calves since licking-behavior can decrease their efficacy.
• See "Therapeutic Approach."

CONTRAINDICATIONS
Anthelmintic classes showing resistance should not be used on that particular operation.

PRECAUTIONS
• Anthelmintic drugs should be used only as labeled and the labeled withholding periods must be followed for each drug.
• Average truck weights should not be used to determine dosing as this perpetuates underdosing of a percentage of cattle. It is safer to base dosage on the heaviest animal, taking into account the margin of safety for the product being used and the variability in the lot of cattle being processed.
• Amprolium may cause thiamine deficiency.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
Anthelmintic resistance, significant production loss

CLIENT EDUCATION
• Clients should be advised that they must adhere to the parasite control program in order to achieve decreased pasture contamination.
• Education regarding the importance of judicious anthelmintic usage (i.e., storage, selection, dosage, administration) is imperative to avoid worsening of anthelmintic resistance.

PATIENT CARE
• On the herd level, fecal egg count reduction tests should be used to monitor the effectiveness of various anthelmintics on individual operations.
• On the individual level, severely parasitized animals should be dewormed using an anthelmintic known to be effective for the parasite in question. Supportive care includes a good-quality diet, hydration support, iron and vitamin B complex in the face of anemia and malabsorption, and appropriate shelter.

PREVENTION
• Maintain lowest possible stocking rates or employ pasture rotations.
• Good sanitary practices are necessary to prevent coccidia and cryptosporidia as both are transmitted by the fecal-oral route with the reservoir being adult cattle.
• If young stock are being intensively reared, such as drylot cow-calf operations, coccidiostats may be continuously fed to prevent coccidiosis.
• A vaccine is licensed in some countries to control *N. caninum* abortions.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• General unthriftiness, poor performance, diarrhea, immunosuppression.
• Bacillary hemoglobinuria (*Clostridium haemolyticum*) may occur secondary to significant damage from liver fluke migration.

ZOONOTIC POTENTIAL
• *C. parvum* is a serious zoonotic pathogen.

PRODUCTION MANAGEMENT
• Good pasture management is imperative to a holistic parasite management program. The goal is to decrease the larval burden on grazing lands through various practices. These practices include:
  ◦ *Pasture rotation:* Ideal rotation time will vary greatly based on climate.
  ◦ *Mowing/hay making:* Mowing pastures for hay after cattle have been grazing and prior to the next rotation will allow for dessication of parasites.
  ◦ *Pasture selection:* Place most susceptible animals (young stock) on pasture not grazed over winter (in mild climates) due to higher parasite burden on pasture.
• Targeted deworming
  ◦ Deworm animals most at risk (i.e., dairy calves reared in a dry lot entering a feedlot are unlikely to need treatment upon entry, whereas unthrifty, pastured stocker calves from the southeastern US are at high risk).
• All anthelmintic dosing equipment should be well maintained and calibrated to ensure proper doses are being administered. The use of scales to accurately weigh and dose animals is ideal.
• Anthelmintics must be stored properly and expiration dates should be observed as efficacy will decline accordingly.

ABBREVIATIONS
• ELISA = enzyme-linked immunosorbent assay
• MLs = macrocyclic lactones
• NAHMS = National Animal Health Monitoring Survey
• PCR = polymerase chain reaction

PARASITE CONTROL PROGRAMS: CAMELID

BASICS

OVERVIEW

• Camelids have a variety of gastrointestinal parasites, some of which can be transmitted to or from sheep, goats, and cattle.
• The most common GI parasites of camelids include:
  ◦ Nematodes (strongyles: *Haemonchus contortus*, *Ostertagia*, *Trichostrongylus*, and *Nematodirus*)
  ◦ Cestodes (*Moniezia*)
  ◦ Whipworms (*Trichuris*)
  ◦ Protozoa (*Eimeria macusaniensis* [large coccidia], *Eimeria* species [small coccidia], *Giardia*, and *Cryptosporidium*)
  ◦ Trematodes (liver flukes: *Fasciola*, *Fascioloides*, and *Dicrocoelium*)
  ◦ *Parelaphostrongylus tenuis* (meningeal worm) is an important cause of central nervous system disease in camelids, which serve as an aberrant host.
• Overcrowding and poor sanitation must be addressed to overcome parasite infestation and to minimize the potential for re-infection.
• Sound management practices, rather than anthelmintics alone, must be implemented to prevent clinical disease from endoparasites.

INCIDENCE/PREVALENCE

• Endoparasitism is common, especially in young, malnourished, and immunocompromised animals subject to overcrowded conditions which propagate re-infection.
• The incidence/prevalence of infection varies with seasonal/climactic factors, and management practices including anthelmintic administration and other methods of prevention and treatment.

GEOGRAPHIC DISTRIBUTION

• Worldwide, especially in temperate climates.
• Cold weather may allow for a break from infection with parasites that rely on pasture consumption (strongyles and cestodes), but not those primarily spread through environmental contamination (coccidia, whipworms, *Giardia,* and *Cryptosporidium*).
• The geographic distribution of specific parasite species also varies substantially with geographic region, climate, availability of hosts and vectors, and management practices.

SYSTEMS AFFECTED

• Digestive
• Nervous
• Multisystemic

PATHOPHYSIOLOGY

• Strongyle infections
  ◦ Include *Haemonchus contortus*, *Ostertagia*, *Trichostrongylus*
  ◦ These are typically the most common gastrointestinal parasites of camelids and small ruminants on farms.
  ◦ Eggs are passed in the feces and under the right conditions of temperature and moisture they hatch into infective larvae.
  ◦ The infective L3 stage is found primarily in the first two inches of pasture, and camelids are infected during consumption of contaminated pasture.
  ◦ Adults reside in the GI tract for months; eggs passed in feces hatch into larvae under favorable conditions of temperature and humidity.
  ◦ Larvae mature to the infective stage in the feces over at least one week (longer if cooler).
  ◦ Larvae dispersed by rain, traffic, etc. follow moisture films up and down grass blades and are consumed.
  ◦ Larvae die more rapidly in hot and dry conditions.
  ◦ *Haemonchus contortus* ("barber pole worm") is ingested from pasture as infective larvae, then adults reside in the C3 stomach compartment of camelids where blood-sucking behavior creates anemia, weakness, and potentially death.
  ◦ Disease can be severe and may be acute with onset in the warmer months and warmer climates since warm, humid weather favors development.
  ◦ *H. contortus* has a short life cycle of approximately 3 weeks from infection to egg-laying adults; adult females are prolific egg producers, releasing up to 5,000 eggs per day; 200 females release up to 1 million eggs per day.
  ◦ Mild winters extend transmission season.
  ◦ Other nematodes can contribute to disease and can cause diarrhea, including *Ostertagia* (brown stomach worm in C3); *Trichostrongylus* (C3 and small intestine); and *Nematodirus* (*N. battus* is considered particularly pathogenic and resides in the small intestine).
• *Trichuris* (whipworm)
  ◦ Life cycle is slightly different than other common GI nematodes; eggs are passed in feces, and infective larvae form inside the egg which is ingested by grazing camelids.
  ◦ Adult parasites reside in the large intestine and can cause diarrhea, severe anemia, and even colonic perforation.
• Tapeworm infection
  ◦ Primarily *Moniezia* species; infection occurs by consuming the intermediate hosts (orbatid mites) from pasture, and adult tapeworms subsequently reside in the small intestine.
  ◦ Not usually an important clinical problem; occasionally cause diarrhea and visible tapeworm segments on the manure pile.
  ◦ Infection occurs sporadically in specific locations, even on the same farm and usually in individual animals.
• Small coccidia (*Eimeria* species)
  ◦ Problematic under conditions of overcrowding, contamination, and re-infestation.
  ◦ Species-specific, with no cross-infection between sheep, goats, camelid, and bovine coccidia.
  ◦ Infective oocysts are consumed on pasture or in other feces-contaminated feed, with a pre-patent period of ~10 days.
  ◦ Usually infection is not a significant clinical problem in adults, and treatment is not required if asymptomatic.
  ◦ Young animals (usually <8 months old) can have diarrhea (occasionally bloody) and poor weight gain.
• *Eimeria macusaniensis (E. mac)*
  ◦ Can be very pathogenic, but oocysts are also commonly identified in animals with no clinical signs.
  ◦ Pre-patent period is approximately 32 days after ingestion of sporulated oocysts from pasture or other feces-contaminated feed.
  ◦ Endogenous development of the parasite in the small intestine of infected hosts gives rise to clinical signs of intestinal damage and the shedding of unsporulated oocysts in the feces.
  ◦ Clinical signs are most likely in compromised adults, or young animals; consisting of transient diarrhea, poor appetite, weakness, and rarely neurologic signs, accompanied by low blood protein (hypoalbuminemia) disproportionate to mild anemia.
  ◦ Severe thickening of the distal small intestine can occur in some cases.
• *Cryptosporidium* and *Giardia*
  ◦ Protozoan parasites spread via the fecal-oral route in feed and in water, as well as by fomites.
  ◦ Diarrhea is the main clinical sign, generated by disruption to the intestinal lining, particularly in the small intestine.
  ◦ Young animals are especially vulnerable to morbidity and mortality (especially crias <14 days old), as are immunocompromised adults which may present with ill thrift and not diarrhea.
  ◦ These are highly infectious pathogens among in-contact animal species, including humans.
• Liver flukes
  ◦ Primarily *Fasciola hepatica* in the high Andes, Pacific Northwest, northern Midwest, and Louisiana delta region of the US.
  ◦ Sporadic appearance of *Fasciola gigantica* and *Fascioloides magna* in US and South America.
  ◦ *Dicrocoelium dendriticum* in central Europe and northeastern US.
  ◦ Intermediate hosts are aquatic snails for larger flukes, and ants and terrestrial snails for *Dicrocelium.*
  ◦ Cattle, deer, and sheep are definitive hosts.
  ◦ Camelids are infected by ingesting larvae from pasture, which penetrate the duodenum and migrate to the liver, maturing in bile ducts.

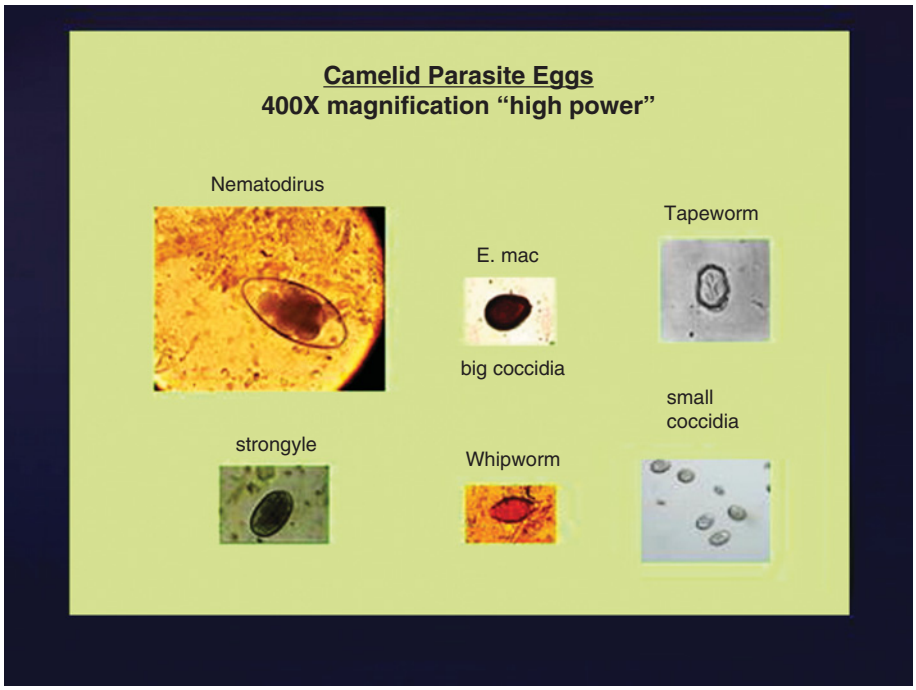

Figure 1.

Ova and oocysts of Common Gastrointestinal Parasites of Camelids

- Liver damage occurs during migration and due to inflammation of the biliary tract; secondary bacterial hepatitis is also possible.
- *Parelaphostrongylus tenuis* (meningeal worm)
  - Camelids are exposed in regions where the definitive host, the white-tailed deer, exists (eastern US).
  - Camelids are infected by ingesting vegetation contaminated by infective L3 larvae in the slime trail from intermediate slug and snail hosts.
  - L3 migrates from the stomach to the spinal cord and brain of infected camelids, causing inflammation, damage, and neurologic signs.

HISTORICAL FINDINGS

- Relate to clinical signs associated with GI disease (poor growth, weight loss, diarrhea, anemia) or in the case of *P. tenuis*, onset of signs suggesting central nervous dysfunction.
- Historical findings might also reveal inadequate management or treatment practices relevant to parasite control.

SIGNALMENT

- Alpacas, llamas, vicunas, and guanacos
- No breed or sex predilection
- GI parasites primarily affect animals <2 years of age, although heavy environmental contamination can lead to older animals displaying clinical disease.

PHYSICAL EXAMINATION FINDINGS

- Thin body condition, evidence of diarrhea, pale mucus membranes, tachycardia, tachypnea, submandibular edema, and dehydration depending on the severity and GI parasite involved.
- Meningeal worm disease can result in lameness, incoordination, weakness, inability to rise, circling or drifting gait, head tilt, depression, and/or blindness. Signs are often asymmetric.

GENETICS

- There is evidence that susceptibility to severe parasitism is related to certain blood lines, likely related to functional immunity.
- It is recommended that mature animals with repeated clinical disease not be used in breeding.

CAUSES AND RISK FACTORS

- Environmental exposure from eating contaminated feed and grazing on infected pastures.
- Malnutrition, overcrowding, and immunosuppression predispose.
- Short pasture lengths (overgrazing).
- Exposure to definitive and intermediate hosts of relevant parasites (white-tailed deer, gastropods).
- Warm and humid climates.
- Access to natural water sources.
- Physiologic status (young or old age, pregnancy, lactation).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- Bacterial or viral enteritis
- Hepatic lipidosis (liver flukes)
- Neoplasia
- Trauma, encephalitis, meningitis (recumbent animals)

CBC/BIOCHEMISTRY/URINALYSIS

- No specific findings: inflammation, anemia, and hypoalbuminemia possible.
- Anemia can be profound in severe *H. contortus* infections (PCV <10%).
- Anemia, hypoproteinemia, and elevated liver enzymes can occur with liver flukes.

OTHER LABORATORY TESTS

Serum ELISA exists for early liver fluke infection before patency.

IMAGING

Not typically utilized; however, ultrasonographic examination can reveal ascites, abnormalities of the liver (flukes), or thickening of small intestine (*E. mac*) in severe infestations.

OTHER DIAGNOSTIC PROCEDURES

- Fecal testing for visual identification of ova, oocysts, and protozoa (see Figure 1) can include Modified Wisconsin test with concentrated sugar solution (SG 1.33); McMasters Slide using concentrated sugar solution; fecal sample centrifugation in water then examine sediment; or Flukefinder® for fluke eggs (also for *Giardia*).
- Individual animals with weight loss, poor body condition, poor growth rate, or diarrhea

PARASITE CONTROL PROGRAMS: CAMELID (CONTINUED)

can be tested, or herd test 25% of animals in each housing group.
• Strongyle eggs are not readily differentiated, hence nematode larval cultures can be used for identification of genus and species to differentiate *Haemonchus* from other trichostrongyles.
• Fluorescein-labeled peanut agglutinin assay can differentiate *Haemonchus* ova from those of other trichostrongyles.
• Immunologic fecal testing for *Cryptosporidium* and *Giardia* (ImmunoCard STAT!® enzyme immunoassay® from Meridian Bioscience, Inc.) or examination of fecal smears.
• Fecal egg count reduction test is used to determine anthelmintic resistance; compare quantitative fecal ova results before and 10–14 days after treatment; count should decrease by 90–95% or drug resistance is present and alternative therapy should be selected.
• FAMACHA-Scoring: Ocular mucosa is compared to a color chart to estimate anemia and the need for active treatment in suspected *Haemonchus* infestation.
• Cerebrospinal fluid can be obtained to evaluate *P. tenuis* infection (eosinophilic pleocytosis).
• Nested PCR assay described for *E. mac* infection.

PATHOLOGIC FINDINGS
Consistent with anemia, cachexia, hypoproteinemia, diarrhea, hepatic fluke migration, or aberrant CNS larval migration depending on the parasite species in question.

TREATMENT

THERAPEUTIC APPROACH
• Successful control of parasitism requires the use of multiple management strategies versus sole reliance on periodic medication with anthelmintics.
• Pasture rotation minimizes exposure to infective parasite stages and avoids re-infection; it can include interspecies grazing with horses.
• Medical treatment should be provided judiciously, to animals with clinical disease, and on the basis of fecal testing to identify at-risk groups.
• Drug resistance is a major concern for GI parasites and describes a change in the gene frequency of a population that is produced by drug selection, whereby more drug is required to exert its effect than was required prior to selection. Drugs lose efficacy because of selection pressure for parasites that have some means of resisting that drug's effects.
• Management practices which hasten development of drug resistance and which should be avoided include:
  ◦ Frequent drug treatments.
  ◦ Treating all animals at once.
  ◦ Underdosing animals.
  ◦ Treating and moving to clean pastures.
  ◦ Treating when there are not many worms on pasture (drought, end of winter).
  ◦ Buying resistant worms within animals.
• All of the above decrease the refugia, which are important to maintain.
  ◦ Refugia = the proportion of the worm population that is not selected by drug treatment and are therefore in "refuge" from drugs.
  ◦ Provides pool of sensitive genes for cross-breeding with other parasites.
  ◦ Dilutes resistant genes.
  ◦ Considered the most important factor in preventing the development of drug resistance.
• Treatment should also be based on the nature of identified parasites; those that are minimally pathogenic, such as tapeworms and small coccidia, do not necessitate treatment.
• Serial fecal examinations may be indicated to detect infection with parasites with long pre-patent periods (*E. mac*) or intermittent shedding (*Trichuris*), and treatment can be appropriate in the face of clinical signs even with a negative fecal result if these parasites are suspected to be causing disease.
• Ideally focus on emphasizing cleanliness in the herd to prevent re-infection; monitor individuals for fecal abnormalities, growth rate, and body condition; and analyze periodic fecal samples to determine which animals might require treatment and to evaluate the effectiveness of the control program.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• See Table 1, best applied for treatment rather than prevention.
• Nematodes can respond to benzimidazoles (albendazole, fenbendazole [strongyles and whipworms], mebendazole, and thiabendazole); macrocyclic lactones (ivermectin, moxidectin, and doramectin); tetrahydropyramidine (pyrantel pamoate); imidazothiazole (levamisole); and quinolones. Aminoacetonitrile anthelmintics (monepantel) represent a new class of drug available in some countries but not the US (used in Australia and New Zealand at 7.5 mg/kg PO against *Haemonchus*).
• Cestodes—praziquantel and pyrantel pamoate
• Liver flukes—benzenesulfonamide (clorsulon) and albendazole. Limited efficacy since damage is most profound during migration of immature fluke stages unaffected by these drugs. Triclabendazole (10–15 mg/kg PO) can be used in some countries outside of the US and has efficacy against migrating flukes.
• *Giardia*—fenbendazole.
• *Cryptosporidium*—no efficacious drugs available, supportive treatment often required while management steps are taken (feces removal) to avoid autoinfection or re-infection.
• *P. tenuis*—early, aggressive treatment maximizes success and can include ivermectin (on days 1, 3, and 5 @ 4 mL/100 lb body weight, SC) plus fenbendazole (5 days at 10–50 mg/kg, PO), dimethylsulfoxide (DMSO) solution (diluted with 3 parts water, on days 1, 3, and 5 at 0.5 mL DMSO per lb body weight, PO) and flunixin meglumine (5 days at 1 mL/100 lb, IM or IV).

CONTRAINDICATIONS
• Albendazole has caused abortion in pregnant camelids and severe neutropenia in overdosed crias.
• Macrocyclic lactones are considered environmental contaminants—the effect of composting on drugs is under investigation.

PRECAUTIONS
Polioencephalomalacia can develop in camelids treated with amprolium; therefore treatment with thiamine (10 mg/kg SC) may be provided at the beginning and/or end of treatment.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Animals should respond to management changes and/or treatment unless repeated or continuous exposure to parasite infection occurs.
• Neurologic signs are expected to improve within 5 days of treatment of *P. tenuis* infestation.

POSSIBLE COMPLICATIONS
• Severe infestations can result in farm quarantine, especially for *Cryptosporidium.*
• Death/euthanasia from liver failure (flukes), severe anemia (*H. contortus*), severe GI disease (nematodes, protozoa), or severe neurologic deficits (*P. tenuis*).

CLIENT EDUCATION
Focus on encouraging periodic fecal analyses and herd health assessments, pasture management, animal selection, and judicious use of anthelmintic medications.

PATIENT CARE
• Evaluate improvement in clinical signs ± fecal ova/oocyst scores after treatment.
• Repeat fecal examinations periodically.
• Monitor body condition score.
• Monitor FAMACHA score when *H. contortus* is a concern.

(CONTINUED) PARASITE CONTROL PROGRAMS: CAMELID

Table 1

Anthelmintics and Coccidiostats used in Llamas and Alpacas

Drug	*Dose/Route*	*Spectrum of Activity*
Ivermectin	0.2 – 0.6 mg/kg SC	Nematodes
Moxidectin	Not advised unless resistant nematodes are documented, then 0.2–0.4 mg/kg PO	Nematodes
Doramectin	0.2 mg/kg SC	Nematodes
Albendazole	10 mg/kg PO (may result in abortion)	*Fasciola hepatica*, *Moniezia*, nematodes
Fenbendazole	10–20 mg/kg PO (high dose for 3 days for *Trichuris*)	Nematodes, whipworms, *Giardia*
	20 mg/kg PO, 5 days	*Nematodirus*
	50 mg/kg PO, 5 days	*Moniezia* and *P. tenuis* (clinical)
Mebendazole	22 mg/kg PO, 3 days	Nematodes
Pyrantel pamoate	8.5 mg/kg PO	Nematodes
	18 mg/kg PO, 3 days	Cestodes
Levamisole	5–8 mg/kg PO or 6 mg/kg SC (not in lactating animals)	Nematodes
Clorsulon	7 mg/kg PO	*Fasciola hepatica*
Praziquantel	50 mg/kg PO	*Dicrocoelium dendriticum*
	2.5–10 mg/kg	Cestodes
Ponazuril	20 mg/kg PO	*E. macusaniensis*
Amprolium	10 mg/kg PO for 5–10 days	Small coccidia (5 days) and *E. mac* (10 days)

PREVENTION

• Avoid overcrowding and exposure of resident herd to new animals.
• Quarantine new herd additions and check their feces after 4–6 days; treat as needed before moving into the resident herd.
• Keep pastures from being overgrazed to decrease infection rate.
• Fence off natural water sources.
• In geographic regions with *P. tenuis*, prevention often involves the administration of injectable ivermectin monthly during snail and slug season (April to January in the northeastern US), which can contribute to anthelmintic resistance and can be detrimental to beneficial soil arthropods and nematodes.
• Deerproof fences, fowl, and gravel paths around camelid enclosures will limit exposure to *P. tenuis.*

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Infectious necrotic hepatitis (*Clostridium novyi*) can occur with liver flukes.
• Rhabdomyolysis and heat stress may occur in animals recumbent with severe cachexia or *P. tenuis* infection.
• Renal failure can result from severe diarrhea and dehydration.
• Hepatic lipidosis can arise due to systemic compromise and anorexia.

AGE-RELATED FACTORS

Young animals and immunocompromised adults are the most susceptible to infection and clinical disease.

ZOONOTIC POTENTIAL

Cryptosporidium and *Giardia* have high potential for zoonotic transmission to animal caretakers or children via fecal-oral contamination.

PREGNANCY

Severe infestations can result in abortion due to metabolic stress, anemia, and cachexia, or inappropriate albendazole administration.

BIOSECURITY

• Avoid infection and spread from outside animals introduced into the resident herd.
• Protective clothing for animal caretakers avoids infection with *Cryptosporidium* and *Giardia.*

PRODUCTION MANAGEMENT

• Avoid overcrowding and check body condition score of all animals periodically.
• Examine manure piles for abnormalities of fecal consistency or presence of tapeworm segments.
• Manure should be removed twice daily to limit pasture contamination.
• Limit exposure of camelids to swamps, ponds, streams and other areas frequented by snail and slug intermediate hosts to reduce exposure to infective larvae of *P. tenuis*.

SYNONYMS

N/A

ABBREVIATIONS

• ELISA = enzyme-linked immunosorbent assay

P

PARASITE CONTROL PROGRAMS: DAIRY

BASICS

OVERVIEW

• Parasite control programs on dairy farms are aimed at decreasing clinical and subclinical disease. This is achieved by decreasing the exposure to parasites and by strategic treatment of exposed or infested animals.
• Because most internal parasites of cattle require pasture or grasslands in their life cycles, cattle in drylot or confinement dairies are at small or no risk for disease from the nematode parasites.
• Dairy cattle or replacements that are pastured are at risk and parasite control programs should be considered.
• Young cattle are at risk of coccidiosis from oral-fecal contamination when they are raised in groups. Young cattle and cattle in their first year on pasture require parasite control.
• Adult cattle tend to develop immunity to nematodes and coccidia with exposure and may not benefit from anthelmintic treatment. Cattle on highly infected pastures will benefit from treatment.

INCIDENCE/PREVALENCE

• Nematode parasitism is common whenever cattle are pastured. Confined cattle are not at risk of nematode parasitism owing to the life cycle of the parasites.
• The reservoirs for coccidiosis and cryptosporidiosis are primarily the calves in a population, although older cattle can be a source of coccidia and cryptosporidia on a farm.
• *Neospora* is very common in dairy cattle in North America.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Digestive,
• Respiratory
• Multisystemic

PATHOPHYSIOLOGY

N/A

SIGNALMENT

• Bovine species.
• Because cattle develop immunity to most parasites with exposure, younger cattle are most susceptible. Exceptions are liver flukes and *Neospora*.
• Mean age and range of clinical disease and infection for cryptosporidia is from 5 days to 3 months and for coccidia from 21 days to 12 months.

GENETICS

N/A

CAUSES AND RISK FACTORS

• The nematode that causes the greatest pathology and economic loss in cattle is *Ostergia.*
• Other nematodes that infect cattle include *Cooperia, Haemonchus, Trichostrongylus,* and *Nematodirus*. Lungworms (*Dictyocaulus*) also parasitize cattle.
• Protozoal parasitism in dairy cattle includes coccidiosis from *Isospora* and *Eimeria*, cryptosporidiosis from *C. parvum* and sometimes *C. muris*, and neosporosis from *Neospora caninum*.
• Coccidiosis is mainly a disease of young confined animals and risk increases with poor sanitation, especially in the feed area, because the route of transmission is fecal-oral.
• Cryptosporidia have a short prepatent period (5 days), a low infectious dose, and often infect young calves.
• *Neospora* infection in dairy cattle is common and the main route of transmission is vertical from dam to calf. Cattle are a secondary host for the parasite and are infected for life. *Neospora* can be a cause of second trimester abortions.

Risk Factors

• Cattle grazing on pasture.
• Young cattle are at risk for coccidiosis and cryptosporidiosis.
• Neosporosis has been associated with canine species interactions (the definitive host) but actual initial infection in a cow or herd has not been documented. Once infected, cattle remain infected and tachyzoites cross the placenta and infect the fetus (vertical transmission).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

Parasitized cattle may have eosinophilia.

OTHER LABORATORY TESTS

• Fecal egg counts can be used to detect nematode parasitism, but the technique is not specific or sensitive for disease.
• Fecal sedimentation can diagnose liver flukes.
• Coccidia can be visualized on fecal flotation.
• Cryptosporidia can be diagnosed by using acid-fast stains on fecal smears.
• Serology can be used to diagnose cows infected with *Neospora*, but confirmation of abortion requires either necropsy of the fetus with detection of *Neospora* lesions associated with mortality or case control studies using serology.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Necropsy examination with histochemistry is the most sensitive and specific way to diagnose parasitism in cattle.

TREATMENT

THERAPEUTIC APPROACH

• Nematode and lungworm parasite control programs based on avermectins or moxidectin should be used when dairy cattle are grazing.
• A common program is to treat cattle twice early in the grazing season, approximately 6–8 weeks apart. Another approach is to treat at the beginning of the pasture season and again at the end. Heavily infested pastures may require treating every 3 weeks with non-ivermectin drugs or every 5 weeks with ivermectin. Fecal egg counts can be used to monitor the program and estimate the level of infestation of the pasture.
• Coccidiosis: Calves with clinical coccidiosis should be treated with sulfamethazine (110 mg/kg for 5 days).
• Cryptosporidiosis: There are no documented effective drugs available for prevention or treatment of cryptosporidiosis in cattle in the United States. In many countries, Halocur® (Halofuginone lactate) is labeled for treatment and prevention of Cryptosporidiosis in calves.

SURGICAL CONSIDERATIONS AND TECHNIQUES

N/A

MEDICATIONS

DRUGS OF CHOICE

• The appropriate anthelmintic to use should be primarily based on the primary parasite being targeted and the season (whether hypobiotic stages of larvae must be targeted). Other factors to consider include available processing facilities and withdrawal times. The facilities may impact whether oral, injectable, or pour-on products are feasible. Oral products are less likely to perpetuate resistance. Pour-on products are generally considered less appropriate for calves since licking behavior can decrease their efficacy.
• Numerous products with zero milk withdrawal time are available in the US (eprinomectin, fenbendazole, morantel, moxidectin). Ivermectin is not approved for dairy cattle of breeding age in the US. Product approval and withdrawal times will vary by country.

CONTRAINDICATIONS

• Anthelmintics should not be administered on dairy operations in which resistance has been shown.

PRECAUTIONS

• Anthelmintic drugs should be used only as labeled and the labeled withholding periods must be followed for each drug.

• Overestimation of weight is preferable to underestimation since underdosing anthelmintics perpetuates resistance.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
Animals should not be treated with avermectin drugs when the larval migration of *Hypoderma* spp. is near CNS tissue. See chapter, Parasitic Skin Diseases: Bovine, for information regarding *Hypoderma* infestation.

CLIENT EDUCATION
Clients should be advised that they must adhere to the parasite control program in order to achieve decreased parasite loads in the pastures.

PATIENT CARE
Fecal egg counts and reductions can be used to monitor parasitism in cattle and the effectiveness of the program.

PREVENTION
• Contagious disease control procedures such as improved sanitation and strict adherence to working only from young to old animals during feeding and treatment should be employed in calf housing systems.
• Do not overcrowd pastures.
• Coccidia and cryptosporidia require fecal-oral contamination for transmission and sanitation is the primary management factor associated with disease from either organism. The reservoir for all of the parasites is older cattle.
• The coccidiostats lasalocid or monensin (1 mg/kg continuously) in the feed in group housing prevents clinical disease. Breakthroughs do occasionally occur due to improper mixing at the feed mill, inadequate intakes, etc. Individually housed calves and adult cattle do not require coccidiostats due to low exposure and increased immunity, respectively.
• A vaccine is licensed in the US to control abortions from *Neospora*.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Anemia, weakness, decreased growth, diarrhea, decreased immune response.

ZOONOTIC POTENTIAL
Cryptosporidia are a serious zoonotic pathogen.

ABBREVIATIONS
• CNS= central nervous system

PARASITE CONTROL PROGRAMS: SMALL RUMINANT

BASICS

OVERVIEW

• In most of North America, *Haemonchus contortus* is the most important nematode pathogen of small ruminants and *Trichostrongylus colubriformis* is the next most common. *Teladorsagia* (*Ostertagia*) *circumcincta* is an important pathogen in cool climates. Other species such as *Trichostrongylus axei, Cooperia* spp., *Oesophagostomum, Trichuris ovis*, *Strongyloides papillosus, Nematodirus* spp., *Coccidia* spp. and *Bunostomum* are less common and by themselves, or in small loads, usually do not cause important levels of disease. *Parelaphostrongylus tenuis* and *Dictyocaulus filaria* are less common. The proportions of each of these nematodes in small ruminant populations vary according to geographic location.
• The number of approved drugs available for use in the treatment of parasites in small ruminants is severely limited.
• Extra-label anthelmintic drug use is a standard practice in small ruminants, but this is an exclusive privilege of the veterinary profession and is only permitted when a bona fide veterinarian-client-patient relationship exists and an appropriate medical diagnosis has been made.
• Anthelmintic resistance is extremely prevalent in gastrointestinal nematodes (GIN) of small ruminants and camelids and must be calculated into all treatment decisions.
• Multiple-drug-resistant parasites are becoming quite prevalent; now and in the future, anthelmintics must be thought of as extremely valuable and limited resources that must be preserved.
• Anthelmintic therapy needs to follow "smart drenching" principles and a medically based selective approach to treatment should be implemented wherever possible.
• Goats metabolize drugs more rapidly than do other ruminants and therefore should receive a dose one and a half to two times greater than is required for sheep and cattle.

GEOGRAPHIC DISTRIBUTION

Climate will greatly affect parasite load and seasonality and therefore programs must be adjusted accordingly.

SYSTEMS AFFECTED

• Digestive
• Respiratory
• Nervous

HISTORICAL FINDINGS

Dependent on parasite species. See "Physical Examination Findings."

SIGNALMENT

• Ruminants and pseudo-ruminants of all ages.
• Young, recently weaned and periparturient animals are at greatest risk for severe diseases.

PHYSICAL EXAMINATION FINDINGS

• Gastrointestinal nematodes
  ◦ Anemia, hypoproteinemia (more common with *Haemonchus contortus* infestation), weakness, weight loss, poor hair coat, diarrhea, death
• Meningeal worm: *Parelaphostrongylus tenuis*
  ◦ Hind leg paresis or paralysis extending to forelimbs, poor anal tone, poor tail tone, alertness, anuria or inability to defecate
• Lungworm: *Dictyocaulus filaria*
  ◦ Moderate to severe coughing, tachypnea, respiratory distress, neck extension, drooling saliva, weight loss

CAUSES AND RISK FACTORS

• Young, recently weaned animals are more susceptible
• Overstocking of pasture
• Poor nutrition
• Periparturient immune suppression
• Drug-resistant parasites
• Over-administration of anthelmintic
• Poor pasture management

DIAGNOSIS

• Clinical examination of the animal affected and recognition of signs of parasitosis.
• Parasite egg identification with fecal flotation-sedimentation and fecal egg count or PCR.
• *Note*: Several methods of fecal flotation exist with sensitivity varying for different parasite species based on method.

PATHOLOGIC FINDINGS

Postmortem visualization of the parasite in the abomasum, small intestine, trachea, spinal cord indicates the causative agent.

TREATMENT

THERAPEUTIC APPROACH

• See Table 1.
• Administration of single anthelmintic class, oral or injectable. Multiple classes of anthelmintics may be used together to increase efficacy (see "Production Management").
• Increasing the dosing frequency at 12 hours apart when using short-acting anthelmintics (fenbendazole).
• Restricting feed intake for 24 hours before treatment slows ingesta flow, increases drug availability and efficacy, and may increase efficacy of benzimidazoles. Ivermectin or levamisole are not affected by fasting.

MEDICATIONS

DRUGS OF CHOICE

CONTRAINDICATIONS

• Most anthelmintics used in small ruminants are administered in an extra-label fashion; therefore appropriate withdrawal times will not be listed on the product label, and it is the responsibility of the veterinarian to ensure that appropriate meat and milk withdrawal times are known by the client. When in doubt, contact the Food Animal Residue Avoidance Databank (FARAD).

PRECAUTIONS

• Appropriate meat and milk withdrawal times must be followed for all anthelmintics administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

N/A

POSSIBLE COMPLICATIONS

If the herd shows signs of parasite resistance, perform a herd investigation to test efficacy of drugs:
• *Fecal egg count reduction test:* Using the modified McMaster technique to determine pre- and post-anthelmintic treatment fecal egg counts. Reduction of 95% in parasite load after deworming is considered optimal.
• *Egg hatch assays larval development tests:* Eggs from feces are incubated with concentrations of the anthelmintic to be tested, and the eggs are allowed to hatch.
• If resistance is noted, consider change in anthelmintic class.
• It is advisable to use the same anthelmintic until the drug is no longer effective. Alternating anthelmintic is not advisable and may cause resistance to multiple drug classes.
• Please refer to chapter, Anthelmintic Resistance, for more information.

CLIENT EDUCATION

Educating small ruminant owners on proper management and anthelmintic usage is extremely important. Most anthelmintics are available over-the-counter and without veterinary advice their inappropriate use will lead to poor efficacy and perpetuate resistance. Ensure that goat owners know about increasing the dose to one and a half to two times the labeled dose when using oral anthelmintics in goats.

PREVENTION

See "Production Management"

(CONTINUED) PARASITE CONTROL PROGRAMS: SMALL RUMINANT

Table 1

Commonly Used Anthelmintics and Coccidiostatic/Coccidiocidal Drugs in Sheep and Goats

		Approved						
Drug	*Class*	*Sheep*	*Goats*	*Dosage (mg/kg)*	*How Supplied*	*Prevalence of Resistance*[a]	*Meat WDT*	*Milk WDT for Goats*
Ivermectin	AM	Yes	No	Sheep: 0.2 Goats: 0.4	Sheep: oral drench	High	Sheep: 11 days Goats: 14 days	Not approved 8 days
Remarks: Injectable formulation not recommended								
Doramectin	AM	No	No	Sheep: 0.2 Goats: 0.4	Injectable	High	ND	NE
Remarks: Not recommended because residual activity promotes resistance								
Moxidectin	AM	Yes	No	Sheep: 0.2 Goats: 0.4	Cattle Pour-on	Moderate	Sheep: 14 days Goats: 23 days	NE
Remarks: Only use pour-on product orally. Use sparingly to preserve efficacy. Kills avermectin-resistant *Haemonchus*, but when used in this fashion, resistance to moxidectin may develop rapidly.								
Levamisole	I/T	Yes	No	Sheep: 8.0 Goats: 12.0	Soluble drench powder	Low	Sheep: 3 days Goats: ND	NE
Remarks: Toxic side effects = salivation, restlessness, muscle fasciculations. Recommend weighing goats before treatment.								
Morantel	TETR	No	Yes	10	Feed premix	Moderate to high	30 days	0 days
Remarks: Approved for use in lactating goats								
Fenbendazole	BZ	No[b]	Yes	Sheep:5.0 Goats: 10.0[c]	Paste Suspension feed block, mineral pellets	High	Goats: 6 days[d] (suspension only)	Not approved 0 days[d]
Albendazole	BZ	Yes	No	Sheep: 7.5 Goats: 15–20	Paste Suspension	High	Sheep: 7 days Goats: 7 days	Not approved
Remarks: Do not use within 30 days of conception.								
Lasalocid	ION	Yes	No	Sheep 20–30 g/ton feed 15–70 mg/head/day	Powder feed additive	Moderate	Sheep: 0 days Goats: not approved	Not approved
Monensin	ION	No	Yes	20 gr/ton feed	Powder feed additive	Moderate	Sheep: not approved Goats: 0 days	Not required
Remarks: Monensin can be toxic to equine and dogs								
Decoquinate	QUI	Yes	Yes	13.6 gr/ton feed	Powder feed additive	Moderate	Sheep: 0 days	NE
Amprolium	THIA	No	No	10–50 or 4 oz/ 50 gal. of water-	Suspension	Moderate	1 day	NE
Remarks: Thiamine supplementation may be necessary during treatment with amprolium.								
Sulfadimethoxine	SULF	No	No	55 loading dose- 27.5 subsequent days	Suspension	Moderate	21 days	NE
Toltrazuril	ST	No	No	20–25	Suspension Paste	Moderate	Not approved	Not approved
Remarks: Coccidiostats and coccidiocidals used for control of coccidiosis in lambs and kids								

Note: AM = avermectin/milbemycin; BZ = benzimidazole; I/T = imidazothiazole TETR = tetrahydropyrimidine; ION = ionophore; QUI = quinolones; THIA = thiamine analogs; SULF = sulfonamide antibiotics; ST = symmetrical thiazinetrione; WDT = withdrawal time, consult with FARAD for WDTs in small ruminants; NE = milk WDT has not been established in goats; product should not be used in lactating dairy goats; ND = meat withdrawal time has not been established in goats. To be safe, it is probably best to double sheep WDT.

[a]In the southern United States. Prevalence of resistance has not been established elsewhere.

[b]Approved in big-horned sheep and wildlife.

[c]Label dose is 5.0 mg/kg but 10–15 mg/kg is recommended.

[d]Listed WDTs are for the 5 mg/kg dose. If used at the 10 mg/kg level, these WDTs should be extended.

P

PARASITE CONTROL PROGRAMS: SMALL RUMINANT (CONTINUED)

MISCELLANEOUS

AGE-RELATED FACTORS

Young, recently weaned, and periparturient animals are at the greatest risk for severe disease.

PREGNANCY

Periparturient ewes and does from approximately 2 weeks before to 8 weeks after parturition have a clinically significant suppression in immunity to GI nematodes.

BIOSECURITY

See "Production Management"

PRODUCTION MANAGEMENT

Smart Drenching

Smart drenching is an approach whereby we use the current state of knowledge regarding host physiology, anthelmintic pharmacokinetics, parasite biology, dynamics of the genetic selection process for resistance, and the resistance status of worms on the farm to develop strategies that maximize the effectiveness of treatments while also decreasing selection for drug resistance. A smart drenching approach requires that a medically based program be used for parasite control, rather than adherence to some calendar-based recipe. The following are the components to a smart drenching program.

Famacha—Selective Rather Than Whole-Herd Treatment

• Famacha is a color-based chart that evaluates sheep ocular mucus membrane color for the detection of anemia. It can be used only where *Haemonchus contortus* is the primary parasite. This approach should only be applied to adult animals.
• For pregnant ewes, lambs, and kids fecal egg count and PCV/TP is more reliable. Lambs and kids have comparatively small blood volume and anemia can progress rapidly from moderate to severe. Ewes and does can have periparturient rise in gastrointestinal nematodes.

Know the Resistance Status of the Worms Infecting the Herd

• With the prevalence of resistance so high, it is critical that anthelmintic efficacy be determined on each farm and be monitored every 2–3 years.
• There are two methods for determining resistance on a farm: (1) perform an on-farm fecal egg count (FEC) reduction test; (2) send in a fecal sample to a laboratory offering the DrenchRite larval development assay.

"In Refugia" Population: Keep Some Animals Untreated

In refugia refers to the subpopulation of parasites that has not been exposed to anthelmintics. Maintaining a percentage of animals untreated on farm secures presence of susceptible parasites, which helps dilute the frequency of resistant genes in the parasite pool on farm. Selection of animals that can be excluded from treatment can be based on fecal egg count results, Famacha score and clinical examination. It is advisable to avoid treating animals with low fecal egg counts, high Famacha scores, with no clinical signs of diarrhea and weight loss. The larger the in refugia population the slower resistance to anthelmintics is formed.

Keep Resistant Worms Off the Farm

• Anthelmintic-resistant worms can come from only two sources: either they are home-grown by selection with drug treatment or they are purchased.
• All new additions to the herd or flock should be quarantined in a dry lot (without any grass) or on concrete and aggressively dewormed upon arrival.
• Recommended protocol: withhold feed for 24 hours (free choice water), and then deworm sequentially with moxidectin, levamisole, and albendazole at recommended individual-drug dosage. 14 days after the last treatment, FEC should be performed and the animal should be allowed to enter the herd only if the fecal test is negative. Simultaneous treatment with different drug families is recommended only for quarantined animals.
• After receiving this treatment, animals should be placed on a contaminated pasture. Never should an animal be placed onto a clean pasture after a triple anthelmintic class treatment regimen is administered, because any surviving worms will be triple resistant and there will be no "in refugia" on pasture to dilute the future transmission of any eggs that are shed.

Vaccination

Successful vaccines have been developed for lungworms in cattle and tapeworms in sheep.

Administer the Proper Dose

• Underdosing exposes worms to sublethal concentrations of drug, which increases the selection for resistance, and several studies have demonstrated that sheep/goat producers often underestimate the weight of their animals.
• Animals should be weighed individually or dosed according to the heaviest animals in the group (except when treating with levamisole in goats where overdosing can be risky).
• Check accuracy of dosing equipment on a regular basis.
• Anthelminthic administration with a drenching gun, syringe, or drench adapter is recommended.

Utilize Host Physiology to Maximize Drug Availability and Efficacy

• All oral anthelmintics should be delivered into the rumen. This helps put ingesta in contact with the drug, therefore inducing slow release as feed particles pass down the digestive tract. This is accomplished by delivering drugs over the back of the tongue using a properly designed drenching apparatus. Presenting a drench to the buccal cavity, rather than into the pharynx/esophagus, can stimulate closure of the esophageal groove with significant drench bypassing the rumen.
• Once in the rumen, the duration of drug availability, as it is absorbed from the rumen and flows to more distal sites of absorption, is largely dependent on the flow rate of the digesta. Restricting feed intake for 24 hours prior to treatment decreases digesta transit flow rate, thereby increasing drug availability and efficacy. This recommendation is most useful for BZ and AM drugs. It is not useful for levamisole.
• Similar increases in efficacy can be achieved by repeating the dose in 12 hours. For levamisole, treatment should be repeated after 24 hours.
• Pour-on formulations designed for cattle are poorly absorbed in small ruminants. If used, these products should only be administered orally.

Drug Selection and Rotation

• Instead of a calendar-based rotation, drug choice should be made after considering many factors, the most important of which are the number of drugs that remain effective on that farm (and level of effectiveness) and the degree of parasite-induced illness in the animals being treated.
• Rotation of anthelmintics is an overblown concept that gives farmers and veterinarians a false sense that they are actually doing something worthwhile in terms of resistance prevention. Rotation actually does very little to prevent the development of anthelmintic resistance, and is not a replacement for proper resistance prevention measures.
• Two different anthelmintics (from different drug classes) given together will produce a synergistic effect, which may significantly increase the efficacy of treatment compared to the individual drugs. This synergistic effect is most pronounced when the level of resistance is low, but once high-level resistance to both drugs is present, the synergistic effect will be lost.
• Since the available drug arsenal is limited, a suggested approach is to use one drug until not effective anymore. This will allow easier monitoring of resistance development on farm.
• Prophylactic treatment against migrating larvae of *Parelaphostrongylus tenuis* in alpaca may induce problems of anthelmintic resistance in other populations of parasites normally infecting susceptible species. Use of long-acting anthelmintics is suggested to reduce frequency of treatments.

Pasture Management

• Good pasture management can significantly reduce the impact of parasitism and dependence on dewormers.

(CONTINUED) PARASITE CONTROL PROGRAMS: SMALL RUMINANT

• To prevent the rapid development of drug resistance, it is important that animals are not treated immediately before moving to safe pasture unless a significant proportion of animals is left untreated.
• Treating animals and leaving them on a confined area for 24–48 hours before moving them to a clean pasture is advisable. In this period animals should be fed from elevated feed bunks to reduce ingestion of parasite eggs. Fecal material passed in the 24–48 hours after treatment should be removed and not applied to pastures that will be grazed by sheep and goats. Dispose of fecal material by incineration or by application to ground that will be grazed by cows.
• Managing pastures so that safe grazing areas (low larval contamination) are available will permit movement of animals to a safe area, reducing the number of treatments that are needed.
• Few parasites are acquired when animals browse forage high off the ground; therefore browse areas should be utilized as much as possible.
• Reducing stocking rates will greatly decrease the number of parasites that sheep and goats are exposed to and also will improve the quality and quantity of forage available to the animals (suggested 6–10 sheep/acre). Overstocking can often make control of *H. contortus* nearly impossible. Co-grazing sheep and cattle (not goats) can reduce density of host and therefore reduce pasture contamination of parasite.
• Alpacas and goats should not graze on the same pastures as white-tailed deer.
Molluscicides, together with drainage of standing water or reducing access to swampy areas, may be considered to destroy or reduce contact with snails and slugs, which serve as intermediate hosts for meningeal worm spread.

Alternative Control Methods

• Copper wire particles may have some anthelmintic activity against abomasal worms, but not other gastrointestinal worms. Copper use should be limited in sheep due to toxicity. 1 g or 2 g of copper wire particles may remove substantial numbers of *H. contortus* in lambs and ewes, respectively. Similar doses may apply in goats but have not been tested adequately.
• Other methods such as tannin-containing forages and nematode-trapping fungi have shown positive effect at reducing intestinal parasite load.

Prevention of Coccidiosis

• Coccidia are the most common parasite causing diarrhea in young small ruminants.
• Prevention is key and involves both management and therapeutics. Cleaning barns before lambing and kidding, maintenance of dry and clean bedding, feeding at elevated bunks reduces environmental loads.
• Several coccidiostatic drugs are labeled for sheep or goats and are incorporated with feeding. Since kids and lambs do not eat enough feed in the first days of life to secure coccidia control, treatment of ewes and does in late gestation may be more beneficial.

PARASITIC PNEUMONIA

BASICS

DEFINITION
Alveolar and interstitial pneumonia in ruminants can be caused by the lungworm *Dictyocaulus viviparus* and aberrant migration of *Ascaris suum* larvae in cattle, and the lungworms *Dictyocaulus filaria*, *Protostrongylus rufescens*, and *Muellerius capillaris* in sheep and goats.

INCIDENCE/PREVALENCE
• Mainly areas with mild climate, high rainfall, intense irrigation, in late summer through fall.
• In southern United States, season of maximum *D. viviparus* infection in calves may be from December to March.
• Typically occurs in groups of animals on pasture.

GEOGRAPHIC DISTRIBUTION
Worldwide, mainly northern temperate climates

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• Generally, lungworms have a prepatent phase when larvae are migrating and adults are not present in large airways, and a patent phase when adults are present in large airways. *D. viviparus* and *D. filaria* have direct life cycles.
• Adults live in the trachea and bronchi, lay eggs, and hatch quickly. First larval stage L1 are coughed up, swallowed, passed in feces, then develop in environment. Third larval stage L3 migrate onto grass and are ingested, penetrate intestine, and are taken by lymphatic drainage to mesenteric lymph nodes. Fourth larval stage L4 travel through blood and lymphatics to lungs, lodge in pulmonary capillaries of caudoventral lung lobes, enter alveoli, and molt to adults in bronchioles.
• *P. rufescens* and *M. capillaris* have indirect life cycles.
• Adults live in trachea and bronchi, lay eggs, and hatch quickly. L1 are coughed up, swallowed, passed in feces. They enter snail or slug intermediate host, develop to L3. Intermediate host and L3 migrate onto grass and are ingested, penetrate intestine, and are taken by lymphatic drainage to mesenteric lymph nodes. L4 travel through blood and lymphatics to lungs, lodge in pulmonary capillaries of caudoventral lung lobes, enter alveoli, and molt to adults in bronchioles.
• *A. suum* can infect cattle exposed to large amounts of eggs in pens heavily contaminated by swine. Cattle are typically affected about 10 days after exposure, with signs due to allergic reaction to the larvae migrating through the lungs. Larvae in the alveoli initiate allergic reaction, with eosinophilic exudate being produced, causing coughing and tachypnea. More larvae tend to be aspirated into the caudoventral lung lobes, with consolidation developing there and in the interstitium as larvae migrate.
• Adult worms in the trachea and bronchi cause inflammation. Generally, larvae in the alveoli cause inflammatory reaction with eosinophilic exudate blocking bronchioles and causing coughing and tachypnea.
• Adult worms in larger airways cause marked inflammatory response with consolidation of caudoventral lung lobes.

HISTORICAL FINDINGS
Areas of high rainfall or intense irrigation, young animals turned out onto infected pasture, older animals moved from nonendemic to endemic areas.

SIGNALMENT
• All ruminant species.
• Beef cattle tend to be less affected by *D. viviparus* since management is more extensive, therefore infective larvae are not as concentrated.
• Mainly a disease of dairy calves.
• *D. viviparus* infection tends to occur in cattle <1 year old, or previously unexposed adults, turned out onto infected pasture.
• Infection also occurs in older cattle, previously infected and considered immune, re-infected when they are moved from nonendemic to endemic areas.

PHYSICAL EXAMINATION FINDINGS
Marked coughing (inconsistent finding in sheep and goats), tachypnea, dyspnea, fever (high fever in *A. suum* larval migration), anorexia, weight loss, harsh breath sounds, and widespread crackles and wheezes on lung auscultation (crackles over dorsal half of lungs in *D. viviparus* infection in cattle).

CAUSES AND RISK FACTORS
• Cattle—*D. viviparus*, aberrant migration of *A. suum.*
• Sheep and goats—*D. filaria*, adults in trachea and bronchi, most pathogenic. *P. rufescens*, adults in bronchioles, lesions smaller, less pathogenic. *M. capillaris*, adults in lung parenchyma, which become encysted so relatively benign; most common but least pathogenic lungworm of sheep and goats; more pathogenic in goats than in sheep; causes a more diffuse inflammation and interstitial pneumonia in goats.
• Exposure to vector (snail or slug) habitat (i.e., marshy land, wet muddy areas around waterholes, areas of high rainfall, intense irrigation).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Acute bovine pulmonary emphysema and edema or ABPEE (atypical interstitial pneumonia, fog fever)—cattle >2 years old suddenly switched from sparse dry forage to lush green pasture.
• Bacterial/viral bronchopneumonia.

CBC/BIOCHEMISTRY/URINALYSIS
May see increase in eosinophils 2–6 weeks after infection.

OTHER LABORATORY TESTS
Baermann sedimentation technique on feces or fluid from transtracheal aspirate to look for lungworm larvae; need to check several animals in herd.

IMAGING
• Radiography—may see consolidation of caudoventral lung lobes.
• Endoscopy—may see adult lungworms in large airways.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Prepatent phase—lungs grossly normal, few atelectic lobules in caudoventral lung lobes. May see larvae in microscopic smears of bronchial exudate, and eosinophilic infiltration.
• Patent phase—bilaterally symmetrical caudoventral lung consolidation. See adult worms in trachea and bronchi, with hemorrhage and fluid exudate.
• *D. filaria*—adult worms mainly in caudodorsal diaphragmatic lung lobes.
• *M. capillaris*—adult worms mainly in lung parenchyma, form grayish nodules 2–3 mm in diameter in subpleural tissue of sheep.

TREATMENT

THERAPEUTIC APPROACH
N/A

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Ivermectin 0.2 mg/kg SC.
• Fenbendazole 5 mg/kg PO, approved for dairy cattle of breeding age in the US.
• Fenbendazole, levamisole, ivermectin, and moxidectin are effective in sheep and goats. See chapter, Parasite Control Programs: Small Ruminant, for dosing information for sheep and goats.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

• Move animals to fresh pasture after treatment to avoid re-infection.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Good prognosis if animal only has cough and tachypnea.
• Guarded prognosis if animal also has dyspnea, fever, or anorexia.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
• Avoid infected pastures
• Vector control (e.g., molluscicides)

PATIENT CARE
N/A

PREVENTION
• Avoid infected pastures.
• Vector control (e.g., molluscicides).
• Strategic deworming (e.g., ivermectin at 3, 8, and 13 weeks after turning out on new pasture).

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Acute infection in young animals or previously unexposed adults turned out onto infected pasture, or re-infection in older animals previously infected and considered immune and moved from nonendemic to endemic areas.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Benzimidazoles (e.g., albendazole) may be teratogenic in first trimester of pregnancy; use with caution.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Control of vectors and implementation of proper parasite control programs in affected herds are important to minimize production losses and improve animal health.

PARASITIC SKIN DISEASES: BOVINE

BASICS

OVERVIEW

• Cattle can be affected by a wide range of parasitic skin diseases which can cause significant production losses and compromised animal welfare.
• External parasites feed on body tissues such as blood, skin and hair, and can cause skin irritation, self-trauma, and secondary infections.
• External parasites also serve as vectors for transmission of many important infectious diseases.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide; influenced by distribution of specific causative species and cattle management systems

SYSTEMS AFFECTED

• Integument
• Ophthalmic

PATHOPHYSIOLOGY

• Warble flies include *Hypoderma bovis*, *H. lineatum*, and *H. sinense*.
  ◦ Adult flies attach eggs to hair in spring to late summer; larvae penetrate skin and migrate in the tissues of the esophagus (*H. lineatum*) or spinal canal (*H. bovis*); they then move to subdermal tissue along the back and emerge from a breathing hole they create, fall to the ground to pupate, and emerge as adult flies.
  ◦ Infection can create focal swellings of the dorsum, poor growth and production, and damage to hides and carcasses. Migration of larvae in the spinal cord can occasionally cause posterior paralysis.
• Pediculosis or louse infestation is common in cattle due to host-specific biting (chewing) lice (*Damalinia bovis*) or sucking lice (*Linognathus vituli, Solenopotes capillatus, Haematopinus eurystemus*, and *H. quadripertusus*). Infestation causes irritation, rubbing, skin damage, decreased milk production, and sometimes anemia.
• Ticks are much less host-specific than lice, and can act as vectors of important blood-borne diseases in addition to reducing production and potentially causing anemia and paralysis.
  ◦ There are two main types of tick that affect cattle: *Argasidae* (soft ticks) for which important examples in North America include *Otobius megnini* and *Ornithodoros coriaceus*; and *Ixodidae* (hard ticks) for which important examples in North America include the genera *Dermacentor, Ixodes, Amblyomma*, and *Rhipicephalus* (*Boophilus*).
  ◦ Ticks tend to be fairly long-lived and environmentally resistant, living away from their hosts for extended periods of time.
  ◦ Tick feeding can result in hide damage, otitis, secondary bacterial infections, and transmission of important diseases including babesiosis and heartwater. Some species are also capable of causing paralysis as a result of the neurotoxins they inject into their hosts during feeding.
• Cutaneous myiasis (infestation with fly larvae or maggots) usually relates to *Calliphoridae* flies. "Blowfly strike" tends to be most problematic in sheep infested with *Lucillia cuprina* or *L. sericata*. Cattle can be significantly affected by screwworms, *Cochliomyia hominovorax* (in the New World) and *Chrysomyia bezziana* (in southern Europe, Africa, and Asia); larvae initially hatch into and feed on damaged skin, but then continue to invade living tissues causing severe damage, inflammation, secondary infection, and toxemia.
• A large variety of other fly species also affect cattle which can cause distress, pain, behavioral changes, reduced feed intake, and reduced productivity. In addition, flies may act as vectors for a variety of parasitic and infectious diseases.
  ◦ Stable flies (*Stomoxys calcitrans*) are present in most countries and are small and gray. They are most significant to confined livestock in North America because they attack cattle to feed on blood. They can serve as mechanical vectors for anthrax and BVDV.
  ◦ Horse and deer flies (*Tabanidae*) are large, robust, blood-feeding flies that are widespread in temperate and tropical regions. Only female flies take blood meals; bites are severe and distressing. These flies can act as mechanical vectors of bovine leukosis, vesicular stomatitis, and anthrax. These flies attack principally the legs and ventral abdomen; attacks lead to bunching of animals which can promote overheating and sometimes stampeding behavior.
  ◦ Horn flies (*Haematobia* spp.) are small gray flies. *H. irritans exigua* occurs in Australia and Southeast Asia, *H. irritans irritans* in Europe, North and South America, and Hawaii, and *H. minuta* in Africa. Both sexes are obligate blood feeders and attack pastured cattle. They can act as a vector for *Stephanofilaria stilesi* spp. which can cause skin lesions on the ventral abdomen of cattle.
  ◦ Biting midges are very tiny flies (1–3 mm long) that belong to the family *Ceratopogonidae; Culicoides* is the most important genus. These are also blood feeders that cause irritation and distress and which can transmit bluetongue and ephemeral fever, and act as an intermediate host for *Onchocerca*.
  ◦ Black and sand flies are small gray to black flies that belong to the family *Simuliidae*. Some important species include *Cnephia pecuarum* (southern US), *Simulium arcticum* (northern Canada), *Austrosimulium pestilens* and *A. bancrofti* (Australia), and *Simulium ornatum* (Great Britain). Female flies are active blood feeders in summer and cause distress, skin wheals and papules, and sometimes blood loss, and can transmit *Onchocerca* spp.
  ◦ Face flies (*Musca autumnalis*) are slightly larger than house flies and gather on the faces of cattle to feed on nasal and lacrimal secretions and saliva. This can cause stress and ocular irritation, and this species can act as vectors for eyeworms (*Thelazia* spp.) and enhance transmission of *Moraxella bovis* (the primary agent of bovine infectious keratoconjunctivitis).
  ◦ Head flies (*Hydrotea irritans*) are similar to house flies but have an olive abdomen and yellow wing bases. They are found mainly in Europe and do not bite, but create irritation, head shaking, rubbing, and scratching which may result in trauma and secondary myiasis. They can aid transmission of summer mastitis.
  ◦ Tsetse flies (*Glossina* spp.) in Africa are blood feeders and critical vectors of trypanosome diseases including Nagana (a complex of disease associated in cattle with *Trypanosoma brucei* infection).
• Several species of mites affect cattle, including *Demodex bovis, Sarcoptes scabei, Psoroptes ovis*, and *Chorioptes bovis*.
  ◦ Demodectic mange (follicular mange) can cause significant damage to the hide. This mite spends its entire life on the host, and spreads between animals by contact. Mites invade the hair follicles and sebaceous glands, creating chronic inflammation and alopecia. Affected animals have small nodules and pustules, general hair loss, and thickening of the skin without pruritus. Lesions occur most commonly on the brisket, lower neck, forearm, and shoulders.
  ◦ Sarcoptic mange (barn itch) related to *Sarcoptes scabiei* var *bovis* infection is usually seen in cattle in overcrowded situations with poor feeding and poor husbandry. *Sarcoptes* is mainly transmitted by direct contact between hosts and it is a zoonotic and notifiable disease in most countries. Affected cattle have small red papules and general erythema, severe pruritus, hair loss and thick scabs distributed over the inner surface of the thighs, the neck, brisket, and tail base.
  ◦ Psoroptic mange (body mange, ear mange) can also affect cattle and is caused by *Psoroptes ovis*. Infection can spread rapidly among animals and cause serious losses. Typical lesions are intensely itchy and appear first on the withers, neck, and around the root of the tail, eventually hair

loss, thickened skin, scabs, and papules occur.
◦ Chorioptic mange (tail mange, leg mange, scrotal mange) is the most common form of mange in cattle, caused by *Chorioptes bovis*. Again, transmission is mainly by direct contact and infection creates allergic, exudative dermatitis affecting the rump, tail, perineum, thighs, caudal udder, and scrotum with erythema, papules, crusts, alopecia, and pruritus.
◦ Psorergatic mange is caused by *Psorobia bos* (itch mite) which is usually an asymptomatic infestation; however, some cattle may display mild pruritus and alopecia.

HISTORICAL FINDINGS
• Vary with the underlying etiology but defining the history of skin disease within the herd, and any relevant treatment or management procedures, is important.
• A description of skin lesion appearance and duration, number of animals affected, and the presence or absence of pruritis are important historical factors.

SIGNALMENT
Generally, any age and breed of cattle are susceptible to parasitic skin diseases; however, *P. ovis* is very common in some breeds of beef cattle, whereas some dairy cattle breeds such as Holstein Friesians are considered resistant.

PHYSICAL EXAMINATION FINDINGS
• Ticks and lice are often readily visible on close examination of the skin.
• Skin should be closely evaluated for characteristics that include pruritis, alopecia, excoriations, lumps, perforations, and other anomalies.
• Signs of anemia or related infectious diseases may be observed.

GENETICS
N/A

CAUSES AND RISK FACTORS
• The presence of specific parasitic agents in the region
• Overcrowding and poor nutrition
• Lack of control and treatment procedures for external parasitism

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Dermatophilosis
• Lymphosarcoma
• Dermatophytosis
• Photosensitization
• *Staphylococcus* spp. dermatitis
• Tuberculosis
• Foot and mouth disease
• Poxvirus
• Pemphigus
• Contact dermatitis
• Trombiculidiasis
• Nutrient deficiency (selenium, zinc, vitamins A, D, or E)
• Pseudorabies
• Chemical burns

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Bacterial culture and sensitivity might be relevant in secondary infections of the skin or ear canals

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Skin scrapings can provide positive diagnosis and clarification of mite-related mange conditions
• Skin biopsy

PATHOLOGIC FINDINGS
• Mites are evident in deep scrapings or biopsies, and the species responsible can be differentiated by morphologic identification.
• Other findings are dependent on the causative etiology.

TREATMENT

THERAPEUTIC APPROACH
• Specific conditions respond very well to topical or parenteral treatment with insecticides provided via ear tags, residual livestock sprays, pour-on formulations, dust bags, back rubbers, oilers, or wipe-ons.
• Animals should be supported via good management, adequate nutrition, and where relevant, good hygiene procedures.
• For reportable conditions, contact appropriate state/provincial/government bodies to determine specific quarantine requirements and treatments.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Skin biopsy is a quick and relatively painless procedure that can be achieved using a 6 mm skin biopsy punch with no preceding preparation of the skin or local anesthesia to avoid lesion disruption and artifact.
• Biopsy sites can be left to heal by granulation but should be protected from invasion by external parasites.

MEDICATIONS

DRUGS OF CHOICE
• Warble flies respond to macrocyclic lactone products (doramectin, ivermectin, eprinomectin, moxidectin). If systemic insecticides are not allowed, tetrachlorvinphos dust can be applied to the dorsum.
• Mange mites are typically also responsive to macrocyclic lactone endectocides.
• Lice respond to treatment with topical pyrethroid insecticides which are effective against chewing and sucking lice, whereas macrocyclic lactone products mainly affect sucking lice.
• Ticks can respond to diazinon, pyrethroids, carbaryl and macrocyclic lactone drugs which can be provided via dipping, pour-on preparations, or injection.
• Flies can be managed through pour-on products, insecticide-impregnated ear tags, oral larvicides, and insect growth regulators to kill fly larvae developing in manure.

CONTRAINDICATIONS
Topical ectoparasiticides that fall under the jurisdiction of the EPA rather than the FDA in the US cannot be applied in an extra-label manner.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Crushing or damaging warble fly larvae during treatment procedures can induce acute anaphylaxis in host cattle.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Depends upon the causative agent; the prognosis for *Demodex* infestation is guarded, but for other mites is fair to good with adequate diagnosis and subsequent treatment.
• Most parasitic conditions of the integument cause anxiety and production loss as the main concern.

POSSIBLE COMPLICATIONS
• Secondary bacterial infection and toxemia
• Cutaneous myiasis

CLIENT EDUCATION
Focus on methods of control and prevention to reduce ectoparasite-related distress and disease

PATIENT CARE
N/A

PREVENTION
• Quarantine new animals before introduction into the herd, with close inspection for skin lesions.
• Lice can live for a limited time off the host (varies with species); therefore, leaving facilities dormant for 1–4 weeks (depending on the species involved) before re-introducing treated animals can help break the life cycle.
• Remove wet, rotting organic matter to reduce habitat for fly larvae; dragging pastures

PARASITIC SKIN DISEASES: BOVINE (CONTINUED)

to break up and dry manure masses is also helpful.
• Sterile male fly release programs have been very successful at controlling screwworm flies.
• Fly traps can be useful additions to the listed treatment methods which also often work in prevention.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Secondary infection
• Cutaneous myiasis

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Sarcoptes scabiei is zoonotic and can cross between species.

PREGNANCY
N/A

BIOSECURITY
• Quarantine new animals before introducing into the herd.
• Isolate affected herd members or whole herds during testing and treatment.
• Contact regulatory bodies if notifiable conditions are suspected.

PRODUCTION MANAGEMENT
Ectoparasites are a significant cause of economic loss due to reduced production including lower weaning weights, hide damage, secondary disease, and treatment expenses.

SYNONYMS
• Hypoderma—cattle grubs, warble fly, heel fly, gad fly
• Stable flies—biting house fly

PARASITIC SKIN DISEASES: CAMELID

BASICS

OVERVIEW

• A variety of parasitic agents cause skin disease in camelids including mites, ticks, lice, fleas and flies.
• External parasites can feed on blood, skin, tissue, and hair, and can cause irritation, self-trauma, and secondary infection.
• External parasites can also facilitate transmission of infectious diseases.

INCIDENCE/PREVALENCE

Varies depending on the parasite and relevant management factors; contagious disorders can achieve high prevalence in herds.

GEOGRAPHIC DISTRIBUTION

Worldwide; variation in distribution of specific agents

SYSTEMS AFFECTED

Integument

PATHOPHYSIOLOGY

• *Mite* infestation is common in camelids.
  ◦ *Chorioptes bovis* is not host specific and lives on the skin surface, feeding on organic material (epidermal scaling, hair, and dandruff). It is the most common mange mite in North America and Europe and is transmitted by direct contact.
  ◦ *Sarcoptes* spp. has incomplete host specificity. It is highly contagious and a serious disease of dromedaries (*Sarcoptes scabiei* var. *camelis*). *Sarcoptes scabiei* var *auchinae* affects new world camelids (NWC). The mite burrows in the stratum corneum layer until reaching living cells in the stratum granulosum and stratum spinosum. Transmission is by direct/indirect contact and mites may survive off host for several days if climate is moist/cool. Mites are transmitted by direct contact and fomites.
  ◦ *Psoroptes* sp. is also not host specific and lives on the skin surface, feeding superficially on lipid emulsion of skin cells, bacteria, and lymph. It is transmitted by direct contact.
  ◦ *Demodex* sp. is a commensal organism with transmission believed to occur from dam to offspring via nursing. The mites burrow in hair follicles/sebaceous glands and destroy the inner root sheath of hair, causing it to fall out. Lesions represent nodules containing developmental stages, inflammatory products, and detritus. *Demodex* has been isolated from camels in Iran and Africa, llamas and alpacas in Bolivia, llamas imported to South Korea and Germany, and alpacas imported to New Zealand.
  ◦ Miscellaneous mites include *Trombicula* spp. (chiggers) which may be seen on the skin surface. *Ornithonyssus sylviarum* (northern fowl mite) and *Dermanyssus gallinae* (red poultry mite) are reported as occasional skin irritants of camelids housed with poultry.
• *Ticks* are potential vectors of bacterial, protozoal, rickettsial, and viral diseases. They tend to be more problematic in old world camelids (OWC) than in NWC.
  ◦ Ticks live on hosts for a short time. Some ticks are able to adapt to climates by altering their life cycles using multiple hosts depending on environmental conditions.
  ◦ Camel host-specific hard ticks: *Hyalomma* spp. most important. *H. dromedarii* is the most common. *H. asiaticum* is the most common tick in Asia (affecting Bactrian camels in Mongolia).
  ◦ Others found in camels include *Amblyomma* spp., *Rhipicephalus* spp., and *Dermacentor* spp.; *Boophilus* spp. reported on dromedaries in Australia and India.
  ◦ Few hard body ticks affect NWC. *Amblyomma* spp. and *Haemaphysalis* spp. have been reported in South America; *Dermacentor* spp. and *Ixodes holocyclus* in llamas in western US, and *Amblyomma* spp. have been reported in vicuñas.
  ◦ Larvae of *H. dromedarii* are implicated in tick paralysis of dromedaries. Other *Hyalomma* spp. and *Rhipicephalus* spp. also reported. The disorder can cause high calf mortality. *Dermacentor* spp. was reported in two llamas in Washington State. A salivary neurotoxin produced by female *Dermacentor* spp. ticks is injected during the blood meal. Ataxia/generalized muscle flaccidity resolves 2–12 hours after tick removal. Death is due to ascending paralysis if untreated. *I. holocyclus* produced serious tick paralysis in one llama in Australia. Animals may not recover after tick removal. Specific tick anti-serum may be administered to save the animal.
  ◦ Soft ticks: *Ornithodoros* spp. live in sandy soils, cracks and crevices, seeking shade from hot arid deserts. Large numbers may be seen in the sand in marketplaces or holding pens where animals co-mingle. *Otobius megnini* (NWC): Adults do not feed. Nymphs molt twice in the ear, fall to ground and molt to an adult. Habitat off host is around outbuildings, feed bunks, wooden fences, or rough-barked trees. Animals in open pastures/rangelands are less commonly affected.
• *Lice* are host specific, and can be seen with the naked eye; sucking lice (spindle-shaped head) are smaller than biting lice (broad blunt head).
  ◦ The life cycle is completed on one host. Females lay eggs (nits) on fiber and secure them there. Lice molt for growth.
  ◦ Transmission occurs by direct contact between animals, or indirectly via contact with equipment, blankets, scratching posts, feed bunks, or dust bath areas.
  ◦ Lice populations increase during colder months.
  ◦ Shearing, exposure to sunlight, and fluctuating temperatures reduce lice populations.
  ◦ Sucking lice: *Microthoracius cameli* (OWC), *M. mazzai, M. minor. M. praelongiceps* (NWC). Occur more often in temperate regions where animals have long winter hair. Sucking lice cause more significant disease than biting lice as they suck blood and lymph from host.
  ◦ Biting lice: *Bovicola breviceps* (NWC). Llamas more often affected than alpacas. Seen in Chile and also on animals imported to New Zealand, Australia and the United Kingdom. Feed on dandruff, lipids, and bacteria.
• *Fleas* are not host specific and spend time on hosts for a blood meal. Eggs are laid in the environment.
  ◦ Fleas can serve as vectors/intermediate hosts of disease pathogens. They are not reported in NWC.
  ◦ *Vermipsylla* spp. and *Dorcardia ioffi* (Bactrian camels in Mongolia) affect OWC. Infestation by the cat flea *Ctenocephalides felis felis* has been reported.
• *Flies* distract animals from feeding and result in decreased productivity. They can also transmit infectious disease agents.
  ◦ Myiasis (infestation with fly larvae) is caused by many fly species.
    ▪ Flesh flies: *Wohlfahrtia magnifica*, *W. nuba,* and *Sarcophaga dux* (OWC in India). *W. magnifica* is an important cause of myiasis in the Mediterranean basin, southern Russia, Turkey, Iran, the Far East, Spain, and Mongolia. Flies deposit eggs/larvae near wounds.
    ▪ Blow flies: *Lucilia cuprina, Chrysomya bezziana* (OWC), *Cochliomyia hominivorax* (OWC/NWC), and *Calliphora* spp., *Phaenicia* spp., *Phormia* spp. (NWC).
      ▫ *C. bezziana* (old world screwworm) affects camels in Africa and Southern Asia. Eggs are deposited at wound edges. Skin trauma from surgery, branding, scalding from dips, tick bites, and injection sites attract flies.
      ▫ *L. cuprina*: Australia, Middle East, India, and Africa. Eggs deposited in carcasses, infected/necrotic wounds, soiled/matted fiber around infected lesions, and on rotting vegetation.

PARASITIC SKIN DISEASES: CAMELID (CONTINUED)

Larvae feed on epidermal cells, lymph, and necrotic tissue.
▫ *C. hominivorax* (new world screwworm) invades fresh wounds and can penetrate healthy tissue, exacerbating lesions.
◦ Biting and nonbiting flies*: Musca domestica*, *M. autumnalis*, *Stomoxys calcitrans*, *Hydrotea* spp., *Haematobia* spp. are vectors/intermediate hosts for some bacterial, viral, helminth, and protozoal disease-causing organisms.
▪ *M. domestica* deposits eggs in feces and decaying organic matter.
▪ *M. autumnalis* lays eggs in fresh cattle feces. Camelids housed with cattle are affected.
▪ *S. calcitrans* lays eggs in feces and decaying organic matter.
◦ *Glossinia* spp.: Important intermediate host for *Trypanosoma* in OWC in tropical Africa.
◦ *Tabanus* spp., *Haematopota* spp., *Chrysops* spp.
▪ *Tabanus* spp. and *Haematopota* spp. are vectors of *Trypanosoma* for OWC in Africa and Asia and potentially NWC in South America; and aid in the transmission of other pathogens. Eggs are deposited in damp soil/organic matter near water sources. Larvae and pupae overwinter in mud.
▪ Tabanids (horse flies, deer flies) are found throughout the world and are diurnal. They are attracted to animals by sight, odor, and body heat. Animals dislodge the feeding flies, which then move from animal to animal to complete feeding. Several blood meals expose multiple animals to potential disease transmission.
◦ *Midges*: Small, biting flies. Transmit viruses, protozoa, and helminthes.
▪ Simuliidae: Related to mosquitoes. Found in warm climates worldwide. Eggs are deposited in running water on the surface, or on submerged stones/twigs/vegetation. Eggs remain there for months (overwintering) or may hatch in a few days. The flies take blood meals from hosts. Swarms are annoying and lead to reduced feed intake by the host. Bites are similar to fleas/mosquitoes.

HISTORICAL FINDINGS

• Vary with the underlying etiology but defining the history of skin disease within the herd, and any relevant treatment or management procedures, is important.
• A description of skin lesion appearance and duration, number of animals affected, and the presence or absence of pruritis are important historical factors.

SIGNALMENT

Any age, species and breed of camelid is susceptible to ectoparasitism; however, some parasites are host-specific.

PHYSICAL EXAMINATION FINDINGS

Mites

• *Sarcoptes* spp.
◦ Severe pruritus leading to excoriation, erythema, cracked/bleeding skin, skin thickening/wrinkling, or alopecia.
◦ Affects nostrils, lips, orbit, chest, interdigital clefts, knee/hock joints, medial thighs, ventral abdomen, axillae, tail, perineum, and prepuce.
◦ May become generalized.
• *Psoroptes* spp.
◦ Pruritus less severe than *Sarcoptes* spp.
◦ Ear canal lesions in NWC. Otitis externa, crusting/alopecia of pinnae, and dry flakes in ear canals. Animal may shake head or appear uncoordinated.
◦ May be generalized without ears being affected. Nares, shoulders, neck, axillae, chest, back, sides, groin, legs, tail head, and perineum.
◦ Erythema, crusting, papules, serum exudate, alopecia.
• *Chorioptes* spp.
◦ Pruritus less severe than *Sarcoptes* spp. or *Psoroptes* spp.
◦ Alopecia and scaling of distal limbs/feet, ventral abdomen, medial aspect of limbs base of tail; forehead, ears, trunk and perineum in severe cases.
◦ Animals may be asymptomatic.
• *Demodex* spp.
◦ Nonpruritic to mildly pruritic papular or nodular alopecic lesions on face, neck, axillary/inguinal regions (may extend to medial upper limbs). May be found in ears without concurrent otitis.
◦ Secondary infections lead to excoriation, erythema, and crusting.
• Trombiculidae: Pruritic dermatitis of distal extremities.

Ticks

• Ticks may be identified in the perineal, inguinal and axillary regions, lips, ears, eyes, nostrils, between toes, and on udder.
• Cause direct/indirect irritation of the skin. Secondary bacterial infection/pyoderma may develop. Chronically skin may become thickened/scarred. Sores may be observed at mucocutaneous junction of nose, lips, vulva.
• *Otobius megnini* larvae/nymphs prefer the ears, causing excess wax production, purulent exudate in ears, and severe inflammation in the outer ear canals. Affected animals shake their heads and may appear uncoordinated. May cause anemia.

Lice

• Movement of lice causes pruritus and restlessness.
• Biting lice affect dorsal midline, base of tail, sides of neck/body. Cause matting of fiber, lackluster coat, ragged coat, and alopecia. Llamas more often affected than alpacas.
• Sucking lice affect flanks, head, neck, and withers causing alopecia. Alpacas more often affected than llamas. May cause anemia. Anemic animals are susceptible to cold stress and secondary infections.
• Lice may be observed if the hair is parted down to the skin which is examined with a light or magnifying glass, or nits may be visible attached to fiber. Sucking lice may be seen on fibers close to skin or embedded in the skin surface.

Fleas/Flies

• Distract animals from feeding, resulting in decreased productivity.
• Fleas: Deposit saliva when biting host, causing an allergic response which varies from mild irritation to marked pruritus. Bites may lead to anemia and death.
• Flesh flies: Ulcerative, oozing lesions.
• *Lucilia cuprina*: Prefer skin folds, especially in the perineal region, neonatal umbilicus, and decubital ulcers. Animals may rub or bite affected areas.
• *S. calcitrans*: Constant irritation may result in decreased production and conjunctivitis.
• *Tabanus* spp.: Prefers ventral abdomen, legs, and inguinal region. Bite wounds may be erythematous and swollen, attracting other flies. Bites are so intensely painful that reduced productivity occurs.

GENETICS

N/A

CAUSES AND RISK FACTORS

• The presence of specific parasites in a region
• Lice and mites tend to be more problematic in the cooler months
• Overcrowding and poor nutrition
• Lack of control procedures for external parasitism

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Camel pox
• Contagious ecthyma
• Dermatophytosis
• Endocrine disorders of the skin
• Foot and mouth disease
• Hyperkeratotic skin disease
• Irritant/Contact dermatitis
• Lymphosarcoma
• Nutrient deficiency (selenium, zinc, vitamins A, D, E)
• Pemphigus
• Photosensitization
• Poxvirus
• Pruritic skin disease

P

• Pseudotuberculosis
• Scrapie
• Tuberculosis

CBC/BIOCHEMISTRY/URINALYSIS
CBC may show anemia or inflammatory leukogram.

OTHER LABORATORY TESTS
Fecal analysis may yield dead mites as a result of pruritis and mite ingestion.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Deep skin scrapings from lesion edges are indicated for *Sarcoptes* and *Demodex* spp. Adding warmed 10% potassium hydroxide to the scraping debris may allow for better visualization.
• Multiple superficial skin scrapings between toes or axillae, or by skin biopsy identifies *Chorioptes* sp.
• Examine swabs or ear exudates for *Psoroptes* sp. or *Otobius megnini*.
• Bacterial culture and sensitivity are relevant for infections.

PATHOLOGIC FINDINGS
• Mites are evident in scrapings or biopsies, and the species responsible can be differentiated by morphologic identification.
• Other findings are dependent on causative etiology.

TREATMENT

THERAPEUTIC APPROACH
• Follow adequate nutrition, management, and hygiene practices.
• Differentiate demodectic nodules from those of tuberculosis. Mites may not always be found and a treatment trial may be warranted using systemic or topical agents.
• Quarantine new animals before introduction to the herd.
• Treat all affected animals and all animals in the herd since they can be asymptomatic carriers. This includes animals in close contact, such as cattle or poultry.
• Multiple treatments are often necessary.
• Traditional topical treatment method (using products made from plants, oils, other) are used frequently by producers throughout the world. These generally require lengthy preparation time and can be laborious to apply.
• Treat secondary bacterial infections and otitis appropriately.
• *Cochliomyia hominivorax*: Treatment is aimed at reducing irritation of the lesion and cleansing of the wound. Remove larvae manually or by insecticides. Topical application of hydrogen peroxide, ether, or chloroform drives larvae out of wounds.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Ivermectin at 0.2 mg/kg SC (repeated at 2-week intervals) is effective against many mites, ticks (nymphs/larvae), sucking lice, and some flies. Not effective for biting lice or *Chorioptes* due to their superficial feeding habits. Clients should be informed of extra-label use.
• Topical and systemic therapies are often utilized concurrently to improve treatment success.
• Topical acaricides must reach the skin layer to be effective. Clean affected areas with keratinolytic solution/soap to loosen and remove scabs. Brush away debris before application. Repeat at 7–14 day intervals.
• NWC fiber does not contain lanolin, reducing efficacy of topical products. Poor penetration of the product into damaged skin also limits efficacy. Many dusts, rinses, dips, sprays, powders containing pyrethroids, amitraz, spinosad, fipronil, avermectins and lime sulfur are safer alternatives to organophosphates/carbamates.
• Fipronil spray and ivermectin have been used in the ear after cleaning to improve efficacy against psoroptic mites. Not recommended if tympanic membrane is ruptured.

CONTRAINDICATIONS
• Corticosteroids are contraindicated in the treatment of mange.
• Corticosteroids should not be administered to pregnant animals.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Use caution when treating young crias with pyrethroids—of toxicity are possible.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis for demodectic mange is guarded, for other mites is fair to good with adequate diagnosis and subsequent treatment.

POSSIBLE COMPLICATIONS
Secondary bacterial infection.

CLIENT EDUCATION
Focus on methods of control and prevention to reduce ectoparasite-related distress and disease.

PATIENT CARE
• Monitor clinical signs and/or repeat skin scrapings.
• Observe animals for re-infestation.

PREVENTION
• Consider arthropod life cycles and length of treatment, as some animals may not show clinical signs.
• Implement scheduled anti-parasite programs (treatment, prevention, control).
• Free-ranging guineafowl or chickens decrease numbers of mites, ticks, and fleas in the environment.
• Management of environment to decrease breeding habitat of flies and mosquitoes. Fly traps/sticks, fly predators, and mosquito repellents may also be used.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Arthropod borne diseases
• Lymphadenopathy

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Sarcoptes scabiei is zoonotic.

PREGNANCY
N/A

BIOSECURITY
• Quarantine new animals before introduction into herd.
• Isolate affected herd members or whole herds.
• Contact state/provincial/government veterinarian for reportable diseases.
• *Sarcoptes* spp. and *Psoroptes* spp. are reportable in the US and other countries.
• New world screwworm and old world screwworm are reportable. New world screwworm has been eradicated from the US, however, recent infestations in wild and domestic animals were reported in Florida in 2016 and 2017.

PRODUCTION MANAGEMENT
Parasites affecting the skin cause significant economic loss as a result of poor growth, reduced milk/meat production, hide damage, poor fiber quality, and death.

SYNONYMS
• Demodectic mange—follicular mange
• Sarcoptic mange—barn itch

PARASITIC SKIN DISEASES: CAMELID (CONTINUED)

• Psoroptic mange—body mange, ear mange, sheep scab
• Chorioptic mange—tail mange, leg mange, scrotal mange

ABBREVIATIONS

• FARAD = Food Animal Residue Avoidance Databank

PARASITIC SKIN DISEASES: SMALL RUMINANT

BASICS

OVERVIEW

• Small ruminants are affected by a range of parasitic skin diseases which can cause significant economic loss and compromise animal welfare.
• External parasites can feed on blood, skin, tissue, and hair, and can cause irritation, self-trauma, and secondary infection.
• External parasites can also facilitate transmission of infectious diseases.

INCIDENCE/PREVALENCE

Varies depending on the parasite and management factors; contagious disorders can achieve high prevalence in herds.

GEOGRAPHIC DISTRIBUTION

• Lice affect sheep and goats worldwide.
• Chorioptic mange is present worldwide and is common in goats in North America and Europe.
• Psoroptic mange is not present in North America. It was eradicated in the United Kingdom but is now present and widespread. It is eradicated from Australia and New Zealand.
• Sarcoptic mange is not present in the United States and is a reportable disease. It is present in Southern European countries.
• Demodectic mange occurs worldwide.
• Myiasis is common worldwide, particularly in warmer climates.

SYSTEMS AFFECTED

Integument

PATHOPHYSIOLOGY

• Pediculosis (louse infestation) is related to lice from order Mallophaga (biting or chewing lice) and order Anoplura (sucking lice).
  ◦ Common species in sheep are *Damalinia (Bovicola) ovis* (biting body louse), *Linognathus ovillus* (sucking face louse) and *L. pedalis* (sucking foot louse).
  ◦ Common species in goats are *D. caprae, D. crassipes,* and *D. limbata* (biting) and *L. stenopsis* and *L. africanus* (sucking).
  ◦ Lice maintain their life cycle on the animal, living off the host for usually very brief periods, with transmission by direct or indirect contact.
• Mites can live off their hosts for more extended periods and transmission occurs by direct contact and indirect contact with fomites.
  ◦ Chorioptic mange: *Chorioptes ovis or C. bovis* in sheep; *C. caprae* in goats.
  ◦ Psoroptic mange: *Psoroptes ovis* in sheep, rare in goats. *P. cuniculi* is an ear mite of sheep and goats that can also affect the face and body.
  ◦ Sarcoptic mange: *Sarcoptes scabei* var *ovis* (sheep) and *S. scabei* var *caprae* (goats).
  ◦ Demodectic mange (demodecosis) generally affects goats. *Demodex caprae* mites live in the hair follicles and can be transmitted from dam to kid; infection is associated with nodular lesions and is usually nonpruritic.
• Cutaneous myiasis (fly strike) is typically caused by blow flies or bottle flies; including *Lucilia* spp., *Phormia* spp., and *Calliphora* spp. Flies are attracted to warm, moist wool, hair, or skin, and to organic matter to lay their eggs. Soiled wool or wounds are particularly attractive. Eggs develop into larvae (maggots) which ingest skin and tissue.
• Screwworm fly (*Cochliomyia hominivorax*) occurs in Central and South America. It has been eradicated from North America and is reportable. Transient re-emergence was documented in Florida in 2016 and 2017. Adult females deposit eggs near wounds and larvae cause severe damage by feeding on body fluids and living tissue. Several other species of fly act in a similar manner.

HISTORICAL FINDINGS

• Vary with the underlying etiology, but defining the history of skin disease within the herd, and any relevant treatment or management procedures, is important.
• A description of skin lesion appearance and duration, number of animals affected, and the presence or absence of pruritis are important historical factors.

SIGNALMENT

Any age, species, and breed of small ruminant is susceptible to ectoparasitism; however, some parasites are host-specific. Demodectic mange tends to affect goats, and *Damalinia limbata* and *D. crassipes* lice are more common in Angora goats.

PHYSICAL EXAMINATION FINDINGS

• Mites typically cause pruritus. Chronic mange can result in hyperkeratinization and lichenification of skin, weight loss, decreased productivity (meat, wool, and milk), infertility, and even death from emaciation.
• Ear mites may cause head shaking and scratching with secondary aural hematomas and scarring of the pinnae.
• Lice tend to cause pruritis in sheep with accompanying wool damage, and are less often pruritic in goats. Large infestations of sucking lice can cause signs of anemia in neonates.
• Demodectic mange is typically nonpruritic, with formation of papules and nodules with a normal appearing coat. Lesions can be found on the face, neck, and shoulders of goats but may be extensive.
• Chorioptic mange can create erythema, papules, crusts, and scaling, usually localized to the lower legs (hind > fore), scrotum, and udder.
• Psoroptic mange lesions start as vesicles and papules resulting in yellow crusts and inflammation. Wool becomes stained and is lost due to pruritus. Lesions typically localize on the dorsal midline progressing to the whole body, or occasionally localize to the ears.
• Sarcoptic mange affects non-wooled areas of the face, ears, neck, scrotum, and legs. Chronically, lesions may become generalized and the skin thickened. Peripheral lymphadenopathy may occur.
• Myiasis usually tends to affect wounds, the breech, and sometimes body areas, and occasionally the tail, poll, genitalia, prepuce, and foot.

GENETICS

N/A

CAUSES AND RISK FACTORS

• The presence of specific parasites in a region.
• Lice and mites tend to be more problematic in the cooler months.
• Angora goats are more at risk of infestation with some species of *Damalinia* lice.
• Overcrowding and poor nutrition.
• Lack of control procedures for external parasitism.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Differential diagnoses for skin lesions in small ruminants besides ectoparasites include zinc-responsive dermatosis, bacterial skin disease (including dermatophilosis), fungal skin disease, and pyoderma.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Bacterial culture and sensitivity might be relevant in secondary infections of the skin or ear canals.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

• Lice are visible to the naked eye. Close examination of the hairs, or use of a flea comb, can yield lice which can be viewed under magnification for further identification. Sucking lice have longer, narrow mouthpieces compared to the flatter, wider mouthpiece of chewing lice.
• Mites are not easily visible to the naked eye. Identification requires sampling via skin scraping (superficial and deep) or skin biopsy. Acute lesions typically yield more mites than chronic lesions, and scraping at the edges of lesions is most helpful. Caseous material expressed from nodules can reveal *Demodex* mites in cases of demodecosis.
• For filarial dermatitis (elaeophoriasis or sorehead), a skin biopsy of the lesion is macerated in isotonic saline solution and rested for ≥6 h at room temperature. Tissue is strained off and the fluid examined for microfilariae.

PARASITIC SKIN DISEASES: SMALL RUMINANT (CONTINUED)

PATHOLOGIC FINDINGS
• Mites are evident in scrapings or biopsies, and the species responsible can be differentiated by morphologic identification.
• Other findings are dependent on causative etiology.

TREATMENT

THERAPEUTIC APPROACH
• Specific conditions respond to topical or parenteral insecticides/pesticides.
• Animals should be supported via good management, adequate nutrition, and where relevant, hygiene procedures.
• For reportable conditions, contact appropriate state/provincial/government bodies to determine specific quarantine requirements and treatments.

SURGICAL CONSIDERATIONS
• Skin biopsy is a quick and relatively painless procedure that can be achieved using a 6 mm skin biopsy punch with no preceding preparation of the skin or local anesthesia to avoid lesion disruption and artifact.
• Biopsy sites can be left to heal by granulation but should be protected from invasion by external parasites.

MEDICATIONS

DRUGS OF CHOICE
• For mites, organophosphate compounds (OPs) (e.g., diazinon and propetamphos) and systemic pyrethroids (e.g., flumethrin and cypermethrin) have been used in plunge dipping, showers, and jetting. Both have significant health implications for operators and the environment, and resistance is widespread. Injectable macrocylic lactones (ivermectin, doramectin, moxidectin) are effective and labeled for use in some countries. Repeated use has implications for development of nematode resistance. In flocks affected with *Psoroptes ovis*, all animals should be treated with injectable macrocylic lactones twice, 7–10 days apart (treatment may be less effective for chorioptic mange). Topical lime sulfur can be effective if repeated every 7 days for prolonged periods. A shampoo that loosens crusts can make topical treatment more effective in chronic cases. Topical amitraz may also be effective for *Demodex*.
• Lice are killed by many topically administered drugs including OPs, and synthetic pyrethroids and pyrethrins. Care must be taken for the product to have contact with the skin for full effect. Treatment should be applied 2–4 weeks after shearing for full effectiveness. Resistance to all drugs has been reported. The louse eggs (nits) are not responsive to these treatments, which should therefore be repeated in 10–14 days. Injectable macrocyclic lactones are effective against sucking lice but not biting/chewing lice.
• Cutaneous myiasis is addressed after removing surrounding wool or hair from the affected area. Severe myiasis may result in shock, dehydration, and secondary bacterial infections which should be treated appropriately. Permethrins can be applied to kill maggots, selecting products that can be applied to open wounds.

CONTRAINDICATIONS
Topical pesticides that fall under the jurisdiction of the EPA rather than the FDA in the US cannot be applied in an extra-label manner.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Depends upon the causative agent; the prognosis for *Demodex* infestation is guarded, but for other mites is fair to good with adequate diagnosis and subsequent treatment.
• Most parasitic conditions of the integument cause anxiety and production loss as the main concern.

POSSIBLE COMPLICATIONS
Secondary bacterial infection

CLIENT EDUCATION
Focus on methods of control and prevention to reduce ectoparasite-related distress and disease

PATIENT CARE
N/A

PREVENTION
• Psoroptes, lice, and keds (wingless flies) can be eradicated from a flock with appropriate treatment and control.
• Prevention of myiasis in sheep can be achieved by decreasing fecal and urine contamination of the fleece by controlling causes of diarrhea (e.g., parasites); shearing the breech region; the mulesing procedure in Merinos; tail docking; use of fly traps; and genetic selection for fewer skin folds (Merinos).
• Drugs used in prevention and control of fly strike include synthetic pyrethroids (e.g., deltamethrin, cypermethrin), insect growth regulators (IGRs) (e.g., cyromazine, dicyclanil), OPs (e.g., diazinon) and permethrins. Use may be restricted depending on location. Dipping, showers, dusting, spray races, and hand jetting have all been used to apply drugs to sheep. There is reported resistance to OPs and IGRs.
• Remove wet, rotting organic matter to reduce habitat for fly larvae; dragging pastures to break up and dry manure masses is also helpful.
• Quarantine new animals before introduction into the herd, with close inspection for skin lesions.
• Lice can live for a limited time off the host (varies with species); therefore, leaving facilities dormant for 1–4 weeks (depending on the species involved) before re-introducing treated animals can help break the life cycle.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Keds (*Melophagus ovinus*) are wingless flies that can cause pruritis and wool staining in sheep. They are visible to the naked eye and the entire life cycle is spent on the animals; hence they can be eradicated through simple control procedures.
• Blackflies (Simuliidae), *Culicoides* gnats, mosquitoes, and biting flies (*Stomoxys* spp. and Tabanidae) may cause insect hypersensitivity and irritation in small ruminants.
• Ticks exist worldwide, are not particularly host-specific and in addition to skin lesions, anemia and reduced production, can facilitate disease including tick paralysis, babesiosis, heartwater, theileriasis, and anaplasmosis.
• Free-living pasture mites (*Trombiculidae* sp.) can cause hypersensitivity and dermatitis.
• *Strongyloides papillosus* larvae penetrate skin and migrate to the lungs. Repeated exposures may cause dermatitis. Similarly, *Pelodera* (*Rhabditis*) *strongyloides* is a soil-living nematode that may cause dermatitis in animals housed in dirty conditions.
• Psorergatic mange (*Psorobia ovis*, itch mite) is often asymptomatic but can cause pruritis and wool damage in some infested sheep and occurs in Australia, New Zealand, Africa, and South America.
• Elaeophoriasis (sore head) is related to infestation with *Elaeophora schneideri*, a deer parasite in western and southwestern US. Transmitted to sheep and goats by Tabanid flies, infection can cause severe neurologic disease and prominent microfilarial dermatitis of the poll, forehead, or face.

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
Sarcoptes mites are zoonotic.

PREGNANCY
N/A

P

(CONTINUED) PARASITIC SKIN DISEASES: SMALL RUMINANT

BIOSECURITY

• Prevent introduction of ectoparasites by quarantine and examination of new arrivals and effective treatment.
• Isolate affected herd members or whole flocks during testing and treatment.
• Contact regulatory bodies if reportable conditions are suspected.

PRODUCTION MANAGEMENT

• Ectoparasites are a significant cause of economic loss due to reduced production (milk, meat, wool), secondary disease, and expenses related to control and treatment.
• Psoroptic mange has significant welfare and economic implications in areas of the world where is it not eradicated.

SYNONYMS

• Demodectic mange—follicular mange
• Sarcoptic mange—barn itch
• Psoroptic mange—body mange, ear mange, sheep scab
• Chorioptic mange—tail mange, leg mange, scrotal mange
• Psorergatic mange—Australian mange
• Elaeophoriasis—sore head, filarial dermatosis, "clear-eyed" blindness

ABBREVIATIONS

PARELAPHOSTRONGYLUS TENUIS (MENINGEAL WORM)

BASICS

OVERVIEW
• Aberrant migration of the larvae of *Parelaphostrongylus tenuis* into the central nervous system of small ruminants, camelids, and specific cervidae including red deer and moose, causes mild to severe neurologic signs.
• White-tailed deer (WTD) are the definitive host and typically show no clinical signs.

INCIDENCE/PREVALENCE
P. tenuis does not affect camelids in regions that do not contain infected WTD; however, in some regions >50% of deer are infested, and there is evidence that the range of infection is expanding.

GEOGRAPHIC DISTRIBUTION
• Reflects the range of the WTD, which includes southern Canada and the continental United States typically east of the Mississippi river.
• Animals co-mingled in artificial habitats (zoos) may be affected outside of this geographic range.

SYSTEMS AFFECTED
Nervous

PATHOPHYSIOLOGY
• The natural host for *P. tenuis* is the white-tailed deer (*Odocoileus virginianus*). Clinical signs or pathologic findings associated with *P. tenuis* infestation in this species are rare.
• Adult worms reside in the subarachnoid space of WTD. Eggs leave the CNS through the venous sinuses and embryonate into first stage larvae which migrate up the trachea, and are swallowed and passed in the feces.
• Larvae penetrate into a snail or slug and mature for 3–4 weeks. Larvae can overwinter in the intermediate host. During the grazing season infected slugs and snails are ingested by WTD. Alternatively, the L3 stage may leave the gastropod and deer ingest them in slime trails on vegetation.
• Ingested larvae penetrate the abomasal wall, migrate through the body to the dorsal gray columns of the spinal cord, and become adults in 20–30 days. They then migrate along the dorsal nerve rootlets to the subarachnoid space.
• The prepatent period is approximately 90 days, and the life cycle is complete in 4 months.
• When aberrant hosts such as sheep, goats, and camelids ingest infected gastropods or slime, the larvae are released in the abomasum and after variable periods of time eventually reach the spinal cord and/or brain, where aberrant migration causes inflammation and disease. Larvae rarely reach maturity in the aberrant host.
• Self-cure has been reported in sheep, and goats.

HISTORICAL FINDINGS
Acute or chronic onset of neurologic signs that commence in the hindlimbs and progress cranially, in an area where *P. tenuis* is known or possible, and in animals not subject to frequent preventive treatment.

SIGNALMENT
The disease is most common in adult camelids ≥2 years of age. Goats, sheep, moose, elk, antelope, and reindeer can be affected.

PHYSICAL EXAMINATION FINDINGS
• Clinical signs vary based on the number and location of migrating larvae.
• Most commonly signs indicate focal, asymmetric disease of the spinal cord, reflected by gait abnormalities (lameness, spasticity, ataxia) and proprioceptive deficits. Paresis, or paralysis, may also be present and animals may present recumbent.
• Cortex and brainstem involvement may cause cranial nerve deficits, blindness, head tilt, circling, scoliosis, altered mentation, and seizures.

GENETICS
N/A

CAUSES AND RISK FACTORS
• The major cause for cerebrospinal nematodiasis in North America is *P. tenuis.* Other parasites such as *Oestrus ovis*, *Coenurus cerebralis*, and *Baylisascaris procyonis* can also cause disease.
• The major risk factor for infestation is grazing low-lying, damp treed pastures in the late summer and fall that are cohabited by WTD. After a killing frost, the risk for infestation is greatly decreased.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Differentials for recumbency and possible spinal cord disease include heat stress, rabies, spinal trauma, abscessation, neoplasia, listeriosis, tick paralysis, and nutritional deficiencies, especially in juveniles (copper, vitamin E/selenium, vitamin D).
• Differentials for signs suggestive of intracranial disease can include rabies, listeriosis, otitis interna, polioencephalomalacia, neoplasia, trauma, cerebral abscessation, and toxicity (lead, salt, plants). In sheep and goats, scrapie, louping ill, and lentivirus infection should be considered.

CBC/BIOCHEMISTRY/URINALYSIS
There are no specific tests for diagnosis of *P. tenuis*. Complete blood count, serum chemistry analysis, and urinalysis may be useful to investigate differentials.

OTHER LABORATORY TESTS
N/A

IMAGING
• Diagnostic imaging (radiographs, CT, MRI) is not specific for *P. tenuis*, but may help rule out differentials.
• Computed tomography with intravenous contrast may reveal subtle multifocal lesions in the brain of animals with intracranial signs.

OTHER DIAGNOSTIC PROCEDURES
CSF cytology—detection of an eosinophilic pleocytosis is highly suggestive for cerebrospinal nematodiasis. A mononuclear pleocytosis may also be observed which is less specific for parasite migration. CSF can be obtained readily from the lumbosacral space of camelids just caudal to the dorsal spinous process of the 7th lumbar vertebra.

PATHOLOGIC FINDINGS
Definitive diagnosis requires histopathologic identification of the parasite within the brain or spinal cord. In cases where the parasites are not definitively identified, microcavitation and spongiosis with multifocal areas of malacia, necrosis, and degenerating axons are often present, suggestive of aberrant parasite migration.

TREATMENT

THERAPEUTIC APPROACH
• Animals that remain standing with relatively mild signs should be separated or housed with a few gentle companions, in an area that is well bedded with a nonslip floor.
• Food and water should be readily accessible. Encouraging mild to moderate exercise is important to promote muscle strength and function.
• Animals with severe signs, such as paralysis of the forelimbs, hindlimbs, or both, require intensive nursing care. This may include use of a sling or a water flotation tank to support the animal and the provision of physical therapy. Food and water need to be immediately accessible.
• Animals that have signs associated with brain lesions present the greatest challenge since they are often recumbent and inappetant. Besides physical therapy, enteral feeding via stomach tube or temporary rumen fistula may be required. Parenteral (intravenous) nutrition may be required for severely affected animals.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Anthelmintics

(CONTINUED) *PARELAPHOSTRONGYLUS TENUIS* (MENINGEAL WORM)

- Fenbendazole: 20–50 mg/kg, PO q24h for 5 days ±
- Diethylcarbamazine: 50 mg/kg, PO q24h for 7 days

• Anti-inflammatory agents
- Dexamethasone: 0.05–0.1 mg/kg, IV or SC, q48h for 2 treatments
- Prednisolone sodium succinate: 0.5–1.0 mg/kg IV or SC, q12–24h
- Flunixin meglumine: 0.5–1 mg/kg IV, q12h for 2–3 days

• Antioxidant agents
- Vitamin E—immediate antioxidant activity: 1 mL/100 lb SC or IM (300 IU/mL)
- Selenium—antioxidant activity will take 7–10 days for effect (Bo-Se®—1 mL/50 lb)

CONTRAINDICATIONS
• Dexamethasone will cause abortion in pregnant camelids, and possibly in small ruminants.
• Ivermectin is suggested to be contraindicated in *P. tenuis* treatment, to reduce the chance of exacerbating damage by crossing a compromised blood-brain barrier.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Damaged nervous tissue may take 6 months or longer to heal, or for an animal to develop compensatory skills. The more severe the neurologic damage, the poorer the prognosis. Recovery may be incomplete and may require prolonged, intensive nursing care.

POSSIBLE COMPLICATIONS
Recumbency may create the risk of heat stress in warmer months, or promote muscle damage if prolonged without intervention.

CLIENT EDUCATION
Promote non-anthelmintic methods of control where feasible to reduce the contribution of frequent preventive treatments to anthelmintic resistance.

PATIENT CARE
Focuses on supportive nursing, provision of nutrition, and providing a safe environment during recovery.

PREVENTION
• Minimize exposure of susceptible animals to infected snails by using fowl, having vegetation-free zones around pastures, and preventing access to low-lying, snail- and deer-infested pastures during cooler, moist periods until after the first killing frost.
• Strategic anthelmintic treatment typically involves periodic treatment with an avermectin product every 30–60 days. Prior to reaching the CNS, *P. tenuis* is susceptible to multiple products using dosages recommended for treatment of gastrointestinal parasites.
• Livestock guard dogs can be used to repel deer, since fencing is typically of limited effectiveness.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Because of the *P. tenuis* life cycle, disease is typically confined to animals of grazing age.

PARENTERAL NUTRITION

BASICS

OVERVIEW

• Parenteral nutrition (PN) refers to the intravenous administration of nutrients.
• Total PN (TPN) provides all daily nutrient requirements while partial PN (PPN) only provides part of daily nutrient requirements.
• PN is indicated when enteral nutrition is either contraindicated (dysphagia, regurgitation, malabsorption, maldigestion, or ileus) or impossible (esophageal obstruction or rupture).
• PN can also be useful in ruminants that have a history of prolonged anorexia and are not voluntarily ingesting enough to meet 75% of their daily maintenance requirements.
• PN can be beneficial and life-saving and should be considered as important as other medications in the management of critically ill ruminants.
• PN solutions usually include dextrose and lipids as energy sources and amino acids (AA) as protein sources.

INCIDENCE/PREVALENCE

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

N/A

PATHOPHYSIOLOGY

Maintenance Nutrient Requirements

• Daily maintenance energy requirements (MER) can be calculated as follows:
  ◦ MER (kcal) = 140 × $BW^{0.75}$ (kg) in cattle **[1]**
  ◦ MER (kcal) = 130 × $BW^{0.75}$ (kg) in small ruminants **[1]**
  ◦ MER (kcal) = 70 × $BW^{0.75}$ (kg) in camelids **[1]**
• Daily maintenance protein requirements (MPR) can be calculated as follows:
  ◦ MPR (g) = 3.5 × $BW^{0.75}$ (kg) in adults **[2]**
  ◦ MPR (g) = 4 × $BW^{0.75}$ (kg) in neonates [2]
• For example, a 50-kg calf should receive about 2,600 kcal and 75 g of protein per day.

HISTORICAL FINDINGS

• Prolonged anorexia
  ◦ 1–2 days in neonates
  ◦ 5–7 days in adults
• Weight loss

SIGNALMENT

N/A

PHYSICAL EXAMINATION FINDINGS

• Evidence of dysphagia or choke
  ◦ Dropping feed from the mouth
  ◦ Ptyalism
  ◦ Feed coming from the nares
  ◦ Neck swelling or pain
  ◦ Free-gas bloat
  ◦ Abnormal jaw or tongue tone
• Evidence of malabsorption or maldigestion
  ◦ Chronic diarrhea
  ◦ Weight loss or cachexia
• Anorexia is common in ruminants with
  ◦ Altered mentation
  ◦ Chronic renal failure
  ◦ Gastrointestinal obstruction or stasis
  ◦ Severe anemia
  ◦ Severe dyspnea

GENETICS

PATHOLOGIC FINDINGS

N/A

TREATMENT

THERAPEUTIC APPROACH

Composition Determination

• First, volume of AA solution required to provide 100% of MPR should be calculated.
• 8.5–10% AA solutions provide 0.085–0.1 gram of protein per mL, respectively.
• Volume of AA solution can be calculated as follows:
  ◦ Volume (mL) = **[2]** / 0.1 with 10% AA solution **[3]**
  ◦ Volume (mL) = **[2]** / 0.085 with 8.5% AA solution **[3′]**
• A 50-kg calf should receive 750 mL of 10% AA solution or 900 mL of 8.5% AA solution per day to provide 100% of MPR.
• Each gram of AA provides 4 kcal and energy provided by AA solution can thus be calculated as follows:
  ◦ Energy (kcal) = **[3]** × 0.1 × 4 with 10% AA solution **[4]**
  ◦ Energy (kcal) = **[3′]** × 0.085 × 4 with 8.5% AA solution **[4]**
• For example, 750 mL of 10% AA solution or 900 mL of 8.5% AA solution provide 300 kcal.
• Second, volume of lipid solution required to provide 25% of MER should be calculated.
• 10–20% lipid solutions provide 1.1 and 2 kcal per mL, respectively
• Volume of lipid solution can thus be calculated as follows:
  ◦ Volume (mL) = (0.25 × **[1]**) / 2 with 20% lipid solution **[5]**
  ◦ Volume (mL) = (0.25 × **[1]**) / 1.1 with 10% lipid solution **[5′]**
• A 50-kg calf should receive 330 mL of 20% lipid solution or 600 mL of 10% lipid solution per day to provide 25% of MER.
• Energy provided by lipid solution can be calculated as follows:
  ◦ Energy (kcal) = **[5]** × 2 with 20% lipid solution **[6]**
  ◦ Energy (kcal) = **[5′]** × 1.1 with 10% lipid solution **[6]**
• Third, volume of dextrose solution required to provide the remainder of the MER should be calculated
• Each gram of dextrose provides 3.4 kcal and 50% dextrose solution contains 0.5 g of dextrose per ml
• Volume of dextrose solution can thus be calculated as follows:
  ◦ Volume (mL) = (**[1]** – **[4]** – **[6]**) / (3.4 × 0.5) with 50% dextrose solution **[7]**
• A 50-kg calf should receive 1,000 mL of 50% dextrose solution per day to provide the remainder of the MER.
• Energy provided by dextrose solution can be calculated as follows:
  ◦ Energy (kcal) = **[7]** × 0.5 × 3.4 with 50% dextrose solution **[8]**
• Lipids can sometimes be omitted to reduce the cost of PN.
• Lipids should be avoided in ruminants with liver dysfunction or hypertriglyceridemia.
• If lipids are not used, volume of dextrose solution should be calculated as follows:
  ◦ Volume (mL) = (**[1]** – **[4]**) / (3.4 × 0.5) with 50% dextrose solution **[7′]**
• A 50-kg calf should receive 1,400 mL of 50% dextrose solution should be administered per day if lipids are omitted.
• Nonprotein calories from dextrose and lipid solutions should be provided at a ratio between 100 and 300 kcal per gram of nitrogen to promote the use of AA for tissue maintenance and repair.
• Each gram of AA provides 0.16 g of nitrogen and amount of nitrogen provided from AA solution can thus be calculated as follows:
  ◦ Nitrogen (g) = **[3]** × 0.1 × 0.16 with 10% AA solution **[9]**
  ◦ Nitrogen (g) = **[3′]** × 0.085 × 0.16 with 8.5% AA solution **[9]**
• For example, 750 mL of 10% AA solution or 900 mL of 8.5% AA solution provide 12 g of nitrogen.

• Nonprotein calorie to nitrogen ratio (NPC:N) can be calculated as follows:
  ◦ NPC:N = ([**6**] + [**8**]) / [**9**]
• For example, a PN solution containing 750 mL of 10% AA solution, 330 mL of 20% lipid solution, and 1,000 mL of 50% dextrose solution, has a NPC:N of 190:1.
• Finally, the osmolarity of the PN solution should be calculated.
  ◦ Osmolarity of AA solution (mOsm/L) = [**3**] × 938 or [**3′**] × 920 = [**10**]
  ◦ Osmolarity of lipid solution (mOsm/L) = [**5**] or [**5′**] × 268 = [**11**]
  ◦ Osmolarity of dextrose solution (mOsm/L) = [**7**] or [**7′**] × 2525 = [**12**]
• Osmolarity (mOsm/L) of the PN solution can be calculated as follows:
  ◦ Osmolarity = ([**10**] + [**11**] + [**12**]) / ([**3**] or [**3′**] + [**5**] or [**5′**] + [**7**] or [**7′**])
  ◦ Osmolarity should not exceed 1,400 mOsm/L to limit the risk of thrombophlebitis.
• PN solution containing 750 mL of 10% AA solution, 330 mL of 20% lipid solution, and 1,000 mL of 50% dextrose solution has an osmolarity of 1600 mOsm/L.
• Therefore, crystalloid fluids should be added to this PN solution prior to administration.

Preparation

• PN solution should be prepared aseptically, preferably under a laminar hood.
• AA, dextrose, and lipid solutions can be added to an empty 3-in-1 mixing bag.
• Crystalloid fluids are usually added to decrease the osmolarity of the PN solution.
• Lipid solution should be added last because lipid destruction droplets can occur if lipids are mixed directly with dextrose solution.
• Lipids can also be administered through a separate line to allow intermittent discontinuation if hyperlipidemia develops.

Administration

• Jugular catheter should be placed aseptically.
• Central venous catheter should ideally be placed.
• PN solution should be administered through a separate catheter to reduce the risks of sepsis and drug incompatibility.
• PN solution should be protected from light as much as possible.
• PN should be initiated gradually
• 50% of maintenance nutrient requirements are usually administered on the first day
• It is important to adjust fluid therapy to maintain hydration in the meantime
• Administration rate is then gradually increased to provide 100% of maintenance requirements on the second or third day.
• Similarly, PN should be gradually decreased before discontinuing PN.
• Administration rate should be decreased if hyperglycemia develops.
• Lipids should be discontinued temporarily if hyperlipidemia develops.
• Amount of AA solution should be reduced in ruminants with liver or renal dysfunction.
• Enteral nutrition should be reintroduced as early as possible.
• Enteral nutrition via rumen fistula is a practical and economical alternative to PN in ruminants with dysphagia or choke.

MEDICATIONS

DRUGS OF CHOICE

• Example of PN solution for a 50-kg calf
  ◦ 1,900 mL of crystalloid fluids
  ◦ 750 mL of 10% AA solution
  ◦ 1,400 mL of 50% dextrose
• Administered at a maintenance rate (3.3 mL/kg/h), this solution provides 100% of maintenance requirements with a NPC:N of 190:1 and an osmolarity of 1,200 mOsm/L.
• Example of PN solution for an 80-kg alpaca
  ◦ 3,000 mL of crystalloid fluids
  ◦ 950 mL of 10% AA solution
  ◦ 900 mL of 50% dextrose
• Administered at a maintenance rate (2.5 mL/kg/h), this solution provides 100% of maintenance requirements with a NPC:N of 100:1 and an osmolarity of 830 mOsm/L.
• Example of PN solution for a 40-kg goat
  ◦ 800 mL of polyionic isotonic fluids
  ◦ 550 mL of 10% AA solution
  ◦ 1,100 mL of 50% dextrose
• Administered at a maintenance rate (2.5 mL/kg/h), this solution provides 100% of maintenance requirements with a NPC:N of 210:1 and an osmolarity of 1,400 mOsm/L.

Other Medications

• B vitamins can be administered every 2–3 days.
• Potassium supplementation (20–40 mEq/L) is indicated in ruminants with hypokalemia.
• Long-acting insulin (0.2–0.4 IU/kg SC) is indicated in camelids with severe prolonged hyperglycemia.
• Minerals, micronutrients, and vitamins should be added to the PN solution if administered for > 7 days.

CONTRAINDICATIONS

• Lipids should be avoided in ruminants with liver dysfunction or hypertriglyceridemia.

PRECAUTIONS

• Careful case selection is necessary because inappropriate use of PN may result in a higher incidence of complications and may worsen the outcome of the patient.

POSSIBLE INTERACTIONS

• Intravenous medications should be administered through a separate catheter and should not be added to the PN solution to reduce the risk of drug incompatibility.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

N/A

POSSIBLE COMPLICATIONS

• Sepsis, hyperglycemia, hyperlipidemia, hypokalemia, hypophosphatemia, and hypomagnesemia can develop in ruminants treated with PN.
• PN solutions are hypertonic and their use has been associated with thrombophlebitis.

CLIENT EDUCATION

• Due to the high cost of PN, this therapy should be considered in the light of the animal's value and prognosis.

PATIENT CARE

• Animals should be monitored closely for evidence of thrombophlebitis.
• Animals should be monitored closely for evidence of sepsis including
  ◦ Tachycardia or tachypnea
  ◦ Hyperthermia or hypothermia
  ◦ Leukocytosis or leukopenia
  ◦ >10% band neutrophils.
• Vitals and blood glucose should be monitored q8–12h.
• Urine output and urine specific gravity can be used to monitor hydration and renal function.
• PCV and total solids can be used to monitor hydration and prevent fluid overload, especially in calves, small ruminants, and camelids.
• Plasma should be evaluated daily for evidence of lipemia.
• Blood electrolytes and liver and renal enzymes should be monitored daily initially.

PENILE DISORDERS

BASICS

OVERVIEW

• Penile disorders in ruminants and camelids are often identified following breeding accidents or as part of a routine breeding soundness examination.
• These disorders affect the male's ability to service females in varying degrees and can lead to decreases in breeding efficiency.
• Penile disorders may be congenital, infectious, or traumatic in origin.
• Males with congenital disorders should be culled from breeding unless used as terminal sires. The most common congenital disorders are
  ◦ Persistent frenulum
  ◦ Short penis
  ◦ Hypospadias
  ◦ Penile deviations
• The most common acquired penile disorders are:
  ◦ Rupture of the tunica albuginea: Mainly seen in bulls
  ◦ Specific or nonspecific balanitis (all species)
  ◦ Penile fibropapilloma (bulls)
  ◦ Acquired peno-preputial adhesion or abscesses
  ◦ Urethral fistulas

INCIDENCE/PREVALENCE

• Persistent frenulum is commonly found in bulls and camelids.
• Ruptured tunica albuginea (broken penis) is expected sporadically in breeding bulls. It is more commonly encountered early in the breeding season when libido would be expected to be at its highest.
• The prevalence of penile fibropapillomas is highly variable within populations but its incidence is higher in populations of young bulls housed together. It has been reported in 60–70% of bulls in a group.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• Congenital defects
  ◦ *Persistent frenulum:* Normally around the time of puberty the penis separates from its attachment to the prepuce. The process of separation is under the influence of testosterone. Complete separation should have occurred by 12 months of age in bulls and by 6–8 months in small ruminants. In SAC, peno-preputial adhesions may persist until 3 years of age, however >70% have separated by 2 years of age. Failure of separation results in incomplete exteriorization of the penis during mating. Incomplete separation in bulls results in a persistent frenulum and causes varying degrees of ventral deviation of the distal penis during erection and breeding. This ventral deviation can potentially lead to breeding failure if the condition limits or prevents penetration during coitus.
  ◦ *Short penis:* Described in bulls and camelids, abnormal development of the penile shaft or abnormalities of the sigmoid flexure result in shortness of the penis and inability to complete mating. Some bulls may be able to breed in their first breeding season, then lose this ability as they grow.
  ◦ *Penile deviations:* Penile deviations are observed during erection in bulls and can be spiral, ventral, or S-shaped. It is not clear whether these deviations are congenital or may be acquired. Spiral deviation is the most common; it occurs normally within the vagina during peak erection and ejaculation. It hinders vaginal intromission if it occurs early and may predispose to penile hematoma.
  ◦ *Hypospadias:* This is a failure of the embryonic urethral groove to close along its entire length or at its distal part.
  ◦ *Vascular shunts:* These are abnormal vascular anastomoses between the erectile tissue and surrounding structures, leading to anomalies of erection.
  ◦ *Diphalia:* Duplication of parts of the free portion of the penis have been reported in bulls.
• Infectious disorders
  ◦ *Penile fibropapilloma or "penile warts":* A common condition affecting young or juvenile bulls, characterized by pedunculated growths on the distal penis. It is caused by the neoplastic growth of fibroblasts in animals carrying the bovine papillomavirus. This virus is common in young bulls and is easily spread from animal to animal via riding activity within groups of bulls. Abrasions on the penile epithelium appear to be the source of entry for the virus.
  ◦ *Specific balanitis:* Infectious balanitis is caused by BoHV1-2 in bulls, caprine herpesvirus in bucks.
  ◦ *Nonspecific balanitis* often observed in camelids.
  ◦ *Abscesses and peno-preputial adhesions:* Usually develop as a complication of preputial lesions or penile hematomas. In camelids, penile adhesions are relatively common in males that frequently masturbate (breed objects or sand).
• Traumatic disorders
  ◦ *Ruptured tunica albuginea:* This condition is reported primarily in bulls and results from an acute bend in the penis against the perineum. The resulting excessively high pressure in the corpus cavernosum of the penis (CCP) causes a rent to occur in the tunica albuginea on the dorsal aspect of the penis at the distal sigmoid flexure. Blood escapes from the CCP forming a hematoma just cranial to the neck of the scrotum.
  ◦ *Urethral fistulas:* Urethral fistulas may occur as a result of trauma, surgical removal of a mass or urethral calculi. This compromises potential semen deposition during mating.
  ◦ *Penile lacerations* are not uncommon in range bulls.

HISTORICAL FINDINGS

• Incidental finding of the lesions during BSE.
• Inability to complete mating: Lack of exteriorization of the penis or abnormal erection.
• Observed abnormality of the external genitalia such as a mass in front of the spermatic cord (hematoma), bloody or purulent discharge from the prepuce, or preputial prolapse.

SIGNALMENT

• Congenital abnormalities are often seen in young virgin males submitted for BSE.
• Acquired disorders are seen in breeding age animals generally early in the breeding season.
• Penile fibropapilloma is more likely to occur in bulls housed with other young bulls.

PHYSICAL EXAMINATION FINDINGS

• Bulls are generally healthy at presentation. The only clinical sign may be an abnormality of the external genitalia.
• Congenital abnormalities of the penis are often discovered at the time of semen collection by electroejaculation.
• Ruptured tunica albuginea: Affected bulls present with a history of an acute onset of swelling at the location of the distal sigmoid flexure. It is also common for bulls to have a concurrent preputial prolapse with this condition.
• Penile fibropapilloma: Scant preputial discharge or bleeding from the prepuce may be observed. Phimosis and in more severe cases paraphimosis can be seen with this condition, depending on the location, number, and severity of the masses.
• Lacerations of the penis due to bites occur in camelid males housed together (fighting injuries).

GENETICS

• Persistent frenulum is considered heritable in bulls.
• Ruptured tunica albuginea is reputedly more common in the Hereford breed.

CAUSES AND RISK FACTORS

• Although several developmental abnormalities of the penis have been described, the causes and risk factors have not been elucidated.

PENILE DISORDERS (CONTINUED)

• Ruptured tunica albuginea: There are no known causes for this condition but there have been risk factors proposed. Young bulls with high libido (early in the breeding season) and bulls who may have lost condition or who have become clumsy in their breeding attempts (late in the breeding season) may be at increased risk for this condition.
• Penile fibropapilloma: The causative agent is bovine papillomavirus (BPV) which is spread among naïve animals through breeding behavior. The primary risk factors include bulls of young age and exposure to other bulls where transmission can occur.
• Balanitis may be caused by specific agents (BoHV1-2 and *Ureaplasma diversum* in cattle, CpHV-1 in goat, OHV-2 in sheep). In sheep balanitis may be a complication of ulcerative posthitis (pizzle rot due to *Corynebacterium renale*) or local infection with other organisms (*Histophilus ovis*, *Streptococcus pyogenes*, *Mycoplasma bovigenitalum*). In camelids, balanitis is often a result of infections of abrasions caused by masturbation against objects or sand.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Ruptured tunica albuginea should be differentiated from other masses. Ruptured urethra, retropreputial abscess would be two primary rule-outs for this condition. Retropreputial abscesses are generally further distal and are more closely associated with the shaft of the penis. Urethral rupture typically involves the ventral aspect of the penis, and urine escaping into the area leads to large areas of swelling typically associated with the ventrum of the bull.
• Persistent frenulum is easily diagnosed during routine breeding soundness examination. The band of tissue connecting the ventral aspect of the penis with the prepuce can vary in size from several millimeters to several centimeters in diameter. Also some persistent bands are flat in their orientation. During erection the band of tissue will restrict the penis's ability to fully extend. This condition should be differentiated from traumatic adhesions.
• Diagnosis of congenital defects is often very straightforward.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Virology for viral causes of balanitis

IMAGING
Ultrasonography may aid in differentiating between a hematoma in the case of ruptured tunica albuginea and other masses (abscess or urine accumulation).

OTHER DIAGNOSTIC PROCEDURES
Radiography (cavernosogram) may be useful for the diagnosis of CCP vascular shunts.

PATHOLOGIC FINDINGS
• Penile papilloma can be submitted for confirmation of the diagnosis with histopathology; however, this is rarely indicated in most cases due to the consistent presentation and clinical signs associated with this condition.
• Viral balanitis is characterized by the presence of pustular lesions on the surface of the penis.

TREATMENT

THERAPEUTIC APPROACH
• Treatment of penile disorders is only indicated in valuable bulls. Bulls with congenital lesions should be discarded from breeding.
• Ruptured tunica albuginea: Conservative treatment involves sexual rest for a minimum of 60 days with antibiotic coverage for the first 1–2 weeks following injury.
• Penile papilloma: Warts involving the penis of bulls are best treated by surgical removal.
• Balanitis: Nonspecific balanitis may be managed by sexual rest and local antimicrobials. Viral balanitis is usually self-limiting.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Surgical treatment of ruptured tunica albuginea should be referred to a facility where there is expertise in the procedure. Bulls selected for surgery should preferably be not more than 10 days post-trauma as the associated fibrosis with older injuries makes a successful surgery and outcome less likely.
• Wart excision may be performed after local anesthesia with 1–2% lidocaine. The mass is excised with a scalpel, an electrosurgical unit, or a CO_2 laser. Large vessels associated with the mass are ligated and closed with 3-0 suture in routine fashion. Some large warts may not be easy to remove completely but can be successfully managed by debulking the mass with attention to adequate hemostasis. Special attention should be made to avoid damage to the urethra during removal. There are anecdotal reports of the benefits of immunostimulants such as Immunoboost (Bioniche Animal Health, USA) in managing large outbreaks. Both commercial and autogenous vaccines have been used with varying results and may help reduce recurrence when large numbers of bulls are affected.
• Persistent frenulum: A small bleb of 2% lidocaine can be injected into each end of the frenulum and a ligature should be tied at each end. The band can then be easily transected. Very small frenulums can be broken down manually but there may be some minor hemorrhage noted.

MEDICATIONS

DRUGS OF CHOICE
Depending on the condition, a combination of local ointment, systemic antibiotics, and anti-inflammatories may be indicated.

CONTRAINDICATIONS
Appropriate meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Most bulls with severe penile disorders will be classified as unsatisfactory and culled from breeding.
• Prognosis is good for bulls with persistent penile frenulum but they should only be used as terminal sires.
• Prognosis is good for penile fibropapilloma if there are no complications.
• Penile hematoma: With proper patient selection 50% of bulls treated conservatively and 75% of bulls treated surgically are able to return to breeding soundness.

POSSIBLE COMPLICATIONS
Extensive fibrosis may limit the bull's ability to extend the penis during coitus without pain.

CLIENT EDUCATION
• All males should be submitted to BSE prior to breeding.
• Males should be closely monitored for any abnormality and submitted for examination by a practitioner immediately.
• Serving capacity is not part of the BSE. Client should observe male activity once joined with the females.

PATIENT CARE
• Sexual rest for a minimum of 60 days is recommended in cases of ruptured tunica albuginea.
• All bulls treated for penile fibropapilloma should be evaluated for complete healing and absence of any regrowth 4–6 weeks following surgery.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
Infertility

AGE-RELATED FACTORS
Congenital defects are often discovered during examination of young virgin males.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
• Introduction of new breeding males into an operation is one of the most frequent causes of introduction of diseases.
• All males should be procured from a reputable source and examined prior to use for breeding.

PRODUCTION MANAGEMENT
Management of a group of males should take into account aggressive behavior which may result in serious injuries.

PENILE HEMATOMA

BASICS

OVERVIEW AND PATHOPHYSIOLOGY
• Hematoma of the penis is probably the most common injury of the penis and is often referred to as a broken or fractured penis.
• Even observant owners/caretakers may not notice this condition for 2–3 days.

INCIDENCE/PREVALENCE
Frequent

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEM AFFECTED
Reproductive

PATHOPHYSIOLOGY
• A bull typically has a fully engorged penis as he mounts in preparation for breeding. After two or three searching motions of the penis near the vulva, he normally makes one very forceful thrust, followed by intromission.
• Thus injury occurs when the penis misses the intended target, hits the cow's perineum, and bends.
• The hematoma results from rupture of the tunica albuginea and the subsequent hemorrhage from the corpus cavernosum. This rupture is typically a 2–7.5 cm tear.
• The initial volume of blood escaping is <250 mL but the size of the resultant hematoma varies as each subsequent erection results in further hemorrhage.
• Therefore the hematoma may range in size from 15 cm to 30 cm.
• The resultant swelling occurs in the sheath over and cranial to the rudimentary teats.

HISTORICAL FINDINGS
Observed lesion

SIGNALMENT
• Although it usually occurs in young inexperienced bulls, it can also occur in the older bull, which due to orthopedic injury or pain has altered his approach during mounting.
• Aggressive, high libido bulls, most commonly 2–4 years old.
• A previous history of this condition places an individual at risk for recurrence regardless of treatment, although surgical repair has been associated with a lower recurrence rate.

PHYSICAL FINDINGS
• A large symmetrical swelling cranial to the scrotum.
• In some instances the prepuce will be prolapsed.

GENETICS
Herefords are predisposed. Charolais are over-represented compared to other breeds.

CAUSES AND RISK FACTORS
• Sudden angulation of the penis during erection caused by misalignment during breeding may result in rupture of the tunica albuginea and hematoma formation.
• Aggressive (high libido) breeding bulls, awkward breeding attempts of novice bulls, over-fit bulls, older bulls with orthopedic problems.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Urethral rupture—swelling is ventral to the sigmoid flexure and more symmetric.
• Retropreputial abscess—this swelling is typically located along the more distal aspects of the penis.

CBC/BIOCHEMSTRY/URIANALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Ultrasonography is helpful in differentiating a hematoma from an abscess.

OTHER DIAGNOSTIC PROCEDURES
• Physical examination:
  ◦ Presence of a large swelling immediately cranial to the scrotum.
  ◦ Bruising of the skin over the hematoma occurs but is only apparent in light-skinned bulls.
  ◦ Secondary preputial prolapse secondary to a penile hematoma; this in fact may be the owner's reason for seeking help.
• Do not attempt to aspirate the swelling as inadvertent introduction of bacteria can convert a hematoma to an abscess.
• Do not attempt to manually extend the penis as this may further damage peri-penile elastic tissue.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Systemic antibiotic treatment for 7–10 days
• Hydrotherapy
• Sexual rest for 60–90 days

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Optimal time for surgery: 5–7 days post occurrence.
• Given that the owner or attendant typically may not notice this problem for 2–3 days and that the patient should be fasted for 36–48 hours prior to surgery, surgery must be scheduled immediately in an attempt to avoid clot organization and fibrosis that begins to occur 10 days post-injury.
• Surgery may again be attempted after 21 days post occurrence.
• Preparation: Antibiotics, fast for 36–48 hours, and withhold water overnight.
• General anesthesia can be utilized or regional anesthesia with heavy sedation.
• Surgery consists of clot removal and repair of the rent in the tunica albuginea.
• Antibiotic coverage should extend for 7 days.
• The bull should have 60–90 days of sexual rest following surgery.
• Seroma formation occurs often enough that it probably should not be considered a true complication.

MEDICATIONS

DRUGS OF CHOICE
Procaine penicillin: 44,000 IU/kg, IM, q12h

CONTRAINDICATIONS
Meat withdrawal time should be followed.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The success rate for medically managed cases is around 60–70% for hematomas measuring <20 cm across and 30% for larger hematomas.
• The surgical success rate is 70–80% regardless of the size.

POSSIBLE COMPLICATIONS
• Abscessation
• Suture dehiscence
• Permanent analgesia to the penis (i.e., loss of sensation, likely results from damage to the dorsal nerve of the penis occurring from the initial injury)
• Reoccurrence

CLIENT EDUCATION
Owner/caretakers should observe bulls daily during the breeding season.

PATIENT CARE
Bulls can be returned to a pasture environment with little oversight as long as they are away from cows.

PERICARDITIS

BASICS

OVERVIEW
• Inflammation of the pericardium with accumulation of fluid or exudate within the pericardial sac.
• In cattle, it most often relates to traumatic reticuloperitonitis (TRP) in which fibrinous septic pericarditis develops following perforation of the pericardial sac by a contaminated, metallic foreign body originating from the reticulum.
• Septic pericarditis can also arise from hematogenous infection or direct extension of infection from pleuropneumonia, pleuritis, or myocarditis.
• Other causes include viral infections, neoplasia, and idiopathic disease.
• Pericarditis can be effusive with accumulation of nonseptic fluid within the pericardial sac; or fibrinous (typically septic in nature), with accumulation of fibrin ± fluid in the pericardial sac which over time can lead to constrictive pericarditis with fibrosis and thickening of the pericardial sac.

INCIDENCE/PREVALENCE
Uncommon; septic pericarditis has high mortality.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Cardiovascular
• Respiratory
• Digestive
• Integument

PATHOPHYSIOLOGY
• Can result from bacterial or viral inflammation, cardiac neoplasia, or is idiopathic.
• Initially, inflammation of the pericardium with hyperemia, fibrin deposition, and small amounts of exudate can cause pain and an audible friction rub due to the pericardium and epicardium interacting during cardiac motion.
• As fluid accumulates in the pericardial sac, friction sounds decrease, heart sounds become muffled, and tachycardia progresses.
• Gas can accumulate in the pericardial space if specific bacteria are present, resulting in more profoundly abnormal cardiac sounds.
• Heart chambers become compressed due to pericardial fluid ± fibrin, leading to cardiac tamponade. Inhibition of venous return may interfere with ventricular filling during diastole, resulting in decreased end-diastolic volume, stroke volume, and cardiac output, leading to congestive heart failure.
• With chronicity, fluid is resorbed and adhesions may form between the pericardium and epicardium, which over time can result in constrictive pericarditis and cardiac failure.

HISTORICAL FINDINGS
• Usually limited to the onset of clinical signs of disease.
• A history of previous cases of TRP is common on poorly managed establishments.
• Exercise intolerance and increased recumbency are common historical complaints in other ruminants and camelids.

SIGNALMENT
• Mature cattle; typically dairy cattle
• Uncommon in small ruminants
• Juvenile and pregnant camelids (*Streptococcus zooepidemicus* infection)

PHYSICAL EXAMINATION FINDINGS
• Early signs in cattle with traumatic reticuloperitonitis include reduced appetite, intermittent fever, tachypnea, tachycardia, elbow abduction, an arched back, and respiratory grunt. There may be pain on palpation of the thoracic wall over the cardiac region, and a "friction rub" evident on auscultation of the heart. Pinching of the withers or upward pressure on the xiphoid region may elicit a grunt on expiration.
• As disease progresses, signs of increased venous pressure/right-sided heart failure can occur, including peripheral edema, bilateral jugular distention ± abnormal pulsation, and abdominal and thoracic cavity fluid accumulation which may decrease lung sounds over the ventral thorax and contribute to dyspnea. A "splashing" or "washing machine murmur" may be apparent if gas is present in the pericardium.
• Diarrhea, dehydration, decreased milk production, decreased GI motility, and signs of toxemia and death can occur.
• In nonseptic pericarditis or in other species with pericarditis, the main findings are peripheral edema, jugular venous distention and pulsation, tachypnea, or dyspnea ± fever.
• Heart sounds are muffled, with an expanded area of cardiac dullness, decreased palpability of the apex beat, and weakened peripheral pulses. Reduced audibility of ventral lung sounds is common.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Ingestion of metallic foreign bodies
• Extension from another focus of infection (e.g., pleuropneumonia)
• Secondary to lymphoma or other neoplasms
• Polyserositis (e.g., *S. zooepidemicus* in camelids)
• Mycoplasmosis in goats

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other causes of cranial abdominal pain and thoracic pain such as perforating abomasal ulcer, hepatic abscesses and pleuritis
• Infectious endocarditis
• Pasteurellosis or mycoplasmosis (cattle, sheep, and goats)
• *Histophilus somni* infection
• Cor pulmonale
• Cardiac lymphoma
• Idiopathic hemorrhagic pericardial effusion of cows
• Heartwater/cowdriosis (Africa and Caribbean)
• Other causes of vagal indigestion

CBC/BIOCHEMISTRY/URINALYSIS
• CBC: Leukocytosis ± left shift, elevated total protein, and hyperfibrinogenemia.
• Biochemistry can reflect heart failure, dehydration, anorexia, and rumen stasis, with azotemia, hypochloremic metabolic alkalosis, hypokalemia, hypocalcemia, increased AST and GGT, and increased CK if recumbent.

OTHER LABORATORY TESTS
• Cardiac troponin I
• Bovine leukemia virus: AGID, ELISA, or PCR

IMAGING
• Ultrasonography
  ◦ Abdominal and thoracic ultrasound assist in ruling out other differentials.
  ◦ Echocardiography determines the presence, amount, and character of pericardial effusion and fibrin, and the integrity of cardiac valves or presence of other anomalies (tumors).
  ◦ Cardiac chamber collapse can be assessed; usually progresses in the order of right atrium, right ventricle, then left side chambers as fluid accumulation increases.
  ◦ Pericardial effusion is imaged between the pericardium and epicardium, around both ventricles.
  ◦ Clear anechoic effusion is most consistent with a transudate, and more echogenic fluid with fibrin is typical of septic or traumatic pericarditis.
  ◦ Evaluating the cranial abdominal region can identify reticular abscesses and adhesions, abnormal reticular contour or wall, and abnormal reticular motility. Rarely, causative foreign bodies might be identified.
• Radiography
  ◦ Main utility is in the detection of metallic foreign bodies and their position within the abdomen, thorax, or reticulum.

◦ Thoracic radiographs may be obscured by pleural effusion or may display cardiomegaly, obscured cardiac silhouette, and gas fluid interfaces within the pericardium or near the reticulum.

OTHER DIAGNOSTIC PROCEDURES

• Pericardiocentesis
◦ Can be performed standing in cattle, and in laterally recumbent goats, preferably using ultrasound guidance. Pneumothorax, cardiac puncture, arrhythmias, hemorrhage, and cardiac tamponade are all risks of this procedure
◦ Aseptically prepare skin over the 5th intercostal space (ICS), then inject local anesthetic over the dorsal and cranial aspect of the 6th rib, blocking skin, subcutaneous tissue, and parietal pleura.
◦ An 18-G spinal needle, or, after a small skin incision, a 4–8 inch intravenous catheter or small chest tube, is advanced through the left 5th ICS just dorsal to the elbow at the anterior aspect of the 6th rib.
◦ For goats, use the right 4th ICS low on the chest wall to avoid lung and coronary arteries.
◦ Fluid can be drained and submitted for analysis (cytology, and protein, lactate and glucose evaluation) and for bacterial/mycoplasma culture and sensitivity.
◦ Traumatic pericarditis tends to produce fluid with a high protein concentration (>3.5 g/dL), high lactate and low glucose concentration, and an elevated cell count (>5,000/µL) composed primarily of neutrophils. The fluid may be discolored, with a foul odor. A mixed population of Gram-positive and Gram-negative aerobic and anaerobic bacteria (GI flora) are usually present.
◦ Cardiac lymphoma is intermittently identified on cytologic evaluation of pericardial effusion.
• Electrocardiogram reveals diminished amplitude of QRS complexes, potentially cardiac arrhythmias, and electrical alternans in animals with significant pericardial effusion.
• Abdominocentesis provides fluid with increased protein concentration (>3 g/dL), cell count (>10,000 cells/µL), and presence of toxic or degenerate cells if suppurative peritonitis is present; however, normal results do not exclude disease or may reflect ascites.

PATHOLOGIC FINDINGS

• Pericardial effusion
• Fibrin tags on pericardial and epicardial surfaces
• Thickening of epicardium and pericardium, which may be adhered to each other
• Lesions of congestive heart failure
• Evidence of reticular penetration and peritonitis in TRP cases
• If present, cardiac lymphoma is typically identified invading the right atrium.

TREATMENT

THERAPEUTIC APPROACH

• Particularly in septic pericarditis, treatment is long-term, costly, and often unsuccessful, so culling is typically recommended. Treatment is not recommended in cardiac lymphoma.
• Broad-spectrum, parenteral, bactericidal antibiotics are preferred, and when possible selected based on cytology, culture, and sensitivity results from pericardial fluid.
• Analgesic and anti-inflammatory drugs as needed.
• If significant effusion is present, the pericardial sac can be drained and lavaged with isotonic, nonirritating fluid followed by installation of an antimicrobial drug. This is of limited use in constrictive pericarditis or neoplasia.
• Diuretics and restriction of dietary salt can be practiced if congestive heart failure is present.
• Idiopathic effusive pericarditis cases can benefit from drainage and provision of corticosteroids or nonsteroidal anti-inflammatory drugs.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• Rumenotomy should be considered to remove definitively identified penetrating foreign bodies.
• If unresponsive to medical therapy, thoracotomy and pericardectomy or pericardiostomy can provide drainage or allow marsupialization of pericardium to body wall in valuable animals with septic pericarditis.

MEDICATIONS

DRUGS OF CHOICE

• Penicillin: 22,000 IU/kg q12h, IM (procaine) or q6h, IV (aqueous potassium penicillin)
• Amoxicillin: 10 mg/kg IM q12h
• Flunixin meglumine: 1.1 mg/kg q24h or 0.5 mg/kg q12h
• Aspirin: 30–100 mg/kg PO q12–24h
• Furosemide: 0.5–1.0 mg/kg IV q12–24h
• Potassium supplement (50–200 g/day PO) if on potassium-wasting diuretics

CONTRAINDICATIONS

N/A

PRECAUTIONS

• Extra-label use of antibiotics often occurs during treatment of septic pericarditis because few are labeled for such long-term therapy.
• Early withdrawal of therapy may result in relapse.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Complete recovery is uncommon with septic pericarditis, with a prognosis likely <30%.
• Prognosis declines with chronicity.
• Idiopathic hemorrhagic pericarditis cases can recover completely.

POSSIBLE COMPLICATIONS

• Chronic disease may result in constrictive pericarditis and cardiac failure.
• Survivors may have myocarditis and arrhythmias.

CLIENT EDUCATION

Focus on maintaining a safe feed supply, particularly avoiding incidental inclusion of metallic foreign bodies in chopped rations.

PATIENT CARE

• Supportive care to maintain hydration, nutritional status, and electrolyte and acid–base balance.
• Appropriate treatment of secondary organ disease or dysfunction.

PREVENTION

• Relies on preventing exposure to metal objects in feed; large magnets can be placed on feed handling equipment.
• Prophylactic administration of forestomach magnets into the rumen at 6–8 months of age to confine ingested metallic objects.
• Protocols to reduce bovine leukemia infection within cattle herds.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Traumatic reticuloperitonitis
• Congestive heart failure
• Myocardial disease
• Bovine leukemia virus

PERINATAL LAMB MORTALITY

BASICS

OVERVIEW
• Mortality in lambs can be high and can significantly limit sheep production.
• Although it is easy to limit mortality in lambs, and essential if rearing sheep is to be profitable, it is often overlooked.
• Perinatal survival is influenced by late-term lamb development, uncomplicated parturition, appropriate udder development, and close monitoring of the ewe-lamb bond.

INCIDENCE/PREVALENCE
• Majority of losses occur during the first week of life (Figure 1a), particularly during the first 72 hours (Figure 1b).
• Mortality in lambs occurs during the last 3 weeks of gestation (15%), during parturition (20%), and the majority in the postpartum period (65%).
• Prevalence is recorded from various countries to be between 9% and 20%; <5% is regarded as good.

GEOGRAPHIC DISTRIBUTION
Worldwide distribution, although causes and timing of losses will vary.

SYSTEMS AFFECTED
Multisystemic

Figure 1a.

Most Neonatal Mortality Occurs During the First Week of Life

Figure 1b.

Mortality Rates are Highest During Days 1, 2, & 3 Following Birth

PATHOPHYSIOLOGY
• Caused by poor flock management.
• Majority of the losses are caused by (1) starvation, hypothermia, and exposure; (2) stillbirth (including dystocia); (3) pneumonia; and (4) abortion.

HISTORICAL FINDINGS
Critical illness leading to death or found dead.

SIGNALMENT
Majority of deaths occur in utero or during the first week after birth.

PHYSICAL EXAMINATION FINDINGS
Dependent on etiology

GENETICS
Some evidence of genetic components within breeds (e.g., Suffolks and spider lamb syndrome). In addition, selective breeding strategies to optimize production in certain breeds will likely reduce mortality.

CAUSES AND RISK FACTORS
There are ten top causes of perinatal lamb mortality.

1. Stillbirth
Usually the cause of mortality in 3–5% of lambs.

2. Death Secondary to Dystocia
• These lambs will often be meconium stained.
• May have rib fractures, ruptured liver, umbilical or abdominal herniation.

3. Hypothermia/Starvation Complex
• Simple hypothermia will be seen in lambs <6 hours old who are wet in predisposing environmental conditions.
• Hypothermia secondary to starvation (50% of lambs in the first week) will be seen in lambs >6 hours old who are usually dry.

4. Pneumonia
• These lambs are usually >4 hours of age.
• Cranioventral lobes affected, abscesses may be visible.
• When pneumonia is secondary to sepsis, lesions will be more extensive.

5. Abortion
• Independent of cause, most abortions are seen in the last month of gestation.
• Individual farms—may see 5–25%.
• Normal rate considered 1–2%.
• Oral transmission route.
• Campylobacteriosis
  ◦ Abortion (132 days), stillbirths, and weak lambs that die shortly after birth.
  ◦ Ewe not sick.
  ◦ Lamb largely normal (immature lung—poor or no inflation).
  ◦ History of ewes added to the flock.
• Toxoplasmosis
  ◦ Abortion, stillbirth, mummified fetuses, weak lambs, open ewes.
  ◦ Mummification of fetuses is common.
  ◦ Fetal thoracic fluid useful to obtain a *Toxoplasma* antibody titer.
• *Chlamydia* (enzootic abortion in ewes)
  ◦ Abortion, stillbirth, and weak lambs.
  ◦ Sick ewes.
  ◦ Often seen in successive years.
• *Coxiella burnetii* (Q fever)
  ◦ Abortion secondary to necrotizing placentitis.
  ◦ Ewes may be well or sick.
  ◦ Can become persistent carriers so low-grade problems remain in herd.
• Schmallenberg virus
  ◦ Orthobunyavirus—transmitted via insects.
  ◦ Caused significant lamb mortality in Europe since 2011—20–70% loss on affected farms.
  ◦ Abortions, stillbirths due to congenital musculoskeletal malformations, weak lambs.
  ◦ Ewes generally not ill.

6. Trauma, Particularly Fractured Ribs
Often secondary to hypothermia and starvation, dystocia, or farm movement procedures.

7. Diarrhea
• *Escherichia coli*
  ◦ Usually causes disease in the first week of life.
  ◦ Particularly seen to cause disease during days 2–4 secondary to poor immunity/failure of passive transfer.
  ◦ Affected lambs will often be found dead within 24–48 hours of developing clinical signs.
  ◦ Usually evident which lambs have diarrhea as they will have a wet, stained tail and rump area.
  ◦ This is often an individual flock problem and may be seen at certain times of year when the weather changes.
• Coccidiosis
  ◦ Seen in lambs 4–6 weeks old.
  ◦ In addition to diarrhea, these animals will strain.
  ◦ Blood in feces is rare.
  ◦ Often an individual flock problem and may be seen at times of year when the weather is changing.

8. Sequelae to Sepsis—Umbilical and Joint Infection
• Seen in lambs 10–30 days (particularly those 2–3 weeks old).
• Due to foci of infection, lambs with be thin with weight loss or poor weight gain.
• Lambs will be lame, often in more than one limb, with distended joints.
• May have a swollen or discharging umbilicus.
• Secondary pneumonia common.
• Will often be seen following changes in weather.

9. Intestinal Obstruction
• History of abdominal pain preceding collapse and death.
• Distended abdomen.

PERINATAL LAMB MORTALITY (CONTINUED)

• Causes include intestinal torsion, volvulus, or intussusception.
• Can be seen secondary to diarrhea, but also common in lambs reared on milk replacer.
• Can be misdiagnosed as overeating disease.

10. Clostridium perfringens Types C and D

• *Clostridium perfringens* type C
  ◦ Present with sudden death in 1- to 3-day-old lambs.
  ◦ Affected lambs collapse, and die within 24–48 hours.
  ◦ Diarrhea rare.
  ◦ More common in unvaccinated flocks and in lambs with failure of passive transfer.
• *Clostridium perfringens* type D
  ◦ Lambs >4 weeks of age found dead.
  ◦ Common in creep-fed and feedlot lambs, but is also seen in orphan lambs raised on milk replacer.

Risk Factors

The following risk factors influence perinatal or postnatal mortality:
• Highest stillbirth rates on smallest and largest farms and those with unaided and unsupervised parturition
• Intensive rearing systems, although housing sheep for parturition reduced losses
• Low lamb birthweight
• Triplets and quadruplets
• Fostering a large number of lambs
• Poor lambing pen hygiene
• Poor ewe condition at breeding and poor ewe nutrition
• Poor mothering leading to failure of passive transfer
• Relationship between losses and low ambient environmental temperatures

P

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

See "Causes and Risk Factors," but these will fall into the following categories:
• Environmental factors
• Management effects
• Genetic factors
• Hygiene and infectious causes

CBC/BIOCHEMISTRY/URINALYSIS

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

• Gross postmortem examination of all dead lambs is of great value.
• Economical means of confirming cause
  ◦ Examine all dead lambs to document flock trends
  ◦ Try to discern whether the lamb has breathed, nursed and the extent of fat coverage.
• Use caution (especially women of childbearing age) when handling dead lambs and placentas, especially if abortion is a problem.
• Use a diagnostic laboratory for persistent or undiagnosed problems.
• Educational tool for producers.
• Focus control programs by classifying into four to six basic categories.

PATHOLOGIC FINDINGS

1. Stillbirth

Necropsy reveals non-aerated lung.

2. Death Secondary to Dystocia

Necropsy reveals meconium staining; and rib fractures, ruptured liver, umbilical or abdominal herniation may be present.

3. Hypothermia/Starvation Complex

• Hypothermia. Minimal findings, but no fat depletion is present and milk may or may not be present in the abomasum.
• Hypothermia/starvation complex. Abomasum usually empty and there is marked fat depletion throughout, particularly evident surrounding the kidney and coronary groove.

4. Pneumonia

Consolidated lung lesions on necropsy will usually be clearly demarcated, may be in the cranioventral lobes, and abscesses may be visible. When pneumonia is secondary to sepsis, there may be evidence of adhesions, where the whole lung is edematous with evidence of epicardial hemorrhage and pericardial effusion.

5. Abortion

• Campylobacteriosis. Placenta normal in appearance; lamb largely normal (immature lung—poor or no inflation).
• Toxoplasmosis.
  ◦ Mummification of fetuses is common
  ◦ White, focal (1–2mm) lesions on cotyledons, but no intercotyledonary lesions
  ◦ Fetal thoracic fluid useful to obtain a Toxoplasma antibody titer
• *Chlamydia* (enzootic abortion in ewes). Placental examination shows necrotic cotyledons and thickened intercotyledonary areas.
• *Coxiella burnetii* (Q fever). Necrotic placental lesions.
• Schmallenberg virus
  ◦ Stillborn lambs with congenital musculoskeletal malformations.
  ◦ Minimal placental changes.

6. Trauma, Particularly Fractured Ribs

Necropsy reveals hemothorax, punctures to the lungs, ruptured liver or spleen leading to hemoperitoneum.

7. Diarrhea

• *Escherichia coli*
  ◦ Wet, stained tail and rump area
  ◦ Necropsy reveals signs consistent with sepsis to include petechial hemorrhages on the epicardium
  ◦ The intestines will have a thin, discolored wall and will be distended and fluid filled
  ◦ There may be intestinal perforation with adhesions and secondary peritonitis
  ◦ May see secondary lesions consistent with the hypothermia/ starvation complex
• Coccidiosis. At necropsy, the intestines will be thin and distended with fluid, but little blood with intestinal contents.

8. Sequelae to Sepsis—Umbilical and Joint Infection

Necropsy will often reveal thin carcasses with minimal fat, lung changes consistent with pneumonia spread hematogenously (changes throughout lungs), liver abscessation due to extension of infection from the umbilical vein; secondary peritonitis; thickened, fibrous umbilicus that may contain purulent, necrotic material; and distended joints with a thickened joint capsule containing thickened, purulent material.

9. Intestinal Obstruction

Necropsy reveals purple discoloration to the affected section of bowel. Changes secondary to sepsis (petechiae) may be present on other organs (epicardium; serosal surface of adjacent pieces of intestine) and peritonitis may also be present.

10. Clostridium perfringens Types C and D

• *Clostridium perfringens* type C. Necropsy reveals increased pericardial fluid, epicardial hemorrhage with or without fibrin. The abomasum often engorged with milk and hemorrhagic abomasitis. Minimal excessive fluid within the intestines.
• *Clostridium perfringens* type D. Necropsy often reveals minimal changes, but will include petechial hemorrhages on organ surfaces and necrotic intestine.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
• Clients must appreciate financial losses with this condition.
• Need to appreciate the value of necropsy evaluation of all lambs in order to find causes and then solutions on all farms where losses are >5%.
• Need to evaluate aspects of rearing likely problematic:
  ◦ Ewe nutrition
  ◦ Hygiene
  ◦ Lamb-ewe bond affecting transfer of immunity
  ◦ Disease control when causes of mortality known.

PATIENT CARE
Good supportive care (i.e., thermal support, fluid therapy, etc.) and biosecurity (i.e., separating sick animals) are imperative to decrease mortality.

PREVENTION
See "Production Management"

MISCELLANEOUS

ZOONOTIC POTENTIAL
Use caution (especially women of childbearing age) when handling dead lambs and placentas, especially if investigating an abortion problem.

PREGNANCY
• Appropriate ewe nutrition and identification of ewes with multiple fetuses will help prevent the birth of weak, small lambs.
• In flocks with sheep breeds producing >2 lambs, have management practices in place to ensure effective provision of colostrum and nutrition.

BIOSECURITY
Buying in ewes can predispose to certain infectious causes of abortion (see "Causes and Risk Factors").

PRODUCTION MANAGEMENT
• Often cannot truly assess or affect losses during the lambing season.
• Losses are seen with individual flock patterns that require assessment over time—losses and causes in one year may not reflect overall problems.
• Information on the cause or causes of mortality allows disease control and management changes to be made in a timely fashion.
• The major management areas to address include:
  ◦ Minimizing effects of the environment and weather
  ◦ Forage resources
  ◦ Ewe nutrition
  ◦ Genetic selection
  ◦ Monitoring of newborn lambs and minimization of mismothering
  ◦ Hygiene and disease control
  ◦ Appropriate use of labor and facilities.
• Lamb mortality should ideally be <5%, but is challenging to achieve; 5–10% is a more realistic goal.

SYNONYMS
• Lamb mortality
• Neonatal mortality
• Postmortem examination
• Preweaning losses

PESTE DES PETITS RUMINANTS

BASICS

OVERVIEW

Peste des petits ruminants (PPR), also known as goat plague, contagious pustular stomatitis, kata, pneumoenteritis syndrome, and pseudo-rinderpest of small ruminants, is an acute viral disease of small ruminants. PPR is a significant threat to food security and sustainable small ruminant production in much of the eastern hemisphere. It is a listed and reportable disease in accordance with the OIE *Terrestrial Animal Health Code* and is a joint OIE/FAO target for eradication by 2030.

INCIDENCE/PREVALENCE

- Significant portions of the world are free of PPRV. The OIE WAHIS interface provides current information on disease status by country.
- Seroprevalence in endemic regions varies greatly by location, with reports ranging from 30% to over 90%. Apparent clinical prevalence may be low.
- Epizootics occur when a susceptible population is exposed. Morbidity rates may approach 100% with case fatality rates approaching 90%.

GEOGRAPHIC DISTRIBUTION

PRRV is widespread across major sections of Africa, the Arabian peninsula, and Asia.

SYSTEMS AFFECTED

- Digestive
- Hemolymphatic
- Respiratory

PATHOPHYSIOLOGY

- Transmission occurs through close contact with infected animals, their infectious ocular, nasal, oral, and fecal secretions, or inhalation of droplet aerosols.
- There is no true carrier state. Incubatory carriers shed virus prior to clinical disease. Affected animals shed virus for 3 weeks post-infection.
- Clinical signs typically appear 4–6 days post-infection and last 2 weeks in survivors. The *peste des petit ruminants* virus (PPRV) replicates in the host cells' cytoplasm, with an affinity for tonsillar, lymphoid, and epithelial tissues.
- PPRV is highly immunosuppressive, causing a profound leukopenia and CD4+ T-cell suppression. Secondary infections are common.
- Extremely high morbidity and case fatality rates occur in naïve herds. Goats and young stock are most severely affected. A peracute form has been observed in goats, causing high fevers, severe depression, and death before the onset of classical lesions. Subclinical infections may occur in enzootic settings.
- Infection with PPRV provokes both cellular and humoral immune responses, primarily targeted against the H, F, and N viral protein antigens. Surviving affected animals are immune for life. Maternal antibodies are capable of virus neutralization for the first 3–4 months of life.

SIGNALMENT

- Goats, sheep, camels, and Indian buffalo.
- Some breed differences have been reported in goats. The West African Dwarf and Alpine breeds are considered highly susceptible; Saanens are reportedly more resistant.
- Young stock >4 months of age, up to about 18–24 months, are at greatest risk.

PHYSICAL EXAMINATION FINDINGS

- Cases observed only in the small ruminant population; co-located cattle are not affected.
- Nonspecific signs of depression, anorexia, and a dull, staring hair coat.
- Pyrexia 104–106°F (40–41°C).
- Profuse serous oculonasal discharge that becomes mucopurulent with chronicity resulting in matted eyes and crusting nasal occlusion.
- Hyperemic nasal and oral mucosa with necrotizing erosions and fibrinous pseudo-membranes on the nares, gingiva, dental pad, hard palate, buccal surfaces, and tongue; a putrid oral odor may be observed.
- Profuse diarrhea.
- Coughing, dyspnea, and other signs of pneumonia.
- Abortion.
- Dehydration.
- Emaciation.
- Death.

CAUSES AND RISK FACTORS

- PPR is caused by the *peste des petits ruminants* virus (PPRV), a paramyxovirus of the genus Morbillivirus. It is a single-stranded negative-sense RNA virus that is antigenically similar to the rinderpest virus.
- Circulating strains of PPRV can be organized into four distinct lineages. Lineages I–III have been associated with African outbreaks while lineage IV was originally found in the Middle East and Asia but is now present across all PPR enzootic regions.
- Major epizootics occur when the virus is introduced to a naïve susceptible population.
- Risk factors include co-mingling at animal centers, movement of transhumant populations, and waning passive immunity in the young stock. Poor nutritional status, stress, and concurrent infections may enhance the severity of disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

- Rinderpest
- Foot and mouth disease
- Bluetongue
- Contagious ecthyma
- Contagious caprine pleuropneumonia
- Respiratory pasteurellosis
- Nairobi sheep disease
- Heartwater
- Coccidiosis
- Plant or mineral poisoning

CBC/BIOCHEMISTRY/URINALYSIS

Leukopenia

OTHER LABORATORY TESTS

- Gold standard is virus isolation: Sample during the acute phase from clear oronasal secretions, buccal or rectal mucosa, anticoagulant whole blood, or erosion debris.
- Antigen and RNA-based diagnostics include immunochromatographic lateral flow, RT-PCR or QRT-PCR, immunohistochemistry, and immunocapture ELISA.
- Diagnostic serology includes serum cELISA, virus neutralization, AGID, and counter immunoelectrophoresis. Paired acute and convalescent serum samples will show a fourfold or greater rise in antibody titer. Cannot currently distinguish vaccinates from natural infections.

OTHER DIAGNOSTIC PROCEDURES

- Postmortem target tissues for virus isolation, antigen and RNA-based diagnostics include tonsils, lymph nodes (retropharyngeal, bronchial, and mesenteric), lung parenchyma, spleen, and intestinal mucosa (ileum and large intestine).
- Fresh tissues should be chilled (not frozen) and delivered cold to the laboratory within 12 hours of collection.
- 10% neutral buffered formalin fixed tissues should be submitted for histopathology.

PATHOLOGIC FINDINGS

- External: Severe emaciation and dehydration, conjunctivitis, and crusting of outer lips and nares.
- Gastrointestinal tract: Necro-erosive lesions from the oral cavity to the rumeno-reticular junction, abomasum, and small intestine. Severe ulceration and necrosis of Peyer's patches. Congestion and/or erosive and hemorrhagic enteritis around the ileocecal valve and ceco-colic junction. Linear congestion of the mucosal folds in the colon and rectum ("zebra stripes").
- Respiratory tract: Small erosions and petechial hemorrhages of the nasal mucosa, turbinates, larynx, and trachea. Severe interstitial bronchopneumonia, consolidation, and atelectasis, often compounded by signs of a secondary bacterial pneumonia. Lung histopathology may identify multinucleated giant cells with inclusions.
- Urogenital tract: Mucosal erosions.
- Hemic/lymphatic/immune: Enlarged and congested spleen and liver. Lymphadenopathy with syncytia and empty germinal centers on histopathology.

(CONTINUED) PESTE DES PETITS RUMINANTS

TREATMENT

THERAPEUTIC APPROACH

• No specific treatment is available for individual animals, but in vitro RNA interference trials are promising.
• Access to veterinary care is limited in most enzootic areas, and individual animal care may not be feasible. Supportive supplementation may be indicated.
• Control for secondary infections.

MEDICATIONS

DRUGS OF CHOICE

• Use antimicrobials for control of secondary bacterial infections.
• Parenteral anti-inflammatory and B-complex vitamin supplementation may be indicated.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• The severity and outcome of disease is correlated with the extent of oral pathology.
• Lesions that resolve in 2–3 days have a better prognosis while halitosis or respiratory signs indicate a grave prognosis.

POSSIBLE COMPLICATIONS

• Secondary bacterial pneumonia, specifically with *Mannheimia haemolytica*, is a frequent complication.
• Immunosuppression may permit secondary parasitemia or recrudescence of other infectious disease processes.

CLIENT EDUCATION

Educate producers on the importance of vaccination to prevent infection in countries where it is approved for use.

PATIENT CARE

• Monitor for respiratory distress due to blocked nasal passages or secondary infections.
• Fluid therapy to resolve fluid deficits and restore electrolyte and acid-base balance.
• Limit handling, stress, and movement to prevent respiratory embarrassment and limit spread of disease.
• Provide a nutritionally appropriate palatable and easily masticated feed.

PREVENTION

• PPR-free countries should prohibit import of animals or animal products from affected locations.
• Sheep and goats in enzootic areas should be vaccinated once maternal immunity has waned (3–4 months of age) and a booster administered every 3 years. In some countries, administration of the vaccine may be restricted to government personnel.
• Four live-attenuated vaccines are currently available. The Nigeria 75/1 (lineage II) and Sungri 96 (lineage IV) are the most widely used products, while Arasur 87 and Coimbatore 97 are sheep and goat origin lineage IV isolates licensed in India. Modifications have been made to make these vaccines more thermostable and decrease reliance on a cold chain.
• Effective live-attenuated vaccines must be administered several days prior to exposure to stimulate an effective immune response.
• New vaccines are in development that focus on recombinant H or F antigen subunit technology and DIVA capabilities.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Secondary bacterial and parasitic infections

AGE-RELATED FACTORS

Young animals, 4–8 months of age, often have worse clinical disease than adult animals.

ZOONOTIC POTENTIAL

None

PREGNANCY

Abortions may occur.

BIOSECURITY

PPRV survives in the environment or on fomites for up to 72 hours in shaded conditions, but is otherwise sensitive to heat, UV radiation, and pH <5.5 or >10.

PRODUCTION MANAGEMENT

Goats and sheep in enzootic areas should be vaccinated by 3–4 months of age and then every 3 years with an attenuated isolate of PPR. Vaccinate ahead of the risk season (e.g., cool, dry season in Africa) or before known periods of mass herd movement.

ABBREVIATIONS

• AGID = agar gel immunodiffusion test
• cELISA = competitive enzyme-linked immunosorbent assay
• DIVA = differentiation of infected from vaccinated animals
• ELISA = enzyme-linked immunosorbent assay
• FAO = Food and Agriculture Organization of the United Nations
• OID = World Organization for Animal Health
• PCR = polymerase chain reaction
• PPR = peste des petits ruminants

P

PETROLEUM PRODUCT POISONING

BASICS

OVERVIEW
Ingestion, inhalation, or topical administration of petroleum products and their chemical constituents or waste products, resulting in morbidity and mortality.

INCIDENCE/PREVALENCE
• Dependent on access to petroleum products.
• Multiple animals are usually affected and may be found dead.

GEOGRAPHIC DISTRIBUTION
• Common in areas where grazing animals and petroleum production, transport, storage or land application of drilling waste or wastewater occurs.
• State regulations may vary on how special wastes and produced water from the petroleum industry are handled.
• Application of salty wastewater to melt road ice may create exposure distant from the source through melt and runoff.
• Dependent on access to petroleum products.

SYSTEMS AFFECTED
• Cardiovascular
• Digestive
• Integument
• Mammary
• Musculoskeletal
• Nervous
• Reproductive
• Respiratory
• Urinary

PATHOPHYSIOLOGY.
• Products with highly volatile hydrocarbon fractions or volatile organic compounds are more likely to result in inhalation or aspiration after ingestion compared to compounds of low volatility or high viscosity.
• Inhalation of volatile petroleum products or emissions from operations target the lungs. Hypoxia, chemical pneumonia, and cerebral anoxia are common.
• Ingestion of petroleum products also targets the lungs through eructation and inhalation, aspiration, or hematogenous exposure. A high salt content in petroleum muds and wastewater may contribute to morbidity and mortality. Expansion of hydrocarbon in the rumen results in bloat and rumen stasis. Petroleum products and associated chemical additives are caustic to gastrointestinal mucosa, resulting in gastroenteritis, colitis, mucosal edema, and hemorrhage.
• Dermal lesions occur when petroleum products are applied topically or used as a vehicle for insecticide sprays or dips resulting in contact dermatitis.

SIGNALMENT
All species and ages are susceptible to exposure, younger animals may be at higher risk due to curiosity and inquisitive nature.

PHYSICAL EXAMINATION FINDINGS
Clinical signs vary, often developing within 24 hours of exposure.
• Pyrexia, dehydration, tachycardia, bradycardia, arrhythmia, cardiac arrest
• Oily nasal discharge, petroleum odor on breath and feces
• Dyspnea, tachypnea, aspiration pneumonia, coughing
• Milk tainted with fuel odor, decreased milk production
• Dry integument with blisters, cracking, unthrifty
• Decreased rumen motility, bloat, displaced abomasum, anorexia, salivation, vomiting, oil in feces and rumen contents, diarrhea or constipation
• Reluctance to move, ataxia, recumbency, paddling, shivering, CNS signs (head tremors, decreased menace response and palpebral reflex, opisthotonus), blindness, coma, death
• Sudden death—multiple animals are usually affected and may be found dead.

CAUSES AND RISK FACTORS
Environmental Factors
• Contamination of feed, soil, or water supply by petroleum products resulting from broken pipes, leaking valves or storage tanks, spills, application of drilling muds or wastewater to grazing land, runoff from application of salty wastewater to melt ice, or road-oil used for dust control.
• Rainfall or flooding may mobilize petroleum products long after a spill occurs. Some components such as BTEX (benzene, toluene, ethylbenzene, and xylene) are highly soluble.
• Ambient temperature and wind factors increase volatility and dispersion.
• Poor-quality pasture may contribute to ingestion.

Animal Factors
• Age, preexisting health, hydration, and nutritional status, duration of exposure, duration of time to treatment.
• Direct application of petroleum product either topically or by drench may result in toxicosis.
• Ruminants willingly ingest petroleum-tainted soil, forage, or water. Petroleum products and waste fluids may have a high salt content that promotes consumption.

Petroleum Factors
• Amount of petroleum product consumed; viscosity, volatility, toxicity of chemical constituents, presence of heavy metals, and concentration of salt.
• The exact composition of proprietary mixtures of drilling compounds and nondisclosure agreements may make the product composition difficult to determine.

DIAGNOSIS

Opportunity for exposure and petroleum odor on breath, skin, or in feces is supportive of the diagnosis.

DIFFERENTIAL DIAGNOSES
Lead or other heavy metal exposure, other chemicals used in petroleum extraction, organophosphate ester poisoning, salt toxicity, nutritional deficiencies, other infectious diseases.

CBC/BIOCHEMISTRY/URINALYSIS
Results vary with exposure and chemical composition.
• Increased PCV, Hgb, Fib, TPP, leukopenia initially followed by leukocytosis
• Elevated AST, GGT, BUN, creatinine, LDH, CPK, cholesterol
• Decreased potassium, calcium, glucose
• Elevated Na^+Cl^-

OTHER LABORATORY TESTS
• Gas chromatography or "fingerprinting" of rumen contents, liver, lung, or kidney tissue, and the suspected source of poisoning.
• Heavy metal analysis of liver, GI contents, kidney, and brain to rule out other causes or as components of petroleum product composition.
• Test suspected soil, vegetation and water sources for salts, total petroleum hydrocarbons, heavy metals.
• Acetylcholinesterase level in blood and brain tissue to rule out organophosphate toxicity.

IMAGING
Thoracic radiography in smaller ruminants has prognostic value.

OTHER DIAGNOSTIC PROCEDURES
Tracheal wash and culture

PATHOLOGIC FINDINGS
Respiratory Tract
• Gross lesions: Cranial and middle lung lobe most often affected; consolidation, congested, dark red to purple, mottled, abscesses, and lesions are usually bilateral, serofibrinous exudate, pleural adhesions, and tracheitis
• Histologic: Lung—necrotizing bronchopneumonia, edema

Gastrointestinal
• Gross lesions: Esophagitis, bloat, enteritis, colitis, fuel odor to GI tract, petechial hemorrhages of GI tract, bloody intestinal contents

• Histologic: GI tract—mucosal and submucosal congestion and mucosal and serosal hemorrhage

Other Histologic Findings

• Brain—meningeal hyperemia, meningeal/choroid edema, parenchymal hemorrhage, malacia
• Heart—myocardial degeneration and necrosis, hemorrhage, edema, mineralization, congested myocardial and epicardial blood vessels, infiltrations of lymphocytes, macrophages, and neutrophils
• Kidney—renal tubular degeneration, interstitial nephritis, granular eosinophilic casts mixed with inflammatory cell infiltrates, renal vessel thrombi
• Liver—periacinar fatty degeneration and periportal infiltration of lymphocytes and plasma cells, bile duct hyperplasia

TREATMENT

THERAPEUTIC APPROACH

• Remove from source; use stomach tube to relieve bloat (use of a trocar increases risk of peritonitis); administer saline laxative.
• Intravenous fluids, supportive care by system.
• Euthanasia may need to be considered.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Rumenotomy and transfaunation may be indicated.

MEDICATIONS

DRUGS OF CHOICE

Broad-spectrum antibiotics, IV or IM, until clinical signs abate.

CONTRAINDICATIONS

Rumen lavage via orogastric or nasogastric tube increases risk of aspiration.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Highly variable depending on type of compound and severity of exposure.
• Some animals survive the initial exposure with few clinical signs while others do poorly for weeks to months, requiring culling.
• Animals with aspiration pneumonia have a guarded to poor prognosis.

POSSIBLE COMPLICATIONS

Chronic wasting or neoplasia. Some chemical compounds are known carcinogens.

PATIENT CARE

• Physical examination and routine blood work as warranted by clinical findings.
• Restrict activity.
• Modifications to diet will depend on rumen motility. Some animals will continue to eat while others will be anorectic for days to weeks.

PREVENTION

• Fence off areas to keep animals away from potential sources.
• Locate petroleum storage tanks and pits away from well or surface water.
• Inspect tanks, pipes, valves, pits, and ponds associated with petroleum extraction and storage for leakage.
• Do not reuse petroleum storage containers for feed or water.
• If constituent chemicals are known, estimate potential risks of soil and water exposure using risk-based screening levels (RBSLs) or toxicity reference levels (TRLs).

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Salt toxicity
• Many compounds associated with petroleum products are known carcinogens.

ZOONOTIC POTENTIAL

Inhalation of petroleum vapors is potentially toxic.

PREGNANCY

Abortions or stillbirths have been attributed to petroleum exposure.

PRODUCTION MANAGEMENT

• Fence off areas to keep animals away from potential sources.
• Quarantine of animals after natural gas exposure has been reported.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

ABBREVIATIONS

• AST = aspartate aminotransferase
• BUN = blood urea nitrogen
• CNS = central nervous system
• CPK = creatine phosphokinase
• Fib = fibrinogen
• GGT = gamma-glutamyl transferase
• GI = gastrointestinal
• Hgb = hemoglobin
• IM = intramuscular
• IV = intravenous
• LDH = lactate dehydrogenase
• PCV = packed cell volume
• RBSLs = risk-based screening levels
• TPP = total plasma protein
• TRLs = toxicity reference levels

PHENOXYL TOXICITY

BASICS

OVERVIEW

• Chlorophenoxylic herbicide compounds, such as 2,4-dichlorophenoxy acetic acid (also known as 2,4-D) and methylchlorophenoxy acetic acid (MCPA), are used to control weeds and aquatic plants, to increase fruit durability in storage, and to prevent premature fruit dropping. Animals' exposure is from accidental ingestion of concentrates or sprays, occasionally from chronic ingestion of treated forages. These herbicides are relatively nontoxic unless ingested in a concentrated form.
• Several hundred commercial products contain chlorophenoxy compounds in various forms, concentrations, and combinations.
• Repeated and massive doses are needed to cause poisoning in ruminants.
• These agents can cause liver and kidney failure, hypotension, and increased cancer risk; also there may be hemolysis.
• Chlorophenoxy compounds have been shown to demyelinate peripheral nerves, depress ribonuclease synthesis, uncouple oxidative phosphorylation, and increase hepatic peroxisomes.
• Examples—2,4-D; 2,4-dichlorophenyl; 2,2-dichloropropionic acid (Dalapon); 4-chloro-2-methylphenoxy acetic acid (MCPA); 2,4,5-trichlorophenoxy acetic acid (Sivex).
• The advent of commercial farming prompted the development of selective weed control chemicals. These organic herbicides are plant growth regulators altering the metabolism of plants and are associated with potential teratogenicity.
• A side effect of the compound's use is the increased levels of nitrates or cyanide in plants that can cause secondary poisoning to ruminants prior to the plant's death.
• Some toxic weeds, such as jimsonweed and nightshade, become more palatable after treatment with this type of herbicide.
• Essentially, usage has been stopped because of the toxic contaminants of dioxins (TCDD, HCDD).

INCIDENCE/PREVALENCE

These herbicides are relatively nontoxic unless ingested in a concentrated form.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Musculoskeletal
Nervous
Urinary

PATHOPHYSIOLOGY

Causes kidney and muscle damage, as the herbicide increases not only serum UA, TP, and CR levels but also CK activity. Reported effects include muscle weakness in cases of myopathy, as well as degeneration of skeletal muscle fibers and increased serum CK activity in cattle.

SIGNALMENT

• Potentially, all ruminant species are affected.
• 10 days of exposure may be required to produce poisoning. However, calves have been poisoned by a single oral dose of 200 mg/kg body weight.
• Oral administration of up to 125 mg/kg body weight to adult dogs did not result in lethality.
• Chronic administration of up to 500 ppm of 2,4-D in the diet for 2 years did not result in any adverse effects.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs are only seen following massive and repeated exposures.
• Anorexia, depression, rumen atony, muscle weakness, especially in hindlimbs.
• Diarrhea, ulceration of oral mucosa, bloating.
• Animals progressively become emaciated and moribund.

CAUSES AND RISK FACTORS

• Feeding up to 2000 ppm herbicide in the diet amounted to 1 ppm in liver and kidneys and <0.05 ppm in the muscle and fat.
• Herbicide residues are not likely to be at >300 ppm in or on forage immediately after treatment at recommended rates for brush and weed control. Residues decline rapidly. Half-life in forage is 1–2 weeks.
• Meat residues occur only with extremely high exposure during continuous ingestion of freshly treated vegetation.
• Withdrawal of animals from treated forages for 1–2 weeks prior to slaughter should decrease any residues.
• Herbicide-treated forages do not seem to affect rumen microbial functions or development in the rumen; they are not readily degraded by ruminal microorganisms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Severe parasitism
• Diseases causing anorexia, depression, rumen atony, muscle weakness, especially of hindlimbs
• Diseases causing diarrhea, ulceration of oral mucosa, bloating
  ◦ Abomasal torsion
  ◦ Acidosis/grain overload
  ◦ Bovine viral diarrhea virus (BVDV)
  ◦ Cathartic/laxatives
  ◦ Coccidiosis
  ◦ Colitis/typhlitis
  ◦ Displaced abomasum
  ◦ Enteritis
  ◦ Heart failure
  ◦ Indigestion
  ◦ Intussusception
  ◦ Jejunal hemorrhage syndrome
  ◦ Johne's disease
  ◦ Liver failure
  ◦ Malignant catarrhal fever
  ◦ Molybdenum toxicity/copper deficiency
  ◦ Parasitism
  ◦ Parasympathomimetic drugs
  ◦ Peritonitis
  ◦ Poisonous plants: Acorn (oak), *Brassica* spp., fungal toxicity, mushroom, oleander, pokeweed, pyrrolizidine alkaloids, rattlebox, selenium accumulators, *Solanum* spp., St. John's wort
  ◦ Salmonellosis
  ◦ Sepsis/toxemia/enterotoxemia
  ◦ Toxins: Aflatoxin, arsenic, chlorpyrifos (Dursban), copper, herbicides, levamisole, lincomycin, monensin, nicotine, phosphorus fertilizers, propylene glycol, sodium bicarbonate, sulfur, trichothecene, zinc
  ◦ Uremia/renal failure
  ◦ Winter dysentery
  ◦ Xylazine, large doses
• Diseases causing weight loss and emaciation

CBC/BIOCHEMISTRY/URINALYSIS

• Major elimination by the kidneys.
• CBC/biochemistry/urinalysis is indicated to monitor parameters for treatment.
• No parent compounds or metabolites found in milk from orally dosed cattle.

OTHER LABORATORY TESTS

• High levels of compound in kidney and liver, decreased levels in fat and muscle.
• Phenoxy acid esters and salts are primarily metabolized by acid hydrolysis, and a minor amount is conjugated.

OTHER DIAGNOSTIC PROCEDURES

Feed analysis, chemical analysis for the chlorophenoxylic herbicide compounds

PATHOLOGIC FINDINGS

• Epicardial hemorrhage
• Hydropericardium
• Bright green, undigested feed from ruminal stasis
• Liver swollen, friable
• Kidneys congested
• Hyperemia, enlargement of lymph nodes and mesenteric vessels
• High levels in liver and kidney, decreased levels in fat and muscle

TREATMENT

THERAPEUTIC APPROACH

• Activated charcoal, alkaline diuresis
• Control seizures; diazepam, phenobarbital
• Cathartic: Administer a dose of a saline or sorbitol cathartic such as magnesium or sodium sulfate (sodium sulfate dose is 1 gram/kilogram). If access to these agents is

limited, give 5–15 mL magnesium oxide (Milk of Magnesia) per os for dilution.

MEDICATIONS

DRUGS OF CHOICE
Control seizures—diazepam, phenobarbital

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Keep toxic chemicals away from livestock. Do not apply toxic chemicals to fields or crops on which animals may feed.
• Consult manufacturer and FARAD if accidental exposure occurs.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Depends on quantity ingested; fair to poor depending on treatment and amount of agent consumed.

PREVENTION
• Withdrawal of animals from treated forages for 1–2 weeks prior to slaughter would decrease any residues.
• Keep toxic chemicals away from livestock. Do not apply toxic chemicals to fields or crops on which animals may feed.
• Meat residues occur only with extremely high exposure during continuous ingestion of freshly treated vegetation.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• A side effect is the increased levels of nitrates or cyanide in plants that can cause secondary poisoning before the plant dies.
• Some toxic weeds, such as jimsonweed and nightshade, become more palatable after treatment.

PREGNANCY
N/A

PRODUCTION MANAGEMENT
Keep all chemicals and sprays away from feeding ruminants.

ABBREVIATIONS
• BVDV = bovine viral diarrhea virus
• CK = creatine kinase
• CR = creatinine
• FARAD = Food Animal Residue Avoidance Databank
• HCDD = dioxone; 1,2,3,4,5,6,7,8-HCDD
• TCDD = the most toxic member of the dioxin and furan family—2,3,7,8-TCDD; 2,3,7,8-tetrachlorodibenzo-p-dioxin
• TP = total protein
• UA = urine albumin

SEE ALSO
• Bovine Viral Diarrhea Virus
• Coronavirus
• Heavy Metal Toxicosis
• Johne's Disease
• Malignant Catarrhal Fever
• Molybdenum Toxicity
• Monensin Toxicity
• Mycotoxins
• Nightshade (*Solanum* spp.) Toxicosis
• Oak (*Quercus* spp.) Toxicity
• Oleander and Cardiotoxic Plant Toxicity
• Pyrrolizidine Alkaloids
• Salmonellosis

PHOSPHORUS DEFICIENCY/EXCESS

BASICS

OVERVIEW

- Essential macromineral.
- Roles: Bone, teeth and cell membrane structure, regulation of metabolism, energy storage, and buffering.
- Elemental phosphorus is highly reactive → in the body phosphorus is present as phosphate (P), in both organic and inorganic (P_i) forms. Methods of determining [P] in body fluids specifically measures [Pi].
- *P deficiency* may manifest as rickets (RK), osteomalacia (OM), pregnancy toxemia (PT), hypophosphatemic down cow syndrome (HDCS), and postparturient hemoglobinuria (PPH).
- *P excess* may manifest as yellow (white) phosphorus toxicity (YPT), osteodystrophy fibrosa (OF), urolithiasis, and sodium phosphate toxicity (SPT).

INCIDENCE/PREVALENCE

- PPH: sporadic and low incidence
- Chronic P excess: uncommon

GEOGRAPHIC DISTRIBUTION

- OM/RK
  - Regional soil deficient in P: Africa, Australia, New Zealand, and arid or tropical regions
  - Reduced sunlight hours in southern and northern latitudes
- PPH: North America, New Zealand
- HDCS: Northern United States and Canada

SYSTEMS AFFECTED

P Deficiency

- Musculoskeletal
- Hematologic
- Cardiovascular

P Excess

- Nervous
- Musculoskeletal
- Urinary
- Digestive

PATHOPHYSIOLOGY

Compartments

- 85% hydroxyapatite (bones and teeth)
- 14–15% intracellular
- <1% extracellular

Homeostasis

- Losses (600 kg dairy cow)
  - Bone and muscle growth
  - Saliva and fecal loss (20–40 g/d)
    - ~80% saliva [P] is recovered by intestinal absorption
  - Urinary loss (<1 g/d)
  - Milk production (20–55 g/d)
  - Late gestation fetal skeletal development (2–6 g/d)
- Uptake
  - Intestinal absorption
    - Primary site: small intestines
    - Ruminal microbes are able to digest phytic acid → phytate-bound P (up to 70% of P in plants), is available for absorption in ruminants.
- PTH: Increases renal and salivary excretion of P but also increases osteoclast activity and increases renal production of 1,25-DHCC.
  - PTH is secreted primarily in response to hypocalcemia rather than P imbalance.
  - Renal tubular cells and bovine salivary gland cells become unresponsive to PTH in states of severe P depletion.
- 1,25-DHCC
  - Enhances intestinal P absorption.
  - Negative feedback to PTH secretion.
- Calcitonin: Decreases renal tubular P reabsorption.
- Phosphatonins: Modulate renal tubular reabsorption of P and inhibit activation of 1,25-DHCC.

P Deficiency

- Chronic P depletion primarily manifests as anorexia and bone demineralization.
  - RK: The cartilaginous matrix at the growth plate and the osteoid matrix formed during bone remodeling fail to mineralize.
  - OM: Failure of osteoid matrix to mineralize.
  - Soils deficient in P are often energy deficient, which when combined with anorexia results in weight loss, impaired fertility, and decreased milk production.
- PT: Fetal growth removes substantial amounts of P from the maternal circulation.
- HDCS: Recumbent hypophosphatemic periparturient cows unresponsive to Ca treatment.
  - Debated whether the P imbalance is a cause (losses in milk) or consequence (anorexia and decreased GIT motility) of recumbency.
  - Negative effects of P depletion on muscle function are well established in human medicine but the mechanisms have not been identified.
- PPH: Intravascular hemolysis during the first 6 weeks of lactation presumably due to intracellular ATP depletion → increased osmotic fragility.
- Refeeding syndrome (RFS): Potentially fatal shifts in fluids and electrolytes in malnourished animals receiving a high carbohydrate diet (particularly artificial enteral or parenteral feeding).
  - Refeeding → insulin release → increased glycogen, fat and protein synthesis, processes that require P, Mg, K, and thiamine → intracellular shift of these electrolytes and water and thiamine depletion
  - Total body P depletion → ATP and 2,3-DPG rapidly depleted → cellular dysfunction and inadequate oxygen delivery

P Excess

- Chronic P excess
  - Inhibits formation of 1,25-DHCC → downregulate P and Ca intestinal absorption
  - Reduced intestinal Mg absorption → hypomagnesemia decreases PTH binding affinity → hypocalcemia. Dry cow rations with a dietary P content >0.5% increase the risk of clinical hypocalcemia
  - PTH release → widespread osteoclastic resorption of bone and its replacement by fibrous tissue = OF
  - Dystrophic mineralization
  - Increased urinary [P] → urolithiasis
- Yellow (white) phosphorus toxicity (YPT)
  - Local irritant to the GIT
  - Distributes to all tissues → ~day 3: cardiac, hepatic, renal and multiorgan failure
- Sodium phosphate toxicity (SPT) (Iatrogenic MSP IV or P enema)
  - P is rapidly absorbed through the mucosa of the colon
  - P enema doses above recommended amounts or concurrent renal or GIT disease might result in toxicosis
    - >11 kg BW: 120 mL (human adult size)
    - <11 kg BW: 60 mL (human pediatric size)
  - Lethal dose in pigs: 20 mL/kg per rectum
  - Hypernatremia → hyperosmolar syndrome
  - Hypocalcemia: PTH-induced losses, intracellular shift, and hypernatremia-induced calciuresis
  - Hypokalemia: increased urinary K excretion
  - Metabolic acidosis
    - Hypertonicity of enema causes fluid influx into the colon (or body cavity if perforation occurs during administration) → dehydration and elevation in lactate
    - Hyperphosphatemia increases the nonvolatile weak acid pool.

HISTORICAL FINDINGS

N/A

SIGNALMENT

P Deficiency

- Cattle > sheep and goats
- RK: Young growing animals
- PT: Beef cows and ewes in late gestation
- HDCS: Postpartum dairy cows
- PPH: Mature, multiparous, high-yielding dairy cows

P Excess

OF: Goats > cattle and sheep

(CONTINUED) # PHOSPHORUS DEFICIENCY/EXCESS

PHYSICAL EXAMINATION FINDINGS

P Deficiency

• General: Anorexia, pica, unthriftiness, weight loss, reduced milk production, reduced reproductive performance
• OM: Shifting lameness, kyphosis, lordosis, spontaneous nonhealing fractures
• RK: Stiffness, lameness, joint enlargement, kyphosis, angular limb deformity
• PT/HDCS: Weakness, recumbency
• PPH: Weakness, marked decrease in milk production, red-brown urine, pallor of mucus membranes, tachycardia, tachypnea, and jaundice
• RFS: Neurologic disorders, seizures, rhabdomyolysis, cardiac arrhythmias, cardiac failure, and death

P Excess

• OF: Stiffness, shifting lameness, facial and physeal enlargement, multiple fractures
• YPT: Diarrhea, abdominal pain, garlic-like breath odor, jaundice, coagulopathies, convulsions, tachycardia, and torsades de pointes
• SP toxicosis: Prosencephalic neurologic signs (dullness, seizures, coma), cardiac arrhythmias, hypocalcemia (tetanic convulsions, weakness), hypokalemia (weakness) and dehydration. Incorrect enema administration → rectal or vaginal trauma

GENETICS

N/A

CAUSES AND RISK FACTORS

P Deficiency

• OM/RK
  ◦ Chronic PO_4 deficiency
    ▪ Diet deficient in P: green cereal crops, mature forages or crop residues; poor P content of soil: regional, heavy rains, continuous removal of crops
    ▪ P binding agents: Diet high in Ca, Al, Mg, and fat
    ▪ Hypovitaminosis D: lack of sunshine; bile duct aplasia
    ▪ Intestinal malabsorption disease
• PT
  ◦ Late gestation
  ◦ P-deficient diet
  ◦ Late winter
  ◦ Usually complicated by concurrent deficiency in Ca, Mg, and energy
• HDCS
  ◦ Initiation of lactation
  ◦ Acidogenic diet increases urinary P excretion
  ◦ Concurrent hypocalcemia → PTH → increased urinary and salivary loss of P
  ◦ Decreased feed intake
  ◦ Not associated with low P diets
• PPH
  ◦ P-deficient diet
  ◦ P deficiency is likely only a contributing factor
  ◦ Cows that have been treated for ketosis
  ◦ Concurrent Se, Cu, and energy deficiencies
• RFS
  ◦ Chronically undernourished animals
  ◦ Little or no energy intake for 10 days

P Excess

• Chronic
  ◦ Diet high in P, low in Ca: bran, grains, oxalates
  ◦ Excessive supplementation of feed with P
  ◦ Hypervitaminosis D: Cholecalciferol rodenticides, *Solanum* spp., *Cestrum diurnum*
• YPT: Rodenticides, fertilizer
• SP: Iatrogenic overdose or incorrect administration
  ◦ Inadvertent transvaginal administration of P enema reported in crias

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• OM/RK
  ◦ Fluorosis arthritis
  ◦ Cu deficiency
  ◦ Physitis
• PPH
  ◦ Babesiosis
  ◦ Theileriosis
  ◦ Bacillary hemoglobinuria
  ◦ Water intoxication
  ◦ Increased oxidative stress: onions, bassicas, Se deficiency
  ◦ Saponins: sugar beet, alfalfa
• SP toxicity: Obstructive urolithiasis, ruptured bladder, renal failure

CBC/BIOCHEMISTRY/URINALYSIS

Serum [Pi] or plasma [Pi]: most commonly used tool to assess P
• Correlates well with short-term dietary P supply
• Chronic P deficiency might be masked by mobilization of P reserves from bone
• Altered acutely by multiple factors, particularly transcellular shifts
• Shift from ECF to ICF
  ◦ Hyperinsulinism: insulin injections, insulin-secreting neoplasm, or response to carbohydrate load (dextrose infusion in cattle can lower plasma [Pi] within minutes by >30% and remain below baseline for 90 minutes)
  ◦ Respiratory alkalosis
  ◦ Catecholamine and cortisol release
  ◦ Sepsis
• Shift from ICF to ECF
  ◦ Myopathies
  ◦ Sick cell syndrome
  ◦ Acute tumor lysis syndrome
  ◦ Acidemia and metabolic acidosis
• Dehydration
  ◦ Hyperphosphatemia is a common finding in cattle with right displaced abomasums or abomasal volvulus and is associated with the degree of dehydration.
• Young, growing animals: Increased growth hormone → increases renal tubular resorption of P.
• Spurious decrease [Pi] by increased conjugated bilirubin; spurious increase with hyperbilirubinemia, monoclonal gammopathy, in vitro hemolysis or delayed harvesting of serum or plasma.

Reference Ranges

• Cattle:
  ◦ Adults 1.4–2.6 mmol/L (4–8 mg/dL)
  ◦ Growing 1.9–2.6 mmol/L (6–8 mg/dL)
• Sheep 1.6–2.4 mmol/L (5–7.3 mg/dL)
• Goats: 1.3–3 mmol/L (4.2–9.1 mg/dL)

Laboratory Findings for P-Associated Diseases

• OM/RK
  ◦ ± hypophosphatemia
  ◦ ± hypocalcemia
• PT
  ◦ Recumbent animals serum [Pi] often <1 mg/dL
  ◦ Herd average serum [Pi] 2–3 mg/dL
• PPH
  ◦ Moderate to marked anemia, polychromasia, and basophilic stippling of RBC, nucleated RBC, anisocytosis
  ◦ Hypophosphatemia common (<1.5 mg/dL)
  ◦ Increased indirect bilirubin
  ◦ Hemoglobinuria, bilirubinuria, and proteinuria
• OF
  ◦ ± hyperphosphatemia
  ◦ ± hypocalcemia
  ◦ Increased fractional excretion of P
• SP toxicosis
  ◦ Hyperphosphatemia
  ◦ Hypernatremia
  ◦ Hypocalcemia
  ◦ Hypokalemia
  ◦ Metabolic acidosis

OTHER LABORATORY TESTS

N/A

IMAGING

Radiographic changes:
• OM: Thin cortices, reduced bone density, noncalloused bone fractures
• RK: Clublike thickening of metaphysis, wide physes, bowed long bones
• OF: Reduced bone density, subperiosteal bone resorption, loss of dura dentes

OTHER DIAGNOSTIC PROCEDURES

• OM, RK, OF: Bone ash : organic ratio 1.2–1.3 (normal 3:2)
• Analysis of dietary P and Ca

PATHOLOGIC FINDINGS

• OM: Soft and brittle bones, thin cortices with large marrow cavities, noncalloused fractures. Accumulation of excess unmineralized osteoid on trabecular bone surfaces.

PHOSPHORUS DEFICIENCY/EXCESS (CONTINUED)

• RK: Bowed long bones, domed cranium, prominent costochondral junctions, rachitic metaphysis, retarded mandibular growth. Failure of osteoid and cartilaginous matrix to mineralize, overgrowth of fibrous tissue in metaphyses, persistent cartilage and irregular physes.
• PPH: Thin watery blood, jaundice of soft tissue, distended gall bladder, pigmenturia, nutmeg liver. Central lobular coagulative hepatic necrosis, bile and hemosiderin pigment in renal tubular epithelial cells and hemoglobin in tubules.
• OF: Thickening of flat bones particularly the calvarium, maxilla and mandible, soft bones, noncalloused fractures. Extensive erosion of periosteal and cortical bone by numerous osteoclasts, compact bone replaced by fibrocellular tissue, herniation of articular cartilage into the epiphysis.
• YPT: Severe icterus and fatty liver with periportal necrosis.

TREATMENT

THERAPEUTIC APPROACH

P Deficiency

Chronic

• Correct any dietary deficiency in P, Ca, or vitamin D
  ◦ Ideal dietary ratio of Ca:P is 2:1
    ▪ Cattle: 150–300 kg body weight require 9–18 g/d of P
    ▪ Sheep: 10–100 kg body weight require 1.9–4.8 g/d of P
• OM/ RK
  ◦ Adequate sunlight
  ◦ Injectable vitamin D: 10,000–30,000 IU/kg

Acute

• Oral drench: 50 g of P (200 g MSP)
  ◦ Duration: 8–12 hours
  ◦ Rumen motility important
• IV: 6 g of P (23 g MSP) or 120 mL phosphate enema (19 g MSP + 7 g DSP) dissolved in 1 L sterile deionized water
  ◦ Administer over several hours to avoid precipitation with Ca, and increased renal P excretion
  ◦ Do not use with Ca- or Mg-containing solutions—precipitation
  ◦ Ca-containing solutions used for milk fever often contain phosphorus but in the form of phosphite or phosphinic acid—remain soluble but are biologically inactive so should not be used with the intent of restoring plasma [Pi].
• RFS
  ◦ Supplementation of P, K, and Mg orally, or IV if severe
  ◦ Thiamine
  ◦ Reduce energy intake → gradually increase over 4 days

P Excess

• Chronic: Reduce dietary P content + supplement Ca during adjustment period
• YPT: No antidote, supportive therapy
• SP toxicosis
  ◦ Correct hypocalcemia only to level that controls clinical symptoms as extra Ca stimulates soft tissue mineralization
  ◦ Correct hypernatremia
    ▪ IV fluids containing relatively lower [Na]
    ▪ Calculate amount Na required using Adrogue formula
    ▪ Acute (24 h): 2–3 mEq/L/h and then slow rate (max total, 12 mEq/L/24h)
    ▪ Chronic (>24h): max 0.5 mEq/L/h (max total of 8–10 mEq/L/24h)
    ▪ Do not allow free access to water if severely hypernatremic.
  ◦ Correct acidosis and dehydration.

MEDICATIONS

See "Therapeutic Approach"

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• OM/RK/OF: Good with appropriate treatment
• PPH: Grave (death in 2–5 days)
• YPT: Grave

POSSIBLE COMPLICATIONS

N/A

PATIENT CARE

• SP toxicosis
  ◦ ECG monitoring during calcium administration
  ◦ Serial monitoring of serum [Na]
• RFS: Monitor serum electrolytes and for signs of fluid overload

PREVENTION

• HDCS: Avoid hypocalcemia.
• P enema toxicosis: Only use in cases refractory to soapy water enemas and aqueous lubricants.

MISCELLANEOUS

ABBREVIATIONS

• 1,25-DHCC = 1,25-dihydroxycholecalciferol
• DSP = disodium phosphate
• HDCS = hyperphosphatemic down cow syndrome
• MSP = monosodium phosphate
• OF = osteodystrophy fibrosa
• OM = osteomalacia
• P = phosphate
• P_i = inorganic phosphorus
• PPH = postparturient hemoglobinuria
• PT = pregnancy toxemia
• PTH = parathyroid hormone
• RFS = refeeding syndrome
• RK = rickets
• SP = sodium phosphate
• SPT = sodium phosphate toxicity
• YPT = yellow phosphorus toxicity

PHOTOSENSITIZATION

BASICS

OVERVIEW

• Photosensitization is an abnormal reaction of the skin to sunlight due to the presence of a photodynamic agent in the dermis. Photodynamic agents absorb certain wavelengths of ultraviolet (UV) light, producing free radicals, which react with proteins in the dermal tissue, causing damage.
• Photosensitization can be divided into four categories: Type I (primary photosensitization), type II (photosensitization due to aberrant pigment synthesis), type III (secondary or hepatogenous photosensitization), and type IV (idiopathic).

INCIDENCE/PREVALENCE

Late spring, summer, and early fall are most common, but if photosensitizing plants are baled into hay, signs may be seen year round.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Integument
• Multisystemic

PATHOPHYSIOLOGY

• In type I photosensitization, the photodynamic agents are absorbed into the blood from the gastrointestinal tract (GI) and react with UV light at the skin surface. Type I reactions may also occur with direct contact to the photodynamic agent (plant, chemical). Once in the dermis, the photodynamic agent absorbs the energy of a light photon and forms free radicals. The oxygen free radical reacts with amino acids, nucleic acids, and membrane lipids in the capillary endothelium and surrounding tissues, causing tissue destruction.
• Type II photosensitization is due to a genetic defect in the individual. The photodynamic agent is a pigment that is produced endogenously by an aberrant metabolic process.
• Type III photosensitization is secondary to liver damage. Chlorophyll is metabolized by microbes in the GI tract, forming phylloerythrin. Phylloerythrin, a photodynamic metabolite of chlorophyll, is absorbed into the bloodstream. Normally phylloerythrin is removed from the blood by the liver, and excreted in bile. With liver damage or biliary obstruction, phylloerythrin cannot be excreted, and thus enters the general circulation. Liver damage can occur from toxins, bacteria, viruses, or neoplasia. Secondary photosensitization is intensified when the consumption of chlorophyll from green plants is high.
• Type IV photosensitization is where the pathogenesis is unknown or the photodynamic agent is not identified.

HISTORICAL FINDINGS

• With plant ingestion, signs may appear from 24 hours to several months after the first ingestion.
• With drug eruptions, cutaneous lesions are noted 24–48 hours after drug administration, although there may occasionally be a longer interval.

SIGNALMENT

• All ruminant species
• White- or light-colored breeds
• Affects all ages, but young may be more susceptible
• Affects both sexes equally

GENETICS

• White- or light-skinned breeds are at higher risk for type I or type III photosensitivity. Black-skinned animals are rarely affected with photosensitization of any type.
• Type II photosensitization has been reported to occur as an inherited autosomal recessive congenital disease in Holstein, Ayrshire, and Shorthorn cattle and Southdown and Corriedale sheep.
• In bovine erythropoietic porphyria ("pink tooth"), affected cattle are deficient in uroporphyrin III cosynthetase, an enzyme needed for proper formation of hemoglobin. Uroporphyrin and coproporphyrin accumulate in the bones, teeth, skin, and urine, as well as other tissues and secretions. Accumulations of porphyrin metabolites in the skin predispose the animals to photosensitization.
• Southdown lambs may have a congenital defect that can cause hyperbilirubinemia and results in hepatogenous photosensitization. Corriedale lambs can have a similar condition, which is characterized by a failure to excrete phylloerythrin and conjugated bilirubin that also results in hepatogenous photosensitization.

PHYSICAL EXAMINATION FINDINGS

• Photosensitization occurs most frequently in hairless and white-skinned areas of the body. Eyelids, lips, ears, nose, white blazes, coronary bands, and other white areas are most commonly involved.
• Signs may be more severe in areas of the body that receive more sunlight (head, neck, back).
• In contact photosensitization, only areas of contact with the photodynamic agent are affected. The affected area first becomes erythematous, edematous, and painful. Honey-colored serum begins to seep from the thickened skin, and extensive scabs can form after 1–2 days. Secondary bacterial infections of the skin can occur.
• Animals tend to be very pruritic in the early stages. As signs progress, they resist handling and may not want to eat due to the discomfort. Occasionally, the eyes will be affected and these animals may become blind. Death is due to starvation or misadventure.

Table 1

Plants That Cause Type I (Primary) Photosensitization

Latin Name	*Common Name*	*Toxin*
Hypericum spp.	St. John's wort	Conjugated quinone (hypericin)
Fagopyrum esculentum	Buckwheat	Conjugated quinone (fagopyrin)
Heracleum mantegazzianum	Giant hogweed	Furocoumarins
Ammi majus	St. Anne's lace	
Cymopterus spp.	Spring parsley	
Thamnosma texana	Dutchman's breeches	

• Signs consistent with hepatic encephalopathy (e.g., ceaseless walking, head pressing, behavior changes, etc.) are seen with secondary photosensitization.
• Animals may be restless and pruritic with reddened and swollen eyelids, muzzle, and lips. Affected animals may also exhibit tachypnea, tachycardia, hyperthermia, diarrhea, salivation, and jaundice (if type III or IV).

CAUSES AND RISK FACTORS

Plants

See Tables 1 and 2

Pharmaceuticals

• Antibiotics (penicillin, sulfas, tetracycline)
• Anticonvulsants
• Local anesthetics
• Nonsteroidal anti-inflammatory agents (NSAIDs), antipyretics (aspirin, phenylbutazone)
• Phenothiazines
• Thiazides

Chemicals

• Carbon tetrachloride
• Copper
• Methylene blue
• Phenanthridium
• Phosphorus

Fungal

• *Pithomyces chartarum, Aspergillus* spp., and *Fusarium* spp. can all produce hepatotoxic mycotoxins and cause secondary photosensitization.

Neoplasia

• Any neoplasia that affects hepatic function can cause secondary photosensitization.
A major risk factor is any underlying liver disorder or genetic defect that decreases excretion of phylloerythrin.

PHOTOSENSITIZATION (CONTINUED)

Table 2

Plants That Cause Type III (Secondary) Photosensitization

Latin Name	*Common Name*	*Toxin*	*Mechanism of Action*
Senecio spp.	Ragwort, groundsel, senecio	Pyrrolizidine Alkaloids (PA)	PAs are metabolized by the liver and the activated pyrrole form alkylates DNA in the hepatocyte, which impairs cell division. This prevents the hepatocyte from undergoing binary fission to regenerate hepatocytes, resulting in hepatocytomegaly and karyomegaly. When large numbers of hepatocytes die, the necrosis triggers a regenerative response accompanied by bile duct proliferation.
Crotalaria spp.	Crotalaria, rattlebox		
Amsinckia intermedia	Fiddleneck		
Echium spp.	Blueweed, viper's bugloss		
Heliotropium spp.	Heliotrope		
Symphytum spp.	Comfrey		
Cynoglossum officinale	Hound's tongue		
Microcystis	Blue green algae	Microcystins	Microcystins cause disruption of the actin filaments of the hepatic cytoskeleton, leading to cellular collapse.
Anabaena			
Oscillatoria			
Nodularia spumigena			
Lantana spp.	Lantana, shrub verbena, yellow sage	Triterpenoid compounds	Triterpenoids affect hepatocytes by inhibiting secretory function and decreasing bile canaliculi ATPase activity resulting in cholestasis and jaundice.
Lippia spp.	White brush		
Helenium spp.	Sneezeweed	Sesquiterpene lactones	Sesquiterpene lactones bind to sulfhydryl groups and other nucleophilic components, inhibiting numerous aerobin and anaerobin enzymes.
Hymenoxys spp.	Rubberweed, bitterweed		
Tetradymia and *Artemisia* spp.	Horsebrush	Furanosesquiterpenens	Tetradymol metabolites uncouple oxidative phosphorylation in electron transport. Phylloerythrin from other plants must be eaten to result in the development of photosensitization.
	Black sagebrush	Sesquiterpene lactones	
Panicum spp.	Panicum, Kleingrass	Disogenin	Lithogenic steroidal saponins (disogenins) are responsible for formation of crystals in the bile ducts resulting in hepatogenous photosensitization.
Tribulus terrestris	Puncture vine, goathead		
Nolina spp.	Sacahuiste, bunchgrass		
Agave lecheguilla	Agave, lecheguilla		
Kochia scoparia	Kochia	Unknown, possibly saponins	Secondary photosensitization
Trifolium hybridum	Alsike clover	Unknown	Primary photosensitization has been seen with ingestion and possibly contact. Secondary photosensitization has been seen with long-term ingestions.
Phyllanthus abnormis	Abnormal-leaf Flower	Unknown	Secondary photosensitization
Descurainia pinnata	Tansymustard		
D. sophia	Flixweed		
Brassica rapa	Turnip	Nitriles?	Unknown photosensitization
B. napus	Rape		
B. oleracea	Kale		
Lotus corniculatus	Bird's-foot trefoil	Unknown	Unknown photosensitization
Trifolium incarnatum	Crimson clover		
T. subterraneum	Subterranean clover		
T. pretense	Red clover		
Medicago denticulate	Burclover		
(*polymorpha*)	Alfalfa		
M. sativa	Black medic		
M. lupulina	Small burclover		
M. minima	Oats		
Avena sativa	Sorghum		
Sorghum	Wheat		
Triticum	Spotted spurge		
Chamaesyce (*Euphorbia*) *maculata*			

(CONTINUED) PHOTOSENSITIZATION

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
- Pemphigus foliaceus
- Irritant dermatitis
- Allergic dermatitis
- Folliculitis/furunculosis
- Dermatophytosis
- Chemical burns
- Thermal burns
- Malignant catarrhal fever
- Pediculosis
- Demodectic mange

CBC/BIOCHEMISTRY/URINALYSIS
- Elevations in GGT, AST, and ALP (most common)
- Elevations in SDH, GLDH, LDH (early in syndrome)
- Hyperbilirubinemia
- Inflammatory leukogram may be present.

OTHER LABORATORY TESTS
- Elevated bile acids
- Prolonged BSP clearance time
- Plasma phylloerythrin (>10 µg/dL is diagnostic) if available

OTHER DIAGNOSTIC PROCEDURES
Skin or liver biopsies can be performed.

PATHOLOGIC FINDINGS
- Dermal lesions vary from minimal reddening to urticarial lesions with erythema and swelling, to skin necrosis. The skin may have a gelatinous appearance extending down into the deeper corium. Microscopically, edema will be accompanied by necrosis and a polymorphonuclear infiltrate in the deeper corium. Both the epidermis and the superficial dermal vasculature may be damaged.
- Animals with secondary photosensitization will have hepatic and other systemic lesions. Bright yellow fat, hepatomegaly, liver cirrhosis, hepatic necrosis, and ascites are common. Depending on the extent of the liver damage, bruising and hemorrhage may be seen.
- If toxicosis is due to PAs, then hepatocytomegaly (always present), fibrosis, and bile duct proliferation may be seen.
- With certain plants, birefringent crystals may be evident in the bile ducts (small ducts may be obstructed), skin, kidney, adrenal gland, and heart.

TREATMENT

THERAPEUTIC APPROACH
- Therapy involves removing the animal from sunlight and preventing reexposure to the photodynamic agent.
- All drugs being administered when photosensitization occurred should be stopped.
- If the liver is involved, appropriate therapy for liver disease must be given.

MEDICATIONS

DRUGS OF CHOICE
- Pain relief with NSAIDs (e.g., flunixin 1.1–2.2 mg/kg PO or IV q6–12h; 72-hour milk withdrawal, 10-day meat withdrawal) if hepatopathy is not involved.
- Antibiotics if pyoderma is present (e.g., ceftiofur 1.1–2.2 mg/kg IM q24h; no milk or meat withdrawal).
- Liver protectants and blood transfusions may be attempted to prolong life in valuable animals.

CONTRAINDICATIONS
- If signs are due to a drug reaction, avoid using any related medications in the treatment of clinical signs.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
If secondary photosensitization, use caution when using drugs that must be metabolized by the liver.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Type I has a good prognosis. Type III has a poor prognosis due to liver involvement.
- The skin eruptions usually subside within 24–48 hours after exposure ceases, although lesions may persist up to 6 months.

POSSIBLE COMPLICATIONS
Prolonged grazing of *Echium* and *Heliotropium* may result in chronic copper poisoning of sheep.

CLIENT EDUCATION
Clients need to inspect hay and pastures for any phototoxic plants.

PATIENT CARE
- As many affected animals stop eating and drinking, supplemental feeding and fluid therapy are important.
- Mortality primarily occurs in lambs because the ewe's udders are so painful that lambs are not permitted to nurse. Cows also refuse to let calves nurse, but calf losses are usually low.
- Soothing skin medication or other pain relief can hasten healing.
- Prevent animal exposure to UV light. Let out on dry pasture only at night.
- Avoid any additional photosensitizing plants.
- Monitor until dermal lesions have resolved or until liver values return to normal.

PREVENTION
- Avoid future exposures to any implicated compounds and related substances.
- Avoid grain and hay contaminated by species of plants known to cause photosensitization.
- Control photosensitizing plants by spraying pastures and crop land with herbicides. Plants along trails and in shipping areas should be removed.
- Less-valuable animals or more resistant species may be used to "pregraze" pastures (e.g., sheep/goats may be used to graze groundsel before cattle).
- Provide supplemental feeding with more nutritious and palatable forage with contaminated pastures and follow a range management program that prevents overgrazing.
- Avoid exposure to blue-green algae by fencing off contaminated ponds.
- Facial eczema can be prevented by breeding animals for resistance, oral dosing with zinc, and spraying pastures with fungicides.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Pyoderma

AGE-RELATED FACTORS
Affects animals of all ages, but increased mortality in young animals.

ZOONOTIC POTENTIAL
PA metabolites are secreted in milk.

PREGNANCY
PAs cross the placenta and can affect the fetus, leading to increased calf losses, even with clinically normal dams.

SYNONYMS
- Bighead = *Tribulus terrestris*, *Chamaesyce maculata*
- Facial eczema = *Pithymyces chartarum*
- Fagopyrism = *Fagopyrum esculentum*
- Geeldikkop = *Tribulus terrestris*
- Hard liver disease = chronic *Amsinkia intermedia toxicosis*
- Seneciosis, Pictou disease, sleepy staggers = chronic *Senecio* spp. intoxication
- Trifoliosis, dew poisoning, big liver disease = *Trifolium hybridum* intoxication

ABBREVIATIONS

PINE NEEDLE TOXICITY

BASICS

OVERVIEW

• Ingestion of pine needles and bark from several north American pine species can induce abortion in cattle and bison and less frequently, systemic toxicity in cattle and sheep.
• Economic impact due to cattle abortions and death loss were estimated between $4.5 million and $20 million annually in the United States.
• Toxic pine trees are found in Western Canada, the US, and Northern Mexico.
• Toxicity has been reported with consumption of Ponderosa pine (*Pinus ponderosa*), Monterey pine (*Pinus radiata*), lodgepole pine (*Pinus contorta*), Monterey cypress (*Cupressus macrocarpa*), common juniper (*Juniperus communis*), Formosan juniper (*Juniperus formosana*), Utah juniper (*Juniperus osteosperma*), Rocky Mountain juniper (*Juniperus scopulorum*), Engelmann spruce (*Picea engelmannii*), Pinyon pine (*Pinus edulis*), single leaf pinyon (*Pinus monophylla*), and Jeffrey pine (*Pinus jeffreyi*).

INCIDENCE/PREVALENCE

Unknown

GEOGRAPHIC DISTRIBUTION

• *P. ponderosa* (Ponderosa or Western yellow pine) is the most widespread found across much of western North America, from southern Canada into Mexico and from Nebraska and Oklahoma to the Pacific Coast.
• *P. contorta* (lodgepole or limber pine) is found in western North America, from Alaska to Mexico and east to South Dakota.
• *P. radiata* (Monterey pine) is found around Monterey, California and cultivated in New Zealand and Australia.

SYSTEMS AFFECTED

• Nervous
• Reproductive
• Respiratory
• Urinary

PATHOPHYSIOLOGY

• The toxic and abortive actions are exerted by acids contained in pine needles and barks.
• Abortifacient effect is induced by pine diterpene labdane acids such as isocupressic acid (ICA). Pine resins compounds such as abietane acid have also neurotoxic and nephrotoxic effects.
• The induction of abortion is dependent on dosage of ICA ingested and on the stage of pregnancy.
• After consumption of pine needles, ICA is absorbed by the rumen into the systemic circulation and metabolized by the liver into agathic acid (AA), dihydroagathic acid (DHAA), and tetrahydroagathic acid (THAA).
• The mechanism of action for the abortion is not completely understood. The metabolites appear to modify hormonal changes, inducing increase in caruncular arterial tone and decrease in uterine caruncular blood flow. An effect on progesterone concentration inducing termination of pregnancy was also proposed.
• Clinical signs of toxicity happen from 24 hours to several days post-exposure.
• Abortifacient effects most often occur with ingestion of 1 kg needles/day for several days or higher amounts for 2–3 days. 100 mg ICA/kg body weight twice daily is required to initiate abortions in cattle. Ingestion of 62–78 mg ICA/kg BW of *Pinus contorta* induced abortion in 8–10 days. Ingestion of 190–245 mg ICA/BW of *Juniperus communis* induced abortion in 3–4 days.

SIGNALMENT

• Affects mainly bison and cattle.
• Sheep generally do not abort but increased incidence of dead lamb is noticed with pine needle consumption.
• Goats, elk, mule deer, and white-tailed deer are tolerant.

PHYSICAL EXAMINATION FINDINGS

Reproductive

• Abortion is more common than toxicity signs.
• Abortion or stillbirth happens in cattle in the second or third trimester of pregnancy, usually 3–4 days after ingestion. Early pregnancies do not seem to be affected. Increased incidence of abortion is noticed as pregnancy progresses.
• Early parturition with signs of depression, mucoid vulvar discharge (often bloody), weak uterine contractions, incomplete cervical dilation, uterine hemorrhage, dystocia, birth of dead or small weak calf. Alive calves are generally weak but stillbirth is also common.
• Maternal complications include retained placenta, septic metritis, agalactia, anorexia, rumen stasis, and death (if untreated).
• While significant exposure does not cause abortion in sheep, the number of dead lambs born at term may increase.

Systemic

• Intoxication and related clinical signs depend upon the amount consumed and the rate of ingestion.
• Initial clinical signs are depression, weakness, anorexia, lethargy, rumen atony, followed by hindlimb paresis and paralysis.

CAUSES AND RISK FACTORS

• Ingestion of pine needles, especially when green.
• Consumption of conifer foliage increases when limited forage is available, during snow cover, inclement weather, and reduced grazing time.
• Cattle with low body condition scores are induced to consume more pine needles compared to those with high body condition score.
• Cattle fed a low protein, high energy diet are induced to consume more pine needles.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Abortion caused by BVD or IBR viruses, neosporosis, leptospirosis, brucellosis, campylobacteriosis, selenium deficiency, or foothill abortion (EBA).

CBC/BIOCHEMISTRY/URINALYSIS

• Systemic toxicity: Azotemia, hypercreatinemia, hyperbilirubinemia
• Increase in AST, CPK, LDH
• Proteinuria with hyaline and granular casts

OTHER DIAGNOSTIC PROCEDURES

• Investigating access to pine needles, presence of risk factors, and clinical signs.
• Collection of fetal thoracic fluid or stomach content for detection of THAA.

PATHOLOGIC FINDINGS

• Reproductive—dams that die exhibit heavy uterine exudate with necrotic placental tissue, edema, and focal ulceration of endometrium and necrosis in the caruncles. Stillborn calves may show malacia of white brain (cerebral leukomalacia) matter or may appear normal.
• Systemic—nephrosis, vacuolation of basal ganglia neutrophils, perivascular and myelinic edema, patchy neuronal degeneration, ischemic myonecrosis of rear leg muscles.

TREATMENT

THERAPEUTIC APPROACH

• Remove source of pine needles from affected animals.
• Bind metabolites and reduce their absorption from digestive system.
• Support patient, treat symptomatically, maintain hydration and electrolytes.
• Treat retained placenta and endometritis.
• Supportive care for calf.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Rumenotomy with evacuation of contents may be worthwhile if performed early.

MEDICATIONS

DRUGS OF CHOICE

• Activated charcoal orally to control absorption of toxins from the GI tract. 2–5 g/kg in a water slurry given orally (1 g charcoal per 5 mL water).
• Na thiosulfate—0.5g/kg BW IV.
• Broad-spectrum antibiotics to treat uterine and/or systemic bacterial infection.

PINE NEEDLE TOXICITY (CONTINUED)

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Dams usually recover with treatment but death has been reported.
- Calf prognosis is dependent on stage of development at birth and supportive treatment for premature birth.
- Incidence of abortion: High abortive rate is expected in acute cases.

POSSIBLE COMPLICATIONS
Dams: Retained placenta, septic metritis, agalactia, anorexia, rumen stasis, and death (if untreated).

PREVENTION
- Prevent animal access to pine needles.
- Providing a proper diet and adequate nutrition to animals will minimize the intake of many toxic plants.
- Feeding 25% or more corn silage has shown to reduce pine intake.
- Increase protein content of diet if diet is composed of high energy and low protein.
- Conditioning cattle with pine needles has been proposed to reduce incidence of abortion but no data is supportive of its efficacy. The dose suggested for conditioning is 66 mg ICA/kg BW.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Nutritional deficiency

PREGNANCY
Reproductive toxicity in last trimester of pregnancy

PRODUCTION MANAGEMENT
- Fence pregnant cows in the last trimester away from pines and provide supplemental feed.
- Reduce animal density at feeding and assure appropriate access to feeders.
- Remove young stands of pines where appropriate.

PLANTS PRODUCING ACUTE RESPIRATORY DISTRESS SYNDROME

BASICS

OVERVIEW
• An afebrile pneumonia-like disease of cattle but occasionally observed in other ruminants. Often called acute respiratory disease syndrome (ARDS). Also called acute bovine pulmonary emphysema and edema (ABPEE).
• Rapid death may result.
• Several etiologies exist for the disease including rapidly changing animals from poor to lush pasture, and the plant *Perilla frutescens* (purple mint, perilla mint). Moldy sweet potatoes, rape, kale, turnips, and moldy pink half-runner beans are also associated with the disease.
• Many lush grasses are associated with ARDS including Bermuda, fescue, alfalfa, and Kleingrass. In the southeastern United States, *Perilla frutescens,* or purple mint, is often associated with ARDS. *Perilla* is an annual weed that grows to a height of 1–2 meters. *Perilla* is readily identified by its square stem and is common along wood lines and waste areas. The plant has small terminal white flowers and a characteristic minty fragrance.
• Lush pasture of many grasses contains high quantities of L-tryptophan. Dry, nonsucculent pastures contain lower quantities of L-tryptophan.
• Perilla mint contains 3-substituted furans (perilla ketone, egomaketone, and isoegomaketone).
• L-tryptophan in high quantities can lead to atypical interstitial pneumonia (AIP).
• Ingestion of moldy sweet potatoes that contain *Fusarium solani* can develop AIP in ruminants.
• *Fusarium solani* produces 4-ipomeanol which is a pneumotoxin.
• 3-substituted furans can be pneumotoxic by their direct affects on the lung.
• The condition is often referred to as bovine asthma, or AIP, in the US and fog fever in the United Kingdom.

INCIDENCE/PREVALENCE
• Usually observed in the fall when cattle are moved from summer pasture to lush fall growth, it has been observed in spring when cattle are turned out on lush pasture after being fed hay over the winter.
• Outbreak usually occur on pastures. The morbidity rate is usually low but occasionally may exceed 50%. The case fatality rate is typically 25–50%.
• ARDS cases in Mexico have involved a variety of irrigated grasses.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• The toxin can vary depending on the substrate but the pathogenesis is similar among the plants producing ARDS toxicants including *Brassica* spp. (kale, turnips), moldy sweet potatoes, and purple mint.
• Bioactivation of a pneumotoxin, primarily in Clara cells and macrophages of the lung rather than in cells in the liver, results in formation of reactive metabolite intermediates such as 3-methylindole (3-MI).
• These reactive metabolites bind to proteins in the lungs and cause tissue destruction, especially of type 1 pneumocytes and epithelial cells. Under the stimulus of factors released by macrophages, type 2 pneumocytes proliferate to replace lost type I cells and in the process cause formation of foci with massive increase in cellularity.
• During this period of proliferation, the ability of type II cells to synthesize and secrete functional surface-active phospholipids (surfactants) is decreased. Surfactant produced no longer effectively lowers surface tension. This compromises lung function.

SIGNALMENT
All ruminants, but cattle primarily

PHYSICAL EXAMINATION FINDINGS
• The clinical course is rapid and cattle may be found dead in 12–24 hours, especially if stressed.
• Animals are observed with very rapid and shallow open-mouth breathing. Foam is evident around their mouth. An expiratory grunt is very audible from 100 feet or more. Animals may be extremely cyanotic and die quickly if stressed.

CAUSES AND RISK FACTORS
• Animals are susceptible whenever moved from dry nonsucculent pasture to lush pasture. Signs may appear within 1 week following the transfer.
• L-tryptophan is metabolized by rumen microorganisms to indoleacetic acid, which is subsequently decarboxylated by *Lactobacillus* spp. to 3-methylindole (3-MI). The 3-methylindole is absorbed and metabolized by the lung mixed-function oxidase system to produce pneumotoxicosis.
• Usually observed in the fall when cattle are moved from summer pasture to lush fall growth, it has been observed in spring when cattle are turned out on lush pasture after being fed hay over the winter.
• If caused by *Perilla frutescens,* usually observed from August through October when this plant reaches maturity. The seed heads are the most toxic. Has been observed in cattle eating hay containing purple mint.
• Consumption of moldy sweet potatoes containing 4-IP can occur year round.
• There have been reports of acute respiratory disease associated with feed wet distiller's grains. There may be a pneumotoxin similar to 4-IP in this feed. Can occur year round but most reports are in the fall.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other causes of pneumonia such as viruses, mycoplasma, and bacteria
• Hardware disease in cattle due to the pronounced expiratory grunt

CBC/BIOCHEMISTRY/URINALYSIS
N/A

IMAGING
• Thoracic radiography.
• Pulmonary emphysema and edema are common.
• Emphysematous bullae may be observed on the lung surface.

OTHER DIAGNOSTIC PROCEDURES
These are used to rule out viral and bacterial causes for the pneumonia.

PATHOLOGIC FINDINGS
• Lungs are enlarged and heavy due to edema, cellular proliferation, and congestion. Foam fills many airways.
• Interlobular edema and emphysema are commonly observed. Emphysematous bullae are often observed on the lung surface.
• Emphysema may extend into the mediastinum and subcutaneous cervical and thoracic areas.
• Microscopically, alveolar epithelial hyperplasia of type 2 pneumocytes is common along with interstitial emphysema, edema, and hyaline membranes.

TREATMENT

THERAPEUTIC APPROACH
• No specific treatment.
• Keeping animals as calm as possible is important.
• If stressed, animals often become anoxic and die.
• Remove animals from etiology (e.g., purple mint, moldy sweet potatoes, or lush pasture). Place on dry feed.

MEDICATIONS

DRUGS OF CHOICE
• No specific drugs are effective.
• Symptomatic treatment such as corticosteroids, atropine, diuretics, antihistamines, and antibiotics.
• Avoid stress (if possible) when treating.
• Weigh the value of therapeutic pharmacology versus the stress involved with handling and treatment.

PLANTS PRODUCING ACUTE RESPIRATORY DISTRESS SYNDROME (CONTINUED)

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Steroids should not be used in pregnant animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Depending on the amount of lung damage, very guarded early prognosis as death may occur within 12–24 hours.
• Clinical course may last 2–3 weeks.
• If animals survive 2 or 3 days and are not stressed, prognosis improves.
• Even severely affected animals may return to normal in 2–3 weeks when the type 2 pneumocytes resolve to type 1.

PREVENTION
• Gradually introduce cattle to lush pasture after feeding on nonsucculent, if possible.
• Inhibit certain ruminal microflora that reduce L-tryptophan to 3-MI with monensin or lasalocid.
• Avoid exposure to perilla mint.
• Supply ample good pasture as perilla is usually consumed only when other better forage is lacking.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Calves fed the flowering perilla plant develop the toxic syndrome, while those fed earlier plants (collected before seed stage) and late plants (collected after frost) remain asymptomatic. Cases in cattle have been reported year round.

PRODUCTION MANAGEMENT
The time of year when *Perilla* reaches the seed stage often corresponds to periods when pasture grass is scarce, forcing cattle to consume plants not normally eaten when ample desirable forage is available.

SYNONYMS
• Atypical interstation pneumonia (AIP)
• Bovine asthma
• Fog fever

ABBREVIATIONS
• ABPEE = acute bovine pulmonary emphysema and edema
• AIP = atypical interstitial pneumonia
• ARDS = acute respiratory distress syndrome
• 3-MI = 3-methylindole
• 4-IP = 4 ipomeanol

POISON HEMLOCK (*CONIUM* SPP.) TOXICITY

BASICS

OVERVIEW
• Poison hemlock (*Conium maculatum*) toxicity in ruminants is an uncommon occurrence.
• Poison hemlock is a member of the Apiaceae family. It is a biennial. The first-year seedling plant contains leaves that are fernlike in appearance—three to four times pinnately divided, and the leaflets are 1/4 in. long and segmented. The foliage has a strong odor like mouse urine, or a parsnip-like odor.
• The mature plant is erect, 3–8 feet tall, with a stout hollow stem (except at the nodes) that is smooth and often purple splotched. The plant has a long white/yellow taproot, which resembles a carrot or parsnip.
• Small, white flowers are arranged in umbrella-shaped clusters at the tips of the uppermost stems.
• It is a commonly encountered weed throughout North America, sometimes forming heavy dense stands that are difficult to control.
• Two types of clinical conditions can be encountered—acute toxicities (nicotinic effects) and malformations in young exposed in utero ("crooked calf disease").
• Treatment is nonspecific in nature, and emphasis should be placed on identification of the plant and preventing access to it.

INCIDENCE/PREVALENCE
Not very common; the plant is not generally considered palatable (particularly the mature plant) and animals do not readily graze it unless forced to do so. Animals may acquire a taste for the plant.

GEOGRAPHIC DISTRIBUTION
Throughout North America

SYSTEMS AFFECTED
• Nervous
• Musculoskeletal

PATHOPHYSIOLOGY
• The piperidine alkaloids have nicotinic-like effects—stimulate, then paralyze the nicotinic receptors. Large exposures cause neuromuscular block, hypotension, and bradycardia.
• Gamma-coniceine is thought to be the agent responsible for the malformations; inhibits fetal movement. Both coniine and gamma coniceine are considered teratogenic in various animals.

SIGNALMENT
• All ruminants, particularly cattle (considered more susceptible).
• Cattle, sheep, and goats appear to be susceptible.

PHYSICAL EXAMINATION FINDINGS
• Abrupt onset (within a few hours of ingestion) of muscle tremors, ataxia, muscle weakness, weakened heartbeat, excessive salivation and lacrimation, mydriasis, and frequent urination and defecation.
• This can progress to recumbency, depression, abdominal pain, respiratory distress, and death from respiratory arrest.
• Skeletal deformations observed when pregnant animals are exposed include arthrogryposis, cleft palate, microphthalmia, and spinal column deformities.

CAUSES AND RISK FACTORS
• Concentrations of the toxic alkaloids vary between parts of the plant and stage of maturity.
• All parts of the plant are potentially toxic, and toxicity is thought to increase as the plant matures.
• Approximate toxic and lethal dose for poison hemlock—cattle >1.0 g fresh plant/kg body weight; sheep >5.4 g fresh plant/kg BW; goats >7.8 g fresh plant/kg BW.
• Some toxicity is lost in drying; but there have been cases where cattle have been poisoned as a result of ingesting contaminated hay.
• Grain that is contaminated by the seeds can be a problem as well. Concentration of the alkaloids is highest in the seeds.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Organophosphate or carbamate poisoning, poisoning with *Lupinus* or *Nicotiana* spp.
• Nitrate
• Cyanide
• Nonprotein nitrogen

CBC/BIOCHEMISTRY/URINALYSIS
No specific diagnostic changes have been reported.

OTHER DIAGNOSTIC PROCEDURES
• One can attempt to confirm exposure through feed microscopy of the rumen contents.
• Piperidine alkaloids can be detected in the rumen contents or urine, also in liver, kidney, and blood.

PATHOLOGIC FINDINGS
• Renal tubule necrosis and skeletal muscle degeneration has been reported in fatal cases involving people.
• A mouse urine or parsnip odor can be detected from the freshly open rumen.
• Skeletal malformations include cleft palate, arthrogryposis, scoliosis, kyphosis, and torticollis.

TREATMENT

THERAPEUTIC APPROACH
• Symptomatic and supportive in nature. Decontaminate the gastrointestinal tract with activated charcoal and saline cathartic.
• Providing adequate respiratory support would be next to impossible in the field.

MEDICATIONS

DRUGS OF CHOICE
Atropine should be used with caution.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Highly dependent on the exposure dose or the severity of the malformations.

PATIENT CARE
Monitor respiratory function.

PREVENTION
• Avoid access to the plant.
• Control chemically with appropriate herbicides.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Depression, abdominal pain, respiratory distress, and death from respiratory arrest.
• Skeletal deformations observed when pregnant animals are exposed include arthrogryposis, cleft palate, microphthalmia, and spinal column deformities.

PREGNANCY
Attempts should be made to prevent pregnant animals' access to the plant during susceptible periods (cattle—days 40–100 of gestation; sheep and goats—30–60 days of gestation).

PRODUCTION MANAGEMENT
• Prevent animals from accessing the plant.
• Some toxicity is lost in drying; but there have been cases where cattle have been poisoned as a result of ingesting contaminated hay.
• Grain contaminated by the seeds can be a problem as well.

POLYARTHRITIS

BASICS

OVERVIEW
Inflammation of multiple joints resulting in persistent lameness

INCIDENCE/PREVALENCE
Varies based on etiology

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Musculoskeletal

PATHOPHYSIOLOGY
Inflammation is a component of all joint disease, regardless of etiology, to varying degrees. The synthesis of inflammatory mediators results in degradation of synovial tissue. A common cause of polyarthritis, septic arthritis, results from the hematogenous seeding of bacteria or, less commonly, viral pathogens from a primary site of entry (e.g., omphalophlebitis, pneumonia). Direct trauma and congenital disorders can also cause polyarthritis, although often seen in a solitary joint. See chapters on each specific etiology for more detailed pathophysiology.

HISTORICAL FINDINGS
• The clinical signs typically observed in animals with polyarthritis include shifting limb lameness, stilted gait, and unwillingness to move. Close examination usually reveals multiple visibly-swollen and distended joints.
• Herd health history is important to narrow down underlying cause.

SIGNALMENT
This varies with the specific syndrome and etiology. All ruminant species can become affected.

PHYSICAL EXAMINATION FINDINGS
• A complete physical examination is important to determine underlying cause of disease.
• Joint capsules are palpably distended and pressure on the joint will cause increased distention of the joint at an alternate site. Warmth and pain upon palpation and flexion of joints may be observed.
• Look for signs of trauma over joints (e.g., puncture wounds, chronic decubital ulceration). Penetrating wounds should be cleaned and probed.
• Systemic signs include any of lameness, fever, lethargy, and inappetence.

CAUSES AND RISK FACTORS
Clinical syndromes presenting with multiple distended and/or painful joints:
• *Mycoplasma* spp. arthritis—fibrinosuppurative and necrotizing arthritis + tenosynovitis in calves and feedlot bison
• *Histophilus somni* arthritis
• Chlamydial arthritis
• Caprine arthritis encephalitis virus (CAEV)
• Polyarthritis secondary to septicemia
• Polyarthritis secondary to bacterial endocarditis
• Osteochondrosis—inheritance and gender are contributing factors
• Septic physitis secondary to salmonellosis
• Traumatic
• OA (DJD)—elbow joints in domestic sheep; cartilage lesions in the patellar groove lesions in bulls; temporomandibular joint in free-living Soay sheep on St. Kilda (geriatric females, predominantly)
• Mineral deficiency
• Osteomalacia
• Hock lesions (tarsal periarthritis) strongly associated with time spent lying on abrasive surfaces, prolonged high local pressure/friction of the hock on hard surfaces, and collisions of hock with cubicle fittings.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
See "Causes and Risk Factors." Make sure to rule out other extra-articular causes of lameness including infectious and noninfectious hoof lesions, some of which will cause swelling around the joints of the distal limb.

Diagnosis Criteria
• Herd histories of preceding or concurrent outbreaks of respiratory disease will greatly increase the likelihood of mycoplasmal, *Histophilus somni,* or chlamydial disease.
• Polyarthritis secondary to septicemia is seen almost exclusively in neonates <1 month of age. Most will have additional diagnoses of clinical signs strongly supportive of septicemia including omphalophlebitis, hypopion, fever, and scleral injection.
• Age of onset will vary among the common causes of polyarthritis. Polyarthritis secondary to septicemia is diagnosed in very young animals. Chlamydial arthritis is most common preweaning. *Mycoplasma* and *Histophilus* polyarthritis are most common in recently weaned calves. Osteochondrosis is most common in cattle between 1 and 2 years of age. Polyarthritis secondary to endocarditis is typically seen in adult cattle.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Microbiologic culture procedures or polymerase chain reaction (PCR) assays may be useful in the identification of the offending pathogens. However, it should be noted that negative results are common and should not exclude the possibility of a diagnosis.
• Serologic tests are available for chlamydia and CAEV.

IMAGING
• Radiography is a useful adjunct to the diagnosis of polyarthritis. Osteochondrosis with or without degenerative joint disease and septic physitis can readily be confirmed or ruled out by radiographic examination.
• Acute stages on radiographs will reveal only nonspecific soft tissue swelling and subchondral bone lysis does not appear until 14 days.
• Septic arthritis on radiographs can have narrowing or widening of the joint space, subchondral bone lysis and periarticular bone proliferation.
• Ultrasound is a reliable method for confirming tentative diagnosis (distention of joint pouch).

OTHER DIAGNOSTIC PROCEDURES
• Arthrocentesis and analysis of joint fluid is the single most useful test in most animals with polyarthritis. Cattle with polyarthritis caused by *H. somni* or endocarditis will generally have joint fluid with a profound increase in leukocytes, the predominant cell type being the neutrophil. Synovial fluid with at least 10,000 nucleated cells/μL and >90% neutrophils is indicative of purulent arthritis. Fluid is grossly cloudy with decreased viscosity compared to normal synovial fluid.
• Joint fluid in cattle with *Mycoplasma* spp. infection has a less dramatic increase in cell numbers and the predominant cell type is mononuclear cells.
• Cattle with either osteochondrosis or septic physitis secondary to salmonellosis will generally have near normal joint fluid composition.
• Fibrinous arthritis cannot always be diagnosed by arthrocentesis.
• Elevations in MMPs (gelatinase enzymes in CT involved in cartilage degradation) (MMP-9 = septic; MMP-2 = aseptic).

TREATMENT

THERAPEUTIC APPROACH
• Varies with the specific syndrome and etiology. See specific chapters for details.
• NSAIDs are indicated for pain management.

MEDICATIONS

Varies with the specific syndrome and etiology. See specific chapters for details.

FOLLOW-UP

Varies with the specific syndrome and etiology. See specific chapters for details.

POLYARTHRITIS (CONTINUED)

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
• Chlamydial arthritis is most common preweaning.
• *Mycoplasma* and *Histophilus* polyarthritis are most common in recently weaned calves.
• Osteochondrosis is most common in cattle between 1 and 2 years of age.
• Polyarthritis secondary to endocarditis is typically seen in adult cattle.
• Polyarthritis secondary to septicemia is seen almost exclusively in neonates <1 month of age.

ZOONOTIC POTENTIAL
Chlamydia spp. and *Salmonella* spp. should be considered zoonotic agents and care should be used in sample collection.

PREGNANCY
Chlamydia spp. and *Salmonella* spp. can cause abortion in herds or flocks.

BIOSECURITY
Recommendations dependent on etiologic agent.

PRODUCTION MANAGEMENT
Recommendations dependent on etiologic agent. When polyarthritis is a result of improper housing conditions, animal husbandry and comfort must be addressed. See chapter, Dairy Cow Comfort (see www.fiveminutevet.com/ruminant), for recommendations.

POSTPARTUM DISORDERS

BASICS

OVERVIEW

• Postpartum disorders are common production diseases which often stem from a problem during the transition period (21 days before expected parturition to 21 days postpartum).
• These disorders may be exacerbated by calving conditions. Calving accidents are a separate entity that is not discussed here.
• The most important postpartum disorders are hypocalcemia, retained fetal membranes (RFM), metritis, displacement of abomasums (DA), ketosis, fatty liver, and udder edema.
• Other conditions such as lameness and mastitis are also related to the transition period but they may occur at any time during the production cycle.
• In beef cattle, prepartum nutrition and trace mineral supplementation affect colostrum quality and calf survival.

INCIDENCE/PREVALENCE

• Incidence of postpartum disorders is extremely variable and depends on factors such as season, geographic location, breed, type of housing and environment, management, herd, etc.
• Dairy cattle are more at risk than beef cattle.
• Reported incidence of various disorders in dairy cattle is
  ◦ Clinical hypocalcemia: 0.2–2%
  ◦ Retained fetal membranes: 8–14%
  ◦ Metritis: 6–12%
  ◦ Clinical ketosis: 2–6%
  ◦ Subclinical ketosis: 10–20%
  ◦ Displacement of abomasum: 0.5–6%.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Reproductive
• Musculoskeletal
• Digestive
• Mammary
• Multisystemic

PATHOPHYSIOLOGY

• The transition period is a very dynamic stage. The fetus grows exponentially and cows start to decrease dry matter intake (DMI), especially during the last week of gestation. As a response, cows start to mobilize fat from adipose tissue. The result is an increase of nonesterified fatty acids (NEFA) in blood, especially in obese cows, which may develop fatty liver.
• Parturition is a stressful process involving metabolic and hormonal changes that contribute to immunosuppression and decrease of host resistance to diseases.
• Mammary gland removes high amounts of calcium from blood; therefore, there is a more intense negative calcium balance with development of hypocalcemia.
• If calving is complicated, hypocalcemia worsens, affecting uterine and gastrointestinal motility. This in turns contributes to increased risks for RFM with consequent metritis and displaced abomasum.
• When lactation advances, energy requirements increase dramatically and DMI recovers slowly. This causes a typical negative energy balance during the first weeks of lactation. In addition, mammary gland extracts large amounts of glucose from blood for lactose synthesis. Therefore, hypoglycemia may develop and ketosis may be established. In addition, a transient stage of insulin resistance may occur during the early postpartum period to promote glucose uptake by the mammary gland (insulin independent organ) and to block glucose uptake by other tissues. This stage of insulin resistance makes NEFA release more abundant, with a progressive likelihood of hepatic lipidosis. Finally, the catabolic stage of fat depots increases immunosuppression because adipocytes are very proactive inflammatory cells producing several cytokines and immunomodulatory responses, negatively affecting white blood cells.

HISTORICAL FINDINGS

• Herd with high rate of RFM, poor production, and increased rate of metabolic disorders
• Individual cows: Dystocia, twinning

SIGNALMENT

• Periparturient dairy cows
• Breed predisposition for some postpartum disorders (Jersey, hypocalcemia)

PHYSICAL EXAMINATION FINDINGS

• Clinical signs of postpartum disorders vary but can be monitored on farm by daily rectal temperature and demeanor and appetite of the cow. Infectious processes are often accompanied by fever, depression, increased heart and respiratory rate, and dehydration. Severe disorders may lead to a down cow syndrome.
• Retained fetal membranes: Visible membranes 24 hours postpartum.
• Metritis: Fever, foul-smelling discharge.
• Hypocalcemia: Musculoskeletal compromise.
• Ketosis: Decrease in milk yield, high ketones in blood, urine or milk.
• Displacement of abomasum (high-pitched "ping" sound at auscultation on left flank, last two rib spaces).

GENETICS

Some calving-related disorders have a hereditary component (ketosis and somatic cell count).

CAUSES AND RISK FACTORS

• Inadequate management of the prepartum, calving, and postpartum period. Improper nutrition, poor environment, and lack of cow comfort.
• Breed, genetic potential, season, herd size, geographic location, parity, and facilities.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Diagnosis of the specific condition is based on thorough physical examination of the animal.
• On herd basis, record analysis shows increased incidence of several postpartum disorders which are associated one to another.

CBC/BIOCHEMISTRY/URINALYSIS

• Ketosis (ketones in urine, blood, or milk)
• Hypocalcemia (plasma)
• Fatty liver (plasma NEFA or liver biopsy).

OTHER LABORATORY TESTS

Liver biopsy

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

THERAPEUTIC APPROACH

Individual animals require appropriate therapy for the specific disorders. This may include antimicrobials, anti-inflammatory drugs, and fluid therapy to correct dehydration and electrolyte imbalances. Hypocalcemia should be addressed immediately.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Surgical correction of DA

MEDICATIONS

DRUGS OF CHOICE

• Drugs should be selected based on the specific diagnosis.
• Broad-spectrum antibiotic therapy.
• NSAIDs.
• Corticosteroid in cases of endotoxemia.
• Fluids: Oral fluids are sufficient in mild cases, IV fluids are important in severe clinical cases. Hypertonic fluid for severely dehydrated animals.
• Feed additives to improve energy and mineral balance such as propylene glycol, niacin, protected choline, calcium propionate, glycerol, vitamin E, selenium, yeasts, and probiotics.

POSTPARTUM DISORDERS (CONTINUED)

CONTRAINDICATIONS

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Most cases can be treated successfully if diagnosed early. However, there will be an effect on reproductive and production performance and increased risk for culling.
- Down cows present a peculiar challenge in its management. Welfare issues should be considered and humane euthanasia is required in severe cases.

POSSIBLE COMPLICATIONS

Postpartum disorders are often associated and it is not uncommon to see cows developing a succession of problems during the same lactation.

CLIENT EDUCATION

- Importance of transition cow management (proper nutrition, calving management).
- Train calving team to recognize dystocia and properly manage it.
- Importance of postpartum monitoring program.
- Importance of cow comfort and welfare issues.

PATIENT CARE

- Monitor response to treatment: Rectal temperature, appetite, manure quality.
- Provide a comfortable area.
- Transfaunation may be necessary in some cases.

PREVENTION

- Proper general and nutritional management.
- Monitoring of body condition score during dry period. Cows should not lose condition or gain excessive weight during the transition period.
- Urine pH should be monitored to evaluate anionic salts during prepartum period for the prevention of hypocalcemia. Urine pH should be between 6.0 and 7.0.
- Proper transition diet. Moderate energy (not more than 16 Mcal/day NE for lactation) and protein levels (not more than 1,200 g/day of metabolizable protein). Prepartum diet with a negative cation-anion difference between –25 and –75 mEq/kg DM. Fiber in sufficient quantity and of appropriate particle size.
- Prepare cows for calving ease.

MISCELLANEOUS

ASSOCIATED CONDITIONS

- Calving-related disorders are intimately related to each other. Cows with hypocalcemia are more likely to develop RFM. Cows with RFM are more likely to develop metritis. Cows with metritis are more likely to develop ketosis, and cows with ketosis are more likely to develop displacement of abomasum.
- Delayed resumption of ovarian activity in beef cattle.

AGE-RELATED FACTORS

Older cows are more likely to develop clinical hypocalcemia, ketosis, and displacement of abomasum.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

Prepartum management is critical for prevention of calving-related disorders. Enough feed bunk space, adequate shade, and comfortable environment are essential for prepartum dairy cows.

POSTPARTURIENT HEMOGLOBINURIA

BASICS

OVERVIEW
• This uncommon and sporadic condition causes intravascular hemolysis in cattle shortly after parturition, resulting in anemia and hemoglobinuria.

INCIDENCE/PREVALENCE
Although the condition is sporadic and the incidence is low, the mortality rate is high.

GEOGRAPHIC DISTRIBUTION
• Cases have been reported worldwide.
• In the United States, disease is more common in the winter months in northern states.

SYSTEMS AFFECTED
• Hemolymphatic
• Cardiovascular
• Urinary

PATHOPHYSIOLOGY
• The exact etiology of this disease is not entirely known; however, inadequate dietary phosphorus leading to hypophosphatemia is often detected in affected cows. Although hypophosphatemia is associated with postparturient hemoglobinuria, most cattle with hypophosphatemia do not experience intravascular hemolysis, suggesting that there are other causative aspects of the disease.
• Hypophosphatemia alters erythrocyte metabolism and membrane permeability, thus rendering the cells more susceptible to intravascular hemolysis.
• Hypocupremia may also be a predisposing factor. Hypocupremia predisposes erythrocytes to oxidative damage and Heinz body formation, also leading to fragility of the red blood cell membrane and intravascular hemolysis.

HISTORICAL FINDINGS
Recent calving, progressive depression, weakness and lethargy, anorexia, decreased milk production, red to brown discolored urine.

SIGNALMENT
• Cattle, most common in dairy breeds
• Multiparous cows within the first month of calving

PHYSICAL EXAMINATION FINDINGS
• The clinical signs depend on the severity and rate at which hemolysis occurs.
• Weakness and recumbency are expected as the condition progresses. In severe cases, signs of hypovolemic shock may be present, including tachycardia, tachypnea, pallor of the mucus membranes, lack of episcleral vessels, and cool extremities.
• A low-grade fever may be present. A grade I to III/VI systolic murmur may be audible over the heart base as blood viscosity decreases with advancing anemia.
• When the plasma hemoglobin concentration exceeds the renal threshold, hemoglobinuria will occur. Within 1–2 days, icterus of the mucus membranes and sclera will develop.

GENETICS
High-producing dairy cattle appear to be most susceptible.

CAUSES AND RISK FACTORS
• Low dietary phosphorus.
• Low dietary copper.
• Parturition.
• Ingestion of alfalfa hay or sugar beet that may contain saponins.
• Copper deficiency.
• High-producing multiparous dairy cow consuming diets low in phosphorus are at greatest risk of disease.
• Drought conditions, grazing phosphorus-deficient soil, prolonged housing, and exposure to extremely cold weather may also predispose to the disease.
• Consumption of rape, turnips, or other cruciferous plants, and large amounts of beet pulp or cold water are associated with the disease. In New Zealand, low blood and liver copper levels and grazing copper-deficient pastures are additional risk factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Any cause of intravascular hemolysis in the cow would cause similar signs: babesiosis, bacillary hemoglobinuria, leptospirosis, onion, rape, or kale plant toxicity, copper toxicity, and autoimmune hemolytic anemia.

CBC/BIOCHEMISTRY/URINALYSIS
• Anemia
• Regenerative anemia 5–7 days after onset (signs of regeneration include an increased MCV, anisocytosis, polychromasia, basophilic stippling, reticulocytes)
• Hemoglobinemia (pink plasma, MCV, and MCHC increased)
• Hemoglobinuria
• Hyperbilirubinemia (unconjugated)
• Azotemia
• Acidosis
• Ketonuria

OTHER LABORATORY TESTS
• Decreased serum phosphorus concentrations are evident.
• In New Zealand cases, decreased blood copper concentration and Heinz bodies in erythrocytes have been noted.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Hemoglobinuria and widespread icterus

TREATMENT

THERAPEUTIC APPROACH
• Emergency inpatient or outpatient care.
• Intravenous fluid therapy with polyionic isotonic fluids is indicated.
• When anemia is severe and clinical or laboratory evidence of hypoxemia is evident (intense lethargy or weakness, profound tachycardia or tachypnea, severe anemia, acidosis, increased anion gap), a whole blood transfusion is indicated.
• The normal total blood volume is approximately 8% of the body weight (i.e., 0.08 × body weight in kilograms equals the total blood volume in liters). Typically, transfusing 1/4 to 1/3 of the total blood volume is adequate.

SURGICAL CONSIDERATIONS
N/A

MEDICATIONS

DRUGS OF CHOICE
• The current recommendation for intravenous treatment for hypophosphatemic cattle is the administration of either 30 g of anhydrous NaH_2PO_4 dissolved in 300 mL of sterile deionized water or 36 g of anhydrous Na_2HPO_4 (or 90 g of $Na_2HPO_4.12\ H_2O$) dissolved in 500 mL of sterile deionized water and administered as slow intravenous infusion. Because products approved for the use in cattle are frequently not available, this treatment would have to be administered in an extra-label manner.
• Human enema formulations that contain a mixture of monobasic sodium phosphate monohydrate and dibasic sodium phosphate heptahydrate in a buffered solution also have been administered to hypophosphatemic cattle orally (preferred) or intravenously but must be diluted with at least 4 mL of water for every 1 mL of enema solution if given intravenously.
• In experimentally phosphorus-depleted lactating Holstein-Friesian cows, 302 g NaH_2PO_4 dihydrate dissolved in 1.5 L warm water (38°C) and 263 g KH_2PO_4 dissolved in 1.5 L warm water administered by orogastric tube were equally effective in raising serum phosphorus concentration within 90 minutes and sustained for at least 24 hours.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
Avoid concurrent use of potentially nephrotoxic drugs.

POSTPARTURIENT HEMOGLOBINURIA (CONTINUED)

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- The prognosis is guarded to poor, even with appropriate treatment.
- The clinical course is acute, progressing to recumbency in 3–5 days. In severe cases, death can occur within hours.
- Surviving cows may need a 4-week period of convalescence.

POSSIBLE COMPLICATIONS
- Renal disease from hemoglobinuria
- Ketosis
- Death from hypoxemia

PATIENT CARE
- Monitor heart rate, respiratory rate, attitude, appetite, PCV, serum phosphorus and copper concentrations, creatinine.
- Keep confined.
- Increase dietary phosphorus intake.

CLIENT EDUCATION
Increase dietary phosphorus intake in unaffected herd mates.

PREVENTION
Ensure adequate dietary phosphorus and copper intake in the early postpartum period.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Ingestion of feeds that contain saponins may predispose to hemolysis.

AGE-RELATED FACTORS
Multiparous cows within the first month of calving

POSTPARTURIENT PARESIS (HYPOCALCEMIA)

BASICS

OVERVIEW
• Increased calcium (Ca) demand with a delay in adaptation of Ca metabolism in dairy cows within the first 72 h postpartum leads to hypocalcemia.
• Hypocalcemia ultimately results in flaccid paralysis and inability to rise.
• The disorder is most easily prevented by altering dietary cation-anion difference (DCAD), which is the balance between absorbable cations and anions in the dry cow ration.

INCIDENCE/PREVALENCE
• Clinical disease in 5–6% of all dairy cows
• Up to 50% of older periparturient dairy cows have subclinical hypocalcemia
• Rare in first-calf heifers

GEOGRAPHIC DISTRIBUTION
Worldwide depending on production factors

SYSTEMS AFFECTED
• Musculoskeletal
• Nervous

PATHOPHYSIOLOGY
• Parathyroid hormone (PTH) controls plasma concentrations and urinary excretion of Ca and phosphorus (to a lesser extent, magnesium)
• PTH is released primarily in response to decreases in serum ionized Ca, and promotes mobilization of Ca from bone, resorption of Ca and magnesium in the renal tubules, and increases urinary phosphorus excretion.
• PTH also stimulates renal production of active 1,25 dihydroxyvitamin D_3, which stimulates active absorption of Ca from the GI tract.
• Rations with a higher ratio of cations (K^+, Na^+, Ca^{2+}, and Mg^{2+}) to anions (Cl^-, SO_4^{2-}, PO_4^{3-}) induce nutritional metabolic alkalosis, creating pseudohypoparathyroidism:
  ◦ Altered conformation of the PTH receptor reduces sensitivity of tissue receptors to PTH
  ◦ Subsequently there is reduced release of Ca from bone and reduced absorption of Ca in the GI tract
• Hypocalcemia impairs muscular contraction by delaying release of acetylcholine at neuromuscular junctions, causing flaccid paralysis.
• Hypomagnesemia prevents production and secretion of PTH and 1,25-dihydroxyvitamin D_3.

HISTORICAL FINDINGS
Recent parturition in mature cows receiving diets with inappropriate DCAD

SIGNALMENT
Female cows of Channel Island and Swedish Red breeds are predisposed, in their third or later lactation.

PHYSICAL EXAMINATION FINDINGS
◦ ***Stage I***
  ▪ Early signs are subtle and transient; animals appear excitable, nervous, or weak without recumbency.
  ▪ Shifting weight frequently, shuffling hind feet, may have fine tremors.
◦ ***Stage II***
  ▪ Sternal recumbency, with low body temperature and poor anal tone
  ▪ Tachycardia and decreased intensity of cardiac sounds
  ▪ Moderate to severe depression and partial paralysis
  ▪ S-shaped curve to the neck
◦ ***Stage III***
  ▪ Lateral recumbency, paralysis and bloat
  ▪ Severely depressed (coma)
  ▪ Tachycardia and weak peripheral pulses

GENETICS
N/A

CAUSES AND RISK FACTORS
• High producing dairy cows in third or later lactation
• Inappropriate DCAD
• Increased dietary phosphorus (blocks renal production of 1,25 dihydroxyvitamin D_3)

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Grass tetany
• Traumatic reticuloperitonitis
• Coxofemoral luxation
• Obturator paralysis
• Lymphosarcoma
• Musculoskeletal or spinal trauma
• Toxemia (mastitis, metritis, pneumonia)

CBC/BIOCHEMISTRY/URINALYSIS
• Serum Ca^{2+} declines from 8.5–10 mg/dL to <7.5 mg/dL (see Table 1).
• Hypophosphatemia, hypo- or hypermagnesemia, and hyperglycemia.
• Neutrophilia, lymphopenia, and eosinopenia with moderately increased serum creatine kinase activity (CK) related to recumbency.

Table 1

Serum Concentrations (mg/dL) of Ca^{2+}, P, and Mg^{2+} in Cows in Different Stages of Postparturient Paresis

	Calcium	*Phosphorus*	*Magnesium*
Stage 1	6.2 ± 1.3	2.4 ± 1.4	3.2 ± 0.7
Stage 2	5.5 ± 1.3	1.8 ± 1.2	3.1 ± 0.8
Stage 3	4.6 ± 1.1	1.6 ± 1.0	3.3 ± 0.8

Ration analysis to determine DCAD

PATHOLOGIC FINDINGS
No gross findings; or evidence of intercurrent diseases (metritis, retained membranes, pneumonia) may be present.

TREATMENT

THERAPEUTIC APPROACH
• Cows with clinical signs require prompt recognition and treatment with Ca to prevent progression and death.
  ◦ Oral Ca supplementation may be adequate in mild cases and reduces risk of cardiotoxicity.
  ◦ Achieving a 4 g rise of calcium in the blood requires oral administration of ~50 g of soluble Ca (Ca chloride or Ca propionate ± propylene glycol).
• Relapses are common (25–30% of cows that initially respond) and may require additional therapy within 24–48 hours.
• Intercurrent diseases should be identified and treated.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Calcium gluconate
  ◦ Can be administered via subcutaneous and intraperitoneal routes, but is most effective IV
  ◦ IV solutions supply 8.5–11.5 g Ca/500 mL; effective IV Ca doses are about 2 g Ca/100 kg BW and may elevate blood Ca above normal for about 4 h.
  ◦ Solutions should be administered over 10–20 min (~1 gram Ca/min) with concurrent auscultation for dysrhythmias.
  ◦ Cows relapsing or failing to respond can be treated again at 8–12 h.
  ◦ Cardioexcitatory consequences of IV Ca can be reduced by administration of magnesium.
• 1α-hydroxycholecalciferol is a synthetic analog of vitamin D_3, which can be given to cattle not responding to IV Ca (~15% cases). Administer at 1 μg/kg BW, half IV and half IM.

POSTPARTURIENT PARESIS (HYPOCALCEMIA) (CONTINUED)

CONTRAINDICATIONS
• Do not give Ca solutions containing formaldehyde or with >25 g dextrose/500 mL SC, and do not give >1–1.5 g Ca (~50–75 mL) at a single SC site.
• Do not use SC route as sole therapy in case of poor peripheral perfusion.

PRECAUTIONS
• Calcium-containing solutions are cardiotoxic and can cause death if given rapidly IV.
• Large doses of oral Ca (250 g soluble Ca) can also cause death.
• Calcium chloride is caustic to oral and pharyngeal mucosa and should not be given repeatedly.
• Cows with stupor and recumbency should not be medicated orally, to avoid aspiration.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Typically cows with hypocalcemia show rapid improvement and 75% should be standing within 2 hours.
• Severe hypocalcemia or intercurrent disease creates a poorer prognosis, especially with delayed treatment, and these animals can die within hours.

POSSIBLE COMPLICATIONS
• Low palatability of anionic salts and overacidification may reduce DM intake.
• Dystocia, uterine prolapse, retained fetal membranes, metritis, abomasal displacement, mastitis, and rhabdomyolysis may occur in cattle with hypocalcemia.

CLIENT EDUCATION
Focus on preventive measures; this is largely a disease of management.

PATIENT CARE
See "Precautions"

PREVENTION
• Reduce the content of potassium in prepartum diets.
• Formulate dry cow ration with a DCAD of –10 to –15 mEq/100 g DM; DCAD can be calculated as $(Na^+ + K^+) - (Cl^- + S^{2-})$.
• DCAD diet should be commenced no further out than 3 weeks from calving, and at least 4–5 days before.
• Measure urine pH during the last week of gestation by collecting midstream samples 6–9 h postprandially:
  ◦ Ideal value for Holstein cows is pH 6.2–6.8 for Jersey cows 5.8–6.3
  ◦ Urine pH of 5.0–5.5 suggests excessive anion supplementation which will reduce DM intake.
• Synthetic bovine PTH given IV 60 h before calving, or IM 6 days before calving.
• Supplement dry cow diet with 20,000–30,000 IU vitamin D/day.
• Minerals in prepartum diet (% DM) should be as follows:
  ◦ Na^+: 0.12%
  ◦ K^+: 1.0%
  ◦ Cl^-: 0.5% less than K^+ in the diet
  ◦ Ca^{2+}: 0.85–1.0%
  ◦ Mg^{2+}: 0.35–0.4%
  ◦ P: 0.35–0.4%
  ◦ S: >0.22% to ensure adequate substrate for rumen microbial amino acid synthesis but no more than 0.4% to prevent sulfur toxicity.
• Prophylactic use of vitamin D preparations or analogs is not ideal but has been used in high-risk cases; performed by feeding or injecting large doses 1–2 weeks prepartum, with the risk of renal damage and metastatic calcification.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Dystocia, retained placenta, ketosis, left displaced abomasum, mastitis, and metritis.
• Rhabdomyolysis (crush syndrome): weight of a down cow can cause ischemic damage to muscles and nerves in as little as 4 h.

AGE-RELATED FACTORS
Incidence increases with age due to higher milk output and reduced number of vitamin D receptors in the intestine.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
This is a disease established in late pregnancy and occurring soon after parturition; colostrum has 8–10 times the amount of Ca^{2+} as milk.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
See "Prevention"

SYNONYMS

PRECOCIOUS UDDER

BASICS

OVERVIEW
• The mammary gland increases in size during puberty in the female due to growth of connective tissue and fat deposition.
• Significant increase in size of mammary gland is observed during late pregnancy.
• A precocious udder is a mammary gland that is more developed than usual at a given age or stage of lactation. It is also called inappropriate lactation or galactorrhea.
• Gynecomastia, enlargement of male mammary tissue, in male goats can occur (e.g., Alpine and Saanen breeds) especially during the summer months.

INCIDENCE/PREVALENCE
Sporadic

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
• Reproductive
• Mammary
• Integument

PATHOPHYSIOLOGY
• Estrous periods stimulate the development of secretory and duct tissues. Growth of lactation tissue is dependent on two hormones: Estrogen from developing follicles and progesterone from the CL.
• Cyclic secretion of estrogen stimulates duct development of the mammary gland.
• Progesterone secretion is cyclic in nonpregnant animals, and nearly continuous in pregnant animals, and causes secretory tissue development.
• Milk secretion is activated by withdrawal of progesterone and increase in cortisol and prolactin at parturition.
• Precocious udder development is associated with many risk factors (see "Causes and Risk Factors") that affect the normal secretion of estrogen, progesterone, or prolactin.

HISTORICAL FINDINGS
• Early development of the mammary gland in the absence of pregnancy is the most common sign of precocious udder.
• Goat kids may be born with significant udders containing milk (witch's milk).

SIGNALMENT
• Precocious udders are most commonly seen in young milking breeds of goats such as the Saanen, Alpine, Toggenburg, LaMancha, and Nubian.
• Young kids may develop precocious udders more frequently during springtime.
• In adult bucks (Saanen and crossbreed) gynecomastia and galactorrhea has been reported unilateral or bilateral, not associated with other sexual organ abnormality, producing almost normal milk, and high testosterone but no changes in estrogen or prolactin.
• It has also been described in cattle and sheep much less commonly.

PHYSICAL EXAMINATION FINDINGS
Enlarged mammary gland with no signs of pregnancy or mastitis.

CAUSES AND RISK FACTORS
• Prolonged progesterone production of false pregnancy
• Estrogen, prolactin, GH, and IGF seem to be involved
• Exposure to high levels of estrogen
• Artificial lactation-induction programs
• Spring season (increased levels of prolactin)
• High estrogen levels in feed (e.g., clover, moldy corn)
• Suckling by herd mates (usually affects a single gland)
• Adrenal adenomas (producing estradiol)
• Ovarian neoplasms

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Mastitis
• Intersex
• Neoplasia
• Fatty udder due to overconditioning

CBC/CHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Imaging (ultrasound) may be useful to rule out neoplasia.

OTHER DIAGNOSTIC PROCEDURES
• The udder should be symmetric, firm to soft tissue consistency, and free of irregular lumps.
• Rule out mastitis by evaluating any secretions that are present for signs of inflammation.
• If abnormalities are found on palpation, especially in older lactation animals, imaging or biopsy of the mass is warranted to rule out neoplasia.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• No treatment is an accepted option since it may stop spontaneously.
• Once mastitis is ruled out, separate the animal from others, especially from young stock that may try to nurse.
• Hydrotherapy.
• If the milk production is persistent, the teats leak, or the animal is very uncomfortable and/or painful, it might be necessary to initiate milking. It should be noted that if milking is instituted, an increased risk of mastitis can be seen.
• The effect of milking on the lifetime production of the animal has not been documented.
• Infusion of iodine, chlorhexidine, and hypertonic solution has been mentioned but not tested. Refer to information in cattle where using these protocols to cause cessation of lactation is commonplace. Be aware that these procedures are not without risk as they cause significant acute inflammation in the mammary gland.
• Feeding management to dry off the animal (e.g., increase the level of poor-quality hay in the diet and eliminate grain).
• With gynecomastia in male goats, reduce energy and protein intake levels during spring and summer months.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• In pet goats with large udders, amputation may be necessary.
• Although not tested, an ovariectomy may prevent this problem in pet goats.

MEDICATIONS

DRUGS OF CHOICE
• $PGF2_{\alpha}$ (5 mg IM has been utilized with persistent CL).
• NSAIDs if painful (flunixin meglumine 1–2 mg/kg IV).
• Diuretics and steroid treatment may be helpful (furosemide 2–10 mg/kg IM, dexamethasone (0.1–1.0 mg/kg IM).

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

PREGNANCY DIAGNOSIS: BOVINE

BASICS

OVERVIEW

• Accurate early diagnosis of pregnancy in cattle is essential for optimization of reproductive performance, particularly in dairy cattle.
• The producer's primary economic incentive for pregnancy diagnosis is to accurately identify cattle that are not pregnant so they may be inseminated again as quickly as possible.
• Direct methods are based on clinical or laboratory findings that are only present during pregnancy. They are often more invasive and require slightly more time after breeding before they are effective. The overall accuracy of these methods tends to be very high.
• Indirect methods for pregnancy diagnosis are based on clinical or laboratory techniques to detect open cows. They are generally less invasive and are often applicable earlier in gestation. They tend to have a high negative predictive value but a low positive predictive value.

HISTORICAL FINDINGS

• Non-return to estrus after artificial insemination or natural mating dates
• Anestrus

SIGNALMENT

Bovine postpubertal female

PHYSICAL EXAMINATION FINDINGS

• See "Diagnosis"

GENETICS

• Age at puberty
• Conception rate (sire/daughter) and calving ease

CAUSES AND RISK FACTORS

• Pregnancy diagnosis is a routine activity in herd management.
• Indicated if there is suspicion of accidental breeding in young stock.

DIAGNOSIS

General Recommendations for Pregnancy Diagnosis

• Early pregnancy diagnosis techniques should focus on accurate identification of nonpregnant cows. In dairy cattle, pregnancy diagnosis should be scheduled no later than 35 days post-breeding.
• The appropriate diagnostic technique to be used in a herd will depend on several factors (heat detection efficiency, method of breeding, cost of labor, cost of the technique, pregnancy rate, size of the herd, etc.). An efficient system should be designed in collaboration between the attending veterinarian and the herd manager.
• Regardless of the method used for pregnancy diagnosis, dairy cows should be reexamined after 45 days of gestation and again after 90 days in order to manage the relatively high rate of pregnancy loss (15% between 30 and 60 days of gestation).
• Transrectal palpation and/or ultrasonography offer the advantage of an immediate result and the ability to diagnose pathology of the reproductive tract.

Observation for Estrus

• Return to estrus is considered a strong indication that a cow is not pregnant; however, up to 5% of pregnant females may display some signs of estrus.
• Nonreturn to estrus can be an indication of pregnancy; however, females that have a persistent CL (e.g., pyometra) or are anestrous contribute to increase in false positive diagnoses.
• Problems with estrus detection accuracy and efficiency on many dairy operations limit the utility of this method.

Clinical Diagnosis

Transrectal Palpation

• Per-rectum palpation of the uterus and its contents is the most commonly used technique for diagnosis and staging of pregnancy.
• Palpation of a CL in conjunction with an enlarged, fluid-filled uterus is suggestive of pregnancy but a positive diagnosis of pregnancy is only established if one of the following is identified:
  ◦ Presence of fetal membrane slip, palpable as early as 30 days but more reliable after 35 days.
  ◦ Palpation of the amniotic vesicle as early as 28 days. Useful for aging gestation between 30 and 60 days and confirming twins.
  ◦ Palpation of placentomes after 75 days. Useful for aging gestation.
  ◦ Palpation of the fetus after 60–65 days as the amniotic vesicle becomes less turgid.
• This technique is very accurate with moderate degree of expertise after 35 days. However, early pregnancy loss (5–12%) should be taken into account.
• Very safe when performed by a skilled practitioner.

DIFFERENTIAL DIAGNOSES

• Early pregnancy: Anestrus, mummification, pyometra, persistent CL, and poor estrus detection.
• Late gestation: Mummification, pyometra, hydropic conditions, and obesity.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Progesterone Assay

• In absence of maternal recognition of pregnancy, luteolysis occurs and progesterone falls below 1 ng/mL approximately 18–24 days after breeding.
• Milk or serum progesterone concentration >2 ng/mL, 18–24 days after breeding, suggests maintenance of CL activity and possible pregnancy.
• Low milk or serum concentration (<1 ng/mL) is very accurate for diagnosis of nonpregnancy.
• In-line milk progesterone testing is available; cow-side tests are intermittently marketed.
• This technique suffers from the same problems with low specificity and positive predictive value as observation for estrus.

Pregnancy-Associated Glycoproteins

• PAGs is a group of specific proteins produced by the trophoblastic binucleate cells from the early ruminant conceptus.
• PAGs testing is available for serum and milk from a number of commercial laboratories.
• The assay is most accurate around 30 days after breeding. PAG concentrations in serum and milk decline between 6 and 10 weeks of gestation and testing at this time may result in more diagnostic errors.
• Sensitivity and specificity of bPSPB increases from 75% and 85% at 26–27 days to 100% and 85% by days 37–45, respectively.
• Most laboratories recommend testing begin 28–30 days after breeding with as much as a 7-day delay for embryo recipients. For both postpartum and post-breeding intervals, always follow the specific recommendations of the testing laboratory. Single-use needles and syringes are required to avoid cross-contamination of samples and errant results.
• PAG may remain elevated for a variable period of time after pregnancy loss.
• A significant limitation of this method is that results are not immediately available and therefore interventions for open cows are delayed.
• Pregnancy confirmation at a later date is still advised, to detect any early embryonic death/pregnancy loss.
• Because no clinical examination is conducted, uterine and ovarian pathologies may go unnoticed for a long time.

IMAGING

• Transrectal ultrasonography with a linear 5 MHz transducer.
• Timing: From 25 days in heifers and 27 days in cows.
• Accuracy: Increases with gestational age and sensitivity, and the specificity of the technique approaches 100% at 32 days. It is considered

PREGNANCY DIAGNOSIS: BOVINE (CONTINUED)

the gold standard for evaluating pregnancy diagnostic tests.
• Specificity: Increases if the operator uses presence of fetal heartbeat as a sign of pregnancy rather than just fetal fluid. This is easily accomplished at 29 days but requires increased examination time.
• Other advantages
  ◦ Increased accuracy of diagnosis of twins and early pregnancy loss.
  ◦ Estimate gestational age (amniotic vesicle diameter, fetal biparietal diameter, abdominal diameter, fetal crown–rump length).
  ◦ Determination of fetal gender by identification of the position of the genital tubercle at 65 ± 10 days of gestation.

OTHER DIAGNOSTIC PROCEDURES
• Early conception factor (ECF), an immunosuppressive hormone, is elevated as early as 48 hours post-conception. Currently there is no reliable commercial assay for this substance.
• Interferon-tau is the initial signal for pregnancy recognition in ruminants. It is secreted by fetal trophectoderm and inhibits corpus luteum regression by suppressing the pulsatile release of $PGF2_{\alpha}$ from the endometrium. It is also responsible for upregulation of specific genes expressed on maternal leukocytes. It peaks in maternal serum about17–21 days after estrus in pregnant cattle. No commercial assay is available.

PREGNANCY DIAGNOSIS: CAMELID

BASICS

OVERVIEW
• Timely and precise pregnancy diagnosis is an important aspect of breeding management.
• The diagnosis of pregnancy is based on history, physical examination (sexual behavior), laboratory evaluation, and ultrasonography.
• Depending on the method used, pregnancy diagnosis can be performed as early as 14 days after mating. However, it is important to recognize that pregnancy loss occurs in 10–50% of females before 60 days of gestation.
• Additional examinations may be warranted in high-risk pregnancies or if a female has a history of recurrent pregnancy loss.
• Early pregnancy diagnosis is beneficial for detecting problems of infertility in either the female or the male.
• Females that are not pregnant after three matings with a proven male should be submitted for a complete breeding soundness examination.
• Evaluation of any pregnant female is warranted if she displays receptivity to the male after a positive pregnancy diagnosis.

INCIDENCE/PREVALENCE
Common procedure

GEOGRAPHIC DISTRIBUTION
Worldwide

PATHOPHYSIOLOGY
N/A

SYSTEMS AFFECTED
Reproductive

GENETICS
N/A

HISTORICAL FINDINGS
• Owners/breeders will often tease mated females to determine if they have ovulated (at 7 days post-mating) and if they are potentially pregnant (at 12 days post-mating).
• If a female does not become pregnant following mating she will be receptive to the male 12–14 days post-mating and can be mated again.

SIGNALMENT
Any postpubertal female that has been mated

PHYSICAL EXAMINATION FINDINGS
• A complete physical examination should be performed on any female presenting for pregnancy diagnosis.
• General health and nutritional status (BCS) is extremely important for pregnancy maintenance and fetal viability.
• Clinical evaluation for pregnancy in camelids is based primarily on two techniques: behavioral changes and transrectal palpation findings.

Behavioral Signs of Pregnancy
• Pregnant camelid females display specific behavior of non-receptivity to male sexual advances starting 14 days after mating.
• In SAC, this behavior is characterized by spitting and running away from the male.
• In camels, the female assumes a characteristic body stance with the head held high and the tail curled upward (tail cocking or tail curling).
• Accuracy of pregnancy diagnosis based on behavior is 83–95%.
• False positive diagnoses (5–30%) are due to other causes for maintenance of elevated progesterone (i.e., exogenous administration of progesterone, luteinized anovulatory follicles, persistent CL, early embryo loss) or abnormal behavior (e.g., dominant or inexperienced females, painful conditions).
• False negative diagnoses are rare (<5%) and mostly due to an overtly aggressive male or a submissive female.
• The major drawback of behavioral testing is the inability to determine the number of embryos and fetal development.

Transrectal Palpation
• Appropriate physical and/or chemical restraint and proper technique are important to prevent complications.
• Size of the hand, pelvic anatomy, and size of the female may limit the veterinarian's ability to perform transrectal palpation in SAC and young camels.
• Pregnancy evaluation by transrectal palpation is possible from 30–35 days post-mating.
• There is no membrane slip in camelids. Diagnosis is based solely on size of the left uterine horn (where almost all fetuses are carried), presence of fluid, and palpation of the fetus.
• The accuracy of pregnancy diagnosis by transrectal palpation increases with gestational age until 160 days, then decreases thereafter when the enlarging uterus is displaced cranially and ventrally and the fetus becomes out of reach.

Transabdominal Fetal Ballottement
Possible after 9 months of gestation

CAUSES AND RISK FACTORS
• Accidental mating may occur if young animals are housed with males. Alpacas and llamas may reach puberty as early as 6 months of age and become pregnant.
• Early pregnancy loss is relatively common in maiden and aged females. Pregnancy should be confirmed several times during pregnancy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Other causes of uterine enlargement: Pyometra/mucometra, mummification, maceration, uterine neoplasia

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS

Progesterone
• Luteal progesterone is required throughout gestation in camelids.
• Serum progesterone concentration >2 ng/mL 14 days post-mating is suggestive of pregnancy.
• Serum progesterone concentrations <1.5 ng/mL are not consistent with maintenance of pregnancy.

Estrone Sulfate
• Estrone sulfate concentrations may be measured in plasma or urine.
• This test is not commonly used in practice.

IMAGING
• Real-time B-mode ultrasonography is the gold standard for pregnancy diagnosis and evaluation of the fetus and placenta.
• Ultrasonography provides the earliest accurate diagnosis along with assessment of embryonic/fetal number, development, and wellbeing.
• Transrectal ultrasonography is performed prior to 35 days of gestation with 5–8 MHz linear transducer. The transducer is mounted on a rigid extension to allow external manipulation in alpacas and small llamas.
• It is recommended to perform pregnancy diagnosis and follow-up pregnancy confirmation/evaluation at 14, 25, and 35 days and between 46 and 60 days. Additional pregnancy evaluations may be recommended in mid- to late-gestation.
• The embryonic vesicle may be visualized as early as 9–10 days post-mating; however, accuracy is greatly increased if pregnancy diagnosis is performed >14 days post-mating.
• Presence, size, and number of CLs should be evaluated at the first pregnancy diagnosis examination. Double ovulations are not rare and increase the risk for twinning.
• The embryo proper is first visualized at 20–22 days as a small echogenic structure within the vesicle. The heartbeat becomes detectable at 22–25 days.
• Transabdominal ultrasonography is performed using a 3.5 MHz curvilinear transducer.
• High accuracy for pregnancy diagnosis using transabdominal ultrasonography can be

PREGNANCY DIAGNOSIS: CAMELID (CONTINUED)

achieved by scanning the right inguinal area between 35 and 120 days of pregnancy.
• Pregnancy evaluation at later stage requires scanning the ventral abdomen all the way to the xiphoid.
• Gestational age may be estimated with measurements of fetal structures (biparietal diameter, thoracic height, aortic diameter, crown–rump length, etc.).

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Abnormal uterine content: Pyometra, mucometra
• Abnormal pregnancies: Early embryo loss, collapsed echogenic embryonic vesicle, placentitis, placental detachment, compromised fetus (tachycardia >130 bpm or bradycardia <50 bpm), fetal death (absence of cardiac activity).

TREATMENT

THERAPEUTIC APPROACH
• Sedation and/or epidural analgesia may be required for transrectal palpation, particularly if uterine torsion is suspected.
• Intra-rectal administration of lubricant containing 2% lidocaine may facilitate transrectal palpation.

PREGNANCY DIAGNOSIS: SMALL RUMINANT

BASICS

OVERVIEW
• Pregnancy diagnosis in sheep and goats provides valuable management information to the livestock producer. It allows timely re-breeding or culling of nonpregnant animals and facilitates supervision at parturition and production planning for dairy operations.
• Diagnostic systems that count fetal numbers allow for separation and selective feeding of females carrying multiple fetuses.
• This chapter will focus on practical, clinically relevant methods of pregnancy diagnosis in sheep and goats.

INCIDENCE/PREVALENCE
• The prevalence of pregnancy in a herd or flock is highly dependent on the fertility of the male and female animals but also depends on the competence of the livestock management system.
• In a well-managed flock or herd, during the breeding season and with natural service, the pregnancy rate should be >95% in mature females and >75% in maiden females.
• It should be noted that the performance of diagnostic tests is not independent of the prevalence of the condition being tested.

GEOGRAPHICAL DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
N/A

HISTORICAL FINDINGS
• Historical findings depends on the primary reason for pregnancy diagnosis.
• In herds or flocks using AI followed by natural mating, producers may want to stage the pregnancies and determine which females are pregnant to AI and which are pregnant to natural service.
• Most flocks or herds will have a marking system to record breeding dates. However, in absence of such a system the dates of introduction and removal of the male should be known.
• Staging of pregnancy is desirable for adequate management of lambing or kidding.
• Pregnancy diagnosis may be sought after suspicion of an accidental mating.
• Pregnancy diagnosis is an essential part of any embryo transfer program.

SIGNALMENT
Postpubertal ewes and does

PHYSICAL EXAMINATION FINDINGS
The principal signs of pregnancy in ewes and does are the absence of estrus followed by abdominal distention and udder development later in gestation.

GENETICS
• Most sheep and goat breeds have been highly selected for fertility so seasonal pregnancy rates should be high, usually above 90–95%.
• Prolificacy (number of fetuses or newborns per pregnancy) is genetically determined and is an important measure of overall reproductive efficiency.

CAUSES AND RISK FACTORS
N/A

DIAGNOSIS

• Practical diagnostic tests for pregnancy in sheep and goats may be either direct or indirect.
• Direct diagnostic tests rely on the detection of physical evidence of pregnancy. They generally involve palpation, imaging, or laboratory detection of pregnancy-specific substances.
• Indirect tests rely primarily on behavior (return to estrus in nonpregnant females).

DIFFERENTIAL DIAGNOSES
• Hydrometra or related uterine pathologies
• Anestrus

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Measurement of serum progesterone concentration is an indirect laboratory test for pregnancy in sheep and goats. It requires either frequent, repeated testing—which is generally not practical—or carefully timed sampling roughly one estrus cycle length after mating. Females with high progesterone concentration at this time are presumably pregnant (~80% diagnostic accuracy); those with low progesterone are almost certainly not pregnant (~95–100% diagnostic accuracy).
• Measurement of pregnancy-associated glycoproteins (PAGs) is a direct laboratory test for pregnancy. These substances are pregnancy specific; however, they will remain elevated in serum for up to a week after fetal death so false positives are a concern. Commercial tests are available and advertise 99% accuracy for open diagnoses 30 or more days after breeding.
• Historically, conjugated estrogen concentrations in serum or milk have been used to diagnose pregnancy. Since estrone sulfate is a product of placental metabolism, its measurement is considered a direct test for pregnancy. Goats may be tested as early as 50 days while sheep are usually tested after 70 days of gestation.

IMAGING
• Real-time B-mode ultrasonography is the gold standard for pregnancy diagnosis in most veterinary species, including sheep and goats.
• Transrectal ultrasonography will provide an earlier diagnosis but is not practical outside of research settings.
  ◦ Use linear transducers with 5–8 MHz frequency mounted on an extension handle.
  ◦ Embryonic vesicles (anechoic) are visible starting at 20 days.
  ◦ Placentomes (echogenic) are visible starting at 21 or 22 days.
  ◦ Embryos are readily visible within the vesicle starting at 25 days.
  ◦ Accuracy is low before 30 days.
  ◦ Up to 16% of pregnancies diagnosed at 30 days may be lost by 60 days.
• Transabdominal ultrasonography is the most commonly used technique in practice.
  ◦ Scanning is done using a sector or curvilinear transducer with 3.5 MHz frequency. Female are scanned in the lower right flank, just above the base of the udder. This region is naturally devoid of fleece in most sheep but goats may need to be clipped to provide good acoustic coupling. The use of rubbing alcohol or coupling gel on the skin is necessary to obtain an image.
  ◦ Pregnancy fluid may be detected as early as 25 days post-mating but accuracy is better at 35 days and continues to improve until about 60 days of gestation. At this early stage of gestation it is important to direct the transducers dorsally and caudally the area of the pelvic inlet. As gestation advances, the fetuses move cranially and ventral in the abdomen. The accuracy decreases after 100 days unless the ventral abdomen is clipped to provide better visualization.
  ◦ The optimal time for fetal number determination is 45–85 days.
  ◦ Sensitivity and specificity of this technique for pregnancy diagnosis are 99% and 100%, respectively.
  ◦ Sensitivity and specificity of fetal number determination are 91% and 100%, respectively.
• Fetal age can be determined by measuring the embryonic vesicle (days 24–40), crown–rump length (days 24–40), and fetal thoracic diameter and parietal diameter (from day 41).
• Fetal gender determination is possible between 60 and 69 days. Accuracy is higher for single fetuses and males.

OTHER DIAGNOSTIC PROCEDURES
Ballottement of the fetus is possible late in gestation but provides limited economic return.

PATHOLOGIC FINDINGS
• A major advantage of diagnostic imaging, ultrasonography in particular, is the ability to detect reproductive pathology. This will allow for timelier, effective treatment interventions or a decision to cull the abnormal animal.
• Abnormal pregnancies: early embryonic loss, mummifications, fetal death.

PREGNANCY DIAGNOSIS: SMALL RUMINANT (CONTINUED)

TREATMENT

N/A

MEDICATIONS

N/A

FOLLOW-UP

EXPECED COURSE AND PROGNOSIS

• Early pregnancy losses are minimal after 45 days and any loss of pregnancy is generally visible.
• In absence of any abortion-causing etiology the lambing/kidding rate should be close to pregnancy rate.

POSSIBLE COMPLICATIONS

• Transrectal ultrasonography requires some expertise and may cause injury to the female if not done properly.
• Early pregnancy diagnosis is associated with both a reduced diagnostic accuracy and a higher rate of spontaneous loss of the pregnancy.
• While the tests described above are generally regarded as safe, testing of herds or flocks for pregnancy should always be done in a manner and in facilities that minimize stress on the animals.

CLIENT EDUCATION

Importance of pregnancy diagnosis in fertility investigation, management of pregnant females, and planning for lambing/kidding.

PATIENT CARE

While earlier pregnancy diagnosis may provide the greatest economic return to producers, the reality is that pregnancy loss rates are much higher in early gestation. Pregnancy diagnosis performed in ruminants before 40–45 days of gestation should always be accompanied by a recommendation to reconfirm pregnancy status sometime after 60 days.

PREVENTION

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Hydrometra
• Fetal mummification

AGE-RELATED FACTORS

N/A

ZOONOTIC POTENTIAL

Diseases that cause abortion in sheep and goats are often zoonotic. Appropriate precautions should be taken when working with these species.

BIOSECURITY

• Equipment used on multiple sites should be sanitized between locations.
• When blood testing for pregnancy, a new syringe and needle must be used for each animal.

PREGNANCY TOXEMIA: BOVINE

BASICS

OVERVIEW
• Pregnancy toxemia is an uncommon metabolic disease in cattle that results from the inability of the dam to maintain glucose homeostasis in the face of increasing energy demands during late gestation.

INCIDENCE/PREVALENCE
• Varies widely between herds and production styles.
• Individual variation may result in sporadic occurrence.
• Mortality rate in affected animals may reach 90% or more.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Nervous
• Musculoskeletal
• Digestive
• Reproductive

PATHOPHYSIOLOGY
• Pregnancy toxemia is characterized by low glucose concentrations and high ketone body concentrations. Insufficient energy use rather than complete lack of energy supply may be a contributing factor.
• The fetoplacental unit requires glucose for energy and may consume up to 40% of the maternal glucose production during late gestation.
• In ruminants, absorption of dietary glucose is limited because of fermentation by the ruminal flora. Serum glucose concentrations are largely maintained by gluconeogenesis, 85% of which occurs in the liver.
• If the dam is unable to maintain glucose homeostasis a state of negative energy balance (NEB) occurs resulting in a metabolic state with a decreased ratio of insulin to glucagon and development of insulin resistance.
  ◦ NEB is defined as insufficient consumption of calories necessary to meet metabolic requirements for late prepartum or early postpartum cows.
  ◦ In cows, particularly dairy cows, the development of NEB and ketosis is more commonly associated with peak lactation.
• Insulin function is critical to glucose uptake by the cells, is an important factor in glucose homeostasis, and ultimately plays a role in the susceptibility of individual animals to development of pregnancy toxemia.
• Development of periparturient ketosis has been attributed to insulin resistance and impaired glucose utilization as a result of overfeeding dairy cattle during the dry period.
• In a state of NEB, NEFAs are mobilized and converted to glucose with production of ketone bodies (acetone, acetoacetate, and BHB) and development of metabolic acidosis.
• Reduced disposal of ketones during late gestation along with an increased rate of hepatic ketogenesis promotes hyperketonemia, facilitating development of pregnancy toxemia.
• Hyperketonemia depresses hepatic glucose production, resulting in a sustained hypoglycemia, and contributes to the pathogenesis of the disease.

HISTORICAL FINDINGS
• Late gestation (often carrying twins); typically 7–10 days prior to calving.
• Inadequate nutrition: overfeeding during the dry period (dairy cattle; BCS > 3.75/5), or obesity followed by limited feed quantity/quality.
• Initial clinical signs are vague: Rough appearance, off feed, obtunded, isolation from remainder of herd.
• Advancement to weakness, decreased rumen motility (firm, dry feces), mental dullness, neurologic signs (generally 10% of affected cows will develop neurologic signs; abnormal licking, head pressing, circling, blindness, tremors, tetany, etc.), recumbency, and eventually death without treatment.
• Even with aggressive therapy, death and culling rates are greatly increased among clinically affected cows.

SIGNALMENT
Mature cows in late gestation are primarily affected.

PHYSICAL EXAMINATION FINDINGS
• Physical examination findings dependent on duration and progression of the disease (vital signs are typically normal).
• Anorexia, weakness, incoordination, mental dullness, decreased rumen fill, firm/scant/dry feces, sweet acetone breath, recumbency, neurologic signs, death.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Pregnancy toxemia is caused by an inability of the dam to maintain glucose homeostasis in the face of increased demand from the fetoplacental unit in late gestation (last 4–6 weeks).
• Primary pregnancy toxemia results from a combination of poor nutrition and a sharp increase in energy needs during late gestation (extreme lack of feed and poor feed quality).
• Pregnancy toxemia can be classified as primary pregnancy toxemia or fat cow pregnancy toxemia (type II ketosis).
• Overconditioning of the dam (body condition score > 4/5) resulting in compromise of gluconeogenic capacity with increased fatty infiltration ultimately leading to reduced glucose availability and increased ketogenesis, development of hepatic lipidosis.
• Cows with twins, having improper, declining, or interrupted nutritional inputs (especially in cows that were overconditioned and then experience a sharp decline in nutrition). Cows with excessive parasite burden, poor dentition, lameness, or those experiencing stress such as sudden cold/wet weather, processing, or hauling may be more susceptible.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Hypocalcemia
• Listeriosis
• Polioencephalomalacia
• Impending abortion
• Copper toxicity
• Ruminal acidosis
• Hypomagnesemia
• Trauma
• Parasitism

CBC/BIOCHEMISTRY/URINALYSIS
• CBS is generally nonspecific but marked neutrophilia may be present.
• Hypoglycemia or normoglycemia, hypocalcemia, and in some cases elevated liver enzymes and hypocholesterolemia. Samples for blood glucose should be processed as soon as possible.
• Serum concentrations of both NEFAs (>0.4 mEq/L) and BHB (subclinical/moderate ketosis >15 mg/dL; clinical ketosis >25 mg/dL) are increased.
• Hypoproteinemia (hypoalbuminemia and hypoglobulinemia) can be observed in clinical cases of pregnancy toxemia and could potentially be attributed to hepatic and/or renal failure.
• In later stages of pregnancy toxemia hyperglycemia (often associated with fetal death), hypokalemia, elevated creatinine, and elevated BUN may be evident.
• Elevated ketones on urinalysis; ketonuria is present and usually detected before ketonemia.

OTHER LABORATORY TESTS
• Cow-side diagnostic tests available for estimation of ketone bodies concentration in milk.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

OTHER PATHOLOGIC FINDINGS
• Gross necropsy findings vary with body condition and initiating causes.
• Twins or a large single fetus present and, depending on when fetal death occurred, autolysis may be present. Some cows will abort or calve prematurely before death.
• The carcass is either emaciated or overconditioned with large quantities of intra-abdominal and subcutaneous fat.
• Variable degrees of fatty liver infiltration with the liver potentially enlarged, pale, and

PREGNANCY TOXEMIA: BOVINE (CONTINUED)

friable; however, the severity of these changes may be difficult to evaluate grossly.
• Histologic lesions include hepatic lipidosis and neuronal necrosis and astrocytosis.
• Aqueous humor concentrations of BHB can correspond to antemortem serum concentrations.

TREATMENT

THERAPEUTIC APPROACH

• Treatment protocols are based on two general principles: Administration of energy sources and removal of factors that increase energy requirements.
• Treatment costs and prognosis should be considered before any treatment is recommended. Individual animals should be segregated from the herd for treatment and monitoring purposes.
• If the cow is in early stages of the disease (prior to anorexia and recumbency), dietary modification and supplementation with glucogenic precursors may be sufficient.
• Without intensive care, cows with pregnancy toxemia are unlikely to recover.
• Propylene glycol, glycerol, calcium propionate, sodium propionate, or liquid molasses are routinely used as glucose precursors.
• Oral propylene glycol and electrolytes are useful to treat mild cases.
• In more advanced stages of the disease, more aggressive supportive therapy is necessary and the prognosis more guarded.
• Acid-base status, degree of dehydration, associated electrolyte abnormalities, and renal function should be evaluated and appropriate treatment and fluid therapy provided.
• To reduce the effects of the negative energy balance and improve the potential response to therapy, cesarean section or induction of parturition/termination of pregnancy to remove the fetus(es) is often recommended in affected females.
• Induction of parturition in cows can be accomplished with the administration of dexamethasone and/or prostaglandin $F2_{\alpha}$ with parturition generally occurring 24–72 hours following administration.
• In cases where the female is severely compromised, euthanasia may be indicated for welfare reasons.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• If induction of parturition or termination of pregnancy does not result in delivery of the fetus(es) within 72 hours, or the animal is severely compromised, a cesarean section should be performed to reduce demands on glucose.
• Often the fetus(es) are nonviable and the procedure is used to save the cow.

MEDICATIONS

DRUGS OF CHOICE

• There are no specific drugs of choice; however, several drugs are occasionally used in individual cases of pregnancy toxemia in combination with glucose administration and fluid therapy.
• Administration of B-complex vitamins to stimulate appetite.
• Dexamethasone (25–30 mg IM) with parturition generally occurring 24–72 hours following administration.
• Prostaglandin F2α or an analog (25 mg dinoprost tromethamine IM; 500 μg cloprostenol IM) with parturition generally occurring 24–72 hours following administration.
• Females that are managed with induction of parturition or cesarean section should be treated with broad-spectrum antimicrobials, a nonsteroidal anti-inflammatory, and oxytocin to facilitate placenta delivery and prevent metritis.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Treatment is often unrewarding and often noneconomic in commercial herds.
• The prognosis is usually poor for recovery if recumbency is prolonged.
• Induction of parturition/termination of the pregnancy or cesarean section is unpredictable for survival of the fetus(es), and if delayed, for the cow as well.

POSSIBLE COMPLICATIONS

Dystocia, retained placenta, and metabolic complications during early lactation are common in dams that survive to the induced or natural initiation of parturition.

CLIENT EDUCATION

• Repeated and prolonged treatments will be needed.
• The owner will need to evaluate the economics of therapy versus probable outcomes.
• Development of pregnancy toxemia in one cow may indicate other cows in the herd at risk; provision of energy supplement is an essential part of treatment on a herd basis.

PATIENT CARE

• Feed intake is a critical factor in monitoring for treatment success. If the animal is recumbent for a prolonged period, the odds of recovery are substantially reduced.
• The goal of therapy in pregnancy toxemia is to restore glucose homeostasis as soon as possible.
• Multiple electrolyte, acid-base, and fluid imbalances in addition to low blood glucose levels will need to be considered in any potential treatment plan.
• The affected cow should be isolated to reduce expenditures of energy and limit competition for feed resources.
• Considerations for management of recumbent cows.
• High-quality forages and concentrates should be offered in an attempt to stimulate intake.
• Transfaunation could be considered if a source of rumen fluid is available.

PREVENTION

• Prevention of future cases of pregnancy toxemia is best accomplished by evaluation of nutritional and management practices within the herd.
• Designing nutritional programs that meet the females' requirements based on the stage of production and relevant environmental and management conditions can prevent most cases of pregnancy toxemia.
• Cows should have an ideal body condition at the beginning of the breeding season through to the end of gestation.
• Appropriate dry and close-up rations in dairy cows.
• Where possible blood samples should be collected to evaluate BHB or NEFA levels. Females with elevated BHB or NEFA levels should be separated and monitored closely.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Correction or treatment of concurrent disease is necessary.

PREGNANCY TOXEMIA: CAMELID

BASICS

OVERVIEW
• Metabolic disease resulting from a disruption in maternal glucose homeostasis associated with increased metabolic demands from the term fetus.
• The syndrome may also affect females during lactation.

PATHOPHYSIOLOGY
• Negative energy balance may occur due to inadequate nutrition to supply fetal metabolic demands, parasitism, or anorexia secondary to systemic disease or stress.
• In the face of negative energy balance, fat is mobilized from peripheral stores as an alternative energy source, causing hyperlipemia.
• Free fatty acids are metabolized into ketone bodies in the liver, resulting in ketosis.
• Bicarbonate conversion and loss leads to metabolic acidosis.
• Excessive accumulation of lipids in hepatocytes (hepatic lipidosis) results in loss of function.
• Osmotic diuresis can contribute to serum hyperosmolarity and dehydration.
• In severe cases with hepatic lipidosis, hepatic metabolism of ammonia into urea is altered, resulting in accumulation of ammonia in blood and hepatic encephalopathy.

INCIDENCE/PREVALENCE
Sporadic

GEOGRAPHIC DISTRIBUTION
Worldwide

• Nervous
• Digestive

GENETICS
N/A

HISTORICAL FINDINGS
• Recent illness or uterine torsion
• Recent social or environmental (heat) stress
• Recent changes in management
• Acute (2 days) or progressive (weeks), severe weight loss

SIGNALMENT
• Reported in llamas and alpacas with variable BCS (overweight, normal or thin).
• Pregnant female in the last 2 months of gestation.
• Signs progress over 3–7 days.

PHYSICAL EXAMINATION FINDINGS
• Anorexia
• Depression
• Recumbency
• Weight loss
• Weakness
• Ataxia
• Mental dullness
• Head pressing
• Abortion
• Death
• Tachycardia
• Tachypnea
• Normothermia
• Reduced gastrointestinal sounds
• Normal to poor body condition

CAUSES AND RISK FACTORS
• Failure to increase the nutritional plane to meet the energy demands of the growing fetus.
• Transient feed deprivation or change in eating behavior associated with stress or disease.
• Concurrent disease affecting appetite and energy utilization.
• Inappropriate nutritional management.
• Obese animals or late pregnant females are at high risk.
• Improper or interrupted energy intake.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Cerebral edema
• Polioencephalomalacia
• Meningitis
• Meningeal worm
• Listeriosis
• Trauma
• Tick paralysis
• Hypomagnesemia
• Peripheral nerve damage

CBC/BIOCHEMISTRY/URINALYSIS
• Hyperglycemia.
• Increased liver enzymes and bile acids.
• Hyperlipemia; late pregnant females should have NEFA concentrations <400 µmol/L. NEFA concentration >800 µmol/L is life threatening.
• Metabolic acidosis.
• Hypokalemia.
• Hypocalcemia.
• Hypophosphatemia.
• Azotemia.
• Ketonuria.
• Glucosuria.

OTHER LABORATORY TESTS
Liver biopsy

IMAGING
• Transabdominal ultrasonography to evaluate fetal wellbeing: Fetal heart rate is particularly important in detection of fetal stress. Fetal heart rate constantly >130 bpm or constantly <50 bpm suggests fetal stress.
• Ultrasonographic evaluation of the liver: Mottled appearance and enlargement.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
Hepatic lipidosis in advanced stages

TREATMENT

THERAPEUTIC APPROACH
• Correct or treat underlying problem.
• Correct hydration, electrolyte imbalances, and acidosis.
• Restore glucose homeostasis.
• Stimulate feed intake.
• Induce parturition with a term fetus.
• Potentially remove the fetus.

SURGICAL CONSIDERATIONS
• Cesarean section is indicated if the fetus is already dead or if the female is debilitated.
• Uterine inertia may result in dystocia and indication for cesarean section after induction of parturition.

MEDICATIONS

DRUGS OF CHOICE
• Insulin: 0.4 IU/kg SC q4–8h (regular crystalline) or q24h (long-acting).
• Vitamin B complex or diazepam (0.05 mg/kg IV) to stimulate appetite.
• Cloprostenol 250 µg IM for induction of abortion or parturition
• Anabolic steroid is an alternative to stimulate appetite and liver function

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
• Fluid therapy should be performed carefully in compromised pregnant female to avoid pulmonary edema and fetal stress.
• Induction of abortion or cesarean section may result in further stress and exacerbate the problem.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis for life of the dam is guarded to poor. Development of hepatic lipidosis worsens the prognosis.
• Prognosis for pregnancy maintenance is guarded to poor and for neonatal survival is guarded to poor depending on the maturational stage of the fetus.

POSSIBLE COMPLICATIONS
• Maternal death
• Pregnancy loss
• Dystocia
• Retained fetal membranes
• Metritis

• Agalactia or hypogalactia
• Neonatal morbidity and mortality
• Hepatic injury and liver failure
• Neuropathy

CLIENT EDUCATION
• Contact a veterinarian promptly if illness, lack of appetite, or depression develops in a pregnant camelid.
• Work with your veterinarian to provide appropriate nutrition, management, and parasite control in pregnant females.
• Avoid stress in pregnant females.

PATIENT CARE
• Animal should be in stall rest in comfortable environment.
• Monitor blood glucose, electrolytes, and acid-base status q4h during treatment.
• Monitor feed intake.
• Monitor fetal wellbeing.
• Monitor for fetal expulsion within 30 h of treatment with closprostenol.
• Transfaunation with bovine ruminal fluid (0.5–1.0 L via orogastric tube).
• Total parenteral nutrition if appetite is not restored.
• Reduce stress and avoid stressful procedures.
• Provide good-quality hay and feed (alfalfa cubes or pellets, sugar beet pulp, fresh grass cuts).

PREVENTION
• Provide appropriate nutritional management.
• Provide appropriate parasite control strategies.
• Avoid stress in pregnant females.

PREGNANCY TOXEMIA: SMALL RUMINANT

BASICS

OVERVIEW
• Pregnancy toxemia is a common metabolic disease in sheep and goats that results from the inability of the dam to maintain glucose homeostasis in the face of increasing energy demands from multiple fetuses during late gestation.

INCIDENCE/PREVALENCE
• Varies widely between flocks/herds and production systems.
• Isolated cases in well-managed flocks; individual variation may result in sporadic occurrence and low morbidity (<3%).
• In contrast, flocks or herds with improper nutritional management could experience outbreaks with morbidity rates exceeding 10% of the ewes or does.
• Insulin resistance during late gestation has been evaluated as a potential predisposing factor to the development of pregnancy toxemia.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Nervous
• Musculoskeletal
• Digestive
• Reproductive

PATHOPHYSIOLOGY
• Pregnancy toxemia is caused by a negative energy balance due to increasing energy demand of rapid fetal growth during late gestation (generally the last 4–6 weeks of gestation) combined with insufficient energy intake.
• Pregnancy toxemia is characterized by low glucose concentrations and high ketone body concentrations.
• The fetoplacental unit requires glucose for energy and may consume up to 40% of the maternal glucose production during the rapid growth that occurs during late gestation.
• In ruminants, limited dietary glucose is absorbed because the ruminal flora is proficient at fermenting glucose. Serum glucose concentrations are largely maintained by gluconeogenesis, 85% of which occurs in the liver.
• Excess glucose is stored in the liver as glycogen but these stores are inadequate to supply the dam's needs in late gestation.
• While it has long been demonstrated that a lack of energy supply is responsible for the development of pregnancy toxemia, it is not likely the only major factor.
• Insufficient energy utilization rather than complete lack of energy supply may be a contributing factor.
• If the dam is unable to maintain glucose homeostasis a state of negative energy balance occurs, resulting in a metabolic state with a decreased ratio of insulin to glucagon and development of insulin resistance may result. It has been demonstrated that insulin plasma concentrations are reduced in ewes carrying more than three fetuses.
• Insulin function is critical to glucose uptake by the cells, is an important factor in glucose homeostasis, in part regulates ketogenesis, and ultimately plays a role in the susceptibility of individual animals to development of pregnancy toxemia.
• In a state of negative energy balance body fat stores in the form of nonesterified fatty acids (NEFAs) will be converted to glucose with the undesirable production of ketone bodies (acetone, acetoacetate, and BHB) and development of metabolic acidosis.
• Reduced disposal of ketones during late gestation along with an increased rate of hepatic ketogenesis promotes hyperketonemia, facilitating development of pregnancy toxemia.
• Hyperketonemia depresses hepatic glucose production, resulting in a sustained hypoglycemia, and contributes to the pathogenesis of the disease.
• It has been suggested that cell-mediated and humoral immunity are altered in subclinical and clinical cases of pregnancy toxemia.

HISTORICAL FINDINGS
• Late gestation ewes or does carrying multiple fetuses.
• Recently sheared, hauled, or fasted for a period of time.
• Initial clinical signs are vague: Isolation from the remainder of the flock or herd, off feed, depressed.
• Advancement to weakness, mental dullness, blindness, disoriented, head pressing, teeth grinding, recumbency, and eventually death within 3 or 4 days without treatment.
• Progression of clinical signs ranges from 12 hours to 7 days.

SIGNALMENT
• The disease occurs more frequently in ewes than in does.
• Prolific breeds may be at greater risk for nutritional mismanagement.
• Breeds consistently delivering >2 offspring per litter are more predisposed.
• Mature ewes and does primarily affected, rare in maiden females.
• Obese or severely underconditioned females.

PHYSICAL EXAMINATION FINDINGS
• Physical examination findings dependent on duration and progression of the disease.
• Anorexia, weakness, incoordination, mental dullness, impaired vision/lack of menace response, hyperesthetic to tactile or auditory stimuli, head pressing, circling, muscle tremors, ataxia, teeth grinding, recumbency, convulsions, death.

GENETICS
• Variation in clinical incidence within flocks and between flocks suggests that some animals may be genetically susceptible to development of pregnancy toxemia.
• Individual variation appears to be related to hepatic metabolic efficiency and ability to maintain functional insulin concentrations and maternal tissue responses, with some breeds more predisposed to the condition.
• Some highly prolific breeds, such as Finnish Landrace and Booroola Merino sheep, do not experience an increased incidence of pregnancy toxemia.

CAUSES AND RISK FACTORS
• Pregnancy toxemia is caused by an inability of the dam to maintain glucose homeostasis in the face of increased demand from the fetoplacental unit in late gestation.
• Dams with multiple fetuses, late gestation, having improper, declining, or interrupted nutritional inputs.
• Pregnancy toxemia can be classified into one of the following general categories:
  ◦ Primary pregnancy toxemia
    ▪ Results from a combination of poor nutrition and a sharp increase in energy needs during late gestation
    ▪ Factors that might predispose to the development of primary pregnancy toxemia: lack of feed availability, decreased feed quality, sudden feed changes, transportation during late pregnancy, shearing, vaccinating, and heat or cold stress.
  ◦ Fat ewe pregnancy toxemia
    ▪ Overconditioning of the dam (body condition score > 4/5) during early gestation, resulting in increased abdominal fat and reduced rumen capacity, possible hepatic lipidosis that also impairs glucose metabolism.
• Secondary pregnancy toxemia
  ◦ Concurrent disease in affected ewes or does; examples would include lameness, pneumonia, water deprivation, heavy parasite infestation, vaginal prolapse.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Hypocalcemia
• Listeriosis
• Polioencephalomalacia
• Impending abortion
• Copper toxicity
• Ruminal acidosis
• Hypomagnesemia
• Trauma
• Parasitism

CBC/BIOCHEMISTRY/URINALYSIS
• CBC is usually nonspecific but potential marked neutrophilia.
• Hypoglycemia, hypocalcemia, and in some cases elevated liver enzymes and hypocholesterolemia; samples for blood

(CONTINUED) PREGNANCY TOXEMIA: SMALL RUMINANT

glucose should be processed as soon as possible.
• Serum concentrations of both NEFAs (>0.4 mEq/L) and BHB (subclinical/moderate ketosis >15 mg/dL; clinical ketosis >25 mg/dL) are increased.
• Hypoproteinemia (hypoalbuminemia and hypoglobulinemia) can be observed in clinical cases of pregnancy toxemia and could potentially be attributed to hepatic and/or renal failure.
• In later stages of pregnancy toxemia, hyperglycemia (often associated with fetal death), hypokalemia, elevated creatinine, and elevated BUN may be evident.
• Elevated ketones on urinalysis; ketonuria is present and usually detected before ketonemia.

OTHER LABORATORY TESTS
Impaired intravenous glucose tolerance test, not practical in clinical practice.

IMAGING
Transabdominal ultrasonography to determine the viability of fetuses in clinical pregnancy toxemia to better determine clinical management strategies.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Gross necropsy findings vary with body condition and initiating causes.
• Multiple fetuses are present and, depending on when fetal death occurred, autolysis may be present.
• The carcass is either emaciated or in good condition with large quantities of intra-abdominal and subcutaneous fat.
• Variable degrees of fatty liver infiltration with the liver potentially enlarged, pale, and friable; however, the severity of these changes may be difficult to evaluate grossly.
• Histologic lesions include hepatic lipidosis, neuronal necrosis, and astrocytosis.
• Aqueous humor concentrations of BHB can correspond to antemortem serum concentrations.
• Complete postmortem examinations are rarely performed.

TREATMENT

THERAPEUTIC APPROACH
• Treatment protocols based on two general principles: Administration of energy sources and removal of factors that increase energy requirements.
• Treatment costs and prognosis should be considered before any treatment is recommended. Individual animals should be segregated from the flock for treatment and monitoring purposes.
• If the ewe or doe is in early stages of the disease, dietary modification and supplementation with glucogenic precursors may be sufficient.
• Propylene glycol (60–200 mL PO q12h for 6 days), glycerol, calcium propionate, sodium propionate, or liquid molasses are routinely used as glucose precursors. Precautions should be taken when administering propylene glycol, as excessive amounts may lead to acidosis and/or cause diarrhea.
• Calf electrolytes for neonatal diarrhea (PO q12h for 1–2 days) can combat acidosis and dehydration.
• In more advanced stages of the disease, more aggressive supportive therapy is necessary and the prognosis more guarded.
• Acid-base status, degree of dehydration, associated electrolyte abnormalities, and renal function should be evaluated and appropriate treatment and fluid therapy provided.
• Glucose levels should be evaluated before initiation of treatment. Severe hypoglycemia should be treated by administration of 250–500 mL of 10–20% glucose solution IV followed by slower infusion of a 5–10% glucose solution. In combination with glucose treatment, insulin therapy should be initiated and monitored closely.
• To reduce the effects of the negative energy balance and improve the potential response to therapy, cesarean section or induction of parturition/termination of pregnancy to remove the fetuses is often recommended in affected females.
• Induction of parturition in ewes is usually accomplished with the administration of dexamethasone (10–20 mg IM) with parturition generally occurring 36–48 hours following administration. However, it is only successful if the fetuses are alive.
• Induction of parturition in does is usually accomplished with the administration of prostaglandin F2α or an analog (2.5–15 mg dinoprost tromethamine IM; 75–125 µg cloprostenol IM) with parturition generally occurring 30–48 hours following administration.
• In cases where the female is severely compromised, euthanasia may be indicated for welfare reasons.

SURGICAL CONSIDERATIONS
• Emergency cesarean section may be elected if the dam is severely compromised.
• If induction of parturition or termination of pregnancy does not result in delivery of the fetuses within 72 hours, or the animal is severely compromised, a cesarean section should be performed.

MEDICATIONS

DRUGS OF CHOICE
• Several drugs are occasionally used in individual cases of pregnancy toxemia in combination with glucose administration and fluid therapy.
• Administration of B-complex vitamins to stimulate appetite.
• Protamine zinc insulin (20–40 units IM q48h) in combination with glucose and fluid therapy.
• Recombinant bovine somatotropin (0.15 mg/kg q24h SC or single injection of 160 mg of slow-release formulation SC) may increase efficiency of glucose and ketone usage. (Not currently approved for use in small ruminants in the US.)
• Dexamethasone (10–20 mg IM) with parturition in ewes generally occurring 36–48 hours following administration.
• Females that are managed with induction of parturition or cesarean section should be treated with broad-spectrum antimicrobials, a nonsteroidal anti-inflammatory, and oxytocin to facilitate placental passage and prevent metritis.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis for dam survival and delivery of live offspring is good if the condition is diagnosed and treated early.
• The prognosis is usually poor if recumbency is prolonged.
• Induction of parturition/termination of the pregnancy or cesarean section is unpredictable for survival of the fetuses, and if delayed, for the dam as well.

POSSIBLE COMPLICATIONS
• Fetal death and septicemia
• Dystocia and retained placenta are common complications in dams that survive to the induced or natural parturition.

CLIENT EDUCATION
• The owner will need to evaluate the economics of therapy versus probable outcomes.
• Awareness of factors contributing to pregnancy toxemia and their avoidance.

PATIENT CARE
• Feed intake is a critical factor in monitoring for treatment success. If the animal is recumbent for a prolonged period, the odds of recovery are substantially reduced.
• The goal of therapy in pregnancy toxemia is to restore glucose homeostasis as soon as possible.

PREGNANCY TOXEMIA: SMALL RUMINANT (CONTINUED)

• Multiple electrolyte, acid-base, and fluid imbalances in addition to low blood glucose levels will need to be considered in any potential treatment plan.
• The affected dam should be isolated to reduce expenditures of energy and limit competition for feed resources.
• High-quality forages and concentrates should be offered in an attempt to stimulate intake.
• Transfaunation could be considered if a source of rumen fluid is available.

PREVENTION

• Prevention of future cases of pregnancy toxemia is best accomplished by evaluation of nutritional and management practices within the flock.
• Designing nutritional programs that meet the females' requirements based on the stage of production and relevant environmental and management conditions can prevent most cases of pregnancy toxemia.
• Ewes and does should have a BCS of 3 or 3.5/5 at the beginning of the breeding season and a BCS of 2.5–3.5/5 one month prior to parturition.
• Transabdominal ultrasonography performed in early gestation (day 40–70) can be useful for determination of fetal numbers and thus to adjust nutrition in the last trimester of pregnancy to meet the demands of twins and triplets.
• Close observation of ewes and does carrying multiple fetuses in the last 6 weeks of pregnancy.
• Avoid stress (transport, shearing) during the last month of pregnancy.
• Where possible blood samples should be collected to evaluate BHB levels. Females with elevated BHB levels should be separated and monitored closely.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Dystocia, retained placenta, respiratory disease

AGE-RELATED FACTORS

• More common in older ewes or does, not generally associated with maiden females.

ZOONOTIC POTENTIAL

• N/A

PREGNANCY

Pregnancy toxemia is present in dams in late gestation (generally the last 4–6 weeks).

PROLONGED PREGNANCY

BASICS

OVERVIEW
• A functional fetal hypothalamic-pituitary-adrenal (HPA) axis is required for onset of parturition in ruminants.
• Prolonged gestation is a rare occurrence resulting from alterations in the HPA axis that render the fetus incapable of secreting cortisol to initiate parturition.
• Prolonged gestation is that which extends beyond the expected mean for the species; 284 ± 10 days in the bovine and 148 ± 7 days in sheep.

INCIDENCE/PREVALENCE
Unknown; sporadic cases have been reported in various breeds of cattle and sheep.

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Parturition involves a cascade of endocrine and biochemical events triggered by the fetal HPA.
• Briefly, under oxygenation limitation in late pregnancy the stressed fetus responds by an increase of ACTH. The fetal pituitary stimulates secretion of adrenal corticoids from the fetal adrenal cortex. Fetal cortisol promotes an enzymatic pathway to convert progesterone to estradiol and causes placental synthesis of $PGF2_{\alpha}$. These events promote luteolysis and stimulation of myometrial contractions and initiation of parturition.
• Prolonged gestation is primarily due to absence of this HPA cascade.
• In camelids, pregnancy length is extremely variable. Prolonged gestation may be due to placental insufficiency. Fescue toxicosis has been suspected but there is no scientific evidence as of yet.

HISTORICAL FINDINGS
• Overdue female based on breeding date.
• Failure of onset of parturition after expected date of parturition.
• In flocks of sheep where the breeding date is not known, ewes may go beyond the window of lambing based on joining period.

SIGNALMENT
• Prolonged pregnancy complaint is reported in cattle, sheep, and quite commonly in camelids.
• Some breeds of cattle are over-represented due to the implication of an autosomal recessive gene: Ayrshire, Belgian Blue, Guernsey, Holstein-Friesian, and Swedish Red.
• Reported gestation lengths in cases of prolonged gestation in cattle are in the range 305–526 days.
• In sheep, gestation lengths up to and exceeding 230 days have been reported.

PHYSICAL EXAMINATION FINDINGS
Lack of mammary development, vulvar edema, or relaxation of the sacro-sciatic ligaments of the dam.

CAUSES AND RISK FACTORS
• In cattle the condition is associated with some fetal abnormalities, genetics, and intoxication.
• In sheep, the condition has been associated with craniofacial deformities of the fetus induced by viral pathogens or teratogens.
• In camelids, prolonged pregnancy has been associated with severe nutritional restriction, harsh environmental conditions, and placental insufficiency.

GENETICS
Autosomal recessive type of prolonged gestation described in some breeds of cattle.

DIAGNOSIS

• First step in diagnosis is determining that insemination and calculated due dates are accurate and that no bull exposure occurred subsequent to recorded natural or artificial breeding.
• Transrectal palpation will reveal a fluid-filled uterus. A fetus may be palpable and its characteristics may differentiate prolonged gestation from fetal mummification or maceration.
• Transrectal ultrasonography may allow visualization of the fetus and placentomes.
• In some cases, prolonged gestation may be accompanied by abnormal fluid accumulation in the uterus resulting in hydrops amnii or hydrops allantois.
• Serial examinations may be necessary to definitively rule out inaccurate breeding dates.

DIFFERENTIAL DIAGNOSES
• Inaccuracies in record keeping due to human error include inaccurate insemination records, incorrect calculations of expected date of parturition, or undocumented natural or artificial breeding following initial insemination.
• Viral causes of hydrancephaly, anencephaly, porencephaly, microencephaly that may interfere with normal pituitary gland development such as Border disease, bovine viral diarrhea virus, Akabane virus, bluetongue virus, or Cache Valley virus.
• Abnormal development of the pituitary gland due to craniofacial deformities induced by ingestion of *Veratrum californicum* or *Veratrum album* during early gestation.
• Fetal death during gestation resulting in mummification or maceration of the fetus and apparently prolonged gestation due to a nonviable fetus.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
• Transrectal ultrasonography to identify structures associated with pregnancy such as placentomes and fetus.
• Transabdominal ultrasonography findings have not been reported to be different from healthy, nonstressed fetuses and would not differentiate prolonged gestation from a normal pregnancy.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• In some cases of prolonged gestation, the fetus continues to grow in utero and may weigh >90 kg at birth. Dystocia often results due to fetomaternal disproportion. These fetuses may also have hirsutism, long hooves, and delayed skeletal ossification.
• Alternately, fetal growth may cease during late gestation and the fetus remains in utero in a vegetative state. These fetuses are smaller in size, weighing 20–30 kg at birth. Affected fetuses may also have hypotrichosis, craniofacial deformities, or developmental arrest of the incisors and molars.
• Hypoplasia or aplasia of the adenohypophysis or adrenal cortex may be present on histologic examination of fetal tissues.
• Placentitis has also been reported in some cases of prolonged gestation.

TREATMENT

THERAPEUTIC APPROACH
• Induction of parturition is indicated upon determination of prolonged gestation.
• Induction in cattle may be achieved by administering a single dose of natural prostaglandin $F_{2\alpha}$ or analog (cloprostenol) or dexamethasone.
• Parturition should occur 24–72 hours following induction with either prostaglandin $F_{2\alpha}$ or dexamethasone. Induction failures may occur in 10–20% of cases.
• Induction in cattle with a combination of prostaglandin $F_{2\alpha}$ and dexamethasone allows for more predictable onset of parturition (25–42 hours in one study) and fewer induction failures.
• Since the ewe only relies on luteal progesterone through day 50 of gestation, prostaglandin $F_{2\alpha}$ alone is unlikely to be effective in inducing parturition in the case of prolonged gestation. Induction in sheep requires administration of dexamethasone (15–20 mg IM) to induce enzymes responsible for converting placental

PROLONGED PREGNANCY (CONTINUED)

progesterone to estradiol and initiate the parturition cascade.
• Induction of parturition in camelids should not be attempted unless the health of the dam is compromised.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• In the case of induction failure or extreme fetal oversize due to prolonged gestation, cesarean section or fetotomy may be required.

MEDICATIONS

DRUGS OF CHOICE
Cattle
• $PGF2_{\alpha}$ (dinoprost tromethamine, 25 mg IM) or cloprostenol (500 mg, IM)
• Dexamethasone (20–30 mg, IM)

Sheep
• Dexamethasone (15–20 mg IM)

Goats
• $PGF2_{\alpha}$ (dinoprost, 15 mg IM) or cloprostenol sodium (75–100 µg IM)

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Animals should be monitored for dystocia, retained placenta, and metritis following induction of parturition.
• Camelids with prolonged pregnancy and no signs of distress should be monitored until natural delivery. Neonates delivered after a prolonged pregnancy (>370 days in alpacas) should be examined for dysmaturity. Examination of the placenta may reveal lesions consistent with placental insufficiency.

POSSIBLE COMPLICATIONS
• Dystocia, retained placenta, metritis
• Neonatal maladjustment or death

CLIENT EDUCATION
Accurate record keeping for breeding and early pregnancy diagnosis

PATIENT CARE
Depends on decision for induction of parturition and follow-up.

PREVENTION

PROTEIN NUTRITION

BASICS

OVERVIEW
• Proteins are nitrogen-containing compounds that occur in plants and animals, which are composed of amino acid (AA) chains of medium to large molecular weight. They are essential nutrients that serve as one of the building blocks of all tissues and can also serve as an energy source.
• In most if not all animal husbandry and production operations, adequate provision of protein represents the single highest cost in the diet, both through expenses associated with supplementation, as well as with production and preservation of forages.
• In animals, proteins function in structure, metabolism, transport, the endocrine system, and the immune system. Muscle, hormones and their receptors, enzymes and many blood constituents such as albumin are protein in nature.
• Prevention of protein-energy malnutrition (PEM) requires intake of essential AA.
• Accurately predicting AA requirements in ruminants poses the challenge of balancing for essential and limiting AA, not only for adequate nutrition, growth and maintenance functions, but also to support an adequate and efficient level of production.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• PEM results from a limited availability of protein, energy sources, or both. It can be primary, due to limited dietary content, or secondary, due to chronic, debilitating conditions.
• Though essential AA deficiency is rare in ruminants, low dietary AA, increased production demands, or chronic loss of protein lead to a catabolic state.

HISTORICAL FINDINGS
History of limited availability of food sources or presence of chronic wasting conditions.

SIGNALMENT
All ruminant species can be affected, without breed, age, or sex predilection.

PHYSICAL EXAMINATION FINDINGS
• Loss of body condition and in advanced cases cachexia, stunted growth, generalized weakness, decreased feed intake, marked loss of muscle mass, diarrhea, edema, impaired wound healing and immunity, and generalized impairment of all functions.
• Early changes in a herd or flock include decreased production, reproductive failure with delayed estrus, increased pregnancy losses, decreased conception rates, and low birthweights.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Inadequate food availability or decreased intake
• Poor dietary formulation with low protein content
• Chronic, debilitating diseases

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
All causes of chronic wasting disease.

CBC/BIOCHEMISTRY/URINALYSIS
None specific. Hypoalbuminemia in advanced stages with or without low urea/BUN.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Diet analysis

PATHOLOGIC FINDINGS
Grossly, a cachectic carcass with complete fat depletion is observed.

TREATMENT

THERAPEUTIC APPROACH
The treatment of PEM is based on correction of dietary deficiencies to guarantee adequate provision of AA (particularly essential and limiting AA) to meet maintenance requirements and to support all production demands.

MEDICATIONS

DRUGS OF CHOICE
• Supplementary sources of enteral or parenteral AA can be used in addition to adequate dietary availability.
• If available and financially feasible, total parenteral nutrition may be used for initial rapid correction of the catabolic status of the patient.

PRECAUTIONS
N/A

CONTRAINDICTATIONS
Administration of partial or total parenteral nutrition is contraindicated in the presence of an active infection.

POSSIBLE INTERACTIONS
Many medications interact negatively with parenteral nutrition formulations.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• If treated promptly and with provision of dietary sources of essential and limiting AA, the prognosis is good. A gradual weight gain, growth in young animals, and a return to production can be expected.
• Advanced cases of cachexia and debilitation secondary to PEM carry a poor prognosis and are unlikely to thrive.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
See "Production Management"

PATIENT CARE
Severely affected, cachectic animals should be sold if suitable for human consumption, or euthanized.

PREVENTION
Adequate access to a well-formulated diet and supplementation (variable for different species and production units)

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Protein-losing nephropathy or enteropathy, neoplasia, and cachexia.
• Protein deficiency will result in partial anorexia, weight loss, stunted growth, delayed estrus, or decreased milk yield.

PREGNANCY
Appropriate protein nutrition is required for optimal fetal development and for normal reproductive function and lactation.

PRODUCTION MANAGEMENT
• Protein requirements vary between and within species. Within species, type and level of production, as well as stage of growth, affect protein requirements.
• Protein intake and essential AA balance is important to all animals.
• Primary methods of harvesting and preserving forage crops include silage making, hay making, green chopping, and pasturing. Each of these methods has benefits and limitations.
• Direct assessment of feed quality by appraisal, such as visual appearance, smell, and feel, are important tools for evaluating forages. Color, leaf content, stem texture, maturity, contamination from weeds, molds or soil, and observations on palatability are examples of useful visual determinations. Though useful, there are distinct limitations

PROTEIN NUTRITION (CONTINUED)

for measuring feed quality in this way only, therefore laboratory assessment is advised.

Protein Nutrition

- Adequate protein nutrition is required for optimal growth, reproduction, and maintenance in all animals, as well as for milk, meat, and wool production.
- Animals produce proteins from AA. Some AA can be synthesized and some, the essential AA, must be available in the diet and are required in the production of virtually all proteins.
- In ruminants, essential AA can be supplied by ruminal protozoa and bacteria. However, for optimal production, supplemental essential AA are usually incorporated into the diet.
- Sources of soluble nitrogen and carbon are required to synthesize bacterial proteins. Soluble dietary proteins are referred to as degradable intake proteins (e.g., soybean meal), whereas ruminal undegradable intake proteins (e.g., blood meal or feather meal) do not provide the ruminal bacteria with AA but must be digested in the abomasum and small intestine to obtain essential AA.
- An adequate balance of degradable and undegradable intake protein is essential for optimal ruminal health.
- Therefore, proper protein dietary formulations are absolutely essential for ruminant production.

Protein Sources and Analysis

- Protein is an important nutrient supplied by forages, and protein analysis assesses the quantity and quality of the protein present in the forage.
- A basic understanding of this analysis is essential for protein nutrition:
  - When a laboratory uses wet chemistry, crude protein will most likely be measured by the standard Kjeldahl procedure, which measures total nitrogen. The crude protein value includes both true protein and nonprotein nitrogen compounds.
  - The true protein derived from various plantstuffs is roughly 70% of the protein in fresh forages, 60% in hay forage, and <60% in fermented forages.
  - Laboratories also frequently report a digestible protein value. This is an estimate of protein digestibility only, having limited value in ration formulation.
- Management and storage conditions of feedstuffs can also affect the nutritional quality and should be considered when assessing dietary protein content of forages:
  - When excessive heating of a forage occurs, a portion of the crude protein may be unavailable. If heat damage is suspected, an analysis for bound protein (acid detergent fiber crude protein, unavailable, insoluble protein) should be requested.
  - If bound or insoluble protein represents >12% of the crude protein content, enough heating to reduce protein digestibility has occurred.
- For ration formulation it is the amount of bound protein that is usually taken into account when determining protein requirements for animals:
  - Some laboratories report percent ACP as crude protein minus bound protein. Technically, this is incorrect as it does not account for the normal amount of bound protein in the forage.

ABBREVIATIONS

- AA = amino acids
- ACP = available crude protein
- BUN = blood urea nitrogen
- PEM = protein energy malnutrition

PSEUDOCOWPOX

BASICS

OVERVIEW
Pseudocowpox is a parapoxvirus that is closely related to contagious ovine ecthyma in sheep and bovine papular stomatitis in cattle.

INCIDENCE/PREVALENCE
Common disease of dairy cattle, less common in beef breeds

GEOGRAPHICAL DISTRIBUTION
Worldwide; common in North America

PATHOPHYSIOLOGY
• Virus spreads locally in the skin.
• The lesions are small, 2–5 mm erythematous macules and papules that develop on the teats, udder, and perineum.
• These lesions eventually rupture and crust over.

SIGNALMENT
• Most cases involve adult milking cows and tend to occur in cyclic infections with the introduction of new naïve animals and the waning of immunity in previously exposed older animals.
• The disease tends not to affect dry cows, heifers, and bulls.
• Calves suckling infected teats can develop oral lesions. Cutaneous lesions on the muzzle and lips of nonsuckling juvenile calves have also been observed.
• In camels, the disease forms proliferative lesions on the lips, muzzle, and eyelids.

PHYSICAL EXAMINATION FINDINGS
• Animals rarely develop fevers but there may be a drop in milk production due to teat irritation.
• Lesions begin as small macules and papules 2–5 mm in diameter, on the teat, udder, and perineum, which slowly expand to round reddened raised lesions 1–2 cm in diameter with an overlying ring-shaped scab or crust.
• Lesion does not usually form a central umbilicated pustule that is commonly observed in most poxvirus infections.
• In nursing calves, the lesions may be located in the oral cavity with raised, umbilicated, circular ulcers on the tongue or palate and can look similar to bovine papular stomatitis.

CAUSES AND RISK FACTORS
• Pseudocowpox, a parapox virus, is the causative agent.
• It is believed that there are no rodent or other animal vectors for pseudocowpox virus.
• Since cattle are the primary source of infection; exposure to virally contaminated milking equipment or udder cleaning supplies are the most common source of infection in adult cattle.
• The drinking of virally contaminated milk or drinking from contaminated bottles are a source of infection for calves.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Herpesvirus mammillitis (Allerton virus, bovine herpesvirus-2): This usually begins as small 2–3 mm vesicles or pustules that rupture, forming small slow-healing ulcers. These can coalesce into larger lesions that are slow to heal.
• Bovine papular stomatitis: This usually occurs in suckling calves but can occasionally be seen on the teats and udder of infected cattle. Lesions are often umbilicated with a central scab.
• Bovine papillomavirus: May cause fibropapillomas on the teats. Often the lesions are verrucous or plaque-like which may scab over due to trauma.
• Cowpox: This is a disease primarily of Europe with lesion having an umbilicated appearance on the udder and teat, which may have a central scab over the umbilicated region.
• Foot and mouth disease (FMD): Vesicles which ulcerate can be observed on teats and udder. Usually the oral vesicles and vesicles in the interdigital space are commonly seen associated with teat lesions, which would make it easy to differentiate from pseudocowpox.
• Vesicular stomatitis virus: Vesicles and ulcers can be seen on teats; however, most vesicles are usually associated with lesions in the mouth and occasionally on feet.
• Buffalo-pox virus (India/Pakistan region): Vaccina-virus with a disease similar to pseudocowpox virus. There are pox-like lesions on teats and udders of domesticated water buffalo and occasionally cattle.
• Brazilian vaccinia viruses: Endemic vaccinia-virus disease in Brazil with papules that develop into painful ulcers on the teats and udder of cattle.

CBC/BIOCHEMISTY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Virus isolation from infected scabs can assist in the identification of the virus.
• PCR testing of scab and other associated material.
• Electron microscopic evaluation of the scab will identify parapoxvirus particles.

PATHOLOGIC FINDINGS
• Gross findings: Small 2–5 mm erythematous macules and papules develop on the teats, udder, and perineum that rupture and crust over.
• As the lesions progress, the lesions enlarge to 1–2 cm in diameter with an erythematous outer rim and a peripheral ring-shaped scab present.
• If the scab is removed, there remains an ulcerated lesion that slowly heals.
• This differs from cowpox in that the lesion is not umbilicated.
• Histologically, the lesion is primarily epithelial with the epidermis undergoing vacuolar (ballooning) degeneration and vesicle formation. Older lesions have neutrophils filling the vesicle.
• Eosinophilic intracytoplasmic inclusions are present in the vacuolated epithelium.

TREATMENT

THERAPEUTIC APPROACH
• The lesions of pseudocowpox are usually self limiting and require little care other than keeping the lesion free of debris and preventing secondary bacterial infections of the open sore.
• In outbreaks, sanitation of the milking parlor equiptment and cleaning supplies is critical in lessening the spread of the disease.

MEDICATIONS

DRUGS OF CHOICE
If lesions become infected by secondary bacterial agents, systemic or topical antibiotics may be appropriate for treatment.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Most animals recover without any problems.

POSSIBLE COMPLICATIONS
Secondary bacterial mastitis or dermatitis can occur in lesions.

PREVENTION
• Little immunity is present after infections.
• Animals probably transmit the disease during milking.

MISCELLANEOUS

AGE-RELATED FACTORS
Calves may become infected with the virus and have lesions in the mouth from suckling on infected teats.

ZOONOTIC POTENTIAL
• This disease can be transmitted to herdsmen working on infected animals.
• Lesions develop on the hands, fingers, and face.
• These lesions are usually discrete, round, slow healing ulcers.

ABBREVIATIONS
• FMD = foot and mouth disease
• PCR = polymerase chain reaction

PSEUDORABIES

BASICS

OVERVIEW
• Pseudorabies is a reportable disease caused by the alphaherpesvirus, Suid herpesvirus-1.
• The name is derived from the clinical similarities to rabies.

INCIDENCE/PREVALENCE
• Common herpesvirus virus of domestic swine; United States is free of the virus in domesticated swine. However, the virus is still identified in wild domestic swine.
• Rare occurrence in ruminants, usually history of cattle, sheep, or goats housed with infected swine.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Nervous

PATHOPHYSIOLOGY
• The primary host are domestic swine with aberrant infections in ruminants causing an encephalitis.
• Ruminants infected by exposure to the virus from infected swine (saliva or nasal secretions) through pig bites, open wounds, or contact with mucus membranes.
• Virus travels centripetally to the spinal cord and brain via peripheral nerves, resulting in a devastating progressive encephalitis/myelitis.

SIGNALMENT
• Swine are the primary host.
• Infections can occur primarily in sheep, goats, and cattle exposed to oral or nasal secretions from infected swine.
• Affected ruminants usually do not transmit the disease to other animals.

PHYSICAL EXAMINATION FINDINGS
• Duration of illness ranges from 2 hours to 3 days.
• Many animals die suddenly without clinical signs of illness.
• Ruminants often develop an intense local pruritus (mad itch) at the point of dermal contact with the pathogen. Sites of pruritus are often the head, shoulder, flank, limbs, and perineum. Head and neck region most commonly affected.
• Animals begin licking at the area, then scratch the skin against inanimate objects.
• This may progress until the animal becomes frenzied, resulting in hair loss, abrasions, or ulceration.
• Goats do not usually exhibit intense pruritus. Signs usually include restlessness, screaming, and profuse sweating.
• Animals progress to ataxia, depression or becomes excited with manic or aggressive behavior (rare). Head pressing, grinding of teeth, unusual bellowing, and convulsions may occur. Pharyngeal paralysis with excessive salivation and loss of tongue tone may occur.
• Elevated rectal temperatures up to 107°F (41.5°C) often are observed.
• Signs progress to lateral recumbency, paralysis, and death.
• Calves often develop oral and esophageal ulcers without pruritus, and clinical signs of an encephalitis in 6–48 hours. Pruritus is often absent.

CAUSES AND RISK FACTORS
• It is caused by a pseudorabies virus (Suid herpesvirus 1), an alphaherpesvirus.
• Close contact with infected swine is the primary source of infection for sheep, goats, and cattle.
• Swine that have recovered from infection are asymptomatic but continue to shed virus intermittently due to infection of the trigeminal ganglia. Viral shedding usually occurs when the pig is stressed.
• In ruminants, viral latency is not common, with these animals being a dead-end host.
• Infection can occur after exposure to the virus by intranasal, oral, intradermal, or subcutaneous routes. Virus spreads by retrograde axoplasmic transport to the CNS.
• Virus may be present in the ruminant's nasal mucosa, secretions, and saliva during acute infection.
• Ruminant and other animals infected (dog, cat, and rat) have a short transient infective period which may (highly unlikely) act as a source of infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Rabies
• Malignant catarrhal fever
• Bovine herpesvirus-1 and 5 (IBR)
• Ovine lentiviral encephalitis
• Bornavirus
• Ovine encephalomyelitis (louping ills, tick-borne encephalitis)
• Bovine spongiform encephalitis/scrapie
• Polioencephalomalacia
• Bacterial meningitis (*Listeria*, *Histophilus somni*, other septic bacterial pathogens)
• Hypomagnesemia/Hypocalcemia
• Toxicity—organophosphate, carbamate, lead, arsenic, salt poisoning, hepatotoxins
• Enterotoxemia (*Clostridium perfringens* type D)
• Pituitary abscess

CBC/BIOCHEMISTRY/URINALYSIS
Usually normal

OTHER LABORATORY TESTS
• CSF findings are consistent with encephalitis. Pleocytosis with increased mononuclear cells (50–200 cells/dL) and increased protein concentration (100–200 mg/dL).
• Virus isolation via cell culture or inoculation of rabbits with infected nervous tissues. Sensory segments of the spinal cord serving the pruritic sites contain high concentrations of the virus.
• Immunofluorescent antibody, immunohistochemistry, or PCR testing on brain tissue may be useful to confirm the diagnosis.
• Serologic testing for rising antibodies is not useful in ruminants or other acutely infected animals.

PATHOLOGIC FINDINGS
• Gross lesions—alopecia, edema, dermal abrasions occur at the pruritic site with the possible presence of secondary bacterial pathogens.
• There is possible swelling or edema of regional lymph nodes.
• Histologic lesions—nonsuppurative meningoencephalitis with mononuclear perivascular cuffing and neuronal degeneration and necrosis observed in the brain.
• Eosinophilic intranuclear (Cowdry type A) inclusion bodies are often identified in neurons and glial cells.

TREATMENT

THERAPEUTIC APPROACH
• No effective treatment in ruminants.
• Supportive therapy and prevent self-injury due to pruritus if possible.
• Humane euthanasia may be the only source of relief if animal continues to deteriorate.

MEDICATIONS

DRUGS OF CHOICE
None

CONTRAINDICATIONS
• Do not vaccinate ruminants with modified-live virus vaccines targeted for use in swine.
• There have been reports of sheep infected by use of syringes contaminated with the MLV vaccine for swine.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
The majority of affected ruminants die within 2–3 days of the onset of clinical signs.

PREVENTION
• Prevent exposure of ruminants to swine or direct contact with any fomites that may transmit the virus from pigs to susceptible animals.

PSEUDORABIES (CONTINUED)

• Recovered swine should be culled as natural infections can result in the typical herpesvirus latency and a carrier state.
• Environmental inactivation of the virus can be achieved by drying, 6 hours of contact time with ultraviolet light, and high temperature (37°C).
• Contaminated pens and other surfaces can be disinfected with 10% bleach solution, quaternary ammonium compounds, iodine compounds, or phenolic compounds. At least 5 minutes of contact time is required before rinsing.
• Be sure to thoroughly clean all surfaces of organic matter before applying a disinfectant.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Infectious bovine rhinotracheitis (IBR) virus shares common antigens with the pseudorabies virus. Serologic tests can be affected by heterospecific antibodies to the IBR virus cross-neutralizing pseudorabies virus antibodies.

ZOONOTIC POTENTIAL

Humans are generally resistant to pseudorabies virus. There have been reports of pruritus when skin wounds came into direct contact with infected tissues. Use caution when working with infected swine or other animals.

BIOSECURITY

Do not allow swine direct contact with ruminants.

SYNONYMS

• Aujeszky's disease
• Infectious bulbar paralysis
• Mad itch

PYELONEPHRITIS

BASICS

OVERVIEW

• Pyelonephritis refers to bacterial infection of the kidney(s) that typically results from ascending infection of the lower urinary tract.
• In cattle, *E. coli* is the most common causal agent followed closely by *Corynebacterium renale* and other *Corynebacterium* species (*C. cystitidis* and *C. pilosum*). Whereas *E. coli* is an opportunistic pathogen of environmental origin, *C. renale* is a normal inhabitant of the ruminant genitourinary tract.
• Cattle subclinically infected with *C. renale* become carriers and can shed the organism in urine. The organism is capable of surviving in the environment for weeks.
• Other organisms associated with pyelonephritis in cattle include *Trueperella pyogenes*, alpha-hemolytic *Streptococcus* spp., *Proteus* spp., *Pseudomonas aeruginosa*, *Klebsiella* spp., and *Oligella urethralis*; some of these organisms establish infection via a hematogenous route (suppurative embolic nephritis).
• In small ruminants, *C. pseudotuberculosis* has been cultured from some renal infections.
• Both kidneys can be affected but pyelonephritis is usually unilateral, and can be acute or chronic in nature.

INCIDENCE/PREVALENCE

• Herd prevalence of pyelonephritis in one study ranged from 0.3% to 2.7%.
• 73% of cases of clinical disease developed within the first 90 days after calving.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Urinary

PATHOPHYSIOLOGY

• Irritation or damage of the caudal genitourinary tract from trauma (dystocia, obstetric manipulation, urolithiasis, bladder catheterization, etc.) provides ideal conditions for bacteria to attach and proliferate in the genitourinary mucosa.
• *C. renale* possesses pili that facilitate attachment to and colonization of the urinary tract mucosa. The organism can be contracted at breeding, from iatrogenic transmission, or through urine splashing and contact from carrier cows.
• Ascending infection to the bladder can result in signs of cystitis, and further ascension via the ureters to the kidneys results in inflammation, necrosis, and abscess formation within renal tissue.
• Fecal contamination of the caudal reproductive tract favors ascending infection with *E. coli*.
• Occasionally congenital disorders (ectopic ureters, abnormalities of the umbilicus/urachus) contribute to the development of pyelonephritis in juvenile ruminants.

HISTORICAL FINDINGS

• Many cases have a recent history of calving or urogenital procedures.
• Acute cases often have a history of sudden anorexia, fever, and reduced milk yield; chronically diseased animals may have a history of weight loss, wasting, diarrhea, and reduced milk production.

SIGNALMENT

Females, particularly adult postparturient dairy cows are most commonly affected.

PHYSICAL EXAMINATION FINDINGS

• Acute pyelonephritis is often represented by fever 103.5–105.5°F (39.7–40.8°C), anorexia, depression, tachycardia, and dehydration (reflected by enophthalmos).
• Some cows exhibit signs of colic such as treading, restlessness, kicking, tail swishing, and arched stance.
• Dysuria, stranguria, polyuria, hematuria, and pyuria can occur.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Trauma to the caudal genitourinary tract associated with dystocia, obstetric manipulation, urolithiasis, bladder catheterization, etc.
• Urine stagnation (bladder paralysis, urolithiasis)
• Abnormal perineal/vulvar conformation
• Rectovaginal fistula
• Pneumovagina/metritis
• Presence of subclinical carriers of *C. renale* in the herd
• Venereal transmission
• Pregnancy

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Enzootic hematuria
• Urolithiasis
• Vaginitis/cervicitis/metritis
• Perivaginal abscess
• Gastrointestinal disorders creating colic

CBC/BIOCHEMISTRY/URINALYSIS

• CBC can display neutrophilic leukocytosis and hyperfibrinogenemia. Anemia may be observed in chronic disease.
• Urine contains increased numbers of RBCs, WBCs; often substantially increased protein, and the presence of bacteria (perform Gram stain).
• Serum chemistry may demonstrate increased globulin and reduced albumin, particularly in chronic cases. Increases in BUN and creatinine can be prerenal (dehydration), renal (bilateral pyelonephritis with renal failure), or postrenal (obstruction of the ureters or urethra by blood clots or fibrin) in origin.
• The presence of azotemia in conjunction with non-concentrated urine specific gravity (<1.020) is suggestive of bilateral kidney involvement and probable renal insufficiency.

OTHER LABORATORY TESTS

Urine should be submitted for bacterial culture and antimicrobial sensitivity testing, preferably after collection by sterile catheterization to avoid sample contamination with skin organisms and reproductive discharge.

IMAGING

• Ultrasound examination may reveal dilation of renal calyces, presence of echogenic flocculent material within renal pelves, and renal enlargement.
• Thickening of the bladder wall might also be appreciated.
• The right kidney can be evaluated percutaneously; the left kidney may be obscured by the rumen in many animals and can be evaluated using per rectum ultrasonography.

OTHER DIAGNOSTIC PROCEDURES

• Per rectum examination may reveal loss of lobulations, increased size, and pain on palpation of the left kidney.
• Per vaginam examination may permit palpation of enlarged ureter(s) through the ventral vaginal wall.
• Cystoscopy allows evaluation of urine quality from each ureteral opening, and sampling of urine from each individual kidney. The bladder may appear inflamed, thickened, or ulcerated when visualized.

PATHOLOGIC FINDINGS

• Gross distortion of renal size and shape.
• Cross-section of affected kidney(s) may detect gray, viscous, odorless exudate in the renal pelvis with extension into the medulla and cortex.
• Renal abscesses may be present.
• Hemorrhage, ulceration, and fibrin deposition may be present on the mucosa of the bladder and urethra.
• Ureteral enlargement may be evident with purulent debris occluding the ureteral lumen.

TREATMENT

THERAPEUTIC APPROACH

• Antimicrobial selection is ideally based on the results of urine bacterial culture and sensitivity, and the ability of the drug to achieve high concentrations in the urine without nephrotoxic effects.
• Long-term (≥3 weeks) of antimicrobial therapy is crucial to treatment success.
• Intravenous or oral fluid therapy promotes diuresis and flushes the urinary tract, which is of value in acute disease.

PYELONEPHRITIS (CONTINUED)

• Acidification of urine to prevent adhesion of *C. renale* and other organisms may be of value.

SURGICAL CONSIDERATIONS AND TECHNIQUES
In cases of severe or nonresponsive unilateral pyelonephritis, nephrectomy may be indicated.

MEDICATIONS

DRUGS OF CHOICE
• Sodium, potassium, or procaine penicillin (22,000–44,000 IU/kg, q6–12h depending on formulation and severity of disease) is the usual drug of choice since *C. renale* is considered uniformly sensitive to penicillin; *E. coli* (despite being a Gram-negative organism) is often sensitive because of the very high concentrations of penicillin achieved in urine.
• Ampicillin trihydrate (11 mg/kg IM, q12h).
• Ammonium chloride (200 mg/kg PO, q24h).

CONTRAINDICATIONS
Nephrotoxic drugs should be avoided in azotemic animals.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Recommendations for specific drugs, including penicillin, involve extra-label administration.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Case fatality rate and cull rate due to pyelonephritis in cattle are approximately 18% and 33%, respectively.
• Bilateral pyelonephritis and pyelonephritis secondary to bladder paralysis, rectovaginal fistula, or other functional problems have a poorer prognosis.
• Chronic pyelonephritis and animals with azotemia are also associated with a lesser prognosis due to loss of renal function and lower likelihood of therapeutic response.

POSSIBLE COMPLICATIONS
• Renal insufficiency
• Renal abscessation

CLIENT EDUCATION
N/A

PATIENT CARE
Urinalysis and urine culture should be assessed one week after treatment is ceased, to ensure resolution; relapse rate can approach 10%.

PREVENTION
• Isolate affected animals to prevent shedding and environmental contamination.
• Practice aseptic technique when performing urogenital and obstetric procedures and thoroughly clean and disinfect equipment.
• Artificial insemination can help control venereal transmission in endemically affected herds.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Renal failure

AGE-RELATED FACTORS
Usually a disease of mature females

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Is a risk factor for this disorder

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Economic losses are associated with decreased production, culling, and treatment expense.

SYNONYMS
N/A

ABBREVIATIONS
• BUN = blood urea nitrogen
• RBCs = red blood cells
• WBCs = white blood cells

SEE ALSO
• Endometritis
• Postpartum Disorders
• Urolithiasis

PYOMETRA

BASICS

OVERVIEW
• Pyometra is an intrauterine accumulation of pus associated with a persistent luteal state.
• It typically affects animals with existing uterine infections during the late postpartum period after the resumption of ovarian activity.
• As seasonal breeders, ewes and does generally deliver their young during the anovulatory season and are at very low risk for developing pyometra.
• Pyometra is described in camelidae but it is rarely associated with CL retention. In these species, pyometra is often the result of severe cervical or vaginal adhesions.

INCIDENCE/PREVALENCE
• Postpartum pyometra is relatively common in dairy cattle.
• Incidence of pyometra is in the range 5–15% in herds experiencing an outbreak of trichomoniasis.
• Pyometra is rare in camelids.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Pyometra develops when ovulation and CL formation occur in the presence of uterine infection, most commonly chronic endometritis.
• Failure of $PGF2_{\alpha}$ release from the endometrium results in luteal retention and maintenance of elevated serum progesterone which perpetuate the condition by keeping the cervix closed and inhibiting uterine contractions.
• In cattle, pyometra often develops following an infection with *Tritrichomonas foetus* and early pregnancy loss.
• The volume of purulent material in the uterus ranges from a few milliliters to several liters.
• In cows with preexisting uterine infections, exogenous GnRH treatment early in the postpartum period can result in an iatrogenic pyometra.
• In camelidae, pyometra has been linked to postpartum metritis, cervical or vaginal adhesions, and prolonged progesterone therapy.

HISTORICAL FINDINGS
• History of dystocia or postpartum complications
• Cattle herds using untested bulls for natural mating

SIGNALMENT
• Sexually mature female animals
• Lactating dairy cows in the postovulatory phase of the postpartum period
• Cycling beef or dairy cattle exposed to bulls infected with *Tritrichomonas foetus*

PHYSICAL EXAMINATION FINDINGS
• Systemic signs of disease are usually absent.
• Anestrus.
• Purulent or mucopurulent genital discharge may be present in some cases.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Animals with retained fetal membranes with or without dystocia.
• Postpartum uterine infection.
• Animals that resume ovulatory cyclicity early in the postpartum and have concurrent endometritis.
• Ewes and does that cycle year-round may have a greater risk of developing pyometra as a sequela to postpartum metritis or endometritis.
• Birthing trauma and cervical adhesions, especially in camelids.
• Natural service with *Tritrichomonas fetus*–infected bulls may result in a post-breeding (as opposed to postpartum) pyometra.
• Although the initial insult is a microbial infection (*Fusobacterium necrophorum* and *Trueperella pyogenes* are most often incriminated), determining the specific etiologic agent is necessary only if *T. foetus* is suspected. Successful treatment of pyometra does not generally require identification of a specific etiologic agent, and newer diagnostic methods suggest that the microbiota of postpartum uterine disease may be vastly more complicated and dynamic than indicated by traditional culture techniques.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Mucometra or hydrometra
• Pregnancy
• Macerated fetus
• Anestrus

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Culture and sensitivity testing as well as cytologic evaluation of the uterine contents are rarely performed. Most affected animals are treated on the basis of physical diagnosis.

IMAGING
Transrectal or transabdominal ultrasonography

OTHER DIAGNOSTIC PROCEDURES
• Palpation per rectum (cattle, camelids)
  ◦ Enlarged uterus with palpable fluid distention, the tone may or may not mimic normal pregnancy
  ◦ Absence of positive signs of pregnancy (fetal membrane slip, amniotic vesicle, fetus, and placentomes in cattle, fetus in camelids)
• Ultrasonography (all species)
  ◦ Transrectal (cattle, camelids) or transabdominal (sheep, goats) ultrasonography provides a definitive diagnosis.
• Vaginoscopy may reveal the presence of purulent material in the cranial vagina. In camelids, vaginal or cervical adhesions may be evident.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• In ruminants, treatment is directed at terminating what is essentially a pseudopregnancy. $PGF2_{\alpha}$ treatment is usually sufficient in cattle, sheep, and goats.
• Camelids may benefit from physical removal of the uterine contents by flushing or lavage followed by local or systemic broad-spectrum antibiotic therapy for 5–7 days. This is only possible if there are no vaginal or cervical adhesions.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Ovariohysterectomy may be considered in companion animals.

MEDICATIONS

DRUGS OF CHOICE
• $PGF2_{\alpha}$ IM (dinoprost, cattle: 25 mg; small ruminants; 5–10 mg) or (cloprostenol, cattle: 500 µg, small ruminants, 75–250 µg) repeated at 11- to 14-day intervals until the uterus is emptied and normal cycles resume.
• Camelids should be treated IM with cloprostenol if a CL is detected by ultrasonography (100 µg for alpacas, 250 µg for llamas, 500 µg for camels).
• Antibiotic therapy is not indicated for pyometra in cattle, but sheep, goats, and camelids may benefit from a 5- to 7-day course of systemic therapy. Intrauterine antibiotic therapy may be used in camelids.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times should be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

PYOMETRA (CONTINUED)

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis for fertility is good to fair in dairy cattle responding to the treatment. Most cattle (90%) will respond to $PGF2_{\alpha}$ treatments by evacuating the uterus. Normal fertility can be expected at the second or third estrus after resolution.
• Cattle with confirmed diagnosis of trichomoniasis should be culled.
• In camelids, prognosis for fertility depends on the cause. Prognosis is poor if there are cervical or vaginal adhesions.

POSSIBLE COMPLICATIONS
• Infertility due to failure to resolve the pyometra is the most frequent complication and may result in a decision to cull the female.
• Salpingitis, ovarian bursitis, and peritonitis may occur if uterine contents are expressed in a retrograde manner.

CLIENT EDUCATION
• Owners should submit anestrus females for reproductive evaluation.
• Trichomoniasis should be ruled out in bull bred herds.
• Use proper procedures during obstetric manipulations.

PATIENT CARE
• Treated animals should be monitored every 1–2 weeks to confirm that the uterine contents have been evacuated and estrous cycles have resumed.
• Most affected ruminants will respond after 1 or 2 treatments but rarely as many as 4 or 5 treatment cycles may be necessary.
• Camelids with vaginal or cervical adhesions should be removed from breeding and monitored for any complication.

PREVENTION
• Management of the peripartum animal to minimize the incidence of dystocia and postpartum uterine disease.
• Pre-breeding examinations.
• Incorporating $PGF2_{\alpha}$ presynchronization into ovulation synchronization programs for breeding dairy cows will prevent most cases of pyometra from developing.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Hydrometra
• Infertility and subfertility
• Metritis
• Endometritis
• Dystocia

PYRROLIZIDINE ALKALOIDS

BASICS

OVERVIEW

• Among ruminants, most cases of pyrrolizidine alkaloid (PA) poisoning occur in cattle.
• Sheep and goats are relatively resistant to PA intoxication.
• Llamas and alpacas appear to be similar to sheep and goats when it comes to susceptibility.
• The three plant families Compositae, Leguminosae, and Boraginaceae contain the majority of PA-containing plants.
• The genera *Senecio* (*S. vulgaris*, common groundsel; *S. jacobaea*, tansy ragwort; *S. riddelli*, Riddell's groundsel; *S. flaccidus*, threadleaf groundsel) and *Cynoglossum officinale* (houndstongue) have been implicated in most of the animal poisonings in the United States.
• Plants in the genera *Amsinckia*, *Crotalaria*, *Heliotropium*, and *Echium* less commonly cause poisonings either because they are not palatable or do not grow in dense enough stands to pose a significant risk.
• Poisonings generally occur as a result of cattle grazing heavily-contaminated pastures (rare—most of these plants are not palatable) or consuming contaminated hay (most common route). Exposures are typically over several weeks to months duration.
• The alkaloid content can vary tremendously among plants; concentrations vary with respect to age and stage of maturity of the plant, and soil and weather conditions.
• Poisonings are most commonly chronic in nature; acute exposures are rare.
• This is generally a herd problem, although individual animals may be selected.
• The clinical signs can be slow and insidious, with general debilitation and weight loss a common complaint. Some affected animals show abrupt onset of signs associated with hepatoencephalopathy.
• The liver is the primary target; kidney, lung, and heart tissue are less commonly affected.
• Megalocytosis, biliary hyperplasia, and fibrosis are commonly reported histologic findings on postmortem examination of the liver.
• Prognosis is guarded to grave for affected animals.

INCIDENCE/PREVALENCE

• Unpredictable and uncommon; however, it is one of the more common causes of plant intoxication in some areas of the US.
• Poisonings can occur all year round through grazing contaminated pastures or ingesting heavily contaminated hay.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Multisystemic
• Respiratory
• Urinary

PATHOPHYSIOLOGY

• PAs are rapidly absorbed from the gastrointestinal tract.
• They undergo extensive metabolism in the liver. Some PAs are detoxified to harmless metabolites, but some are converted to highly toxic pyrroles.
• It is these pyrroles that alkylate DNA, leading to inhibition of cell mitosis and the ultimate histologic change of megalocytosis. As these megalocytes die, they are replaced by fibrous connective tissue.
• Though the liver is the primary target, lung, kidney, and heart tissue may be affected as well.

SIGNALMENT

• Cattle are most susceptible.
• Sheep, goats, llamas, and alpacas are relatively resistant.
• Resistance appears to be partly due to differences in rumen metabolism.
• Young animals appear to be more sensitive.

PHYSICAL EXAMINATION FINDINGS

• Some animals suffer chronic weight loss and debilitation associated with chronic liver insufficiency.
• Weakness and sluggishness.
• Secondary photosensitivity and icterus.
• Some animals exhibit an abrupt onset of signs associated with hepatic encephalopathy—mania, derangement, aimless walking, head pressing, blindness, and ataxia.
• Less commonly observed signs include inspiratory dyspnea (reported in horses), GI impactions, ascites, and diarrhea.

CAUSES AND RISK FACTORS

• A minimum of 2–4 weeks, up to several months, of exposure to these plants is generally required in order to induce toxicity.
• Acute exposures can occur if animals ingest 5–10% of their body weight of plant material within a few days to a few weeks (rare).
• It is more common to see poisonings in animals that ingest 25–50% of their body weight in plant material over a period of several months.
• Signs can occur suddenly in animals where the exposure to PA-containing plants ceased weeks or months previously.
• Approximate chronic toxic dose (for tansy ragwort) for an adult cow is 0.4 kg dry plant or 1.7 kg fresh plant per day for several weeks.
• For Riddell's groundsel, approximately 33 g dry or 176 g fresh plant daily for 3 weeks could be toxic to an adult cow.
• An approximate toxic dose of threadleaf groundsel in adult cows is 150 g dry or 750 g fresh plant daily for 2 weeks.
• A daily dose of 136 g dry or 680 g fresh houndstongue daily could be toxic to cattle over a period of a few weeks.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Acute hepatitis or cholangiohepatitis, liver abscess, viral or bacterial encephalitis, aflatoxicosis, exposure to nitrosamines, hepatotoxic cyanobacteria.

CBC/BIOCHEMISTRY/URINALYSIS

• Inflammatory leukogram can be observed.
• Hyperbilirubinemia.
• Elevations in gamma-glutamyl transpeptidase, alkaline phosphatase, aspartate aminotransferase, and sorbitol dehydrogenase may also be elevated.
• Hypoalbuminemia, hypoproteinemia, and low blood urea nitrogen are less consistent abnormalities.

OTHER LABORATORY TESTS

• Severely elevated bile acids
• Characteristic histologic lesions of a liver biopsy

IMAGING

Ultrasound may reveal a small liver.

OTHER DIAGNOSTIC PROCEDURES

• One should examine the diet for the presence of PA-containing plants.
• Pyrrole testing of blood or hepatic tissue has been done, but it is not commonly performed at diagnostic laboratories. The analysis is not quantitative nor sensitive, particularly in the late stages of the disease.

PATHOLOGIC FINDINGS

• Poor body condition.
• Jaundice.
• Ascites and generalized edema.
• Small, pale, firm liver with mottled cut service may be visualized on necropsy.
• Characteristic lesions of hepatic megalocytosis with piecemeal necrosis, biliary hyperplasia, and generalized fibrosis.
• Kidney changes may include megalocytosis of the proximal convoluted tubules, glomerular atrophy, and tubular necrosis,
• Other less commonly recognized lesions include myocardial necrosis, gastrointestinal edema and hemorrhage, adrenal cortical hypertrophy, pulmonary edema, interstitial pneumonia, and status spongiosus of brain tissue (not all reported in ruminants).

TREATMENT

THERAPEUTIC APPROACH

• Find and remove the suspect source or remove animals from the contaminated environment.

PYRROLIZIDINE ALKALOIDS (CONTINUED)

• Most animals respond poorly to treatment, because by the time the disease is diagnosed, adequate regeneration of the liver is not possible.
• No specific treatment regime has been shown to be effective in treating these animals.
• Dietary changes could include switching to one that is highly digestible, high in calories, and low in protein.
• Treatment is typically not an economically viable option for most producers.

MEDICATIONS

DRUGS OF CHOICE
None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The more severely affected animals have a poor prognosis. Many are euthanized due to debilitation and poor response to therapy, or because of financial constraints.
• Patients showing severe neurologic signs often do not respond well to treatment.
• Some patients may survive after several months of intensive supportive care, but often are not able to regain their former activity or production level.

POSSIBLE COMPLICATIONS
• Avoid using medications that require extensive hepatic metabolism.
• Pneumonia and chronic wasting.

PATIENT CARE
• Monitor appetite, weight, and serum chemistries to evaluate liver enzymes, albumin, and protein.
• Serum chemistry panels should be run periodically to evaluate liver function.

PREVENTION
• Be able to recognize PA-containing plants either in the pasture or in hay.
• Avoid feeding "weedy" hay.
• Appropriate herbicide use can control the growth of these plants in the field.
• Sheep and goats can perhaps be used to control stands of these plants through rotational grazing.

MISCELLANEOUS

AGE-RELATED FACTORS
Young animals appear to be more susceptible.

PREGNANCY
PAs have been shown to cross the placenta and some are secreted into the milk. The risk of these routes having a significant impact on the developing fetus or nursing young is extremely low.

PRODUCTION MANAGEMENT
Avoid feeding "weedy" PA-containing hay. Be able to recognize these plants in pastures or hay.

SYNONYMS
• Seneciosis
• Venoocclusive disease

Q FEVER (COXIELLOSIS)

BASICS

OVERVIEW

• Q (Query) fever is a highly infectious zoonotic disease caused by the intracellular bacterium *Coxiella burnetii* that primarily affects goats, sheep, cattle, and humans. Other species less commonly affected include dogs, cats, rabbits, a variety of wild and domestic mammals, and birds.
• The majority of *C. burnetii* infections in ruminants are subclinical, but abortion and infertility are common manifestations when naïve groups are exposed to the organism.
• Asymptomatic animals can shed *C. burnetii* for long periods of time in reproductive secretions, milk, urine, and feces.
• Epidemiologic studies indicate that Q fever is a public health problem in many countries.
• In humans, Q fever is considered an occupational hazard with the majority of infections occurring in livestock workers, veterinarians, and personnel of animal research facilities.
• In the United States, *C. burnetii* is classified as a category B potential aerosolized biological weapon.

INCIDENCE/PREVALENCE

• Information on the prevalence of Q fever in animal species is limited. Worldwide prevalence of serum antibodies from animal-based or farm-based surveys varies from 0% to 48% and from 0% to 100%, respectively.
• Q fever can be endemic in areas where reservoir animals are found.

GEOGRAPHIC DISTRIBUTION

Q fever is a zoonosis with a worldwide distribution with the exception of New Zealand.

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• *C. burnetii* is an obligate, intracellular, Gram-negative bacterium that replicates within the phagolysosome of infected cells.
• Among ruminants, *C. burnetii* is transmitted mainly through inhalation of contaminated dust or droplets and by ingestion of contaminated feed or water.
• After experimental inoculation of pregnant goats, the chorioallantoid membrane is the primary target for *C. burnetii*. The organism also localizes in the mammary gland, supramammary lymph nodes, and uterus in domestic ruminants.
• As with other infections, the initial antibody response is mediated by IgM, subsequently switching to a predominately IgG reaction.
• A characteristic of *C. burnetii* is its phase variation due to partial loss of polysaccharide that results in antigenic drift. During the acute phase of infection, ELISA can detect predominately IgM antibodies against phase II antigens. Later, IgG, IgA, and to a lesser extent IgM antibodies against phase I antigens appear. Studies to characterize the cellular immune response against phase I and II *C. burnetii* antigens in domestic animals are lacking.
• After inoculation, *C. burnetii* phase II specific antibodies, both IgM and IgG, can be detected 2 weeks post-infection and remain increased for up to 13 weeks. Antibodies directed against *C. burnetii* phase I increase as well, but about 4 weeks later compared to the phase II antibodies. Serum antibodies in infected animals can be detected for several months up to years.
• The organism can be shed in milk, urine, feces, placenta, and parturient discharges during subsequent pregnancies and lactations.
• In chronically infected animals, *C. burnetii* is also shed in the feces and urine.
• *C. burnetii* is highly resistant to heat, desiccation, and many common disinfectants, and can survive in the environment for long periods of time.
• Ingestion and inhalation of contaminated aerosols from amniotic fluid or placenta of infected animals are considered the main avenues of transmission.
• Contaminated hides and wool, and dust from barns, can be a source of infection for people and other animals either by direct contact or by inhalation of airborne particles.
• Consumption of raw milk contaminated with *C. burnetii* can be a risk factor for Q fever infection in humans and animals.
• *C. burnetii* has been found in the semen of bulls and rams, but the likelihood of this route of transmission is not well documented.
• Over 40 tick species can be naturally infected with *C. burnetii* and a sylvatic cycle based on *C. burnetii* tick-borne transmission has been proposed. However, the recent discovery of many tick-borne *Coxiella*-like bacteria with cross-reactivity to *C. burnetii* suggests that tick transmission may not be important.
• Dogs and cats may be infected by consumption of placentas or milk from infected ruminants, and by the aerosol route.

HISTORICAL FINDINGS

N/A

SIGNALMENT

• Sheep, goats, cattle, and ticks (ixodid and argasid) are considered the primary reservoirs. In general, goats are considered more susceptible than sheep.
• Humans and other animal species, including dogs, cats, rabbits, horses, pigs, rodents, pigeons, and other fowl, may also get infected with *C. burnetii.*
• Infection causes the greatest mortality in fetal or newborn animals. Adult animals are usually asymptomatic.

PHYSICAL EXAMINATION FINDINGS

• In domestic animals, Q fever is mostly associated with abortion outbreaks in small ruminants and sporadic abortions in cattle. The incubation period of Q fever is variable.
• Affected adult ruminants are usually asymptomatic; when clinical disease occurs, reproductive failure is usually the only signs. This can manifest as abortions, stillbirths, retained placentas, infertility; or the birth of weak neonates.
• Late-term abortions are typical and occur over a 2- to 4-week period. Between 5% and 50% and in some cases up to 90% of pregnant ewes or goats in a group may abort, with no previous clinical signs.
• An increased incidence of postpartum metritis has been observed in dairy goats that experience abortions caused by *C. burnetii*.
• Some infected animals can become carriers and the infection may be reactivated in subsequent pregnancies, resulting in shedding of the organism even though pregnancy may result in normal, viable offspring.
• In cattle, infertility, sporadic abortion, and low birthweights are seen.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Parturient materials containing *C. burnetii* are highly infective and can contain large numbers of the organism.
• *C. burnetii* is extremely stable in the environment and can be transmitted to other animals via aerosol (airborne droplets or contaminated dust) and direct contact with placental tissues and parturient fluids, feces, or urine of infected animals.
• Fomites (e.g., wool, bedding, clothing), ingestion of parturient material, contaminated water or raw milk, or arthropods may also play a role in transmission.
• The infective dose of *C. burnetii* is very low, and it is considered that one to ten organisms can initiate an infection. In addition, due to the highly resistant nature of the organism to adverse environmental conditions, particles carrying *C. burnetii* can remain infectious for months and be transported long distances by wind currents.
• Young naïve pregnant small ruminants are very susceptible and abortion storms are common.
• The risk of animals in a herd or flock being infected increases in geographic areas with high wind speed, open landscape, high environmental temperature, low precipitation, and high animal densities.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Differentials include other causes of abortion and infertility, such as brucellosis,

Q FEVER (COXIELLOSIS) (CONTINUED)

leptospirosis, campylobacteriosis, salmonellosis, listeriosis, chlamydiosis, mycotic abortion, toxoplasmosis, BVD, and IBR.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Currently, the preferred method to establish the diagnosis of Q fever in aborted fetuses is the demonstration of *C. burnetii* DNA within the affected placenta or other tissues, using several polymerase chain reaction (PCR) formats including conventional PCR, real-time PCR (RT-PCR), multiplex PCR, and nested PCR.
• Samples for PCR diagnosis include placenta, vaginal discharges, and liver, lung or stomach contents of aborted fetuses. However, performing necropsies of aborted fetuses of small ruminants in a veterinary clinic setting or farm facilities is discouraged due to the high risk of contaminating the premises. The entire placenta and fetus should be submitted overnight to the diagnostic laboratory, double bagged with refrigerant (gel coolants), and sealed in a leakproof insulating container.
• *C. burnetii* real-time PCR also has been used to detect the organism in vaginal swabs, milk, and colostrum of dams that have aborted.
• In general, the sensitivity of real-time PCRs based on multicopy genes (e.g., IS1111) is higher than those based on single copy genes.
• Loop mediated isothermal amplification (LAMP) assays have been developed with reportedly reliable results, but are not available in veterinary diagnostic laboratories.
• The demonstration of *C. burnetii*-specific antibodies in the serum of adult animals is the most practical indirect method to establish a diagnosis of Q fever. In domestic animals ELISA and complement fixation (CF) test are most often used.
• Testing of bulk tank milk samples by ELISA or real-time PCR has been used infrequently in sheep and goats.
• Currently, microagglutination and immunofluorescence assay (IFA) are less frequently used. Phase II antibodies dominate the humoral immune response in the acute phase of the infection, whereas phase I antibodies are prominent in the chronic phase. IFA is no longer available in most veterinary diagnostic laboratories.
• The sensitivity and specificity of ELISA and CF test vary depending on the tests used. When the sensitivity and specificity of two commercially available ELISA kits and the CF were compared, the sensitivity of the ELISA was in the range 97–100% and the specificity was in the range 95–100%. The sensitivity and specificity of the CF test was 89% and 82%, respectively.
• Serologic tests are good indicators of previous exposure but provide no information on the infectious status of individual animals.
• *C. burnetii* does not grow on artificial media, but can be isolated in cell culture, embryonated chicken eggs, and some laboratory animals, such as mice and guinea pigs. *C. burnetii* can be detected from vaginal discharges, the placenta, placental fluids, aborted fetuses, as well as milk, urine, and feces. However, cultivation of *C. burnetii* is not recommended for routine diagnosis because the process is difficult, time-consuming, and dangerous; culture requires a biosafety level 3 (BSL-3) laboratory practice because the organism is highly infective and represents a health hazard for laboratory workers.
• *C. burnetii* does not stain well with the traditional Gram technique, but takes a magenta color with the Gimenez, modified Ziehl-Neelsen, or Macchiavello stains and stains purple with Giemsa stain.
• Confirmation of the diagnosis in formalin fixed tissues can be achieved by immunohistochemical staining.
• *C. burnetii* is a BSL-3 zoonotic agent; therefore, personal protective measures should be taken.
• Due to the recent identification of many *Coxiella*-like bacteria, future research about potential cross-reactivity between *C. burnetii* and *Coxiella*-like bacteria is necessary to better evaluate the current specificity of diagnostic methods and screening tools used in vertebrates.

PATHOLOGIC FINDINGS
• Macroscopically, the placenta (chorioallantoic membrane) is often affected and is the preferred sample for confirmation of the diagnosis.
• Grossly, the intercotyledonary areas are thickened, with a leathery appearance, and are covered with white-yellow or brownish-red exudate. Cotyledons are swollen and exhibit a yellow or brownish-red discoloration.
• In the majority of cases, Q fever-aborted fetuses do not show gross lesions, are generally fresh, and less often autolytic.
• Microscopically, the characteristic lesions consist of necrotic placentitis. The chorionic epithelium exhibits necrosis and accumulation of cell debris and leukocytes on the surface. The stroma of the intercotyledonary areas shows severe infiltration of leukocytes.
• Often, chorionic trophoblast cells are filled with large numbers of small intracytoplasmic coccobacilli that are visible in hematoxylin and eosin-stained sections. The organisms are Gram-negative and stain a magenta color with Gimenez stain.
• The organism cannot be differentiated by microscopic examination of tissues from other Gram-negative intracellular bacteria, such as *Brucella* or *Campylobacter*, hence confirmation of the diagnosis requires ancillary tests.
• In the majority of cases, affected fetuses do not show microscopic lesions. Some fetuses may be found to have bronchopneumonia or mild granulomatous hepatitis.

TREATMENT

THERAPEUTIC APPROACH
Because *C. burnetii* replicates in phagolysosomes of infected cells, the effectiveness of antibiotics is theoretically limited by their ability to penetrate these organelles and remain active at the low pH that prevails in this environment.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Two successive injections of long-acting oxytetracycline (20 mg/kg SC) during the last month of pregnancy is often used in females that are still pregnant once an outbreak starts. However, the beneficial effect of antibiotic treatment in reducing *C. burnetii*-induced abortions and shedding is not well documented.
• Humans require long-term therapy with drugs including doxycycline and hydroxychloroquine.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
• Stillbirth or abortion in pregnant ruminants and humans.
• Chronically infected humans can develop endocarditis.

CLIENT EDUCATION
Education should focus on potential sources of infection and ways to reduce environmental contamination from infected placental membranes and aborted materials, and to avoid consumption of raw milk.

(CONTINUED) # Q FEVER (COXIELLOSIS)

PATIENT CARE
N/A

PREVENTION
• In the United States, there are no vaccines available for the prevention of Q fever in ruminants.
• Q fever vaccines for humans and animals are available in other countries. Vaccination of noninfected small ruminants before their first mating with a phase I vaccine leads to significant reduction of abortion rates and subsequent shedding of bacteria.
• Since the start of a compulsory vaccination campaign of all dairy sheep and dairy goats in the Netherlands in 2010, no abortions caused by *C. burnetii* have been reported. On average, it took 2–7 years to eradicate Q fever from a herd with preventive vaccination after this outbreak in the Netherlands.
• In addition to vaccination, sound biosecurity and management practices should be established in ruminant herds. Replacement animals should be obtained from Q fever-free flocks and herds.
• Aborted fetuses and placentas should be collected quickly and submitted to the laboratory for diagnosis or disposed of by incineration or deep burial.
• Lambing areas should be cleaned and disinfected with Lysol, bleach, or hydrogen peroxide.
• *C. burnetii* is highly resistant to physical and chemical agents. Variable susceptibility has been reported for hypochlorite, formalin, and phenolic disinfectants; a 0.05% hypochlorite, 5% peroxide, or 1:100 solution of Lysol® (benzalkonium chloride) may be effective.
• High-temperature pasteurization destroys the organism.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
• Q fever in humans has different epidemiologic patterns. Often, it may consist of sporadic cases that are problematic to diagnose because clinical signs of acute infection are nonspecific and easily confused with those of other diseases.
• In some Mediterranean countries, such as France, Spain, and Israel, where Q fever is endemic, the disease is more frequently diagnosed in humans and animals.
• Epidemic outbreaks affecting large numbers of non-occupation related people and animals occur sporadically, as was the case in the Netherlands where more than 4,000 human cases were diagnosed and 50,000 goats were euthanized between 2007 and 2010.
• In the US, approximately 50–60 cases of Q fever in humans are reported each year, but it is believed that they are underdiagnosed and underreported and that these numbers do not reflect the true incidence of disease.
• Humans are highly susceptible to Q fever by exposure to aerosols when assisting infected animals during parturition, when handling infected placental tissues, by performing necropsies on aborted fetuses, during slaughter or laboratory procedures, and by drinking raw, unpasteurized milk from infected animals.
• In the acute phase, Q fever in humans can manifest as fever, chills, retrobulbar headache, myalgia, chest pain, dyspnea, productive cough, and liver failure; however, in the majority of cases infection is asymptomatic.
• In a small proportion of infected individuals the infection may progress to a chronic phase characterized by chronic heart failure due to valvular endocarditis, vasculitis, granulomatous hepatitis, osteomyelitis, or by chronic inflammation in several other organs. At this stage, the infection is often life threatening and complicated by the fact that antibiotic therapy is generally not effective.
• Q fever occurring during pregnancy in humans is associated with a risk of miscarriage.
• Q fever clinical disease is more frequent among HIV-infected patients and other immunocompromised individuals.
• Several studies have shown that living in the proximity of a small ruminant farm with a history of *C. burnetii* abortions is a risk factor for Q fever in humans.

PREGNANCY
Abortion and pregnancy loss

BIOSECURITY
• Biosecurity consists of management practices to prevent the introduction and spread of infectious diseases in a herd.
• Unless other farms or animals have equal health status, do not loan or share bucks, do not breed does for other producers, and do not mix animals with other producers' animals.
• Do not share equipment unless it is disinfected after each use.
• Limit access by visitors to the farm and to the animals.
• Control cat, dog, bird, rodent, and insect populations as much as possible.

PRODUCTION MANAGEMENT

RABIES

BASICS

OVERVIEW
• Rabies is a disease caused by an RNA virus. Rabies virus is an important cause of acute viral encephalomyelitis in ruminants, with public health implications.
• Once clinical signs appear, the disease is consistently fatal.
• Exposure most commonly occurs subsequent to a bite, usually from an infected feral or wild animal. After infection in CNS neurons, the virus travels to the salivary gland, from where it may be transmitted to other mammals.
• Prevention and control of the disease involves vaccination; however, vaccination is not commonly performed in livestock.
• Humans risk exposure by reaching into the mouth of an infected ruminant when a foreign body is suspected due to inability to swallow or hypersalivation.

INCIDENCE/PREVALENCE
• Cattle are most frequent domestic ruminant in which cases of rabies are reported.
• In the report on rabies surveillance in the United States during 2013, 49 states and the District of Columbia and Puerto Rico reported 5,865 cases of rabies in nonhuman animals and 3 cases in human beings to the Centers for Disease Control and Prevention, a decrease of 4.8% from the 6,162 cases in nonhuman animals and 1 case in a human being reported in 2012. Hawaii was the only reporting jurisdiction in the US where no confirmed cases of rabies were reported. The majority of cases (92.0%; 5,398 cases) were in wild animals, whereas 8.0% (467 cases) were in domestic species.
• Rabies cases in cattle are usually <100 cases per year in the US (approximately 1.0% of all rabies cases), although a spike in rabies cases in cattle was reported in 2012 (115 cases, 1.87% of all rabies cases).
• Rabies cases among sheep and goats in the US average <0.25% of all cases, and numbers of cases have ranged between 6 and 13 individual cases each year during 2009–2013.
• The relative contributions of the major groups of animals reported to have rabies in 2013 were: raccoons (32.3%, 1,898 cases), bats (27.2%, 1,598), skunks (24.7%, 1,447), foxes (5.9%, 344), cats (4.2%, 247), dogs (1.5%, 89), and cattle (1.5%, 86).

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Nervous

PATHOPHYSIOLOGY
Exposure most commonly occurs subsequent to a bite by an infected animal. After an animal is bitten, the rabies virus replicates locally. The virus travels by retrograde axonal transport to the brain. After infection in CNS, virus travels by antegrade axonal transport to the salivary gland and nasal epithelium. Shedding of the virus in saliva and nasal secretions may precede clinical signs.

SIGNALMENT
All ruminants

PHYSICAL EXAMINATION FINDINGS
• Early clinical signs are nonspecific and highly variable between individuals.
• In cattle, disease may manifest as different forms (furious or paralytic), although clinical signs associated with each form are not mutually exclusive. Oropharyngeal paralysis is considered one of the most common clinical signs of cattle, and rabid cattle can present with clinical signs indistinguishable from choke (esophageal obstruction).

Furious Form
• Restlessness, expression of anxiety, dilated pupils.
• Exaggerated response to auditory or tactile stimuli; aggression with minimal provocation.
• Animals may charge through stall doors or gates and roam extensively.
• Other signs can include bloat, convulsions, pruritis, pica, or tenesmus.
• Affected animals become progressively ataxic and eventually develop paresis.
• Death usually occurs within 10 days of onset of clinical signs.

Paralytic or "Dumb" Form
• Initial signs often include anorexia, depression, ataxia, shifting leg lameness, and fever.
• Paralysis of the masseter muscles.
• Laryngeal and pharyngeal paralysis.
• Cattle may bellow incessantly with altered phonation.
• Profuse salivation and inability to swallow.
• Abrupt cessation of lactation in dairy cattle.
• Flaccidity of the tongue, tail, anus, and urinary bladder. Some animals exhibit long periods of tenesmus.
• If able to stand, animals have a wide-base stance. Knuckling of the hind fetlock joints may occur.
• Paresis progresses rapidly to paralysis of all parts of the body.
• Death within 10 days of onset of clinical signs.

CAUSES AND RISK FACTORS
• Rabies is a disease caused by RNA viruses in the genus *Lyssavirus* (family Rhabdoviridae).
• Different variants of the rabies virus are endemic to a specific host population within a given geographic region. In the US, raccoons are the primary host species along the eastern seaboard, skunks in the north central and south central states, and the fox in Texas. Various species of bat also carry different strains of the rabies virus.
• Skunks and bats can become asymptomatic carriers serving as reservoirs.
• Antigenic variations in the rabies virus result in different reservoir species depending on geographic area, although extension to other species is common.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Behavioral aggression unrelated to disease.
• Oral or esophageal foreign body.
• Grass tetany, polioencephalomalacia, milk fever, nervous ketosis, nervous coccidiosis, hypoxemia (anaplasmosis), bacterial encephalitis (thromboembolic meningoencephalitis).
• Transmissible spongiform encephalopathy: Scrapie, bovine spongiform encephalopathy, or chronic wasting disease in elk and deer.
• Neurotoxins such as carbamates or organophosphates.
• Other viral encephalitis diseases in ruminants include bovine herpesvirus encephalomyelitis, pseudorabies, malignant catarrhal fever, ovine and caprine lentiviral encephalitis, West Nile virus encephalitis, Borna disease, paramyxoviral sporadic bovine encephalomyelitis, and ovine encephalomyelitis (louping ill).

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
CSF may be normal or have increased protein, mononuclear cells, neutrophils, eosinophils, or xanthochromia. Remember to handle CSF with extreme caution, as the virus may be present in this cytologic specimen.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
In ruminants, rabies is diagnosed using a direct fluorescent antibody test conducted on fresh CNS tissues (preferably brainstem and cerebellum).

PATHOLOGIC FINDINGS
• There are no gross findings specific to rabies infection.
• On histology, Negri bodies, cytoplasmic inclusion bodies containing rabies viral antigen, may be found in the hippocampus, cerebellum, or medulla oblongata. These cytoplasmic inclusion bodies are considered diagnostic for rabies but may not be present in up to 30% of cases.
• Diffuse encephalitis can be seen with perivascular cuffing and neuronal necrosis.

TREATMENT

THERAPEUTIC APPROACH
• No effective treatment.

(CONTINUED) RABIES

• Any animal suspected of being exposed to rabies must be securely quarantined as required by state public health department regulations.

MEDICATIONS

DRUGS OF CHOICE

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Incubation period varies from a few weeks to a year. The average incubation period is 2–6 months. Animals bitten near the head have shorter incubation periods than those bitten on an extremity or on the trunk.
• Death usually occurs within 10 days of the first symptoms.

PATIENT CARE

• Animals suspected to have rabies must be securely quarantined.
• Monitor for changes in behavior and attitude, or clinical signs suggestive of rabies.
• Check state regulations on specific requirements. Rabies is a reportable zoonosis.

PREVENTION

• Inactivated vaccines are the only licensed product for prevention of rabies in livestock in the US. The modified-live vaccines that are available for use in domestic dogs and cats may potentially produce fatal allergic or viral encephalitis when injected in ruminants.
• Due to the extreme public health concerns, state, provincial, and local regulations have been put in place and must be followed completely.
• The Compendium of Animal Rabies Control is compiled and updated annually by the National Association of State Public Health Veterinarians (NASPHV) and summarizes the most current recommendations for the US and lists all USDA-licensed rabies vaccines.
• Environmental disinfection can be accomplished with household bleach in a 1:32 dilution (4 ounces per gallon).

MISCELLANEOUS

ZOONOTIC POTENTIAL

• Extreme risk. Observe strict quarantine of animals suspected to have rabies.
• Humans risk exposure by reaching into the mouth of an infected animal when a foreign body is suspected due to inability to swallow or hypersalivation.

RECTAL PROLAPSE

BASICS

OVERVIEW
Prolapse or eversion of the rectum through the anus

INCIDENCE/PREVALENCE
• Cattle: 0.1–1.5% within a population. • Sheep (lambs): 7.8%, 4% and 1.8% with respectively short, medium and long tail docking.

GEOGRAPHIC DISTRIBUTION
Feedlot lambs have higher incidence than grazing lambs.

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• Increase in pressure gradient in the abdominal and pelvic cavities • Exposure of rectum from anus • Straining • Reduced blood circulation, with secondary vascular congestion, edema, and necrosis • Secondary tissue trauma is common

HISTORICAL FINDINGS
May be predisposed by:
• Increased abdominal fill
• Tenesmus • Coughing • Feed changes

SIGNALMENT
• Cattle aged 6–24 months, sheep aged 6–12 months.
• No breed or sex predilection.

PHYSICAL EXAMINATION FINDINGS
Grading system: • Grade 1 mucosal prolapse, small or intermittent • Grade 2 prolapse of all layers from mucosa to serosa, variable length • Grade 3 prolapse of the large colon • Grade 4 intussusception of rectum and colon through anus

GENETICS
• Inherited anal sphincter laxity may play a role. • Genetic analysis of rectal prolapse using half siblings indicated a low heritability factor.

CAUSES AND RISK FACTORS
• Increased abdominal fill • Growth implant administration • Obesity with excessive pelvic fat deposition • Parasitosis • Bloat • Dystocia • Retained fetus • Uterine torsion • Vaginal or uterine prolapse • Increased number of fetuses • Diarrhea • Enteritis or colitis • Urinary obstruction • Decreased perianal and anal tone (may be secondary to short tail docking) • Neuropathy secondary to trauma or breeding injury • Mounting during estrus • Spinal lymphoma • Epidural alcohol blocks • Diet: Clover, high estrogenic compound feedstuff (soybeans) • Toxins • Respiratory disease • Chronic coughing

DIAGNOSIS

Diagnosis is straightforward and based on physical examination. Underlying disease diagnosis is fundamental.

TREATMENT

Transport before rectal prolapse correction is contraindicated if prolapse is very large.

THERAPEUTIC APPROACH
• Perform epidural block • In case of extensive straining, perform mild standing sedation. • Clean prolapsed rectum with warm and clean water. • Identify any area of laceration or necrosis. • Suture lacerated areas. • Apply osmotic agents to reduce rectal edema (hypertonic saline, dextrose, or glycerol). • Gently reduce the prolapse manually with the aid of lubricant. • When replaced, gently invert rectum in the pelvis. • Perform purse-string suturing through the skin 2–4 cm from the anus, maintaining some patency for defecation. • Individuate and treat the primary cause of the prolapse.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Severely traumatized or necrotic rectal tissue may necessitate amputation. • Perform only if severe damage to the rectum is present. • Perform mucosal resection and anastomosis if only the mucosa is damaged. • If more severely compromised, a prolapse ring can be applied. • A commercial prolapse ring or open-ended tube (PVC pipe) is inserted into the rectum. • Application of prolapse ring or elastrator band is used to stop blood supply to the area. • The necrotic area and ring will slough off in 7–10 days.

MEDICATIONS

DRUGS OF CHOICE
• Broad-spectrum antibiotic therapy
• NSAIDs (flunixin meglumine) • Osmotic agents (hypertonic saline or dextrose)
• Lubricating agents

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is guarded with tendency for recurrence unless causative agents are controlled.

POSSIBLE COMPLICATIONS
• Bleeding from rectal laceration or due to surgical amputation • Recurrence • Skin suture dehiscence or abscessation
• Constipation • Bladder retroversion
• Eventration of small intestine • Rectal stricture • Septic peritonitis • Death

CLIENT EDUCATION
• Animal's value should be discussed when deciding on treatment options. • Educate clients on controllable risk factors such as appropriate tail docking, parasite control programs, prompt treatment of respiratory disease, nutrition and body condition monitoring, and avoidance of estrogenic plants.

PATIENT CARE
• Restriction of activity is indicated.
• Maintenance of soft feces can help risk of constipation post-suture placement (e.g., legume diet, mineral oil, cathartics such as magnesium hydroxide). • Remove purse-string sutures in 7–10 days.

PREVENTION
Proper management practices such as feeding to control body condition, long tail docking, and prompt attention to reproductive, gastrointestinal, and respiratory disease can reduce the risk of prolapse.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Enteritis • Vaginal or uterine prolapse
• Bloat • Urolithiasis

PREGNANCY
May be more common in animals carrying multiple fetuses or very large fetus.

PRODUCTION MANAGEMENT
Market value and intended use of animal will determine treatment option

ABBREVIATION
• PVC = polyvinyl chloride

SEE ALSO
• Reproductive Prolapse • Uterine Prolapse

REINDEER MANAGEMENT: OVERVIEW

BASICS

OVERVIEW
• Historically, more than 25 indigenous ethnic groups residing in the Eurasian circumpolar regions have participated in reindeer herding.
• Currently, the reindeer industry is a primary focus of the Koryak, Chukchi, Komi, Nenet, Yakut, Enets, Even, Evenk, Nganasan, Dolgan, and Sami (see map at https://en.wikipedia.org/wiki/Reindeer#Reindeer_husbandry).
• There are approximately 1.5 million domesticated reindeer in Russia, 200,000 in Finland, 250,000 in Sweden, and 200,000 in Norway.
• Although <1% of the total meat consumed in Fennoscandia is reindeer, its production is a vital source of income to remote regions of this subarctic region.
• Reindeer also plays a central role in the traditions of the circumpolar indigenous herding groups which are the few remaining groups that have maintained a traditional lifestyle.

INCIDENCE/PREVALENCE

HISTORICAL FINDINGS
N/A

SIGNALMENT
Species
• *Rangifer tarandus* is a circumpolar species consisting of seven subspecies formed through the isolation of populations during the ice age.
• North American subspecies of *Rangifer tarandus* are called caribou, while Eurasian subspecies are called reindeer.
• Peary caribou (*R.t. pearyi*) and Svalbard reindeer (*R.t. platyrhyncus*) inhabit the high Arctic.
• Alaskan caribou (*R.t. granti*), barren ground caribou (*R.t. groenlandicus*), and Eurasian reindeer (*R.t. tarandus*) inhabit the taiga; woodland caribou (*R.t. caribou*) and woodland reindeer (*R.t. fennicus*) inhabit the boreal forests.
• *Rangifer tarandus* are polygamous and sexually dimorphic with males being approximately twice the size of females.
• North American caribou are all wild.
• Eurasian reindeer: Both wild and domesticated herds exist.
• Domesticated reindeer are highly gregarious and form large herds, particularly during migration and periods of insect harassment.

Breed Predilections
• Eurasian reindeer are smaller than caribou.
• Females reach maximum body size at the age of 4–5 years, and senescence starts at the age of 7–10 years.
• Females are ~60 kg and males 120 kg at their prime. Body weights vary markedly depending on range conditions.
• Calves are born in April–June (one calf per year).
• Females with poor nutritional status have reduced fecundity and delayed calving.
• Birthweight is ~5 kg (males are 0.5 kg heavier) and is positively associated with neonatal survival.
• Weaning ends in September/October (i.e., when the rut starts), but the calf may follow its mother for a year.
• Calves following their mothers have easier access to food and are more likely to survive the winter. Males are less likely to follow their mothers and have higher mortality rates.
• Age of maturity is 1–3 years in females and 2–5 years in males. Poor nutritional conditions during early development may delay maturity. Conversely, good conditions may result in early maturity (age 1) in females, and this premature reproduction effort can permanently stunt somatic growth.

TREATMENT

THERAPEUTIC APPROACH
• The most important food during winter is lichens (*Cladina* spp.).
• During summer, the diet is more variable, and includes vascular plants, grasses (graminoids), herbs, shrubs such as willow (salicaceae), heathlike shrubs (ericoids), trees, and fungi.
• Inadequate harvesting and subsequent population growth exceeding the carrying capacity of the ranges have led to degradation of the winter pastures in many areas.
• Supplementation with hay and commercial feed pellets during winter is practiced (in Finland hay is subsidized by the European Union).

REINDEER MANAGEMENT: OVERVIEW (CONTINUED)

PRODUCTION MANAGEMENT

Herding Systems

• Reindeer management has been recently introduced into Siberia and regions (Inuit in Alaska and Canada, and the Greenland Eskimos).
• The most intensive and modernized management of domesticated reindeer is found among the Sámi people in Fennoscandia. There, herding is a cooperative operation based on year-round free range with seasonally defined ranges and migration routes, intensive use of mechanical transportation for herding (motorcycles, snow mobiles, helicopters), and supplemental feeding during poor range conditions.
• Reindeer are in general individually owned in most regions of Fennoscandia, but reindeer cooperatives with joint ownership are common in Finland, southern Norway, and most of Siberia.
• Reindeer husbandry requires access to extensive land areas (34% of the land area in Finland, 50% in Sweden, and 40% in Norway).
• When available, coastal regions, with their moist climates, nutrient-rich grazing, and a relatively low intensity of flying, biting insects are used for summer range. Drier continental ranges with dense lichen beds, less snow, and stable cold conditions during the winter months are used for winter range.
• Historically, reindeer herders in Russia, Finland, Sweden, and Norway migrated freely across national borders.
• Governmental restrictions regarding crossing geopolitical boundaries have tended to break up traditional, ecologically determined migration patterns and seasonal ranges.
• During the nineteenth century, the Russian and Finnish borders were closed, and today severe restrictions exist on the movement of reindeer between pastures in Norway and Sweden. This has led to reduced availability of appropriate summer and winter pastures.
• Many Norwegian reindeer herds are forced to survive on winter pastures along the coast where heavy snowfall and ice prevent efficient foraging. This has been remedied to some extent by supplemental feeding during some of the winter months.
• Finnish and Swedish reindeer lack access to nutrient-rich pastures along the coast during the summer and experience a very high burden of parasites (nasal bot flies, *Cephenomyia trompe* Modeer and warble fly, *Hypoderma tarandi* L.).

Economic Considerations

• Historically, reindeer were used for clothing, milk production, transportation (sled and draft animals), and meat production.
• Today, meat production is the primary goal in reindeer husbandry. Reindeer meat is considered a delicacy and an organically, free-range-raised meat, and commands a high price in European markets.
• More recently, with incorporation of modern technology into the husbandry techniques, it became necessary to produce adequate revenue to support the increased mechanization (e.g., snow mobiles, modern dwellings).
• The length of time domesticated reindeer are in close contact with humans varies greatly among different management practices, from only a few times a year when the calves are marked in the summer or early fall, and in the fall when animals are slaughtered, to almost year-round with prolonged periods of round-the-clock surveillance.
• Herders follow the reindeer on their migration between the winter and summer pastures.
• Calves are marked to signal ownership by cutting away small parts of the ear (see https://merker.reindrift.no/sok.aspx) in complex patterns of markings. These marks are passed down from generation to generation.
• Families, or family groups, often share pastures and herd their reindeer together in cooperative style management operations.

Predation

• Wolverine (*Gulo gulo*), lynx (*Lynx lynx*), and golden eagle (*Aquila chrysaetos*) are important predators of reindeer.
• In some regions, bears can be significant predators.
• Wolf (*Canis lupus*) may be an important predator, but has effectively been removed by humans from most reindeer-herding areas.
• Red fox (*Vulpes vulpes*) may be an important predator on neonates.
• Neonates are particularly vulnerable to predators.
• Food limitation increases risk of predation.

REINDEER MANAGEMENT: POPULATION DYNAMICS

BASICS

OVERVIEW
• High-density herds (populations exceeding carrying capacity) have reduced fecundity and calf growth, and are more vulnerable to density-independent factors (e.g., climatic events). Particularly calves, yearlings, mature bulls (weakened by the rut), and old (>10 years) females with worn teeth, are at risk of starvation.
• In the absence of overgrazing, excessive mortality, or heavy animal harvesting, reindeer herds grow until their populations exceed carrying capacity and crash or move to new feeding regions.
• Reindeer in poor nutritional condition are more susceptible to parasites, disease, and metabolic deficiencies, which can increase winter losses of meat, hides, and antlers.
• Basic range management plans can prevent overgrazing and subsequent starvation of overpopulated reindeer herds.

PREVENTION
• Semi-domesticated reindeer, like all free-ranging animals, are exposed to a wide variety of parasite species and infectious diseases. However, only a few species have substantive economic impact.
• Parasite burdens are to a large extent determined by density-dependent factors; herds exceeding carrying capacity, or that do not migrate seasonally to new ranges, may experience high transmission pressure and high parasite burdens. In addition, climate and weather play an important role (e.g., weather conditions influence the ability of flying parasites to breed and infect their hosts).
• *Elaphostrongylus rangiferi* Mitskevich (Nematoda: Metastrongylidae) causes cerebrospinal and muscular nematodiasis and mortality in the reindeer of the Palearctic.
• *E. rangiferi* likely has the greatest economic impact; epizootics have resulted in up to 25% mortality in a single year in select herds of northern Norway.
• The oestrids, *Hypoderma tarandi* L. (warble fly) and *Cephenomyia trompe* Modeer (nasal bot fly), cause substantial harassment during the warmer summer months, resulting in reduced feeding time and body mass growth.
• Finnish and Swedish reindeer lack access to nutrient-rich pastures along the coast during the summer and experience a very high burden of flying parasites such as nasal bot flies (*Cephenomyia trompe* Modeer) and warble fly (*Hypoderma tarandi* L.).
• Gastrointestinal nematodes (*Trichostronglyus*, *Ostertagia, Nematodirus, Marshallagia, Trichuris, Skrjabinema* species) have a detrimental impact on weight gain and somatic growth, but usually not a direct impact on survival.
• In North America and Siberia, brucellosis outbreaks in reindeer herds have caused serious morbidity,d mortality, and economic consequences.
• Brucellosis is a contagious, infectious, and communicable disease caused by bacteria of the genus *Brucella.*
• Because brucellosis is zoonotic (causing undulant fever in humans), eradication through a vaccination program has been a major veterinary medicine focus in recent years.

PREGNANCY
N/A

BIOSECURITY
• Isolation and quarantine of new stock entering the herd.
• Treat and or cull new animals for disease conditions prior to herd introduction.

REINDEER MANAGEMENT: POPULATION DYNAMICS (CONTINUED)

PRODUCTION MANAGEMENT

Population Dynamics

• Sex ratio in domesticated herds is highly skewed toward females (i.e., 1:10–20) due to selective harvest.
• A skewed sex ratio increases growth and productivity due to the higher growth efficiency (per unit feed) of younger animals.
• Large variations in regional climate and management strategies, including harvest intensities, have led to profound variation in reindeer densities, size, and productivity.
• As a rule of thumb, summer range conditions are most important determinants for somatic growth, while winter range conditions are most critical for survival and population growth rates.
• Populations with access to winter pastures with little precipitation (snow) and stable (cold) continental conditions have good access to food in winter and higher survival rates.
• Intensive harvesting is needed to regulate such populations to sustainable levels that are appropriate for the winter range.
• Populations with winter pastures in coastal areas are exposed to high precipitation levels, bringing deep snow alternating with rain and ice. Resultant ice crystals embedded in the lichen beds reduce access and palatability, causing reindeer to wander constantly rather than graze with stability.
• High-density herds (populations exceeding carrying capacity) have reduced fecundity and calf growth and are more vulnerable to poor environmental conditions such as periods of poor winter weather. Particularly calves, yearlings, and mature bulls (weakened by the rut) and old (>10 years) females with worn teeth, are at risk of starvation.

Future Challenges

• Closing of national borders led to suboptimal use of pastures for reindeer in Fennoscandia, and international range-sharing agreements could lead to improved productivity.
• Increased pressure on reindeer pastures due to development of infrastructure for other activities such as mining, oil drilling, and power plants may permanently reduce the sustainability of reindeer herding activities.
• The recovery of predator populations, such as wolverine and lynx, has increased predation on reindeer in Fennoscandia.
• Reindeer densities are in many regions above sustainable levels. In such areas increased reindeer management plans, that increase harvest, are needed to match population densities to the food resources on the available pastures.

REPEAT BREEDER MANAGEMENT

BASICS

OVERVIEW
• "Repeat breeding" (RB) is defined as a failure of conception fallowing three or more services or artificial inseminations in the absence of obvious abnormalities
• RB is associated with considerable economic loss due to decreased productivity, veterinary expenses, replacement cost, loss of genetic gain, semen cost, and involuntary culling.
• RB is a common complaint in dairy cattle and camelids.

INCIDENCE/PREVALENCE
Incidence varies from 5% to 20% and is affected by herd size, age of the cows, season, and production.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• RB is due to fertilization failure or embryonic death before maternal recognition of pregnancy.
• Fertilization failure may result from poor insemination protocol (e.g., heat detection inaccuracy, improper timing, handling or placement of semen). Semen factors (post-thaw quality and intrinsic fertility of the male) may play a role.
• Failure of fertilization or increased early embryonic death (EED) may be due to:
  ◦ Poor oocyte quality due to age, metabolic disorders, and heat stress
  ◦ Poor survival of the gametes or embryo due to poor uterine (i.e., endometritis) and endocrine environment (luteal insufficiency in high-producing cows).
• Derangement in synthesis of estrogen, progesterone, and luteinizing hormones is implicated in RB through impairment of oocyte competence and development.
• Failure of ovulation is a common cause of repeat breeding in camelids.

HISTORICAL FINDINGS
• Herd records show increased services per conception, increased calving interval, and increased interval from calving to conception.
• Increased rates of dystocia, postpartum disorders, metabolic disorders.
• High milk production.
• In individual females, history of infertility.

SIGNALMENT
Reproductively mature, parous females

PHYSICAL EXAMINATION FINDINGS
Most animals appear healthy.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Dystocia and postpartum disorders
• Metabolic disorders (negative energy balance)
• Heat stress
• Poor breeding management

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Rule Out Management/Human Factors
• History and analysis of conception rate by inseminator and method of heat detection
• Evaluation and retraining of inseminators

Rule Out Semen Factors
• Analysis of conception rate by bull and semen/tank batches
• Evaluation of semen tank management and semen handling
• Evaluation of a semen sample
• Breeding soundness evaluation of males if natural mating

Rule Out Fertilization Failure
Failure of fertilization may be due to:
• Defective oocytes: Estimated as a cause in 3–8% of RB. Aged oocytes may be implicated in repeat breeding of individual animals. In herd situations, poor oocyte quality is the result of poor timing of insemination (too late), heat stress, and negative energy balance.
• Oviductal anomalies: Estimated as a cause in 6–15% of RB. Bilateral congenital (segmental aplasia, hydrosalpinx) or acquired (salpingitis, pyosalpinx, perisalpingitis) conditions of the uterine tube or bursa (hydrobursitis, ovario-bursal adhesions) will interfere with gamete transport and prevent fertilization. Diagnosis requires detailed examination of the reproductive tract.
• Abnormalities of the uterus: The most common cause of fertilization failure is endometritis, which compromises sperm viability. Diagnosis of endometritis requires careful examination during estrus; uterine cytology and culture may help in diagnosis of endometritis. Immunologic reaction against semen may be a significant factor in some cases.
• Abnormalities of the cervix: Double cervix, cervical adhesion, double cervix or double external os of the cervix, cervicitis and pericervical adhesions/abscesses may be a cause of fertilization failure in individual cases but rarely as a herd problem. In some breeds (e.g., Santa Gertrudis), cervical morphology may be an important factor in poor conception rate. These disorders present as a difficulty to bypass the cervix and deposit semen into the uterus.
• Hormonal imbalances: Synchronization using MGA results in poor fertility of the induced heat. Improper timing or dosage of estrogens and GnRH used in some synchronization protocols. In dairy heifers, repeat breeding has been associated with prolonged duration of estrus, delayed LH peak, prolonged lifespan of preovulatory follicle, late postovulatory rise in plasma progesterone, and the tendency for suprabasal periovulatory progesterone levels. Recent studies have shown that hormonal imbalance may also affect expression of epidermal growth factors in the uterus, which are important for embryonic development.

Rule Out EED
• Females experiencing EED before embryo-uterine signaling (day 16 of the cycle in cattle, day 9 in camelids) will have a normal cycle length and would manifest as a repeat breeder syndrome.
• In dairy cattle, EED before day 16 is estimated at 40–50% of all conceptions.
• EED can result from poor quality embryos originating from poorly timed insemination (aged oocytes), heat stress, aging, poor oviductal or uterine environment due to inflammation or hormonal imbalances, and genetics.
• In dairy herds, one of the most important causes of EED is heat stress.

Infectious Disease
• Infectious diseases may be implicated in increased RB in a herd.
• Most of these agents predispose to RB due to inflammatory changes to the ovaries, ovarian bursa (viruses), and/or the uterus, cervix and vagina. These include *Brucella abortus, Mycobacterium tuberculosis,* BVDV, IBR, *Ureaplasma diversum, Mycoplasma bovigenitalium, Histophilus somni, Leptospira harjo bovis, Tritrichomonas foetus,* and *Campylobacter fetus* ssp. *Venerealis.*

CBC/BIOCHEMSTRY/URINALYSIS

PATHOLOGIC FINDINGS
Endometritis, cervicitis, salpingitis

TREATMENT

THERAPEUTIC APPROACH
• Treatment of RB focuses on improving environmental conditions and addressing deficiencies in heat detection and insemination procedures.
• Intrauterine administration of antimicrobials is used in cows suspected to have endometritis, but this treatment is not

R

REPEAT BREEDER MANAGEMENT (CONTINUED)

approved in some countries (e.g. United States).

SURGICAL CONSIDERATIONS AND TECHNIQUES
Unilateral ovariectomy in the case of uterine tube abnormalities

MEDICATIONS

DRUGS OF CHOICE
Depends on diagnosis

CONTRAINDICATIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Pregnancy may be achieved if predisposing factors are addressed. However, delayed conception may lead to decision for culling.
• Embryo collection and transfer may be considered in valuable animals.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCTION
• Work with the veterinarian to set up a herd health monitoring program.
• Consider appropriate methods to combat heat stress.
• Emphasize the importance of parturition management and postpartum protocols.

PRODUCTION MANAGEMENT
• Address human/management factors
  ◦ Improve heat detection efficiency and accuracy.
  ◦ Use fixed-time insemination.
  ◦ Periodic retraining of inseminators.
• Address female factors
  ◦ Cull cows with congenital or acquired nontreatable conditions.
  ◦ Determine causes of uterine infection and setup protocol for prevention (parturition management, retained placenta, nutrition, vaccination protocols).
  ◦ Early identification and treatment of uterine infection.
  ◦ Reduce ovulation failure/ovulation problems by the implementation of an ovulation synchronization protocol or systematic injections of GnRH at the time of insemination in RB cows.
  ◦ Improve embryo survival by administration of hCG or GnRH to create accessory corpora lutea and supplemental progesterone (CIDR) 6 days after insemination.
  ◦ Administration of 500 mg BST has been shown to improve embryo survival.
• Semen/Male factors
  ◦ Use semen from high fertility males.
  ◦ Use a double insemination regime.
  ◦ Use deep horn insemination (if technician is well trained).
  ◦ Perform breeding soundness evaluation on males.
  ◦ Use clean-up bulls only on cows that are known not to have an infectious cause of infertility.
• Address environmental factors
  ◦ Use cooling system during summer.
  ◦ Decrease incidence of uterine infection by improving calving conditions.
  ◦ Improve heat detection by addressing problems such as crowding and floor-surface issues.

REPRODUCTIVE PHARMACOLOGY

BASICS

OVERVIEW
• Reproductive pharmacology includes the indications for usage, dosage, and efficacy of different drugs in the treatment of reproductive disorders or for manipulation of reproductive functions.
• Reproductive disorders can be of inflammatory, infectious, or hormonal origin.
• Pharmacologic agents used to treat or prevent these problems include antimicrobials, antiseptics, hormones, and enzymes as well as other compounds.

INCIDENCE/PREVALENCE
Common

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Reproductive disorders may originate from inflammatory or infectious processes or endocrine dysfunction.
• The most common treatable inflammatory/infectious disorders in the female are endometritis and metritis. These disorders often result from contamination during parturition or breeding. In the male ruminant, the most common inflammatory disorder treated is seminal vesiculitis.
• Among the treatable hormonal disorders is cystic ovarian disease.

HISTORICAL FINDINGS
Depend on the condition treated

SIGNALMENT
• All ruminant species and camelids may be concerned. However, in production medicine, individual treatment of endometritis is often limited because of cost and regulations.
• In camelids, a wide variety of pharmacologic substances are used in countries which do not consider these species as food-producing animals.

PHYSICAL EXAMINATION FINDINGS
Depends on the condition treated

GENETICS

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH

Antimicrobials
• Antimicrobials are used for the treatment of reproductive infections and in outbreaks of specific bacterial abortion agents in small ruminants.
• Efficacy of antimicrobials depends on several factors:
  ◦ Sensitivity of the causative organism
  ◦ Achievable concentration (minimum inhibitory concentration) in the tissue or site of infection
  ◦ Physiologic properties of the target organ (lipid content, blood flow)
  ◦ Dose, route of administration, and duration of treatment.
• In ruminants, antimicrobials are primarily administered systemically whereas in camelids, systemic or intrauterine administration is often used.
• Regulations restrict the in utero use of antimicrobials in food-producing animals in some countries.
• Residues are found in milk following intrauterine administration of antimicrobials but there are no guidelines for withdrawal time determination.
• Intrauterine delivery of an antimicrobial is only effective if the uterus is small and the milieu is compatible with drug activity (pH, pKa, and lack of debris).
• The antibiotic carrier is very important, as some antibiotics are inactivated by saline solutions.

Systemic Antibiotic Therapy
• Systemic antibiotic therapy is used to treat uterine infections or as part of perioperative management (cesarean section, castration).
• In the face of bacterial abortion storms of small ruminants, systemic antibiotics are often used as a first line of defense.
• In males, systemic antibiotics are often used to treat reproductive tract infections (e.g., seminal vesiculitis), although efficacy of this treatment is often poor.
• Antimicrobial selection
  ◦ Legal use of an antibiotic is dictated by the FDA (or equivalent agency).
  ◦ Antimicrobial culture and sensitivity patterns are generally not performed in production animals, and most practitioners will select a drug based on the most common isolates.
  ◦ For treatment of seminal vesiculitis:
    ▪ Most antibiotics do not reach the glands at high concentration.
    ▪ Tulathromycin and tilmicosin have had success in treating some bulls infected with *T. pyogenes* and *H. somni*.

Intrauterine Antimicrobial Therapy
• Indicated for the treatment of endometritis.
• In cattle, penicillins and cephalosporins (e.g., ceftiofur) are the drugs of choice if culture is not possible. Tetracyclines are not recommended because of negative effects on sperm and the endometrium. Ozone infusions have been shown to have antimicrobial action. The volume of the infusion solution depends on the size of the uterus (25–100 mL).
• In camelids, treatment of endometritis should be preceded by culture and sensitivity. Uterine lavage prior to infusion is recommended to remove any inflammatory debris.
  ◦ Ceftiofur: 0.5 g/infusion
  ◦ Penicillin: 1×10^6–3×10^6 IU/infusion
  ◦ Oxytetracycline (povidone based): 0.5–1 g/infusion
  ◦ Ticarcillin: 0.5–3 g/infusion
  ◦ Infusions should be performed daily for 3–5 days. Indwelling catheters are highly discouraged.

Antiseptics
• Antiseptics have been used traditionally to treat uterine infections in cattle. These compounds, at higher concentrations, can result in uterine inflammation and intraluminal adhesions.
• Selection of an agent:
  ◦ Povidone iodine solution or foam:
    ▪ Cattle: 0.5%–2% solution
    ▪ Camelids: 0.1% solution
    ▪ Iodine is an irritant with bactericidal and fungicidal properties.
  ◦ Chlorhexidine solution: 1%–2% of the stock solution
  ◦ Hydrogen peroxide diluted in saline at a ratio of 1:4

Uterine Lavage
• Uterine lavage is commonly practiced following dystocia and in cases of metritis.
• Uterine lavage should only be performed when uterine wall integrity is maintained.
• Large quantities of warm fluids (tap water for bovine and ovine or lactated Ringer's solution for camelids and goats) are used until the efflux, collected by gravity, is clear.
• The addition of a small volume of povidone iodine solution may be helpful.
• Excessive uterine lavage may prolong involution and inhibit the immunologic function of the uterus.

Hormonal Therapy
Gonadotropin Releasing Hormone (GnRH)
GnRH is a decapeptide produced in the hypothalamus. It stimulates the release of

REPRODUCTIVE PHARMACOLOGY (CONTINUED)

FSH and LH. It is used for the induction of ovulation, induction of accessory corpora lutea in cattle, synchronization of ovulation, and treatment of follicular ovarian cysts (not all cysts are responsive to this treatment as some may lack receptors for LH).

Follicle Stimulating Hormone (FSH) and Equine Chorionic Gonadotropin (eCG)

- FSH is a glycoprotein secreted by the anterior lobe of the pituitary.
- eCG is a glycoprotein secreted by the endometrial cups of pregnant mares.
- Target tissues include granulosa cells of the ovary where it promotes follicular development, and Sertoli cells of the testis where it promotes Sertoli cell function and seminiferous tubule activity.
- In females these hormones are used for ovarian superstimulation or treatment of some forms of anestrus.

Luteinizing Hormone (LH) and Human Chorionic Gonadotropin (hCG)

- LH is a glycoprotein secreted by the gonadotropic cells of the anterior lobe of the pituitary.
- Human chorionic gonadotropin is a glycoprotein with LH activity secreted by the trophoblast of human blastocysts.
- Target tissues are the theca interna of the ovary, which when stimulated results in luteinization or ovulation, and Leydig cells of the testis, which when stimulated results in increased testosterone secretion.
- Indications:
  - In the female:
    - Induction of ovulation
    - Treatment of ovarian follicular cysts
    - Development of accessory corpora lutea. In cattle, hCG given 5 days after insemination will luteinize large follicle(s) to help maintain pregnancy.
  - In the male:
    - Increased testicular function (requires combination with FSH)
    - Diagnostic testing for cryptorchidism (hCG stimulation test).

$PGF2_\alpha$ and Analogs

- Prostaglandin $F2_\alpha$ ($PGF2_\alpha$) is a C-20 fatty acid which is derived from arachidonic acid. It is secreted by the endometrium. It has a very short half-life and is eliminated by the respiratory system. Target tissues include the corpus luteum and smooth muscle, particularly the myometrium (female) and epididymis (male) where it causes contractions. $PGF2_\alpha$ and analogs are most effective to induce luteolysis at least 5 days after ovulation.
- Indications:
  - Luteolysis as a treatment for:
    - Induction of abortion
    - Estrus synchronization
    - Endometritis
    - Pyometra
    - Mucometra/Hydrometra in goats
    - Induction of estrus following treatment for cystic ovarian disease
  - Elimination of fetal mummies
  - Induction of parturition (alone for camelids and goats or in combination with dexamethasone in cattle and sheep)

Oxytocin

- Oxytocin is an octapeptide synthesized by the hypothalamus and released by the posterior lobe of the pituitary.
- It is also synthesized by the corpus luteum of ruminants and potentiates the activity of $PGF2_\alpha$.
- Target tissues in the female include the myometrium and myoepithelial cells of the mammary gland.
- Indications and dosage:
  - To enhance uterine contraction
  - To promote placental detachment in the first 24 hours postpartum, after obstetric manipulation or cesarean section
  - Milk letdown

Progesterone and Progestagens

- Steroids produced by the corpus luteum and placenta.
- Target tissue: Hypothalamus, uterus, mammary gland.
- Several natural and synthetic progestagens are available for use as injectable or oral formulations, or as vaginal pessaries.
- Indications
  - Estrus synchronization
  - Maintenance of pregnancy in camelids with a history of recurrent pregnancy loss due to low progesterone
    - Can increase risk of failure of cervical dilation
    - Altrenogest is not orally bioavailable
  - Induction of lactation (use not approved in several countries)

Estrogens

- Steroids produced by granulosa cells, placenta.
- Target tissues: Hypothalamus, uterus, cervix and ovaries, mammary gland.
- Effects: Luteolysis, induction of estrus behavior, stimulation of ovulation, stimulation of cervical mucus production, induction of mammary gland development, induction of uterine contraction.
- Common preparations: Estradiol benzoate (EB), estradiol cypionate (ECP). Their use is not approved in food-producing animals in several countries.
- Indications: Estrogens are used in estrus synchronization programs in countries which allow them.

Testosterone

- Steroid produced by Leydig cells and theca cells.
- Target tissues: Accessory sex glands, seminiferous tubules, skeletal muscle.
- Effects: Development of male characteristics, male behavior, and anabolic growth.
- Indications:
  - For preparation of teaser animals (cows or steers):
    - Testosterone enanthate 500 mg IM + 1.5 g SC followed by 500–750 mg every 2 weeks.
    - Testosterone propionate 200 mg IM on day 1, 4–9; 1,000 mg IM on day 10, and every 10–14 days thereafter.
    - Wethers treated with lower doses of testosterone can be used for heat detection in sheep and goats.
  - For its anabolic steroid effect in feedlot animals.

Steroid Combination Implants

- These products are implants which contain androgens and estrogens (primarily synthetic) and are placed subcutaneously in the ear.
- These hormones increase rate of gain and feed efficiency in feedlot animals.
- Not approved in many countries.

Other Drugs Used in Reproductive Medicine

Anti-Inflammatory Agents

- Nonsteroidal anti-inflammatory drugs (NSAIDs):
  - Flunixin meglumine; Meloxicam

Ionophores

Decoquinate (2 mg/kg BW/day) or monensin (15–30 mg/animal/day) have been used for the prevention of abortion due to toxoplasmosis in sheep and goats.

Enzymes

- Collagenase administered directly into the umbilical arteries will result in faster detachment of placental membranes in cows.
- Its use may not be permitted in all countries.

Domperidone

May be used to treatment agalactia in camelids.

MEDICATIONS

DRUGS OF CHOICE

Antibiotics

- Penicillin or one of its synthetic analogs (20,000–30,000 IU/kg q12h): Active against most organisms that cause postpartum metritis.
- Ceftiofur (1–2 mg/kg q12h): Broad-spectrum antimicrobial action.
- Oxytetracycline: Not a good choice because minimal inhibitory concentration required for *T. pyogenes* is not reached in the uterine lumen.
- For the treatment of some bacterial abortion in small ruminants: Tetracycline can be used in the feed (200–300 mg/animal/day). Higher doses (300–500 mg) for leptospirosis infections. Long-acting tetracycline (20 mg/kg q48h). Tylosin (10 mg/kg IM daily for up to 5 days) can be used for tetracycline-resistant *Campylobacter* and *Chlamydophila* isolates.

Hormones

• GnRH IM or IV: Gonadorelin hydrochloride or gonadorelin diacetate tetrahydrate (natural GnRH, cattle and camels: 100 µg; sheep, goats, alpacas, and llamas: 50 µg); buserelin (synthetic GnRH with longer half-life, cattle and camels 8 µg, sheep, goats, alpacas, and llamas, 4 µg).
• eCG IM. Not approved for use in food animals in some countries. Animals may become refractory to eCG if it is used often. eCG is used generally in a single (long half-life) IM injection following a course of progesterone treatment.
  ◦ Ovarian superstimulation (cattle: 1,500–3,000 IU, sheep and goats 800–1,500 IU, alpacas and llamas: 750–1,000 IU, camels: 1,500–6,000 IU).
  ◦ Smaller doses are used in anestrous cows (500 IU) and out-of-season synchronization in small ruminants (250–500 IU).
• FSH (porcine and ovine FSH, IM) is most commonly used for ovarian superstimulation (see chapters, Embryo Transfer).
• hCG is administered IV and can cause anaphylaxis
  ◦ Cattle: 3,000–10,000 IU IV
  ◦ Sheep and goats: 500–1,000 IU IV
  ◦ Alpacas and llamas: 500–1,000 IU IV
  ◦ Camels: 1,000–1,500 IU IV
• $PGF2_{\alpha}$ IM, dinoprost tromethamine (cattle and camels: 25 mg, sheep 10 mg, goats 2.5 mg, alpacas and llamas: 5 mg) or cloprostenol (synthetic, cattle and camels: 500 µg, sheep: 125–250 µg, goats: 50–100 µg, alpacas and llamas: 250 µg).
• Oxytocin (IM or IV) (cattle: 20–40 IU; sheep and goats: 5–10 IU; alpacas and llamas: 5–10 IU; camels: 30 IU).

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
Dinoprost has been shown to cause respiratory distress in a few llamas.

REPRODUCTIVE PROLAPSE

BASICS

OVERVIEW
• A prolapse is a falling down or sinking of an anatomic structure from its normal position.
• Reproductive prolapses involve the uterus, cervix, and vagina in the female and the prepuce in the male. Uterine prolapse is covered separately; see chapter, Uterine Prolapse.

INCIDENCE/PREVALENCE
• Highly variable with calving management and genetic selection programs.
• Prepartum vaginal prolapse is relatively common in sheep (1–10% of ewes are affected in production flocks annually).

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Vaginal prolapse occurs commonly in the later part of the pregnancy and is often the result of a combination of processes including the physiologic relaxation of the tissues (pelvic ligament) supporting the vagina and factors increasing the abdominal pressure.
  ◦ In sheep, increased abdominal pressure can be due to presence of large multiple fetuses, tenesmus or straining due to other pathologic processes (lungworm, diarrhea), or obesity. In this species, a genetic component is suspected.
  ◦ In cattle, late term vaginal prolapse is observed in older, generally thin, large frame cows.
  ◦ In camelids, vaginal prolapse is observed in older females.
  ◦ In all species, prepartum or postpartum vaginal prolapse may also result from traumatic disruption of the perineal body and the vestibulovaginal sphincter following excessive, forceful obstetric assistance.
• Prolapse of the cervical folds into the cranial vagina is relatively common in multiparous cattle and is assumed to be secondary to calving trauma. In *Bos indicus* cows, this may progress to the point of cervical eversion through the vulva.
• Preputial prolapse in males is often secondary to trauma. Preputial prolapse in bulls should not be confused with the intermittent eversion of the prepuce commonly seen in polled bulls. Preputial prolapse is commonly seen in camelids that have the tendency to masturbate against objects or the ground.

HISTORICAL FINDINGS
Cases are reported by owner after observing the abnormality.

SIGNALMENT
• Sexually mature ruminants or camelids.
• Vaginal prolapse is most common in late gestation and occurs more frequently in cattle, camelids, and sheep.
• Preputial prolapse is common in bulls and camelids.

PHYSICAL EXAMINATION FINDINGS
• Prolapse of the vagina and prepuce are generally visually obvious.
• Local tissue irritation and pain may lead to straining.
• Some affected animals may strain to urinate.

GENETICS
• Vaginal prolapse is often hereditary in beef cattle and sheep, so a standard recommendation is to cull the affected animal after weaning and avoid using female offspring as replacements.
• Preputial prolapse is more common in *Bos indicus* cattle and their crosses (e.g., Santa Gertrudis).

CAUSES AND RISK FACTORS
• Vaginal prolapse should be assumed to be a hereditary defect in beef cattle unless another cause can be established. Trauma and repeated superovulation treatment can also cause the condition.
• The hormonal milieu and abdominal fill of late gestation predispose to prolapse of the vagina.
• Excessive body condition can also predispose to vaginal prolapse.
• In dairy cattle, postpartum vaginal prolapse often occurs secondary to premature or excessive obstetric interventions, especially in heifers.
• Breeding injuries to the prepuce (e.g., preputial laceration) or penis (e.g., penile hematoma) can result in prolapse of the prepuce.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Eversion of the bladder
• Retained placenta
• Tumors

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Ultrasonography can assist with locating the bladder or diagnosis of abscessation in chronic cases.

OTHER DIAGNOSTIC PROCEDURES
• Visual inspection and manual palpation are usually sufficient to make the diagnosis.
• Vaginal prolapse can be graded as to severity.
  ◦ Grade 1: Intermittent protrusion of vaginal tissue during recumbency
  ◦ Grade 2: Continuous prolapse of vaginal tissue
  ◦ Grade 3: Continuous prolapse of the vagina, cervix, and bladder
  ◦ Grade 4: A chronic case resulting in tissue compromise that will result in fetal death and possibly peritonitis.

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• See "Surgical Considerations and Techniques"

SURGICAL CONSIDERATIONS AND TECHNIQUES
Vaginal Prolapse
• Treatment of vaginal prolapse depends on the value of the animal, the stage of gestation, and the severity of the condition. An epidural anesthetic is administered before beginning. The prolapsed tissue is cleaned and replaced and the bladder emptied.
• In cattle, options for retaining the tissue include:
  ◦ A Caslick's suture may suffice for grade 1 prolapse if no straining occurs. This is often the case with postpartum vaginal prolapse due to calving trauma, as frequently observed in Holstein dairy cattle.
  ◦ A Buhner suture is an effective treatment for more severe grades but must be closely monitored to allow timely removal before delivery. Variations on this purse-string approach include a bootlace technique and placement of horizontal mattress sutures across the vulvar opening. With the Buhner and horizontal mattress sutures, leave about a 3 cm opening (access for two fingers) ventrally to allow for urination.
  ◦ More complicated surgical options that allow for unobserved calving include the Minchev vaginopexy and the Winkler cervicopexy.
• In the ewe, especially if many animals are affected, a commercially available retaining device can be used. The device is tied to the body to maintain the vagina in place.
• In camels, options similar to those used in cattle are appropriate for camels. In SAC, a bootlace technique is preferable.

Preputial Prolapse
• The primary objective of treatment for preputial prolapse is to replace the swollen tissue and avoid surgery. The prolapsed tissue is cleaned and covered with a lubricating ointment.
• In bulls, a drainage tube is placed into the preputial cavity to allow urine to drain. The exposed tissue is covered with a stockinette and then bandaged from the distal end with an elastic tape that is applied with enough tension to reduce the swelling. The tape encircles the prepuce and is anchored to the

hair of the skin at the preputial opening. The bandage is changed as needed, usually daily or every other day, until the prepuce can be returned to the preputial cavity. A sling may be needed if the sheath is especially pendulous. The sling should be of porous material so that urine is not trapped. Once the prepuce is in place, it should be held in place with another bandage, changed as before and continued until it remains in place. Allow at least 60 days of sexual rest and then evaluate for normal penile erection and extension.
• In camelids, the prolapsed tissue is cleaned and covered with a lubricating ointment, replaced within the prepuce, and held in place with a purse-string suture on the preputial orifice. An antibiotic ointment is applied daily into the prepuce. Sutures are removed after 7–10 days.

MEDICATIONS

DRUGS OF CHOICE
• Systemic, broad-spectrum antibiotic therapy is indicated for chronic cases or when cellulitis is suspected.
• Flunixin meglumine or meloxicam can be used to reduce inflammation and for pain relief.

CONTRAINDICATIONS
Appropriate meat and milk withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Vaginal prolapse: Good prognosis for fetal survival after normal delivery if detected and managed early, poor otherwise.
• Preputial prolapse: Guarded prognosis for normal fertility in cases where surgical treatment is necessary.
• In camelids, if the male returns to masturbation against objects, preputial prolapse will recur with increased severity of tissue damage and adhesion formation and a poor prognosis.

POSSIBLE COMPLICATIONS
• Cellulitis, abscessation, and scarring with phimosis may occur after preputial prolapse.
• Abortion, dystocia, and peritonitis may complicate cases of chronic vaginal prolapse. In postpartum cattle, chronic vaginal prolapse may cause infertility.

CLIENT EDUCATION
Cull females with recurrent vaginal prolapse.

PATIENT CARE
• Vaginal prolapse: Frequent monitoring is required for the remainder of gestation in pregnant animals to assure normal delivery.
• Preputial prolapse: Daily monitoring is required during treatment to assure urine passage and absence of straining.

PREVENTION
• Sound genetic selection program for herd or flock replacements.
• Avoid unnecessary, premature, or excessive obstetric assistance.
• Select bulls with good sheath conformation.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Penile hematoma
• Preputial laceration

REPRODUCTIVE TUMORS

BASICS

OVERVIEW
Tumors can arise in several locations of the female and male reproductive tract. In females, the ovary, uterus, cervix, vagina, and vulva can be affected. In the male, the testis and penis are the most common locations. Clinical signs are dependent on the tumor type, location, severity, and possible metastasis.

PATHOPHYSIOLOGY
• Tumors of the reproductive tract are highly variable in nature, depending on the tissue of origin, chronicity, malignancy, and location. In some cases, neoplasia of other tissues can metastasize to the reproductive tract.
• Females with ovarian tumors may present for infertility, anestrus, nymphomania, or male-like behavior, depending on the hormonal output of the tumor.
• Females with uterine, cervical, vaginal, or vulvar tumors may present for observation of a mass on examination or transrectal palpation, hemorrhagic discharge from the vulva, or abnormalities identified during artificial insemination.
• Reproductive tract tumors may have a metastatic component, depending on the tissue of origin and malignancy. Affected animals should be examined for metastasis to the lungs, liver, and kidneys. Metastasis may result in chronic weight loss, respiratory dysfunction, and dysuria.
• Males with testicular tumors may present for nonpainful, chronic enlargement of the scrotum.
• Males with penile tumors may have reduced libido, lower pregnancy rates in co-mingled females, and observation of hemorrhagic discharge from the prepuce.

R

SYSTEMS AFFECTED
Reproductive

GENETICS
N/A

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
Worldwide

HISTORICAL FINDINGS
• In females, the history may include irregular estrous cycles, including persistent estrus or anestrus, male-like behavior, and a history of infertility. Vaginal discharge may be a complaint.
• In males, the history may include progressive enlargement of the scrotum, or discharge from the penis or prepuce. Decreased libido may also be reported.

SIGNALMENT
• Cows, sheep, goats, camelids.
• Although tumors are most often recognized in adult breeding animals, granulosa-theca cell tumors (GTCT) have been diagnosed in calves and nulliparous heifers.

PHYSICAL EXAMINATION FINDINGS
• Reproductive tumors in the female should be suspected if any or a combination of the following are observed:
  ◦ Abnormal or palpable masses in or around the ovaries, uterus, or cervix
  ◦ Hemorrhagic vaginal discharge
  ◦ Irregular estrus cycles (including anestrus, nymphomania, or male-like behavior)
  ◦ Mammary gland development and lactation in nonpregnant young animals
  ◦ Stranguria, dysuria, straining
  ◦ Abnormal ultrasonographic appearance of the ovaries, uterus, or cervix
  ◦ History of infertility
• Reproductive tumors in the male should be suspected if any or a combination of the following are observed:
  ◦ Deterioration of semen quality in the absence of detectable inflammatory, traumatic, degenerative, or environmental causes
  ◦ Chronic progressive, nonpainful enlargement of the testis
  ◦ Hemorrhagic discharge from the penis
  ◦ Observation of proliferative lesions on the penis
• The general physical examination may reveal nonspecific signs such as weight loss, vaginal or preputial discharge, or behavior changes.
• Specific examination should include palpation per rectum in large species, or palpation/ballottement of the abdomen or scrotum. Ultrasonography should be performed on any suspicious masses.
• The animal should be examined for metastasis, which can include imaging of the lung fields and liver.

CAUSES AND RISK FACTORS
Specific Tumor Types in Females
• Ovary
  ◦ Ovarian tumors are classified as epithelial, germ cell, sex cord, or mesenchymal in origin.
  ◦ Epithelial tumors
    ▪ Includes papillary adenoma or carcinoma, cystadenoma, cystadenocarcinoma, and adenocarcinoma.
    ▪ Papillary adenoma or adenocarcinoma are very rare and arise from the surface epithelium, subsurface epithelial structures, or rete ovarii.
    ▪ Cystadenomas, large single-cavity cystic structures, arise from the epoophoron and/or rete ovarii.
    ▪ A cystadenocarcinoma was reported in a cow, with metastasis to the peritoneum and iliac lymph nodes, kidney, and other organs.
    ▪ Adenocanthoma, carcinoma with squamous metaplasia, has been reported in a cow.
  ◦ Germ cell tumors
    ▪ Dysgerminoma has been reported in the cow as a firm, spherical, red-gray mass, 15 cm in size, which can metastasize. Hyperplasia of the endometrium can occur secondary to hyperestrogenism.
    ▪ Teratomas arise from all three germinal layers, with tissue representing any organ except ovary or testis. Teratomas of different sizes and content (cartilage, hair, bone, teeth, etc.) have been reported in sheep, cows, goats, and camelids.
    ▪ Dermoid cysts, or cystic ovarian teratomas, have been reported in Zebu cattle and water buffalo and vary in size and weight from 5.7 to 45 kg. Metastasis has been reported.
  ◦ Sex cord tumors
    ▪ GTCT dominate this category of tumor. Others include thecoma (theca cell tumor, a firm white/yellow/orange tumor), and luteoma (an interstitial cell tumor which is smooth, slightly lobulated, orange, and produces progesterone).
    ▪ GTCT can result in anestrus, nymphomania, or male-like behavior and development of male secondary sex characteristics (particularly of the head and neck). Mammary enlargement may be observed.
    ▪ GTCT have been reported in cows, sheep, goats, and camelids. They can occur in adults as well as newborn or prepubertal females.
    ▪ Typically the affected ovary is enlarged and the contralateral ovary small and inactive, due to effects of inhibin produced by the tumor. The tumor is generally benign.
    ▪ Serum endocrinology typically shows high anti-mullerian hormone, testosterone, estrogen, and inhibin.
  ◦ Mesenchymal tumors: This category includes hemangioma, leiomyoma, fibroma, and lymphoma (lymphosarcoma).
• Uterus
  ◦ Epithelial tumors
    ▪ Adenoma: Polyps of the endometrium are considered hyperplastic and rare.
    ▪ Adenocarcinomas have been reported in cows, goats, sheep, and camelids. Clinical signs include infertility, bloody vaginal discharge, palpable mass(es), depression, respiratory disease, and stranguria. Metastasis to the lungs, peritoneum, lymph nodes, and other organs can occur. Lesions from the endometrium may invade the myometrium.
  ◦ Mesenchymal tumors
    ▪ Fibromas are rare, hard, white, spherical tumors of the uterine wall.
    ▪ Fibrosarcomas are very rare.

▪ Leiomyomas are benign, firm, tan, nodular tumors which generally affect the myometrium.
▪ Leiomyosarcomas are very rare.
▪ Uterine lymphosarcoma is common in cattle, associated with infection with bovine leukosis virus. Masses may be multiple, irregular shaped, and soft.

- Cervix
  - Cervical neoplasia is typically epithelial in origin, including adenocarcinoma and squamous cell carcinoma.
  - Cervical adenocarcinomas are relatively common in older goats and should be differentiated from cervical hyperplasia. Metastasis of adenocarcinoma is possible.
  - Mesenchymal tumors such as leiomyomas are typically associated with the uterus or vagina.
- Vagina and vulva
  - Papillomas and squamous cell carcinomas have been reported in cows, sheep, and goats.
  - Risk factors for squamous cell carcinoma include surgical resection of perineal skin folds to reduce myiasis, tail-docking of ewes, and pink vulvas of certain breeds.
  - Lesions may become ulcerated, necrotic, and covered by exudate and blood.
  - Fibropapillomas are firm, elevated, white or pink masses, smooth or cauliflower-like in texture, and are transmissible tumors in heifers.

Specific Tumor Types in Males

- Testes
  - The most common neoplasia of the testis is seminoma, followed by sustentacular cell tumors (Sertoli cell tumor, tubular adenoma, tubular adenocarcinoma), and interstitial cell tumors (Leydig cell tumors).
  - Seminomas have been reported in male cattle, sheep, goats, and camelids. The affected testis is usually enlarged, with variable effects on semen quality.
  - Sertoli cell tumors have been reported in bulls and rams, and an intersex goat. The affected testis is usually enlarged, with normal or decreased semen quality. The tumor is pale gray and firm with an irregular surface when sectioned.
  - Leydig cell tumors are often characterized by poor semen quality, large ejaculate volume with low motility, and low concentration of spermatozoa.
  - All testicular tumors are treated by hemilateral castration of the affected testis. Semen quality should be monitored postoperatively. The animal should be examined for metastasis.
- Penis
  - The most common penile tumor is the fibropapilloma, a result of the fibropapilloma virus. It is most often diagnosed in young bulls.
  - Treatment is by surgical excision.
  - The tumor can be prevented by use of autovaccines.

DIAGNOSIS

- Diagnosis in the female with suspected neoplasia is based on:
  - Transrectal (cow) or transabdominal (sheep and goat) palpation and ultrasonography of an enlarged ovary, uterus, or cervix. Transrectal ultrasonography may be performed in small ruminants and camelids with the transducer mounted on an extension rod.
  - Biopsy or *en bloc* excision of the mass via laparoscopy (sheep, goats, camelids) or laparotomy (cows). A fine needle aspirate may be performed for vaginal or vulvar masses.
  - Serum endocrinology: Elevations of anti-mullerian hormone are diagnostic for GTCT. Sex steroid hormones and inhibin are often assessed in conjunction.
- Diagnosis in the male with suspected neoplasia is based on:
  - Semen evaluation
  - Testicular measurements, palpation, and ultrasonography
  - Testicular biopsy (may be ultrasound-guided)
  - Exteriorization and examination of the penis

DIFFERENTIAL DIAGNOSES

- For females:
  - Other causes of ovarian enlargement (adhesions, large cysts)
  - Other causes of uterine masses (uteroperitoneal adhesions, mummified or macerated fetus, tuberculosis)
  - Other causes of cervical masses (cervicitis, abnormal cervical conformation, double cervix)
- For males:
  - Other causes of scrotal or testicular enlargement (testicular hematoma, abscess, orchitis, inguinal hernia)
  - Other causes of preputial hemorrhage or phimosis (preputial or penile laceration, preputial abscess or adhesions)

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

Assay of serum anti-mullerian hormone concentrations can aid in the diagnosis of GTCT preoperatively.

IMAGING

- Ultrasonography is invaluable in the diagnostic evaluation of reproductive tract neoplasia. Transrectal and transabdominal ultrasonography can be performed in females, and ultrasonography of the scrotal contents in males.
- Radiography of the lungs can be useful in the diagnosis of metastasis.

OTHER DIAGNOSTIC PROCEDURES

- Biopsy of the mass is often performed to obtain a diagnosis prior to surgical excision; however, it is not required. Often the mass (or ovary or testis) is excised *en bloc* and submitted for histopathology.
- Penile fibropapillomas can be submitted for histopathology after removal.

PATHOLOGIC FIDINGS

On histopathology, each tumor type will demonstrate specific findings.

TREATMENT

THERAPEUTIC APPROACH

Animals which undergo surgical treatment should be treated with appropriate antibiotics, anti-inflammatories, and tetanus toxoid. Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

SURGICAL CONSIDERATIONS AND TECHNIQUES

- In females, ovarian neoplasms are treated by ovariectomy. Ovariectomy is performed using a standing paralumbar flank approach in cattle and camels. In small ruminants and camelids a midline laparotomy or laparoscopy-assisted approach is preferred.
- Uterine and cervical masses require hysterectomy or partial hysterectomy. These techniques may be considered for companion goats or SAC. A midline laparotomy approach under general anesthesia is the best approach.
- Vulvar masses may be excised.
- In males, testicular neoplasms are treated by orchiectomy. Penile fibropapillomas are surgically excised, often with electrocautery.
- Animals submitted for surgery have the usual postoperative considerations of infection, incisional dehiscence, hemorrhage, and seroma formation.
- Surgical treatment may not be appropriate for animals with metastasis, or metastasis may need to be addressed after removal of the primary tumor.

MEDICATIONS

DRUGS OF CHOICE

- Depends on the surgical approach selected.
- General anesthesia is required for ovariectomy, hysterectomy, and ovariohysterectomy in small ruminants and camelids. Induction with xylazine, butorphanol, and ketamine is followed by maintenance with isoflurane in oxygen.

REPRODUCTIVE TUMORS (CONTINUED)

• Paralumbar flank approach for ovariectomy in cattle and camels: Sedation, paralumbar or inverted "L" block.
• Hemicastration in breeding bulls can be performed under heavy sedation.
• Hemicastration in small ruminants and camelids should be performed under general anesthesia.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Highly dependent on the tumor type, location, malignancy, progression of disease, and metastasis.
• Breeding males can retain good fertility if no complications occur after unilateral castration of the affected testicle.
• Prognosis for fertility is fair to good after unilateral ovariectomy.

POSSIBLE COMPLICATIONS
• Metastasis to lungs, liver, and other organs is possible, particularly in cases of adenocarcinomas.
• Mastitis in subsequent pregnancies may be a complication of GTCT in young animals with premature udder development.
• Surgical complications for ovariectomy and ovariohysterectomy: Adhesions, peritonitis (infertility and recurrent pregnancy loss for unilateral ovariectomy).
• Surgical complications after castration: Hemorrhage, infertility in cases of hemicastration (compromise of spermatogenesis in the remaining testicle due to inflammation).

CLIENT EDUCATION
• Emphasize regular breeding soundness examinations in valuable breeding males.
• Seek veterinary consultation if behavioral abnormalities are observed.

PATIENT CARE
• Patients should be monitored for any surgical complication in the immediate period following surgery.
• Animals should be monitored for evidence of metastasis or recurrence of the tumor, particular at the vulva if excision was elected.
• Animals which undergo surgical treatment should be fasted appropriately prior to anesthesia to prevent regurgitation and aspiration as well as to reduce intestinal contents to increase visibility and handling of the ovaries and/or uterus, in females.

PREVENTION

RESPIRATORY DISEASE: BOVINE

BASICS

OVERVIEW
• Bovine respiratory disease (BRD) or the BRD complex refers to the general development of respiratory disease in cattle. BRD most commonly occurs in weaned beef cattle as they move through the production cycle from weaned calves to the feedlot.
• BRD can also affect adult dairy animals with vaccine failure, immunosuppression caused by a primary microbial infection, transition from dry to lactation status, or transport.
• BRD is commonly called "shipping fever," or in preweaned calves, enzootic calf pneumonia.
• The etiology of BRD is often multifactorial, and may include viruses, bacteria, parasites, nutrition, environmental stressors, and host susceptibility. Many bacterial pathogens isolated from the lower airway are normal flora of the upper respiratory tract. The severity of BRD outbreaks is often influenced by the relative combination of these factors, and timing of disease is most often associated with transport.

INCIDENCE/PREVALENCE
BRD is the most prevalent and economically significant disease of the beef industry.

GEOGRAPHIC DISTRIBUTION
Worldwide; distribution influenced by management systems

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
Stress (immunosuppression) + viral or *Mycoplasma bovis* infection + bacterial overgrowth = BRD (Figure 1).

HISTORICAL FINDINGS
Clinical signs become apparent 6–10 days after cattle are stressed or exposed to new animals.

SIGNALMENT
Younger animals under stressful conditions are most at risk.

PHYSICAL EXAMINATION FINDINGS
• Fever.
• Reduced appetite.
• Mild depression and separation from herd mates.
• Lowered head, drooped ears, and oculonasal discharge.
• Inducible or spontaneous cough.
• Reluctance to rise, exercise intolerance.
• Severely affected cattle may have dyspnea, extend the head and neck, and protrude the tongue.
• Thoracic auscultation may identify moist or dry crackles and harsh bronchovesicular sounds in the cranioventral thorax.

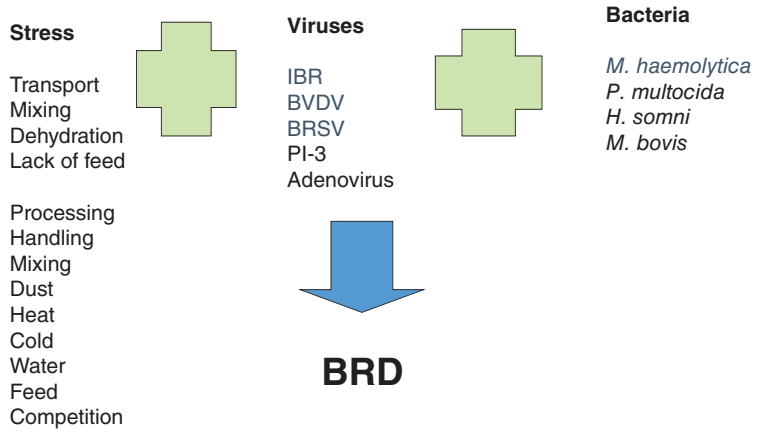

Figure 1.

Bovine Respiratory Disease is Multifactorial

• Consolidated areas of lung associated with bronchopneumonia (or large abscesses) are silent due to lack of air motion.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Viruses commonly incriminated in BRD include BHV-1, BVDV, BRSV, parainfluenza-3, BRCV, and adenoviruses.
• Bacteria commonly involved in BRD include *Mannheimia, Pasteurella multocida, M. bovis, Histophilus somni, Bibersteinia trehalosi,* and *Trueperella pyogenes*.
• Environmental stressors increase the risk of BRD and include poor sanitation, poor ventilation, and overcrowding.
• Weaning, transport, co-mingling of cattle from multiple sources and other stressors.
• Lack of preconditioning (vaccination, dehorning, castration, deworming) of animals prior to movement.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Interstitial pneumonia
• Aspiration pneumonia
• Pulmonary edema
• Pulmonary fibrosis
• Verminous pneumonia

CBC/BIOCHEMISTRY/URINALYSIS
• CBC may indicate acute and/or chronic inflammation with neutrophilia and hyperfibrinogenemia.
• Biochemistry may indicate chronic inflammation with hyperglobulinemia and hypoalbuminemia, and systemic illness with azotemia and electrolyte anomalies.

OTHER LABORATORY TESTS
Culture and antimicrobial sensitivity or PCR can be performed on nasopharyngeal swabs, lung tissue, transtracheal aspirate, or bronchoalveolar lavage fluid.

IMAGING
• Ultrasonography permits visualization of pulmonary consolidation and can be performed with a 5.5 MHz linear rectal probe with standard scoring systems available.
• Radiography is useful to define the extent and distribution of disease in valuable animals.

OTHER DIAGNOSTIC PROCEDURES
• Clinical scoring systems for respiratory disease are popular but accuracy relies on consistent and trained personnel. Automated systems have been assessed to identify affected cattle, but human observation remains the most sensitive detection method.
• Bacterial culture of nasal swabs are not diagnostic for several BRD bacterial pathogens that are normal flora of the upper respiratory tract, but can determine antimicrobial sensitivity patterns and the presence of *Mycoplasma* spp.
• PCR for bacterial pathogens may be helpful to identify presence of *Mannheimia* and *Histophilus*, which can be difficult to culture and are easily overgrown by other bacteria such as *Pasteurella*.
• Bacterial culture and/or PCR of transtracheal wash and bronchoalveolar lavage fluid can definitively identify pathogens.
• Necropsy provides useful information regarding etiologic agents and pathologic processes. Perform necropsy early in the course of the disease and prior to antibiotic therapy for the best results.

PATHOLOGIC FINDINGS
• Gross lesions depend on pathologic agents and chronicity.
• Necrotizing lesions of the upper respiratory tract and trachea most commonly represent viral pathogens.
• *M. bovis* associated otitis and otitis media are common with purulent debris in the

RESPIRATORY DISEASE: BOVINE (CONTINUED)

external ear canal, fluid or purulent material in the tympanic bullae, and bony changes in the walls of the bullae.
• Pneumonic lesions are typically bilateral and cranioventral, often with a sharp line of demarcation between normal and abnormal, consolidated lung.
• Varying degrees of pleural adhesion between lung lobes and to the chest wall.
• Diseased lung parenchyma typically has a lobulated pattern that imparts a marbled appearance on both the pleural and cut surface.
• Affected parenchyma is firm and ranges in color (pink, tan, red, red-black) depending on the amount of necrosis.
• Necrotic tissue may progress to abscessation.
• Histology is consistent with consolidating bronchopneumonia due to secondary bacterial pathogens. Samples submitted from cattle early in the disease process may show interstitial changes.

TREATMENT

THERAPEUTIC APPROACH
• Antimicrobials should be selected for efficacy against common BRD bacteria, and should provide coverage for a minimum of 7–10 days.
• Supportive care for individual animals may include NSAIDs, nutritional support, and fluid therapy.
• Moving sick cattle to separate pens reduces the stress of competing for food with healthy cattle.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Common classes of antibiotics used in BRD include beta-lactams, tetracyclines, macrolides, and fluoroquinolones.
• Ancillary treatments such as NSAIDs, corticosteroids, antihistamines, and vitamin injections may be of value on an individual basis.

CONTRAINDICATIONS
Some antibiotics with a respiratory disease label are illegal for use off-label. AMDUCA does not apply in these cases.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Some macrolide antibiotics are cardiotoxic to humans if injected by mistake. Read the label for precautionary warnings.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Prognosis is generally favorable if intervention occurs early and the selection and time course of antimicrobial therapy is appropriate.
• If intervention is started early, most cattle respond to treatment in 24–72 hours but require extended antimicrobial coverage to decrease risk of treatment failure and recrudescence of clinical signs.
• Failure to respond to multiple treatments or development of complications generally indicates advanced disease and the prognosis is then guarded.
• Weight gain is associated with a good prognosis; continued weight loss is a poor sign.

POSSIBLE COMPLICATIONS
• Pericarditis
• Endocarditis
• Pleuritis
• Peripheral vestibular disease (*M. bovis* associated otitis media)
• Polyarthritis (*M. bovis* and *H. somni* pneumonia)
• Thromboembolic meningoencephalitis (TEME) and endocarditis can occur with *H. somni* pneumonia.

CLIENT EDUCATION
Management factors play a key role in influencing respiratory disease.

PATIENT CARE
• Daily observation of attitude and appetite will provide a good indication of treatment success. Available clinical scoring schemes aid in daily monitoring.
• Reduction of rectal temperature in 24–48 hours post-treatment suggests a good prognosis.
• Development of head tilt or ear droop is a negative prognostic indicator.

PREVENTION
• Ensure successful passive transfer of maternally derived antibodies via colostrum.
• Parenteral immunization against common BRD pathogens at 4–6 weeks prior to movement or stressful events.
• Intranasal immunization 2 weeks prior to movement or stressful change.
• Preconditioning (dehorning, deworming, castration) 2–4 weeks prior to movement or stressful change.
• Minimizing stressful events, e.g., direct sale of cattle to avoid sale barns and co-mingling from multiple sourced animals.
• Maintaining well-ventilated and sanitary environments with plenty of bunk space and water availability.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Arthritis
• Pericarditis
• Meningoencephalitis
• Otitis

AGE-RELATED FACTORS
Weaned calves are at high risk due to waning maternal antibodies and stress from weaning and transport for sale.

ZOONOTIC POTENTIAL
N/A

PREGNANCY

RESPIRATORY DISEASE: CAMELID

BASICS

OVERVIEW
• Respiratory disease in camelids most commonly reflects upper airway disorders, primary lung disease, or diaphragmatic paralysis.
• Diagnostic evaluation can be challenging, since llamas and alpacas may display subtle clinical signs despite progressive or severe respiratory disease.

INCIDENCE/PREVALENCE
Typically sporadic unless a contagious disorder is involved.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• Upper airway dysfunction can arise from choanal atresia in which failure in embryologic development of the nasopharyngeal opening creates unilateral or bilateral, membranous or osseous, and complete or partial obstruction of nasal air flow in species that are obligate nasal breathers. Allergic rhinitis, nasopharyngeal feed impaction, neoplasia, sinusitis, and *Oestris ovis* infestation can cause upper airway disease in older animals.
• Lower airway disease can arise from infectious broncho- or pleuropneumonia, aspiration of medication, feed, or milk (neonates), and from neoplasia. Hematogenous pulmonary infection can occur in association with bacterial sepsis in neonatal crias (*E. coli*, *Enterococcus* spp., *Listeria monocytogenes*, and *Citrobacter* spp.). Secondary suppurative bronchopneumonia is documented in persistently BVDV infected crias.
• The etiologic diagnosis of diaphragmatic paralysis is unknown; genetic, metabolic (oxidative stress), infectious (aberrant parasite migration, EHV-1), traumatic, nutritional (vitamin E deficiency), and toxicologic causes have been proposed.

HISTORICAL FINDINGS
Dependent on the underlying etiology. While viral infections can present as a herd concern, neoplastic, fungal, and protozoal disease will generally affect individual animals.

SIGNALMENT
Choanal atresia is usually reported in crias with respiratory distress since birth.

PHYSICAL EXAMINATION FINDINGS
• Tachypnea, increased respiratory effort, open-mouth breathing, nostril flare, and asynchronous breathing may occur.
• Thoraco-abdominal asynchrony most commonly accompanies upper airway obstruction, phrenic nerve dysfunction, diaphragmatic or intercostal muscle paralysis, and diaphragmatic fatigue due to chronic airway disease.
• Changes in respiratory characteristics may also reflect nonrespiratory disorders including metabolic derangements (e.g., severe acidosis), pain, abdominal crisis, fever, high environmental temperatures, and excitement. Clinical signs of pulmonary disease can be nonspecific and difficult to differentiate by physical examination alone in camelids.
• Complete choanal atresia often presents with congenital respiratory distress and lack of air flow through the nares, while partial choanal atresia can be difficult to diagnose due to subtle or absent clinical signs.

GENETICS
Choanal atresia is considered a heritable disorder with a complex mode of inheritance.

CAUSES AND RISK FACTORS
• Bacterial pneumonia: Tuberculosis, nocardiosis, *Rhodococcus equi*-associated lymphadenitis
• Viral pneumonia: Coronavirus, adenovirus-associated pneumonia, bovine herpesvirus type 1, enterovirus
• Pulmonary neoplasia: Adenocarcinoma, squamous cell carcinoma, lymphosarcoma
• Fungal pneumonia: Pulmonary aspergillosis, pulmonary histoplasmosis, coccidioidomycosis, cryptococcosis
• Protozoal pneumonia: *Pneumocystis jiroveci*
• Pleuritis: *S. zooepidemicus,* penetrating thoracic wounds
• Lipoid pneumonia (endogenous or from oil aspiration)
• Diaphragmatic paralysis
• Risk factors include exposure to environmental pathogens, temperature extremes, poor ventilation, dust, overcrowding, stress, and transportation. Dysphagia can relate to structural abnormalities of the upper airways (cleft palate, malformation, cyst, or mass), central nervous system or cranial nerve disorders, and marked laryngeal inflammation.
• Risk factors specifically for crias include dystocia (meconium aspiration), failure of passive transfer (leads to lack of specific antibody protection as well as impaired neutrophilic function in neonates), prematurity or immaturity (lung immaturity, immature immune system), and neonatal weakness (neonatal encephalopathy, sepsis, vitamin E or selenium deficiency).
• Iatrogenic risk factors include bottle feeding in the absence of a strong suckle reflex, and administration of mineral oil, rumen fluid, or medications.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Nonpulmonary causes of altered respiratory function include anemia, hypovolemia, cardiac disease, acidosis, hypoglycemia, botulism, nutritional myodegeneration, pain, fever, hyperthermia, and birth asphyxia.
• Developmental or noninfectious respiratory diseases in neonates include respiratory distress syndrome (hyaline membrane disease), diaphragmatic hernia, pulmonary hypoplasia, and persistent pulmonary hypertension.
• Differentials related to trauma include pneumothorax, rib fracture, and traumatic airway obstruction.

CBC/BIOCHEMISTRY/URINALYSIS
• Complete blood count changes include neutrophilic leukocytosis and hyperfibrinogenemia in bacterial infections.
• Neutropenia is often observed in neonatal crias with sepsis and in patients with viral diseases.
• Significant lymphopenia may be found in acute viral diseases, and in sepsis.

OTHER LABORATORY TESTS
• Arterial blood gas (ABG) analysis: Samples are best obtained from the medial saphenous artery (medial hindlimb above the stifle). The following ABG results (mean ± 95% confidence interval) have been documented in 14 healthy adult, male and nonpregnant female alpacas (mean age and weight: 4.5 years; 62 kg) and in 12 healthy neonatal alpaca crias (2–7 days old, 7.8 kg mean weight):
  ◦ pH = 7.47 (7.46–7.48)
  ◦ Bicarbonate (mEq/L) = 20.4 (19.6–21.3)
  ◦ PaO_2 (mmHg, adults) = 104.6 (100.7–108.4)
  ◦ Neonatal PaO_2 = 92 (87.7–96.4)
  ◦ $PaCO_2$ (mmHg, adults) = 27.7 (26.4–28.9)
  ◦ Neonatal $PaCO_2$ = 30.5 (27.2–33.8)
• Pleural fluid analysis: The preferred site of pleurocentesis is the 6th or 7th intercostal space, 10–15 cm dorsal to the midline ventrum or 2–4 cm dorsal to the costochondral junction of the ribs. The reported total nucleated cell count of pleural

RESPIRATORY DISEASE: CAMELID (CONTINUED)

fluid from 17 healthy llamas was in the range of 200–1500 cells/μL (mean: 576 ± 361 cells/μL); with small lymphocyte, mononuclear cell, and neutrophil percentages representing 80–100%, 0–20%, and 0–10% of cells, respectively. Pleural fluid total protein concentrations were in the range <2.5–3.5 g/dL.
• Transtracheal aspirate fluid in clinically healthy adult llamas contained primarily vacuolated macrophages (60–100%), with 0–40% neutrophils, and fewer lymphocytes (0–2%), eosinophils (0–3%), and ciliated respiratory epithelial cells (0–10%).
• Bronchoalveolar lavage fluid from healthy alpacas contained 59 ± 12% alveolar macrophages, 31 ± 14% lymphocytes, 11 ± 9% neutrophils, 0% mast cells, and several ciliated epithelial cells.

IMAGING
• Thoracic radiographs are generally limited to lateral views in adult camelids.
• Thoracic ultrasonography can be useful to detect pulmonary consolidation, pleural effusion, abscesses, penetrating thoracic wounds, and rib fractures. However, lesions that do not involve the periphery of the lung or the pleural cavity cannot be imaged by this means.
• Upper airway endoscopy is useful to assess nasal and tracheal patency, and laryngeal and pharyngeal function, and to permit tracheal wash.
• Positive contrast rhinography, nasal catheter placement, endoscopy, and computed tomography (CT) have all been used to diagnose choanal atresia in camelids.

OTHER DIAGNOSTIC PROCEDURES
Noninvasive pulmonary function testing, including respiratory inductive plethysmography and pneumotachography, forced oscillatory mechanics, and assessment of functional residual capacity, have been described in camelids.

PATHOLOGIC FINDINGS
Vary depending on the underlying disease

TREATMENT

THERAPEUTIC APPROACH
• Antimicrobial therapy if indicated, preferably based on bacterial culture and sensitivity testing.
• Supportive care might include fluid therapy, enteral or parenteral nutrition, bronchodilators, gastroprotectants, and NSAIDs.
• Provision of oxygen via mask, nasal catheter, or potentially mechanical ventilation of neonates to address hypoxemia.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgical intervention (with balloon dilation) may be beneficial in the membranous forms of choanal atresia, although the prognosis remains poor.

MEDICATIONS

DRUGS OF CHOICE
Camelid-specific pharmacokinetic data is available for the following antimicrobials:
• Ceftiofur (Naxcel®): 2.2 mg/kg IM q12h in alpacas will maintain plasma concentrations > 0.25 μg/mL. Naxcel® is usually dosed at higher amounts in the clinical setting (4.4–6.6 mg/kg SC q12h) to target more resistant bacteria. A long-acting ceftiofur crystalline-free acid (CCFA) formulation (Excede®) will also maintain plasma concentrations >0.25 μg/mL for 5–6 days if dosed at 6.6 mg/kg (effective for *Streptococcus* spp.)
• Enrofloxacin: 5–10 mg/kg, q24h SC or IV. Enrofloxacin will not target streptococcal, enterococcal, or anaerobic infections and is commonly used in combination with ceftiofur or penicillin.
• Florfenicol (Nuflor Gold®): 40 mg/kg SC q48h. Monitor serum protein concentrations during long-term use.
• Florfenicol (Nuflor®): 20 mg/kg IM q24h or 20 mg/kg SC q36–48h (use only for highly susceptible pathogens with an MIC ≤0.5 μg/mL). Monitor serum protein concentrations during long-term use.
• Ampicillin: 12 mg/kg IV q6–12h in llamas. Efficacy is expected against ampicillin-sensitive bacteria (with an MIC of 1–3 μg/mL).
• Gentamicin/amikacin: Use with caution while monitoring renal function.
• Penicillin-G (targets Gram-positive and some anaerobic infections): 22,000 IU/kg SC q12h.
• Long-acting tetracycline (200 mg/mL): 20 mg/kg SC q48h.
• Gastric protectant (C3): Pantoprazole 1 mg/kg IV or 2 mg/kg SC q24h.

CONTRAINDICATIONS
• Fluroquinolones should be avoided in neonatal crias.
• Avoid aminoglycosides in dehydrated animals.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Pulmonary disease is associated with a higher mortality in neonatal crias. Early diagnosis is essential for successful treatment.
• State and federal regulations impact management of animals with reportable disease.

POSSIBLE COMPLICATIONS
C3 ulceration

CLIENT EDUCATION
N/A

PATIENT CARE
• Serial chest radiographs are useful in monitoring the progress of lower respiratory tract conditions. Radiographic changes may, however, either follow or precede the onset of clinical signs and persist after their resolution.
• Repeated laboratory and clinical evaluation.

PREVENTION
Appropriate biosecurity for incoming animals (new members to the herds, animals returning from shows, breeding, etc.).

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Sepsis
• Concurrent congenital defects in neonatal crias

AGE-RELATED FACTORS
Congenital conditions are most commonly observed in neonatal camelids.

ZOONOTIC POTENTIAL
Tuberculosis

PREGNANCY
Severe hypoxemia, as well as certain infectious diseases (e.g., BVDV and coronavirus infection), may be associated with reproductive losses.

BIOSECURITY
Relevant for individual contagious diseases including tuberculosis and coronavirus.

PRODUCTION MANAGEMENT
N/A

SYNONYMS
N/A

(CONTINUED) **RESPIRATORY DISEASE: CAMELID**

ABBREVIATIONS

- BVDV = bovine viral diarrhea virus
- C3 = third compartment of the camelid GI tract

RESPIRATORY DISEASE: SMALL RUMINANT

BASICS

OVERVIEW
• A variety of upper and lower respiratory tract problems affect small ruminants.
• It is important to differentiate between upper and lower respiratory tract problems.
• Pathologic sounds may be referred from the upper airway and audible in the thorax.
• Auscultation has limitations in all species. Imaging modalities including ultrasound improve the accuracy of respiratory disease diagnosis.
• Lung sounds are typically easier to hear in small ruminants, which normally have fairly harsh inspiratory sounds.

INCIDENCE/PREVALENCE
• Variable; contagious disorders can achieve a high prevalence.
• Prevalence often influenced by herd or flock management.

GEOGRAPHIC DISTRIBUTION
• Variable depending on disorder.
• Pasteurellosis occurs worldwide.
• Contagious caprine pleuropneumonia is absent from the United States, but reported in other countries.

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• Often involves a primary infectious organism with secondary bacterial invasion creating or enhancing respiratory system injury.
• Upper airway disorders include neoplasia, pharyngeal trauma, *Corynebacterium pseudotuberculosis* infection, sinusitis, and *Oestrus ovis* infestation.
• Lower airway disease can arise from bacterial infections (*Pasteurella*, *Mannheimia Mycoplasma*, *Corynebacterium*), parasite infestation (*Dictyocaulus, Muellerius, Protostrongylus*), viral infections (OPP, OPA, CAE), aspiration of medication, feed, or milk (neonates), and from neoplasia.

HISTORICAL FINDINGS
Dependent on the underlying etiology. While viral infections can present as a herd concern, neoplastic, fungal, and protozoal disease will generally affect individual animals.

SIGNALMENT
Any breed or age of sheep and goats; respiratory disease may be more common in younger animals under stressful conditions.

PHYSICAL EXAMINATION FINDINGS
• Stridor or stertor, hyporexia inspiratory difficulty, limited air flow through the nostrils, facial asymmetry, and nasal discharge (especially unilateral) can indicate upper airway disease.
• Tachypnea, expiratory effort, exercise intolerance, fever, hyporexia, and coughing can indicate lower airway disease.
• Poor body condition suggests chronicity.

GENETICS
N/A

CAUSES AND RISK FACTORS
• A predisposing agent and/or stress (transport, poor nutrition, extreme weather, poor ventilation, overstocking, parasitism, weaning, and general husbandry procedures) may collaborate to overwhelm host immunity, allowing an opportunistic pathogen to invade the lower respiratory tract.
• Predisposing agents may be viral or bacterial and may include parainfluenza-3, respiratory syncytial virus, *Mycoplasma ovipneumoniae*, *Bordetella parapertussis*, adenovirus type 6, and *Chlamydia*.
• Pasteurellosis is one of the most important infectious bacterial diseases in sheep and goats, causing acute bacterial pneumonia. The condition is primarily associated with *M. haemolytica*, though *P. multocida* has been implicated. These are normal inhabitants of the upper respiratory system and opportunistic invaders of the lower respiratory system. *Bibersteinia trehalosi* (formerly *P. trehalosi*) results in systemic pasteurellosis and septicemia.
• Progressive pneumonia can result from viral infections, OPP, OPA, or from progressive interstitial retroviral pneumonia (PIRP) associated with CAE in goats. These are chronic disorders that progress over time, with weight loss and respiratory distress in afebrile animals as common signs.
• Mycoplasma pneumonia is also called atypical pneumonia, enzootic pneumonia, and chronic nonprogressive pneumonia. *M. ovipneumoniae* is thought to be the primary causative organism with secondary invading organisms.
• The *Mycoplasma mycoides* cluster is the most important group for goat mycoplasma pneumonia. *M. capricolum* ssp. *capripneumoniae* is the cause of contagious caprine pleuropneumonia (CCPP). This is very contagious with morbidity approaching 100% and mortality 60–100%. This is an exotic disorder in the US.
• *Mycoplasma mycoides* ssp. *capri* and *M. mycoides* ssp. *mycoides* large colony type are a common cause of arthritis and pneumonia in goats.
• Parasitic infestations of the respiratory tract can cause dyspnea, coughing, tachypnea, and weight loss particularly in young, pastured animals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Ovine progressive pneumonia
• Bacterial pneumonia
• Caprine arthritis encephalitis
• Verminous pneumonia
• Causes of upper airway disease
• Other causes of weight loss and bacterial infection

CBC/BIOCHEMISTRY/URINALYSIS
A CBC may show inflammatory leukogram, a left shift, and increased fibrinogen and total protein concentrations.

OTHER LABORATORY TESTS
• Transtracheal aspiration or tracheal wash are superior for bacteriology.
• Bronchoalveolar lavage is superior for cytology.
• Baermann test on fresh feces is appropriate to detect verminous pneumonia.

IMAGING
• Ultrasonography with a 5–7.5 MHz probe allows visualization of the pleural cavity, pleural surface, and lung parenchyma (if consolidated at the pleural surface).
• Radiographs are useful for upper and lower respiratory tract lesions.
• Computed tomography under sedation provides excellent visualization of the upper and lower respiratory tract, particularly with intravenous contrast administration.

OTHER DIAGNOSTIC PROCEDURES
• Necropsy of affected representative individuals for flock/herd benefit
• Culture or PCR of tracheal wash and lung sections

PATHOLOGIC FINDINGS
• Fibrinopurulent pleuropneumonia
• Excess pleural and peritoneal fluid
• Lung abscessation and lung consolidation
• Verminous infestation

TREATMENT

THERAPEUTIC APPROACH
• Early detection and treatment with antibiotics is beneficial in bacterial disorders.
• Supportive therapy as needed.
• Vitamin C and E may be of additional benefit.
• Progressive pneumonias are terminal.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

(CONTINUED) # RESPIRATORY DISEASE: SMALL RUMINANT

MEDICATIONS

DRUGS OF CHOICE
• Common antibiotics include oxytetracycline (200 mg/ml at 20 mg/kg q72h), penicillin (22,000–44,000 U/kg q12–24h), ceftiofur (1.1–2.2 mg/kg q24h), florfenicol (20 mg/kg q48h, or 40 mg/kg once), tylosin (10–20 mg/kg q12–24h), tilmicosin at 10–20 mg/kg once in sheep only, and tulathromycin at 2.5 mg/kg once.
• Antibiotic selection may be based on drug cost, dose interval, culture and sensitivity results, and past effectiveness on each property.
• Oxytetracycline is commonly prescribed due to spectrum and cost effectiveness.
• Tylosin, tetracycline, and macrolides are appropriate for mycoplasma infections.
• Nonsteroidal anti-inflammatory drugs may benefit an individual animal for control of fever or to provide analgesia and to improve appetite.
• Anthelmintics are indicated for *Oestrus ovis* infestation and verminous pneumonia.

CONTRAINDICATIONS
• Tilmicosin is toxic to goats.
• Fluoroquinolones are illegal or prohibited from extra-label use in some countries.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Notifiable diseases must be reported to the appropriate regulatory bodies.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Progressive pneumonia is terminal; euthanasia and flock/herd implications need to be considered.
• For chronic pneumonias a prolonged course of therapy can achieve fair to good results.
• With mycoplasma infections, the hosts often remain carriers of the pathogens even with clinical recovery.

POSSIBLE COMPLICATIONS
• Polyarthritis
• Mastitis
• Otitis interna
• Septicemia

CLIENT EDUCATION
Management factors play a key role in respiratory disease. Depending on the causative agent, clients should be educated in regard to what management changes they can make to reduce the likelihood of additional cases.

PATIENT CARE
• Once to twice daily monitoring of attitude and appetite is a good indirect indication of therapy success.
• Imaging repetition can aid in disease monitoring.
• Normothermia within 48 hours of treatment is a good prognostic indicator in bacterial infections.

PREVENTION
• Isolate affected animals.
• Treat affected animals with antibiotics if definitively indicated.
• Reduce stress factors such as overcrowding and unnecessary handling.
• Divide up animal groups by age and production purpose.
• Consider vaccination for diseases such as caseous lymphadenitis and pasteurellosis.
• Purchase goat kids from herds with negative bulk tank culture for *Mycoplasma* and no history of kid deaths from arthritis and pneumonia.
• Isolate newcomers and culture milk before mixing goats with the rest of the herd.
• Provide neonates with heat-treated colostrum and milk.
• Practice good milking hygiene; teat dips, individual cloths for udder preparation.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Polyarthritis
• Leukoencephalomyelitis (goat kids with CAEV)
• Indurative mastitis (CAEV, OPP)
• Secondary bacterial pneumonia

AGE-RELATED FACTORS
Some conditions are more common in younger animals, such as septicemic pasteurellosis.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
• Quarantine new animals for 30–45 days.
• Visitors should wear clean clothes and footwear and wash their hands.

PRODUCTION MANAGEMENT
Minimize stress and biosecurity breaches.

SYNONYMS
• Ovine progressive pneumonia = maedi-visna
• Ovine pulmonary adenocarcinoma = sheep pulmonary adenomatosis, Jaagsiekte

ABBREVIATIONS
• CAEV = caprine arthritis encephalitis virus
• CCPP = contagious caprine pleuropneumonia
• OPA = ovine pulmonary adenocarcinoma
• OPP = ovine progressive pneumonia
• PCR = polymerase chain reaction
• PIRP = progressive interstitial retroviral pneumonia

RETAINED PLACENTA

BASICS

OVERVIEW

• Retained placenta (RP) or retained fetal membranes (RFM) is failure to expel the placenta (fetal membranes) within 12 hours after parturition in cattle and small ruminants and within 6 hours in camelids.
• Various authors define RP at 6, 12, or 24 h. Among cows that expelled the placenta within 24 h, 77% occurred within 6 h and 94% occurred within 12 h after calving. The 24 h definition may be most practical for monitoring in the field.

INCIDENCE/PREVALENCE

• The median lactational incidence risk was 8.6%, with a range of 1.3–39.2% of lactations affected in dairy cows in the United States.
• RFM is more common in sheep than in goats.
• RFM is rare in alpacas and llamas.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• Ruminant placentation is classified as synepitheliochorial cotyledonary nondeciduate. Cotyledonary refers to the presence of localized areas of proliferated trophectoderm that constitute the fetal portion of the placentome. The placentome is formed by chorionic villi from the cotyledons that grow and interdigitate with corresponding maternal caruncular crypts, providing a finger-in-glove arrangement. Domestic ruminants have 75–125 placentomes.
• Placentation in camelids is epitheliochorial microcotyledonary diffuse nondeciduate. The placenta is delivered rapidly. RP is likely to results from uterine atony.
• The exact mechanism of placental detachment is not completely understood. Placental maturation along with appropriate structural, endocrinologic, and immunologic changes result in the separation and expulsion of the placenta. Critical biochemical, vascular, contractile, and involution changes occurring at the uterine-placental interface before and during parturition assist in separation and expulsion of the placenta.
• After expulsion of the fetus and loss of fetal circulation to the cotyledons, capillaries within the villi collapse, resulting in a decrease in size. Uterine contractions result in flattening of the caruncles and shrinkage of the caruncular stock, further enhancing the separation of the allantochorion.
• RFM results from the failure of detachment of the fetal-maternal interface following parturition.
• The increased incidence of RP after induced parturition or abortion supports the observation that placentome immaturity may be a contributing factor in ruminants.
• In a mature placenta, maternal immunologic recognition of fetal MHC class I proteins triggers immune and inflammatory responses that contribute to the detachment of the cotyledonary portion of the allantochorion at parturition. MHC compatibility has significant molecular consequences and can result in an increased incidence of RP. Given that immune function is critical to normal placental detachment, it is likely that molecular genetics has a role in RP.
• Production of neutrophil-activated factors and the chemotactic activity to neutrophils are important for successful immune-assisted detachment of the cotyledonary portion of the allantochorion. Prepartum immunosuppression, specifically impairment of neutrophil function, is a critical factor in RP. The function of peripheral leukocytes may be reduced in cases of RP, with decreased neutrophil function occurring 1–2 weeks before calving in cows that develop RP.
• Failure of proteolysis of the cotyledon and, in particular, a failure of collagenolysis to release the cotyledon from the caruncle also plays a role in RP. Injection of collagenase into the umbilical artery within the uterus (after RP occurs) or into the uterine artery during cesarean section is associated with detachment of the placenta within hours.
• In RP, detachment occurs around day 6–10 following parturition due to necrosis of the caruncle and liquefaction of the cotyledonary villi. While the RP is present in the uterus, partial necrosis contributes to bacterial growth, which along with ongoing metabolic activity by the placental tissue results in inflammation of the uterus, which may progress to clinical metritis.

GENETICS

RFM is more common in dairy cattle and camels.

HISTORICAL FINDINGS

• Recent parturition
• Dystocia
• Failure to find an expelled placenta

SIGNALMENT

• Bovine—more common in dairy cattle than in beef cattle
• Small ruminants—occurs uncommonly
• Camelids—rare

PHYSICAL EXAMINATION FINDINGS

• Presence of all or part of the placenta in the uterus >12–24 hours after parturition; commonly observed on inspection from a distance, with part of the placenta hanging downward from the vulva.
• Within 1–3 days a fetid odor and/or fetid red-brown discharge from the vulva are likely to be present.
• Other clinical signs or physical examination findings that might be observed include pyrexia, decreased milk yield, obtundation, tachycardia, loss of body condition, and marked systemic illness. These clinical signs are often associated with development of either clinical endometritis or metritis.
• In some cases, inspection or palpation per vagina is necessary to confirm the presence of placental tissue and rule out an RP.

CAUSES AND RISK FACTORS

• Failure of detachment of the fetal cotyledon from the maternal caruncle at the time of parturition in ruminants.
• In camelids, RFM is often due to failure of uterine contraction.
• Abortion, twins, fetal gigantism, induced parturition, dystocia, cesarean section, stillbirth, intensive heat stress, negative energy balance, trace mineral and vitamin deficiency (suboptimal availability of selenium, vitamin E, etc.), and milk fever (hypocalcemia) are all associated with an increased risk of RP.
• Cows with elevated serum NEFAs (>0.5 mEq/L) and/or suboptimal vitamin E status in the last week prepartum (serum α-tocopherol : cholesterol ratio $<2.5 \times 10^{-3}$) are more likely to develop RP. Lower prepartum serum cholesterol concentration has also been associated with increased risk of RP.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Diagnosis is straightforward.
• If pyrexia (temperature >39.5°C) is present together with RP (in the absence of other causes), it is important to consider development of clinical/toxic metritis, particularly if dullness, decreased milk production, loss of appetite, anorexia, or signs of toxemia (dehydration, tachycardia, diarrhea, weakness, cold extremities) are also present.

CBC/BIOCHEMISTRY/URINALYSIS

May be indicated if signs of systemic illness are present.

OTHER LABORATORY TESTS

Potentially haptoglobin and serum amyloid A concentrations could potentially be used to identify cows at risk for RP.

IMAGING

Transrectal (cattle) and transabdominal ultrasonography (small ruminants and SAC) may be helpful in confirming RP in cases where the cervix may be closed making digital vaginal examination impossible.

OTHER DIAGNOSTIC PROCEDURES

Transrectal palpation or digital vaginal examination may be needed to confirm the diagnosis of RP.

PATHOLOGIC FINDINGS
Animals with RP have necrotic placental tissue attached at the caruncles, abundant mixed bacterial growth in the uterine lumen, and variable severity of inflammation of the layers of the uterus.

TREATMENT

THERAPEUTIC APPROACH
- The basic goals of any therapeutic plan should be to return the cow to reproductive usefulness as soon as possible and prevent complications that can lead to economic losses.
- Uncomplicated ruminant cases require no treatment. Treatment is often initiated early in the case of camelids.
- Manual removal should be attempted only if the placenta is detached and easy to remove.
- In camelids, oxytocin therapy with or without systemic antibiotic is considered the standard of care.
- In ruminants, intrauterine antibiotic treatment is generally not recommended. In cases when antibiotic treatment is necessary, systemic administration is recommended. Absorption of systemic antibiotics is not impaired as in local treatments; antibiotic concentrations attained in the uterine tissue are similar in blood concentrations.
- In ruminants, if the RP persists for >48 hours and the animal develops pyrexia or other clinical signs it should receive immediate attention and a treatment plan be developed. Therefore it is imperative that cows in the postpartum period are evaluated daily for attitude, appetite, and rectal temperature, with closer monitoring initiated in instances where an RP is identified.
  - Several studies have demonstrated that approximately 50% of cows with untreated RP will have a temperature >39.5°C on at least 1 day. It is not clear if all of these cases require systemic antibiotic treatment. At a minimum, it establishes that approximately 50% of cows that develop RP do not require antibiotic treatment because they never become febrile. Therefore, automatic treatment of all cows having an RP with antibiotics is questionable.
  - Limited published data evaluating conservative management (no antibiotic treatment) of cows developing a fever following an RP leaves an unclear picture as to the health or economic benefits of treating all cows with an RP, or even all febrile cows with an RP, with systemic antibiotics.
- Uterine lavage may be considered in cases where development of metritis or other secondary clinical signs are observed.
- Other agents that have been considered for intrauterine use include chlorohexidine, hydrogen peroxide, and more recently ozone.
- The use of ecbolic drugs has been suggested as a way to improve uterine and myometrial contractions to aid in the separation and expulsion of the placenta.
  - Although there are some reports of benefits of $PGF2_{\alpha}$ or oxytocin, especially within 1 hour after calving, the data are limited and contradictory. There are persistent anecdotes in circulation, and some controversy in the scientific literature, but these arguments are not based on data from field studies of naturally occurring cases. There is no strong evidence that any of the suggested treatments hasten the passage of the RP, reduce the risk of displaced abomasum (DA), or improve subsequent reproductive performance.
- Estradiol compounds have been advocated as an adjunct treatment option to aid in the restoration of the endometrium and prevent metritis; however, lack of conclusive scientific evidence and lack of availability in some parts of the world due to regulatory measures precludes its use in many circumstances.
  - Estradiol cypionate (ECP) in cows with RP did not reduce the incidence of fever with fetid discharge within 7–30 DIM, but significantly prolonged the time to pregnancy relative to no treatment in cows with RP.
  - Similarly, in two other studies, ECP administration failed to reduce the incidence of fetid discharge (with or without fever).

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
- Ceftiofur (Na- or -HCl): 1–2.2 mg/kg IM q24h for 3 days; up to maximum of 5 days if clinically improving but not resolved (WD = 0 milk, 3 d meat) – Labeled for use in cattle with metritis.
- Ceftiofur crystalline free acid: 6.6 mg/kg SC q4d (administration of 2 doses) (WD = 0 milk, 13 d meat). Labeled for use in cattle with metritis.
- Procaine penicillin G: 21,000 IU/kg IM q12–24h for 3–5 days (WD = 4–5 d milk; 10–30 d meat).
- Oxytocin IM administration q4h in the first 24 hours postpartum may be helpful (cattle and camels 20 IU, small ruminants and SAC 5–10 IU). Oxytocin administration is more helpful in the management of RFM in camelids.

CONTRAINDICATIONS
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Manual removal is contraindicated in ruminants. There is some evidence that manual removal can exacerbate damage to the endometrium, increasing the risk of toxemia, and may delay return to cyclicity.
- Use of estrogen in food-producing animals is not legal in some countries.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- The expected impact of RP depends on complications, which range from none (other than an esthetically unappealing condition for 1 week) to impaired reproductive performance, or progression to severe metritis and toxemia. The course of this disorder depends on immune function of the animal.
- The ability of the uterine immune system to respond to RP, inflammation, and increased bacterial challenge determines whether the animal will go on to suffer metritis or impaired reproductive performance.
- RP is a risk factor for metritis and endometritis. It is also a risk factor for DA in cattle. Conversely, many animals with RP do not have any clinical complications, even if untreated.
- In cattle, although many studies report negative impacts of RP on reproductive outcomes, the results are variable. The best analyses estimate that affected cows become pregnant approximately 15% more slowly (i.e., hazard ratio for pregnancy = 0.85) than unaffected cows (e.g., reduction in 21-day pregnancy rate from 15% to 12.8%).
- It is not clear whether impaired reproductive performance is directly attributable to RP, or (more likely) only if metritis or clinical and/or subclinical endometritis result.
- There are some reports of short-term reductions in milk yield associated with RP, but meaningful loss of production appears to be confined to those individuals that progress to clinical metritis. Likewise, RP itself appears not to increase culling risk.

POSSIBLE COMPLICATIONS
Metritis, endometritis, ketosis, DA, mastitis, increased time to pregnancy (days open), decreased probability of pregnancy, increased risk of culling.

RETAINED PLACENTA (CONTINUED)

CLIENT EDUCATION
See "Prevention"

PATIENT MONITORING
• In camelids, aggressive treatment is usually instituted quickly to reduce the chance of complications.
• Ruminants with RP should be inspected daily until the placenta is expelled, to detect progression to metritis. Observation of the cow's attitude, appetite (if possible), and daily milk production is likely a useful screening test.
• Measurement of rectal temperature is indicated in animals that are dull, inappetant, producing less milk than expected, or declining in milk production. Some authors advocate daily monitoring of rectal temperature in all cows with RP for 10 days postpartum. More large-scale field studies are needed to determine if this approach results in early detection and mitigation of metritis, avoidance of other related diseases (e.g., displaced abomasum), and/or improved reproductive performance, or if this approach leads to medically or economically unnecessary treatment.
• It is recommended that all cows affected with RP be examined 20–30 days after expulsion of the placenta to determine the progress of uterine involution.
• Animals with RP will plausibly benefit from extra effort to provide easy access to feed and bedding space, as well as unrestricted access to water and heat abatement measures. It is important to recognize, however, that all transition cows may benefit from such measures.

PREVENTION
• In cattle, because the cause of RP is multifactorial, it is important to recognize that no one preventive measure will be universally effective. The principle for prevention is to optimize peripartum immune function.
• In general, best management and nutritional practices (i.e., transition diet to meet National Research Council [2001] requirements for >3 weeks prepartum with average DIM >12 kg/cow/day, >60 cm manger space/cow, calving at body condition score of 3.5 out of 5, lack of crowding, heat abatement measures above 27°C, free access to clean water) will plausibly help prevent RP.
• In particular, the prepartum diet should include 0.3 ppm selenium and 1,000–2,000 IU/cow/day of vitamin E. Among animals with suboptimum circulating vitamin E in the last week prepartum (serum α-tocopherol : cholesterol ratio $<2.5 \times 10^{-3}$), injection of 3,000 IU α-tocopherol SC or IM 1 week before expected calving reduced the risk of RP. Unfortunately, there is no simple way to identify individuals or herds that may benefit from this treatment. In two studies, peripartum oral administration of calcium (one to three treatments of 60 g Ca within a 24 h period around calving) did not reduce the incidence of RP.
• One economic analysis estimated that at a herd incidence of 7% the economic loss was minimal. Therefore, decisions about preventive interventions should consider the magnitude of the problem as well as the evidence for the expected costs and benefits of proposed measures.
• In camelids, animals at risk of having RFM (i.e., following dystocia or C-section) are systematically treated with oxytocin and systemic antibiotics.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Abortion, twins, dystocia, metritis, endometritis
• In SAC, RFM and peritonitis has been reported following uterine rupture

RIFT VALLEY FEVER

BASICS

OVERVIEW
Rift Valley fever (RVF) is an acute febrile viral disease affecting cattle, sheep, goats, and camelids. It causes high mortality in neonates, necrotizing hepatitis, and abortion. It is reportable in the United States and a notifiable disease of the International Office of Epizootics (OIE).

INCIDENCE/PREVALENCE
• Sheep are most susceptible to infection, and mortality is influenced by age. Newborn lambs are highly susceptible, with a mortality rate >90% in lambs <1 week old, associated with acute necrotic hepatitis.
• Mortality rate in adult ruminants is 10–30%; the abortion rate can range between 40% and 100%.

GEOGRAPHIC DISTRIBUTION
• Endemic throughout much of the African continent. Epidemics occur every 5–10 years in eastern Africa.
• The virus has emerged in the Middle East, northern Egypt and the Comoros archipelago.
• The geographic range is likely to expand due to presence of appropriate vectors over a much larger geographic range

SYSTEMS AFFECTED
• Reproductive
• Digestive

PATHOPHYSIOLOGY
• RVF is caused by a mosquito-borne phlebovirus, family Bunyaviridae. It is a single-stranded RNA virus with a single serotype but with strains of variable virulence.
• The virus is transmitted mainly by *Aedes* mosquitoes, which are also a reservoir, but >20 species of mosquito can transmit RVF including *Culex, Anopheles*, and *Mansonia*; transovarial transmission occurs in *Aedes* spp.
• The virus circulates between wild ruminants and mosquitoes in endemic areas without causing disease.
• Viral replication occurs mainly in the liver and spleen of infected animals, although the brain may be affected; lesions arise mainly due to the lytic effects of the virus.
• Generalized infection in the mosquito is necessary for effective transmission, and movement of virus from the insect gut is facilitated by the presence of microfilariae in ingested blood.
• Cattle, sheep, and goats are considered the primary amplifying hosts.
• Virus is carried to the placenta and fetus during viremia with the liver as the target organ for multiplication.
• Peracute, acute, subacute, chronic, and convalescent forms of disease can occur in mature sheep and cattle.

HISTORICAL FINDINGS
Abortion or sudden neonatal death may be reported.

SIGNALMENT
• Most commonly infects cattle, goats, and sheep which are amplifiers of the virus, but RVF has been reported in other species including camelids, wild ruminants, African monkeys, and domestic carnivores.
• Lambs, kids, and calves are the most likely to show clinical disease.
• Pregnant females very commonly display abortion with infection.

PHYSICAL EXAMINATION FINDINGS
• The incubation period is approximately 12–36 hours, and viremia typically lasts for 1–3 days (up to 10 days).
• The mortality rate in infected newborn lambs is 95–100%, with death within two days. Affected lambs display high fever, which may be biphasic, loss of appetite, decreased activity, and prostration about 12–18 h prior to death. Salivation, diarrhea, and colic may occur.
• Adult sheep and cattle are often asymptomatic, though fever, bloody nasal discharge, and bloody diarrhea can occur, as can sudden death.
• Abortion occurs in the vast majority of pregnant animals.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Heavy rainfall and flooding often precede outbreaks.
• Irrigation and dam building can promote RVF in a region.
• Exposure of pregnant animals to competent arthropod vectors presents great risk.
• Biting midges and ticks are also implicated in transmission.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Include other causes of abortion such as toxoplasmosis, brucellosis, trichomoniasis, ovine enzootic abortion, Q fever and campylobacterioisis.
• Additional differentials include ephemeral fever, Wesselsbron disease, enterotoxemia (sheep), peste des petits ruminants, toxic plant ingestion, pasteurellosis, heartwater (*Ehrlichia ruminantium* infection), and anthrax.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Virus isolation from whole blood or serum during the febrile stage, and from brain, liver, spleen, and fetal membranes of aborted fetuses via ELISA, serum neutralization, complement fixation, RT-PCR, agar gel diffusion, and immunohistochemistry
• Tests can be supplemented by virus isolation from inoculated rodents or cell cultures
• Cross-reactivity can be an issue between RVF virus and other phleboviruses in tests identifying serum antibodies to RVF; virus neutralization tests are the most specific. An IgM ELISA exists by which recent infection can be determined from a single serum sample.

PATHOLOGIC FINDINGS
• Gross findings include hepatomegaly with patchy congestion; petechial, ecchymotic to suffusive hemorrhages in skin, parietal and visceral serosal surfaces; enlarged and hemorrhagic lymph nodes; and hemorrhagic abomasitis and cholecystitis are often evident. Fetal malformations (arthrogryposis, brain defects) may occur.
• Histopathology identifies multifocal to massive coagulative or lytic hepatic necrosis often preserving portal areas; eosinophilic rod-shaped, round or oval intranuclear inclusions are evident in hepatocytes in 50% of affected ovine fetuses. Necrosis of the villi of the distal jejunum and ileum may occur; lymphoid depletion in spleen and lymph nodes; placentitis; and degenerative lesions in heart and renal tubules.

RIFT VALLEY FEVER (CONTINUED)

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Symptomatic adult animals are likely to recover quickly from abortion and other clinical signs in most cases.
• Severe illness and rapid death is expected in infected neonatal ruminants.

POSSIBLE COMPLICATIONS
Abortion is the most likely complication of infection in the pregnant female.

CLIENT EDUCATION
• Ensure clients understand that RVF is a zoonotic disease that can be readily transmitted to humans via inhalation or direct contact with body fluids from infected animals (some of which may be asymptomatic).
• All animal products should be pasteurized or cooked prior to consumption.

PATIENT CARE
N/A

PREVENTION
• Both live and killed vaccines exist for ruminants, including the live Smithburn strain which induces good immunity within a week after vaccination, and a naturally attenuated avirulent isolate (clone 13).
• Vaccination is not recommended during outbreaks due to the risk of inadvertently amplifying outbreaks through the use of multidose vaccine vials and reuse of needles.
• It is also not recommended to use live attenuated vaccines in areas where RVF is not endemic.
• Lambs can be vaccinated at 6 months old, and pregnant ewes and cows can be vaccinated (twice in 3 months) with the formalin inactivated vaccine to provide protection to the fetus and colostral immunity.
• Vector control should be practiced.
• Quarantine may be appropriate for preventing infection or reducing spread in outbreak situations.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
• Greatest mortality occurs in fetuses and neonates of cattle, sheep, and goats.
• Decreased susceptibility to disease with age.

ZOONOTIC POTENTIAL
• Human infections can arise from mosquito bites, or through exposure to infected animals or animal tissues, since infected animals (sheep in particular) can display high titer viremia.
• Generally humans are asymptomatic or experience a short febrile illness with infection, sometimes with recurring fever and headaches for up to 10 days followed by 2 weeks of weakness before recovery.
• Some humans may develop severe disease with acute hepatitis, jaundice, encephalitis, renal failure, and hemorrhagic complications.

PREGNANCY
• RVF causes abortion, neonatal death, and fetal malformations in sheep, cattle, and goats.
• The live vaccines should not be administered to pregnant animals due to the risk of abortion or fetal defects.

BIOSECURITY
Notifiable OIE disease and requires mandatory reporting.

PRODUCTION MANAGEMENT
• Vector control
• Movement of animals to higher elevations
• Vaccination prior to breeding season
• Quarantine

SYNONYM
Enzootic hepatitis

ABBREVIATIONS
• ELISA = enzyme-linked immunosorbent assay
• IgM = immunoglobulin M
• OIE = International Office of Epizootics
• RT-PCR = reverse transcription-polymerase chain reaction
• RVF = Rift Valley fever

BASICS

OVERVIEW
• Nondilation of the cervix that results in prolonged lambing (kidding), weak-born or dead lambs (kids), and cervical trauma or secondary infections in the ewe (doe).
• Mortality is often high in dam and offspring, even with veterinary intervention.

INCIDENCE/PREVALENCE
Incidence is usually higher in maiden dams; however, older animals may also present with ringwomb. The number of cases within a given flock or herd can vary dramatically from year to year. Predisposing factors are not well established.

GEOGRAPHIC DISTRIBUTION
Ringwomb is apparently common in most regions of the world, although complete data on distribution with emphasis on individual species have not been reported.

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Complex interactions between fetal and maternal neural, endocrine, and paracrine systems lead to the efficient delivery of normal lambs or kids.
• Increased levels of fetal plasma cortisol result in an increase in estrogen and a decrease in progesterone in maternal plasma and an increase in maternal uterine prostaglandin production. These changes lead to the induction of normal delivery including efficient and coordinated myometrial contractions, dilation of the cervix, delivery of the fetus, and expulsion of the placenta.
• The exact mechanism by which estrogen and other hormonal factors regulate cervical ripening and dilation is not completely known.
• Failure of the cervix to dilate is referred to as ringwomb. (For a complete review of endocrine and paracrine regulation of preterm and birth processes, see Challis et al. (2000) in "Suggested Reading").

HISTORICAL FINDINGS
• Dystocia: Failure to progress through the second stage of parturition
• Depressed or down female
• Overdue ewe or doe

SIGNALMENT
• Commonly ewes and does in labor.
• Less commonly, cattle and camelid may present with failure of cervical dilation.
• In sheep and goats, all ages are affected; first or second parity dams are most commonly affected.

PHYSICAL EXAMINATION FINDINGS
• Affected ewes and does may go undetected until the fetuses have died from hypoxia, and the ewe is suffering systemic effects from uterine toxemia.
• Often the first indication of ringwomb is the presentation of fetal membrane through the vagina without concurrent evidence of active labor. The ewe may act restless or appear normal.
• Similar signs are observed in does, although vocalization may be more prominent.
• The cervix is not sufficiently dilated to allow expulsion of the fetus. Often, only a finger may be inserted through the cervical os on vaginal examination.
• Status of the fetus should be determined by stimulating fetal movement if possible. Oftentimes the presence of a malodorous discharge will confirm the demise of the lamb and impending metritis and septicemia in the ewe.

GENETICS
A clear genetic linkage has not been determined; however, there is anecdotal evidence that suggests that certain bloodlines within a particular breed may have an increased incidence of ringwomb.

CAUSES AND RISK FACTORS
• Nondilation of the cervix.
• Risk factors are not well understood.
• There is limited evidence of unknown genetic factors that may predispose to ringwomb.
• Infectious causes including *Chlamydophila ovis* have been implicated; however, many flocks have problems with enzootic abortion and report no significant problems with ringwomb.
• Factors that have been considered in the past but are not supported scientifically include trace mineral deficiencies, exogenous estrogen in feedstuffs, or simple malpresentation of the fetus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Dystocia
• Uterine torsion
• Early dilation syndrome

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Transabdominal ultrasonography to determine fetal viability and integrity of the uterine wall.

OTHER DIAGNOSTIC PROCEDURES
Vaginal examination readily confirms nondilation of the cervix.

PATHOLOGIC FINDINGS
Often, postmortem examinations are not performed. If performed, gross examination reveals term or near-term fetuses that are fresh or variably autolyzed. The cervix is usually only slightly dilated to allow expulsion of minimal fetal membranes.

TREATMENT

THERAPEUTIC APPROACH
• Hormonal therapy (estrogen or application of misoprostol) may help dilate the cervix, although the response is variable and often delayed. In addition, neither product is approved in food animals in many countries.
• Oxytocin may stimulate uterine contractions but, if the cervix is not dilated, contractions will not be productive and will result in uterine tearing.
• Producers will often attempt to manually dilate the cervix with digital pressure. If care is taken, and the cervix is slowly dilated (30 minutes or more) with minimal tearing, live lambs or kids may deliver. More often, this procedure results in delayed delivery with dead fetuses and trauma to the dam's cervix that results in the need to treat aggressively for secondary bacterial infection of the cervix and uterus.

SURGICAL CONSIDERATIONS AND TECHNIQUES
If fetuses are alive, a cesarean section is the most reliable way to achieve a positive outcome for the dam and offspring.

MEDICATIONS

DRUGS OF CHOICE
• Broad-spectrum antibiotics are usually needed as follow-up therapy after manual dilation.
• Estrogen products have been recommended to assist in cervical dilation; however, the effects are minimal and the response is often delayed.
• Oxytocin administered IM, will stimulate uterine contractions; however, the cervix is usually not dilated and the uterus may tear or rupture.
• Calcium preparations have been administered as a preventive approach if hypocalcemia is suspected; however, a link between low blood calcium and ringwomb has not been established.

CONTRAINDICATIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Goats are extremely sensitive to the effects of lidocaine.

PRECAUTIONS
N/A

RINGWOMB (CONTINUED)

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Affected dams will usually recover if trauma to the cervix is minimized. However, all ewes experiencing ringwomb will need to be culled from production.
• Secondary infection is usually responsive to antibiotics.
• If trauma to the cervix is severe or the dam is toxic and the fetuses are dead at the time of presentation, the prognosis is poor.

POSSIBLE COMPLICATIONS
• Fetal death and toxemia
• Uterine rupture
• Post-surgical complications (retained placenta, peritonitis, surgical incision infection)

CLIENT EDUCATION
• All the risk factors for ringwomb are not known.
• If manual dilation is attempted, the ewe will need to be culled from production. If the producer has examined the dam prior to veterinary intervention, it is an appropriate time to provide education on the zoonotic risks associated with lambing ewes.

PATIENT CARE
Standard care following cesarean section: Monitor female for appetite, fever, and demeanor.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
All ages are affected; first or second parity dams are most commonly affected.

ZOONOTIC POTENTIAL
Any assisted delivery in the ewe and doe has the potential to transmit several zoonotic pathogens including *Chlamydophila abortus*, *Campylobacter jejuni*, and *Coxiella burnetii*. Appropriate safety precautions should be observed.

PREGNANCY
Ringwomb is a condition of parturition. If unresolved quickly, the fetal survival is compromised.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Cull females which survive from breeding.

SYNONYM
Nondilation of the cervix

Consulting Editor Ahmed Tibary

RODENTICIDE TOXICITY

BASICS

OVERVIEW

• A variety of rodenticides can be used around feedstuffs and buildings used for livestock or could be maliciously fed to animals. The livestock owner needs to monitor use of rodenticides in an operation and prevent access of animals to the chemicals.
• The US Environmental Protection Agency recently cancelled the registrations of a variety of second-generation anticoagulant rodenticide formulations. Products containing second-generation anticoagulants must be sold in large bait containers for use in professional applications or for use in or near agricultural structures. The use of over-the-counter rodenticide small package use has shifted away from anticoagulants to bromethalin and cholecalciferol.
• Much of the specific toxicity data and treatments for rodenticides is focused on small animals, and ruminant information is lacking.
• In some cases, the time between rodenticide ingestion and clinical signs is prolonged and the opportunity to use GIT decontaminants is no longer a viable option. Often, specific antidotes are not an option and treatment is supportive and symptomatic.

INCIDENCE/PREVALENCE

Anticoagulants

• Anticoagulant rodenticides were developed after investigations of moldy sweet clover (dicumarol) toxicosis in dairy cattle. Warfarin, a first-generation anticoagulant rodenticide, was synthesized during these investigations.
• Because of warfarin resistance in rodents, second-generation anticoagulants were developed with greater toxicity. The second-generation anticoagulants include brodifacoum, bromodiolone, chlorophacinone, coumafuryl, difenacoum, difethialone, and difacinone. These second-generation anticoagulants are more potent and longer acting, can poison with one exposure, and require longer treatment with vitamin K1 as an antidote.
• The anticoagulant rodenticides are well absorbed with oral exposure and are highly bound to plasma proteins. Anticoagulants can be dislodged from binding by drugs, including sulfonamides, phenylbutazone, phenobarbital, and adrenocorticosteroids; check veterinary drug handbooks for potential interactions.
• The anticoagulants are metabolized in the liver and some can undergo enterohepatic recirculation. The half-life of anticoagulants varies greatly with the compound and the species. The duration of action of anticoagulants in large animals is about 14 days for warfarin, 21 days for bromadiolone, and 30 days for brodifacoum.

Bromethalin

• Bromethalin is a substituted diphenylamine developed as a neurotoxin rodenticide for commercial use. Bromethalin is commercially available as 0.01% bait pellets, bars, and or place packs. It is marketed under a variety of trade names, including Assault®, Gladiator®, Trounce®, Fastrac®, and Tomcat®. Bromethalin can be sold to commercial pest control operators in bulk and in concentrated (2–10%) liquid or solid form.
• The toxic dose for ruminants has not been determined, but for other species appears to range from approximately 1–15 mg/kg body weight for an acute, single dose oral LD50.

Cholecalciferol

• Vitamin D or cholecalciferol toxicosis can occur after ingestion of rodenticides containing cholecalciferol, including the following products: Rampage Rat and Mouse Bait, Quintox Rat and Mouse Bait, Ceva True Grit Rampage, Mouse-B-Gone. These products can be manufactured as flakes, granules, cakes, briquettes, etc. containing 0.075% cholecalciferol (vitamin D3).
• Clinical signs can be seen in companion animals at 0.5 mg/kg body weight. Any dose causing clinical signs in an animal should be considered serious.
• Cholecalciferol and its metabolites have high lipid solubility and are slowly eliminated from the body; the terminal half-life of cholecalciferol is weeks to months.

Sodium Monofluoroacetate (Compound 1080)

• Monofluoroacetate naturally occurs in many plants in Africa, Australia, and South America and causes death in livestock. These plants belong to the Fabaceae, Rubiaceae, Bignoniaceae, Maliipighiaceae, and Dichapetalaceae families.
• Sodium monofluoroacetate or Compound 1080 has been used as a rodenticide since the 1940s in the United States. Currently, it is a restricted use rodenticide in the US with use in livestock protection collars in sheep and goat flocks throughout several western states. These livestock protection collars contain 30 mL with 1% active ingredient (300 mg of fluoroacetate).
• Monofluoroacetate is used for vertebrate pest control in New Zealand and other countries. Sodium monofluoroacetate also appears to be available over the counter in the US in foreign rodenticide products or herbal pesticides.
• Monofluoroacetate is a colorless, water-soluble salt, which is similar in appearance to flour or powdered sugar. The oral lethal dose for cattle is 0.15–0.62 mg/kg body weight, for goats is 0.3–0.7 mg/kg body weight, and for sheep is 0.25–0.5 mg/kg body weight.

Strychnine

• Strychnine baits are composed of red or green colored grains mixed with 0.5–1% strychnine alkaloid. Some formulations may contain higher strychnine concentrations. Most baits are used to control rodent populations with below-ground use of these products.
• The lethal oral dose of strychnine for cattle is reported as 0.5 mg/kg body weight. Strychnine is rapidly absorbed from the GIT and metabolized by hepatic enzymes. Strychnine is widely distributed in the body with a small portion excreted unchanged into the urine.

Zinc Phosphide

• Zinc phosphide is a metallophosphide that is a dull, gray-black crystal with a faint, pungent odor. It is available as a paste, tracking powder, or grain-based pellet in concentration ranges 0.5–10%.
• The primary use of zinc phosphide is control of gophers and moles. The average lifetime of the bait when placed on wet soils is approximately 20 days, although the bait may retain some toxicity for several months in the field.
• In acid environments, zinc phosphide hydrolyzes to release phosphine gas, a dangerous systemic poison; the odor of phosphine gas is similar to rotten fish or acetylene. The lethal dose of zinc phosphide in ruminants is approximately 60 mg/kg body weight.

PATHOPHYSIOLOGY

Anticoagulants

• Clinical toxicology is caused by a coagulopathy occurring because of reduction of the activatable forms of clotting factors II, VII, IX, and X. The reduction occurs due to insufficient amounts of vitamin K1 at sites of post-translation modification of these clotting factors.
• The lag time between ingestion of an anticoagulant bait and the onset of clinical signs is normally 3–5 days.

RODENTICIDE TOXICITY (CONTINUED)

• The vitamin K1-dependent clotting factors are involved with one-stage prothrombin time, activated partial thromboplastin time, and activated clotting time that become prolonged.
• After depletion of clotting factors, hemorrhage can occur from any site.

Bromethalin

Post-ingestion, bromethalin is rapidly absorbed and metabolized by the liver to desmethylbromethalin (DMB), the active metabolite that uncouples mitochondrial oxidative phosphorylation leading to decreased cellular ATP production and disruption of sodium-potassium ATPase pumps.

Cholecalciferol

• Cholecalciferol is rapidly absorbed following oral ingestion.
• Cholecalciferol and its metabolites are tightly bound to vitamin D-binding protein, an α2-globulin; the primary circulating metabolite is 25-hydroxycholecalciferol. The liver converts cholecalciferol to 25-hydroxycholecalciferol, which can become activated in the kidneys to 1,25-dihydroxycholecalciferol.
• Clinical effects occur within 48 hours and include altered cell membrane permeability, altered calcium pump activity, decreased cellular energy production, and cellular necrosis.
• The vitamin D3 metabolites increase plasma calcium and phosphorus, stimulate calcium and phosphorus transfer from bone to plasma, and increase renal calcium reabsorption.

Sodium Monofluoroacetate (Compound 1080)

• Monofluoroacetate is readily absorbed from the GIT, but is slowly absorbed through intact skin. It is metabolized to monofluoroacetic acid, and reacts with coenzyme A to form fluoroacetyl CoA and then fluorocitrate.
• Fluorocitrate inhibits aconitase in the Krebs or tricarboxylic acid cycle resulting in energy depletion, citrate and lactate accumulation, and a decrease in blood pH.
• In general, monofluoroacetate causes cardiotoxic effects.

Strychnine

• Strychnine acts by blocking both inhibitory actions of glycine on the anterior horn of the cells in the spinal cord and that of the endogenous transmitter released from Renshaw cells.
• The inhibition leads to excessive neuronal activity and mild to severe muscle spasms and hyperextension of the limbs and body. Convulsions can occur.

Zinc Phosphide

• Phosphine gas can block cytochrome C oxidase, resulting in disruption of oxidative phosphorylation in mitochondria. The blockage of energy pathways leads to cell death and multi-organ failure.
• Brain, heart, liver, and kidney are most affected due to high metabolic rates and high demands for oxygen.
• Because of the higher pH of the rumen, ruminants should be more resistant to phosphide toxicants as compared with monogastric animals.

SIGNALMENT

All ruminants can be affected. See "Incidence/Prevalence.".

PHYSICAL EXAMINATION FINDINGS

Anticoagulants

• Hemorrhage can occur from any site, including hemorrhage into lungs, GIT, urine, joints, epidural and subdural spaces, and major body cavities.
• Animals can also exhibit pain, dyspnea, abdominal distention, collapse, seizures, abortions, and death.

Bromethalin

• Clinical signs of intoxication involve the central nervous system (CNS), including muscle tremors, hyperthermia, hyperexcitability, hyperesthesia, and focal to generalized seizures that appear to be stimulated by light or noise, and death.
• Clinical signs develop within 2–24 hours after ingesting near lethal doses.
• Animals ingesting sublethal doses have a more delayed onset of signs that develop within several days of exposure and can include lethargy, hind leg ataxia, and paralysis.

Cholecalciferol

• Clinical signs in companion animals occur within 12–36 hours after ingestion and include GIT damage and possible diarrhea, anorexia, depression, and polyuria/polydipsia.
• Acute renal failure and death can occur within 24–48 hours; animals that survive can have loss of renal function and musculoskeletal function, and cardiac abnormalities.

Sodium Monofluoroacetate (Compound 1080)

• Clinical signs can appear 30 minutes to 2 hours post-ingestion.
• Sheep tend to show a combination of cardiac and CNS responses, including restlessness, frequent urination, muscular tremors, polypnea, and tachycardia.
• Cattle ingesting lethal quantities of monofluoroacetate can stagger, tremble, sweat, and show GIT signs. In general, herbivores develop cardiotoxic effects.

Strychnine

• Clinical signs can occur 10 minutes to several hours post-ingestion.
• Initial signs can involve nervousness, increased respiratory rate, and excessive salivation.
• Subsequently, muscle spasms, stiffness, and generalized convulsions that are tonic extensor in nature develop. These convulsions can be stimulated by loud noise, bright lights, and touch.
• Death results from impaired respiration and hypoxia.

Zinc Phosphide

• Clinical signs can occur 15 minutes to 4 hours or sometimes are delayed for as long as 12–18 hours post-ingestion. Animals ingesting lethal doses rarely survive longer than 48 hours.
• Clinical signs in ruminants are ruminal tympany and bloat, followed by ataxia, weakness, recumbency, hypoxia, dyspnea, and struggling. Some animals exhibit convulsions.
• Zinc phosphide tends to induce vomiting in animals that can vomit; this protective action prevents the conversion of zinc phosphide to phosphine gas and subsequent clinical signs.

CAUSES AND RISK FACTORS

See "Incidence/Prevalence" and "Pathophysiology"

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Anticoagulants: Dicumarol, trauma.
• CNS signs: Organophosphorus/carbamate/chlorinated hydrocarbons, trauma, botulism, metaldehyde or lead toxicosis, tremorgenic mycotoxins, sodium ion toxicity, *Clostridium tetani*
• Cholecalciferol: Hypercalcemic diseases, renal failure, granulomatous diseases
• 1080: Cardiotoxic plants

CBC/BIOCHEMISTRY/URINALYSIS

• **Anticoagulants** Can cause prolonged one-stage prothrombin time, activated partial thromboplastin time, and activated clotting time.
• **Bromethalin** Changes in serum electrolytes are generally unremarkable.
• **Cholecalciferol** Can affect serum calcium, phosphorus, BUN, and creatinine.
• **Sodium monofluoroacetate (1080)** Can cause hyperglycemia and increased serum citrate, hypocalcemia (ionized), and acidosis.
• **Strychnine** No specific serum or blood chemistry changes occur following strychnine ingestion.
• **Zinc Phosphide** No specific clinical pathology or histopathology is reported in zinc phosphide toxicosis.

IMAGING

Cholecalciferol Calcification of tissues can be observed in radiology/ultrasound/histopathology.

OTHER DIAGNOSTIC PROCEDURES

• **Anticoagulants** Analytical methods can identify specific anticoagulant rodenticides in blood, serum, plasma, liver, GIT contents, and bait; some anticoagulants can be detected in plasma for over 3 weeks.

• **Bromethalin** Diagnosis is based on the history of exposure to a toxicant and clinical signs observed. DMB can be detected in tissues, such as liver, brain, and adipose tissue. Detection of DMB in adipose tissue provides a possible antemortem confirmation of exposure. Methods using mass spectrometry or liquid chromatography-mass spectrometry have been developed for detection of DMB in tissues; check with veterinary diagnostic laboratories for availability of this analysis.
• **Sodium monofluoroacetate (compound 1080)** A diagnosis is based on clinical signs, history of exposure, and detection of monofluoroacetate in GIT contents, kidney, liver, or bait; contact a veterinary diagnostic laboratory for available testing. Sodium monofluoroacetate can be detected in tissues using a gas chromatography-mass spectrometry method; detection limit is 10 µg/kg in tissues.
• **Strychnine** The diagnosis of strychnine can be confirmed by identification of strychnine in GIT contents, bait, liver, kidney, or urine.
• **Zinc Phosphide** Because zinc phosphide quickly hydrolyzes to phosphine gas, samples of GIT contents, liver, or kidney should be frozen in airtight containers prior to sending to a veterinary diagnostic laboratory for analysis. The detection of zinc phosphide is difficult.

PATHOLOGIC FINDINGS

• **Anticoagulant** After depletion of clotting factors, hemorrhage can occur from any site, including hemorrhage into lungs, GIT, urine, joints, epidural and subdural spaces, and major body cavities.
• **Bromethalin** A postmortem of DMB diagnosis is indicated by diffuse white matter vacuolization in the CNS (intramyelenic edema) and spongiosus.
• **Cholecalciferol** Lesions can include mineral crystal deposition in cortical tubule basement membranes and Bowman capsules. GIT lesions can include mucosal necrosis, sloughing, and hemorrhage. Cardiac lesions include necrotic, disrupted, and mineralized myocytes.
• **Sodium monofluoroacetate (compound 1080)** Postmortem lesions are generally nonspecific. Sheep and cattle can develop endocardial and epicardial petechiae and brain edema.
• **Strychnine** No specific lesions are noted; although, necrosis of the cerebral cortex and brainstem have been reported in strychnine poisoned humans.
• **Zinc Phosphide** The kidneys and liver can show congestion. Histologically, renal tubular degeneration and necrosis can be observed and congestion of the liver and kidneys.

TREATMENT

THERAPEUTIC APPROACH

Anticoagulant

• Treatment includes GIT decontamination shortly after ingestion.
• The use of vitamin K1 as an antidote may depend on presence or absence of coagulation abnormalities.
• If vitamin K1 therapy is not initiated, a clotting parameter can be checked periodically at 36 and 96 hours post-exposure for evaluation.
• If clotting times are prolonged, vitamin K1 treatment and whole blood (plasma) transfusions may be required. The use of vitamin K1 treatment may need to be prolonged (3 weeks or longer if necessary) with exposures to second-generation anticoagulants.
• Additional supportive treatment, oxygen therapy, IV fluid therapy, antibiotics, and stall rest to minimize trauma, may be needed.

Bromethalin

• Treatment immediately post-exposure includes the use of repeated doses of activated charcoal to stop absorption and prevent enterohepatic recirculation of bromethalin.
• It is very important to control cerebral edema and elevated intracranial pressure in a toxicosis. The use of mannitol and dexamethasone have been implemented in small animal cases, with varied success.
• Additionally, maintenance of animal hydration is important along with symptomatic and supportive care.

Cholecalciferol

• In general, treatment consists of GIT decontamination (activated charcoal at 1–4 g/kg PO as a slurry and saline cathartic) shortly after exposure, reduction of hypercalcemia and hyperphosphatemia, restriction of dietary calcium and phosphorus, and supportive therapy (such as 0.9% saline) to maintain adequate hydration, tissue perfusion, and urine flow.
• Corticosteroids have been used to suppress bone resorption and reduce intestinal calcium absorption.
• In small animals, calcitonin has been used for treatment of vitamin D hypercalcemia.

Sodium Monofluoroacetate (Compound 1080)

There is no antidote for monofluoroacetate toxicosis, and the rapid onset of clinical signs can prevent effective decontamination of the GIT with activated charcoal.

Strychnine

• Treatment initially involves GIT decontamination (activated charcoal) if appropriate and supportive and symptomatic care to reverse the hyperthermia and hypoxia.
• More importantly, the convulsions and muscle tremors have to be controlled and respiratory activity needs to be monitored.

Zinc Phosphide

• Treatment includes quick GIT decontamination following ingestion.
• The use of oral aluminum or magnesium hydroxide to slow the hydrolysis of zinc phosphide to phosphine gas is suggested.
• Gastric/rumen lavage with 5% sodium bicarbonate mixture is also recommended to slow the hydrolysis of zinc phosphide to phosphine gas.
• No specific antidote is available for zinc phosphide or phosphine gas.
• Therapy may also be directed towards treating respiratory difficulties (oxygen), treating shock, and supporting animals with liver failure.
• Additional symptomatic and supportive care may be required.

MEDICATIONS

DRUGS OF CHOICE

• **Anticoagulant** A dose of Vitamin K1 in large animals is 0.5–2.5 mg/kg body weight, either IM or SC.
• **Bromethalin** None
• **Cholecalciferol** None
• **Sodium monofluoroacetate (compound 1080)** None
• **Strychnine** None
• **Zinc phosphide** None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• **Anticoagulant** Depending on the severity of hemorrhage, the prognosis can be guarded. Analytic methods can identify specific anticoagulant rodenticides in blood, serum, plasma, liver, GIT contents, and bait; some anticoagulants can be detected in plasma for over 3 weeks.
• **Bromethalin** Mild poisoning cases may recover; however, the prognosis is usually poor for recovery.
• **Cholecalciferol** Animals with progressive azotemia and elevated serum calcium and phosphorus values have a guarded prognosis.
• **Sodium monofluoroacetate (compound 1080)** Severely affected animals generally die within days of exposure. The prognosis is generally poor. No long-term effects on health or reproductive performance were reported in ewes that survived experimental dosing with a single near-lethal dose of 1080.
• **Strychnine** Because of the difficulty in treating large animals with convulsions, the prognosis is poor.

RODENTICIDE TOXICITY (CONTINUED)

• **Zinc phosphide** The prognosis for animals with clinical signs is poor. Animals ingesting lethal doses rarely survive longer than 48 hours.

PATIENT CARE

• **Anticoagulants** Animals can develop mild to severe anemia, thrombocytopenia, hypoproteinemia, and prolonged clotting factors.
• **Cholecalciferol** Serum calcium, phosphorus, BUN, and creatinine should be monitored. If these values stay in the normal range for 96 hours and the animal remains asymptomatic, no further monitoring is necessary.

PREVENTION

Keep rodenticides away from livestock.

MISCELLANEOUS

PREGNANCY

Anticoagulant rodenticides can potentially cause early embryonic death and abortions.

BIOSECURITY

Monitor all use of rodenticides around feedstuffs. Keep rodenticides away from livestock.

PRODUCTION MANAGEMENT

Keep rodenticides away from livestock and facilities.

ROTAVIRUS

BASICS

OVERVIEW

• Most common cause of neonatal ruminant diarrhea.
• Causative agent, a rotavirus.
• There are several serogroups of rotaviruses A, B, and C affecting ruminants: Serogroup A being the more common in calves and B (pararotavirus) being the more common in kids and lambs.
• Pathogenicity is related to serogroup and load of exposure, level of immunity to the virus, concurrent infection with other neonatal pathogens, and stress.
• Most infections are concurrent with other neonatal pathogens.
• Virus may survive for 9 months in the environment.
• Virus is ubiquitous with seroprevalence in the adult herd of 80–90%.

INCIDENCE/PREVALENCE

• Prevalence of rotavirus infections range from 50% to 100% with a large variation in mortality.
• Depending on immunity, calves may appear normal except for a mild voluminous diarrhea. Farmers often report that this "normal" diarrhea is due to the cow producing too much milk, "milk scours."

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Gastrointestinal

PATHOPHYSIOLOGY

• The virus is acquired through the ingestion of fecal contaminated material.
• Absorptive epithelial cells lining the distal portions of the villi are infected, starting in the proximal portion and moving distally to the middle and distal portions of the small intestine.
• Infected cells contain large numbers of virus particles and are desquamated into the lumen.
• The villi become shortened due to exfoliation of the epithelial cells, resulting in the loss of digestive enzymes contained within the glycocalyx and decreased absorptive capacity of the villi.
• The virus produces an enterotoxin, NSP4, and also stimulates neurotransmitters which increases intestinal secretions.
• The loss of epithelial cells results in a maldigestive as well as a malabsorptive type diarrhea. Undigested carbohydrates undergo bacterial fermentation resulting in an increase in osmotic pressure and water being drawn into the intestinal lumen. Maldigestion and malabsorption alter bacterial flora which may contribute to the diarrhea.
• Diarrhea results due to increased osmotic pressure and decreased absorption.
• The physical loss of epithelial cells results in increased susceptibility to other pathogens due to loss of villous integrity and decreased secretion of lactoferrin and lysozymes.
• Epithelial damage predisposes attachment of ETEC and attaching and effacing *E. coli* to the intestinal villi.
• The loss of electrolytes, bicarbonate, and water leads to dehydration and metabolic acidosis.

HISTORICAL FINDINGS

• Sudden onset of diarrhea that spreads rapidly through the neonatal population.
• Initially a few cases are noted but the frequency of cases increases as the calving season progresses due to increased viral load in the environment.
• An increase in the number of cases is frequently observed following periods of stress such as a snowstorm or cold wet weather.
• Individuals within a specific population may develop diarrhea at the same day of age.

SIGNALMENT

• Bovine, caprine, and ovine.
• Most infections occur between 7 and 14 days of age.
• Range 1 day to 8 weeks.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs will vary from mild to severe diarrhea. In uncomplicated disease, diarrhea may exist for 1–2 days.
• Secondary bacterial infection may result in diarrhea for 3–5 days.
• Mild to severe watery white diarrhea, often with large amounts of mucus; color, consistency, and composition vary with coexisting infections.
• Dehydration and depression with degrees of inappetance or reluctance to nurse.
• Some animals may be weak to the point of recumbency.

CAUSES AND RISK FACTORS

• Rotavirus serogroup A most common in calves.
• Rotavirus serogroup B, pararotavirus in small ruminants.
• Inadequate colostral transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia.
• Lack of local colostral immunity in the case of neonates fed milk replacers.
• Lack of specific antibodies against the infective serogroup or type of rotavirus in colostrum.
• Birthing areas and neonatal housing contaminated with virus resulting from a build-up of manure or inadequate cleaning and disinfection.
• Neonates housed or maintained in a cold wet environment.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• *E. coli*, coronavirus, cryptosporidia, *Salmonella* spp., and *Clostridium perfringens* type C are disease agents commonly cause diarrhea during the first 3 weeks of life.
• Nutritional causes of diarrhea may be differentiated from rotaviral diarrhea if history contains a dietary change or identification of nutritional deficiencies or excesses.

CBC/BIOCHEMISTRY/URINALYSIS

• CBC: Hemoconcentration, increased plasma proteins.
• Serum chemistry: Metabolic acidosis with low plasma bicarbonate. Glucose and electrolyte values may be low depending on severity of diarrhea.

OTHER LABORATORY TESTS

• Feces should be collected as soon as diarrhea is noted, within 48 hours of onset, because exfoliation of virus-laden enterocytes is short-lived and occurs early in the disease process.
• Bovine rotavirus (BRV) real-time PCR detects at least 30% more cases of group A rotaviruses in feces and intestinal tissues than antigenic detection methods.
• Feces can be submitted for electron microscopy and identification of virus. A few drops of formalin can be added to 10 mL of feces for preservation.
• Feces can be submitted for ELISA and latex agglutination tests for detection of viral antigens.
• Fresh sections of the small intestine, preferably mid ileum, tied at the cut ends to contain intestinal contents can be submitted on ice for fluorescent antibody testing.

PATHOLOGIC FINDINGS

• No gross lesions except for increased fluid contents throughout the intestinal tract.
• Histopathology: Intestinal villi are shortened.

TREATMENT

THERAPEUTIC APPROACH

• Fluid therapy is needed to correct dehydration, circulatory impairment, and electrolyte and metabolic imbalances.
• Fluid deficit should be calculated as well as maintenance requirement, 80–100 mL/kg, and fluid loss in the diarrhea to determine volume of fluids needed during a 24-hour period.
• Fluids may be administered orally or intravenously. Commercial oral electrolyte solutions containing glucose and a

ROTAVIRUS (CONTINUED)

non-bicarbonate alkalinizing agent are recommended if the neonate is still nursing. Although oral electrolytes are less likely to be absorbed due to enterocyte pathology, not all enterocytes are affected so some absorption does occur.
• Neonates without a suckle response need IV fluids. IV administration of isotonic 1.3% sodium bicarbonate solution initially (2 L) followed by lactated Ringer's solution.
• Dextrose solutions (2.5–5%) are indicated in cases of hypoglycemia. With hypoglycemia and after correcting acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.
• Although not specific for rotaviral infections, in cases of failure of passive transfer and depending on value of the animal, plasma transfusion may be warranted.

MEDICATIONS

DRUGS OF CHOICE
• Broad-spectrum antibiotics may be considered because of the potential for mixed infections as well as the loss of mucosal integrity.
• Oral amoxicillin trihydrate 10 mg/kg PO q12h for nonruminating calves, 20-day slaughter withdrawal (extra-label in small ruminants). Amoxicillin trihydrate-clavulanate potassium 12.5 mg combined drug/kg PO q12h for 3 days (extra-label usage).
• Parenteral ceftiofur 2.2 mg/kg IM q24h for 3 days (extra-label usage).
• Drug withdrawal times must be determined and maintained in the treated animal.

CONTRAINDICATIONS
Do not use kaolin and pectin as may increase electrolyte loss.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• In uncomplicated infections, diarrhea is present for 1–2 days.
• Prognosis is good, as this infection tends to be self-limiting and generally requires minor supportive care.
• Duration of diarrhea may be 3–5 days with secondary bacterial infections.
• Prognosis is dependent on the degree of pathology produced by the secondary bacteria.
• Prognosis is good to fair with supportive care.

POSSIBLE COMPLICATIONS
• Hypovolemic shock
• Secondary bacterial infections

CLIENT EDUCATION
• Neonates should be kept dry and in a draft-free environment.
• Animals should be moved and fed in such a way as to reduce the build-up of mud and fecal material in the neonate's environment.
• Diarrheic animals should be isolated from healthy neonates as they are sources for large numbers of pathogens.

PATIENT CARE
• Monitor attitude, suckling response and appetite, fecal color and consistency, and hydration status every 6–12 hours.
• Monitor age cohorts for signs of diarrhea.
• Neonates with a suckle response should be left with the dam and allowed to nurse.
• Animals being reared artificially should remain on their diet or switched to whole milk or colostrum. If the diarrhea becomes worse or the calf becomes depressed, removal from the dam or milk is warranted. In case of hand-fed neonates that are depressed and not interested in sucking, or neonates not nursing the dam, neonates should receive daily a high-energy electrolyte solution at a rate of 10% of body weight divided into a minimum of 4 feedings.
• Once neonates are suckling, feed milk at a rate of 5% of body weight in 4 feedings a day, increasing the amount per feeding gradually so calf is back on full feed within 2 days.
• Calves should also receive 5% of their body weight in electrolyte solutions spacing 2 hours before or after milk feedings. Milk should not be withheld longer than 24 hours and can be given via an esophageal feeder. No more than 1 liter should be tubed at a time.
• Oral electrolytes containing bicarbonate should not be fed when calves are receiving milk as milk digestion may be disrupted.

PREVENTION
• Reduce viral exposure, by calving in clean maternity areas and moving to a clean area after birth.
• Diarrheic animals should be isolated from healthy neonates as they are sources for large numbers of pathogens.
• Feed youngest animals first and oldest animals last.
• Those handling sick neonates should practice biosecurity measures to reduce exposure to healthy neonates, wash hands and disinfect boots, maintain clothes free of fecal material.
• Vaccination of dams prepartum according to manufacturers' recommendations with a rotaviral vaccine may increase colostral antibody. Effectiveness will be dependent on field virus serogroup and type and that contained in the vaccine.
• Oral vaccination of neonate with a modified-live oral vaccine will produce IgA and IgM. This vaccine is cumbersome for management as it is to be given prior to colostrum consumption and colostrum must be withheld for several hours after vaccination. This may increase the opportunity for bacterial infections and failure of passive transfer.
• In the case of dairy animals, feed neonates colostrum for 30 days if rotavirus is an endemic problem.
• Eliminate areas of fecal build-up.
• Keep environment dry and draft free.

MISCELLANEOUS

AGE RELATED FACTORS
• Most cases between 7 and 21 days of age.
• Range 1 day to 8 weeks.

ZOONOTIC POTENTIAL
• Isolates from neonatal ruminants have not been infective to humans.
• Some human isolates have been found to be infective for calves.

BIOSECURITY
• Diarrheic animals should be isolated from healthy neonates as they are sources for large numbers of pathogens.
• Feed youngest animals first and oldest animals last.
• Those handling sick neonates should practice biosecurity measures to reduce exposure to healthy neonates, wash hands and disinfect boots, maintain clothes free of fecal material.
• Disinfect with bleach, or phenolic or peroxymonosulfate compounds. Surface must be free of organic material and surface contact is a minimum of 10 minutes.

ABBREVIATIONS

RUMEN DYSFUNCTION: ALKALOSIS

BASICS

OVERVIEW
Indigestion resulting from rumen inactivity or toxins that promote alkaline rumen pH and dysfunction.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• Usually relates to continued production and swallowing of alkaline saliva during periods of reduced microbial fermentation that produce insufficient acid to neutralize saliva. • Continued absorption of VFAs, especially acetate, across the rumen wall also contributes to alkalinity because of bicarbonate generation in the rumen fluid. • Rumen alkalosis can occur due to excessive ammonia production related to overfeeding of NPN sources or toxin ingestion.

HISTORICAL FINDINGS
Reduced feed intake or dietary accidents may be reported.

SIGNALMENT
Functional ruminants of any age can be affected.

PHYSICAL EXAMINATION FINDINGS
- Forestomach dysfunction
  - ◦ Decreased appetite ◦ Rumen hypomotility
  - ◦ Bloat ◦ Abnormal regurgitation
  - ◦ Abdominal pain
- Signs of urea toxicosis
  - ◦ Diarrhea ◦ Muscle tremors ◦ Incoordination
  - ◦ Weakness ◦ Tachypnea ◦ CNS excitation
  - ◦ Rapid deterioration and death

GENETICS
N/A

CAUSES AND RISK FACTORS
• Mild alkalosis (rumen pH 7.0–7.5) can result from prolonged anorexia, microflora inactivity, ingestion of poorly digestible roughage, and some cases of simple indigestion. • Severe alkalosis (rumen pH >7.5) usually relates to excessive ingestion of NPN sources such as urea, biuret, ammonium phosphate, and ammonium salt containing fertilizers.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Rumen acidosis • Simple indigestion • Vagal indigestion • Other systemic or primary diseases causing anorexia

CBC/BIOCHEMISTRY/URINALYSIS
• Dehydration is reflected by increased hematocrit, BUN, creatinine, and total protein. • Leukocytosis (stress) may occur. • Hypokalemia and hypocalcemia. • Alkalemia.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Ruminocentesis/ororuminal tubing for rumen fluid analysis • Rumen fluid pH 7.5–8.5 • Strong odor of ammonia
- ◦ Poor microbial activity under light microscopy ◦ Exposure of tube to oral cavity during ororuminal tubing can falsely elevate pH due to exposure of tube to alkaline saliva.

PATHOLOGIC FINDINGS
• In acute cases, the rumen fluid pH is 7.5–8.5 and may smell of ammonia if NPN ingestion is the cause. • Histopathologic examination might show rumen epithelial exfoliation and, in cases of urea toxicity, lesions in other organs have included lymphocytic abomasitis, necrotic enteritis, follicular cholecystitis, and meningoencephalitis.

TREATMENT

THERAPEUTIC APPROACH
• Identify and manage primary disease. • Correct acid-base and electrolyte aberrations with appropriate fluid therapy. • Establish normal rumen volume as relevant.
- ◦ Increase volume with 8–16 L of rumen fluid and balanced oral electrolytes.
- ◦ Decrease volume by removing abnormal rumen contents by siphon or rumenotomy.
- ◦ Resolve rumen impaction.

• Can provide acetic acid 4–10 L in cold water orally to correct rumen pH and diminish systemic ammonia absorption from the rumen.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgical evacuation of the rumen via rumenotomy may be relevant in cases of acute intoxication.

MEDICATIONS

DRUGS OF CHOICE
• Medications as indicated by primary disease. • B vitamin supplementation since B vitamin production will be diminished during rumen dysfunction.

CONTRAINDICATIONS
Do not administer magnesium hydroxide if rumen alkalosis is present.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Mild cases are often easily corrected with transfaunation and gradual provision of good-quality feeds. • Severe alkalosis caused by intoxication may require rumen evacuation, along with rumen fluid replacement and supportive care, and the prognosis is poor.

POSSIBLE COMPLICATIONS
Rumen putrefaction can occur: high rumen pH and inoculation with bacteria such as coliforms and *Proteus* spp. from spoiled or fecal-contaminated feeds leads to putrefactive decomposition.

CLIENT EDUCATION
See "Prevention"

PATIENT CARE
• Monitor patient for return to appetite and normal rumen motility • Some cases may require repeat transfaunation

PREVENTION
• Good feed management • Provision of quality digestible feedstuffs • Proper administration of NPN sources • Securing fertilizers

MISCELLANEOUS

ASSOCIATED CONDITIONS
Rumen putrefaction

PRODUCTION MANAGEMENT
Prevention requires good management of feedstuffs and good security of fertilizer storage.

ABBREVIATIONS
• BUN = blood urea nitrogen • CNS = central nervous system • NPN = non-protein nitrogen • VFA = volatile fatty acids

R

RUMINAL ACIDOSIS

BASICS

OVERVIEW

• Acute ruminal acidosis is the most dramatic form of indigestion in ruminants and, in some cases, can lead to death in <24 hours.
• Subacute ruminal acidosis (SARA) results from chronic indigestion leading to short- or long-term production inefficiencies.
• In camelids, the disease is known as forestomach acidosis. Similar to cattle and sheep, the clinical presentation can be acute or chronic.
• Ruminal acidosis results from ingestion of excessive quantities of rapidly fermentable carbohydrates (RFC). Therefore, it represents a major challenge for ruminants on high-concentrate diets (e.g., feedlot cattle).
• Rumen pH of 4.5–5.0 and 5.2–5.5 are used as benchmarks for acute and chronic ruminal acidosis, respectively.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Digestive
• Multisystemic

PATHOPHYSIOLOGY

Acute Ruminal Acidosis

• Excessive consumption of RFC leads to a rapid fermentation with production of short-chain fatty acids and both D- and L-lactic acid. This causes a decrease in ruminal pH to physiologically inappropriate levels.
• Decreased rumen pH causes significant changes in the ruminal microbiome, especially rapid proliferation of the amylolytic or sugar-utilizing bacteria such as *Streptococcus bovis*.
• Under low pH conditions, lactate-producing bacteria (e.g., *Lactobacillus* spp.) also grow faster, increase in number, and produce excessive amounts of D- and L-lactate.
• The rumen's ability to use lactate is exceeded when large amounts of lactate are produced, resulting in its accumulation.
• If sufficient substrate is available, production of lactate by *S. bovis* continues, leading to a profound reduction in ruminal fluid pH (4.5–5.5) and a severe increase in ruminal osmolality.
• Low pH and high ruminal fluid osmolality kill or inhibit small protozoa which normally limit the production of lactate by using small sugars, and lactate-utilizing bacterial species (e.g., *Megasphaera elsdenii*, *Propionibacterium shermanii*, and *Selenomonas ruminantium*).
• Under these low pH conditions (pH ~ 4.5), lactate-producing bacterial species outnumber lactate-utilizing species (the number of *S. bovis* is decreased and the number of *Lactobacillus* species is increased) leading to a further lactic acid accumulation.
• Rapid increase of ruminal osmolality and accumulation of lactic acid draws fluid into the rumen producing dehydration, third space fluid sequestration, ruminal distension, and, in severe cases, circulatory shock.
• Lactic acid and increased ruminal fluid osmolality cause damage to the ruminal epithelium and vascular bed that can result in loss of albumin, absorption of enteric toxins or translocation of bacteria with subsequent toxemia, septicemia/bacteremia, SIRS and MODS associated hypovolemic and septic shock.
• Thiamine deficiency can be triggered by thiaminases produced by rumen bacteria under low pH conditions, causing polioencephalomalacia and neurologic signs.

SARA

• Similar to acute ruminal lactic acidosis, SARA has been associated with feeding starch-rich diets.
• Unlike ruminal acidosis, SARA results from continued ingestion of these feeds over a prolonged period of time rather than sudden exposure without adequate adaptation.
• Upon induction of SARA, an increased concentration of toxin (LPS) is observed within several compartments of the rumen.
• Chronic ruminal wall lesions allow penetration of bacteria and endotoxin with dissemination to the bloodstream, predisposing the cow to a chronic systemic inflammatory response and laminitis.
• Translocation of bacteria frequently results in liver abscess.

SIGNALMENT

• Potentially all ruminant species.
• Sheep appear to be more susceptible to acidosis than other ruminants.

PHYSICAL EXAMINATION FINDINGS

Acute Ruminal Acidosis

• Anorexia
• Marked decreased milk production
• Diarrhea or loose feces
• Dehydration, circulatory shock, and death
• Tachycardia and tachypnea
• Laminitis or founder
• Vomiting
• Totally static rumen
• Polioencephalomalacia

Acute Forestomach Acidosis in Camelids

• Depression
• Weakness
• Ataxia
• Head arched over the back
• Abdominal distension
• Diarrhea

SARA

• *Herd:* Increased incidence of abomasal diseases, lameness (due to laminitis), indigestion
• Decreased milk production and milk fat content
• Reduced metabolic efficiency and overall performance

Chronic Forestomach Acidosis in Camelids

• Ill-thrift
• Cycles of weight gain and loss
• Intermittent diarrhea

CAUSES AND RISK FACTORS

• Feedlot cattle during the period of adaptation to high-concentrate diets.
• Feedlot cattle adapted to high-concentrate diets that suddenly ingest large quantities of RFC.
• Acute and chronic ruminal acidosis can occur in grazing cattle when large amounts of high-starch supplements are fed.
• Dairy cattle during the early postpartum period due to the introduction of high-concentrate diets containing more RFC than those fed during the dry period.
• Sources of RFC include immature/rapidly growing forages (i.e., high in intracellular carbohydrates), tubers/root crops (i.e., high in sugars), and cereal grains (i.e., high in starch).
• Cereal grains are considered the most important source of RFC (wheat is more fermentable than corn or milo).
• Cold weather as it promotes consumption of large amounts of feed, predisposing feedlot cattle to acidosis.
• Accidental ingestion of large quantities of grain by gaining access to the grain room (cattle and camelids).
• Improper mixing of total mixed rations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• *Acute ruminal acidosis*—Causes of acute abdomen in cattle and small ruminants.
• *SARA*—Causes of reduced metabolic efficiency and overall performance.
• *Chronic forestomach acidosis in camelids*—Causes of weight loss and chronic diarrhea. See chapter, Diarrheal Diseases: Camelid, for details.

CBC/BIOCHEMISTRY/URINALYSIS

Acute Ruminal and Forestomach Acidosis
• Hemoconcentration—dehydration

RUMINAL ACIDOSIS (CONTINUED)

• Neutropenia with left shift—septicemia/bacteremia
• Metabolic acidosis—increased D- and L-lactate and anion gap
• Hypocalcemia and hypomagnesemia
• Increased liver enzymes—dehydration, hypovolemic and septic shock
• Aciduria
• Azotemia—dehydration and shock
• Hyperglycemia—camelids

SARA
• Chronic inflammatory response (i.e., cattle with liver abscessation)
• Hypocalcemia
• Decreased milk fat content

OTHER LABORATORY TESTS

Analysis of Ruminal Fluid

Acute Ruminal Acidosis
• Acidic odor.
• Rumen pH of 4.5–5.0 (normal 6.0–7.0 on roughage and 5.5–6.5 on grain).
• Sedimentation and reduction-oxidation times are prolonged.
• Protozoa—reduced numbers.
• Bacteria—predominance of Gram-positive cocci and rods.
• Rumen osmolality—increased >300 mOsm due to accumulation of solutes such as VFA, lactate, glucose, and minerals.

Acute Forestomach Acidosis in Camelids
Ruminal fluid pH drops to 40–4.5 (normal 6.4–6.8).

SARA
• Rumen pH drops daily to <5.5 for a given period of time. This has negative effects on fermentation and the subsequent utilization of nutrients.

Chronic Forestomach Acidosis in Camelids
• Ruminal fluid pH drops to 5.5 (normal 6.4–6.8).
• Ruminal fluid pH below 6 is suspicious.

OTHER DIAGNOSTIC PROCEDURES

Acute Ruminal Acidosis
• History of feeding in the herd, physical examination, analysis of ruminal fluid.
• Biochemical profile, acid-base and electrolytes abnormalities.

SARA
• Made at the herd level rather than individual animals.
• Determination of ruminal pH.
• Ruminocentesis is preferred to oro-ruminal collection to avoid contamination with saliva.
• Collection should be performed 4–8 h post-feeding.
• A pH <5.5 in 40% or more of the cows from a sample of 12 animals from the herd has been suggested for diagnosis of SARA.

PATHOLOGIC FINDINGS

• Rumenitis, reticulitis, and inflammation of the small intestine.
• Liver abscesses (especially in chronic cases).

TREATMENT

THERAPEUTIC APPROACH

Acute Ruminal Acidosis

• Clinicians must decide whether surgical treatment is required or medical therapy will be sufficient.
• Rumen can be evacuated via rumenotomy or, in less severe cases, ruminal lavage can be performed using a Kingman tube or a large oro-ruminal tube.
• Rumen contents must be evacuated and the rumen washed with water several times.
• Magnesium hydroxide (500 g/450 kg body weight) can be administered once the rumen has been evacuated.
• Administration of good-quality hay (via rumenotomy)
• Rumen transfaunation may help to restore the ruminal microbiome.
• Determine fluid requirements—replacement, maintenance, and ongoing losses.
• Animals estimated to be more than 8% dehydrated: Rehydrate IV initially, and then may be maintained with IV or oral fluid therapy.
• Oral fluid therapy: Large volumes of water and rehydration solutions can be administered.
• The volume (L) of fluids to replace the deficit can be calculated as: Volume (L) = body weight (kg) × % *dehydration.* Lactated Ringer's solution or isotonic 0.9% saline at 20 mL/kg/h (highest rate reached through a 14-gauge catheter) is recommended for fluid replacement.
• Maintenance fluid rate: Recommended 2–4 mL/kg/h of lactated Ringer's solutions or isotonic 0.9% saline.
• Cows with mild acidemia (base deficits <10 mmol/L): Administer lactated Ringer's solution supplemented with potassium chloride and calcium.
• Cows with more severe acidemia (base deficits <10 mmol/L): Administer isotonic sodium bicarbonate (156 mmol/L).
• Bicarbonate requirements—calculate from values of base deficit (BD) obtained from the blood gas measurement. Bicarbonate (mmol) = body weight (kg) × base deficit (mmol/L) × 0.3.
• If blood gas is not available, BD can be calculated from values of TCO_2 provided in biochemical profiles. BD = 25 – TCO_2.
• Calcium, magnesium, and phosphates should be supplement to correct deficits.
• See chapter, Diarrheal Diseases: Camelid and chapter, Diarrheal Diseases: Small Ruminant, for fluid therapy recommendation in those species.
• Remove the RFC source from the diet.

SARA

Increasing buffer input from the diet and/or through salivation by increasing forage levels in the diet, especially long hay to stimulate rumination.

MEDICATIONS

DRUGS OF CHOICE

• Analgesic and anti-inflammatory drugs—flunixin meglumine or meloxicam to decrease the effects of the systemic inflammatory response.
• Antimicrobials—oxytetracycline and penicillin (ceftiofur in camelids) can be administrated to prevent or treat bacteremia and liver abscess development.
• Broad-spectrum antimicrobial therapy can predispose to mycotic rumenitis.
• Prevention of polioencephalomalacia: Administer thiamine HCl (10 mg/kg, IM or IV q4h).

CONTRAINDICATIONS

• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Broad-spectrum antimicrobial therapy can predispose to mycotic rumenitis.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

N/A

POSSIBLE COMPLICATIONS

N/A

CLIENT EDUCATION

N/A

PATIENT CARE

N/A

PREVENTION

• Gradual adaptation of animals to high-concentrate diets. A 4-week adaptation period may provide the time necessary for adjustment to a new diet.
• Feeding long forages or by-products containing high fiber at 10–15% of dry matter will promote rumination and stimulate salivation (increase the quantities of buffers in the rumen).
• Decrease the amount of cereal grains. Wheat can increase the risk of ruminal acidosis.
• Management and close monitoring of feeding processed grains such as steam-flaked corn. The gelatinization of starch during

steam flaking increases its rate of fermentation.
• Close monitoring of daily intake of diets containing high RFC levels.
• High protein and 6% fat in the diets.
• Oral administration of buffers such as sodium bicarbonate at 1% or 2% of dry matter to increase the buffering capacity of the rumen.
• Allow access to fresh feed and water at all times.
• Administration of ionophores including monensin and lasalocid—to alter rumen fermentation, allow adjustment to high-starch diets by inhibiting lactate-producing bacterial species.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Diarrhea, frequently seen in small ruminants and camelids
• Laminitis
• Decreased rate of body weight gain
• Decreased milk production
• Polioencephalomalacia
• Rumen atony
• Liver abscess

PRODUCTION MANAGEMENT
• Ruminal acidosis has high economic significance because a large number of cattle and sheep are finished on high-concentrate diets.
• Economic losses include death and decreased performance of animals.

ABBREVIATIONS
• BD = base deficit
• LPS = lipopolysaccharides
• MODS = multiple organ dysfunction syndrome
• RFC = readily fermentable carbohydrates
• SARA = subacute ruminal acidosis
• SIRS = systemic inflammatory response syndrome
• TCO_2 = total carbon dioxide
• VFA = volatile fatty acids

RYEGRASS STAGGERS (PERENNIAL, LOLITREM B)

BASICS

OVERVIEW
Infection of perennial ryegrass (*Lolium perenne*) with endophyte fungus *Neotyphodium lolii.*
• Consistent problem in Australia and New Zealand and occasional problem in the United States (north coast of California).
• Different from annual ryegrass (*Lolium rigidum*) staggers which is a much deadlier disease.
• Summer and fall during hot and dry weather.
• Same disease as bermudagrass staggers and paspalum staggers.

INCIDENCE/PREVALENCE
• In outbreaks, morbidity may reach 80–90%, but mortality is low (0–5%).
• Deaths are usually accidental, often by drowning when drinking from ponds or streams, or due to the inability to forage for food and water.

GEOGRAPHIC DISTRIBUTION
• US (California)
• Australia
• New Zealand

SYSTEMS AFFECTED
Nervous

PATHOPHYSIOLOGY
• Lolitrem B, produced by the endophyte, is a neurotoxic indole-diperpenoid.
• Currently it is thought that lolitrem B impairs or inhibits potassium channels.
• Caused by interference with neuronal transmission in the cerebellum.

HISTORICAL FINDINGS
Occurring mainly in the summer and fall during hot, dry weather, the disease has become quite common in certain areas.

SIGNALMENT
• Bovine, ovine
• Any age that grazes pastures

GENETICS
Within flocks and herds, individual susceptibility varies greatly, and this trait is heritable.

PHYSICAL EXAMINATION FINDINGS
• At rest, animals may exhibit only a fine tremor of the head or neck.
• When forced to move they move with a stiff, stilted, uncoordinated gait and may collapse.
• When in recumbency animals exhibit opisthotonus, nystagmus, and flailing of stiffly extended limbs.
• In less severe cases, the attack soon subsides, and the animal regains its feet within minutes.
• Reduced milk yield in cows has been recorded in New Zealand and Australia.

CAUSES AND RISK FACTORS
• Tremorgenic toxin
• Exposure to endophyte-infected plant

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Fungal tremegons
• Grass tetany
• Mycotoxins
• Polioencephalomalacia
• Oxalate toxicity

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic changes

OTHER DIAGNOSTIC PROCEDURES
• Analysis of grass for *Neotyphodium lolii*
• History of exposure to the endophyte infected plant
• Clinical signs

PATHOLOGIC FINDINGS
No specific gross or histologic lesions are recognized.

TREATMENT

THERAPEUTIC APPROACH
• Remove from source.
• Because movement and handling of animals exacerbates signs, individual treatment is generally impractical.
• Recovery is spontaneous in 1–2 weeks if animals are moved to nontoxic pastures or crops.

MEDICATIONS

DRUGS OF CHOICE
None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Full recovery when removed from source.
• Recovery is usually complete within a few days to a week. Occasionally, tremors are elicited in cattle several weeks later when they are handled.
• Death is rare.

PATIENT CARE
Avoid stressing the animals. If the animal is forced to run, the episode is repeated. Signs are most severe when the animal is heat stressed.

PREVENTION
• Control by grazing management can help reduce or prevent the disease.
• Lolitrems and ergovaline are concentrated in the leaf sheath and inflorescences. If pastures are not overgrazed down into the leaf sheath zone or grazed when the plants are flowering, then animals should be relatively safe even when a high proportion of the ryegrass plants are infected with endophytes.
• Encouragement of growth of other grass species and legumes in established swards also reduces the intake of toxic grass.

MISCELLANEOUS

PRODUCTION MANAGEMENT
• Good pasture management is essential.
• New pastures can be established using ryegrass seed with little or no endophyte infection. However, the presence of endophyte in grasses makes the plants resistant to attack from many insects; thus, infected pastures are more persistent than endophyte-free pastures.
• Cultivars of ryegrass artificially infected with a strain of endophyte that does not produce lolitrem B or ergovaline are available in New Zealand.

SYNONYMS
• Bermudagrass staggers
• Perennial ryegrass staggers
• Paspalum staggers

SEE ALSO
• Fungal Tremogens
• Grass Tetany/Hypomagnesemia
• Mycotoxins
• Ovine Encephalomyelitis (Louping Ill)
• Oxalate Toxicity

SALMONELLOSIS

BASICS

OVERVIEW

• *Salmonella* infections are the second most economically important bacterial disease affecting the gastrointestinal system in ruminants.
• The severity of the disease is dependent on the virulence of the serovar, dose of organisms, the immune status of the animal, and environmental stressors.
• Infections in young animals are associated with contaminated environments and immune status.
• Outbreaks in adults are associated with stress and exposure to a virulent serovar.

INCIDENCE/PREVALENCE

• As farm size and concentration of animals has increased, so has the incidence of disease.
• Once an outbreak has occurred on a farm, the environmental prevalence of the organisms may be high, but the incidence of clinical disease is usually low.
• The farm prevalence of *Salmonella* was determined to be 9.2% for cow calf operations and 30% for dairy operations, based on the US National Animal Health Monitoring System Beef 07-08 study and Dairy 2002 study.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Cardiovascular
• Digestive
• Musculoskeletal
• Nervous
• Respiratory
• Urinary
• Multisystem

PATHOPHYSIOLOGY

• *Salmonella* organisms are most commonly acquired through the fecal-oral route or consumption of contaminated feeds.
• Carrier cows may secrete organisms directly into milk, especially *S.* Dublin.
• Young calves are susceptible to infection because the organism easily passes through the rumen and the abomasum. There are no volatile fatty acids in the rumen nor is the abomasal pH low enough to kill the organism. Likewise, calves lack colonization resistance within the intestines.
• The organism attaches, via adhesins, to mucosal cells of the ileum, cecum, and colon invading epithelial cells, moving through the mucosa, resulting in an inflammatory response with macrophage uptake and entrance into lymphoid tissue and the bloodstream.
• Various virulence and host factors determine the extent of damage and invasiveness of the organism.
• The organism secretes exotoxins that stimulate fluid secretions and damage host cells. In addition, lipopolysaccharide (LPS) is released during bacterial replication and death. These LPSs stimulate the inflammatory cascade leading to tissue damage, cardiovascular changes, and signs of toxemia.
• Diarrhea results from increased cellular secretions, malabsorption, and maldigestion due to mucosal damage and the inflammatory response.
• Pneumonia results from septicemia.
• Dry gangrene results from cold agglutinins.

HISTORICAL FINDINGS

• Salmonellosis in animals >3 months of age is often associated with the introduction of a carrier animal into the herd as well as recent exposure to new water or feed sources.
• Periods of stress such as grouping of animals, late pregnancy, parturition, early lactation, transport, feed or water deprivation, surgery, or antibiotic usage are often associated with cases or outbreaks.

SIGNALMENT

• Bovine, caprine, and ovine.
• In calves, infections occur from 14 days to 2 months of age.
• All animals, regardless of age, are at risk of developing salmonellosis.

PHYSICAL EXAMINATION FINDINGS

• The disease may have three different presentations, including peracute, acute, and chronic.
• Acute infections may result in a chronic state.
• Depending on the virulence of the specific serotype and immune status of the host, the organism may be contained within the intestinal tract or invade the circulatory system resulting in multiple organ pathology.
• Clinical signs are often associated with the release of endotoxins and the development of endotoxemia.
• Animals infected with non-host adapted *Salmonella* may be convalescent carriers up to 6 months.

Peracute Infections

• May observe anorexia, depression, right-sided abdominal distension, and dehydration prior to sudden death, in cattle >6 months of age.
• Signs of overwhelming septicemia, meningitis, opisthotonus, and convulsions may be observed in animals <6 months.
• Signs of diarrhea and colic are not common consistent findings.

Acute Infections

• Most frequently encountered state.
• Animals exhibit enteritis, fever, anorexia, depression, and dehydration.
• Feces initially are watery in nature, becoming voluminous with a foul odor and may contain shreds of mucosa, fibrin casts, and frank blood.
• Animals are severely dehydrated, have sunken eyes, and may be too weak to stand.
• Body temperature initially is elevated but decreases and may be subnormal in the terminal stages of the disease.
• Calves infected with *S.* Dublin are unthrifty in appearance, weak, anorectic, and die acutely.
• Many calves will develop meningoencephalitis, polyarthritis, osteomyelitis, and pneumonia. Some calves, especially if infected with *S.* Dublin, may develop dry gangrene of the distal extremities, ears, and tail.
• Calves may have concurrent pneumonia due to septicemia.
• Adult animals exhibit fever; anorexia, diarrhea, dehydration, and pregnant animals may abort. Heat stress exacerbates clinical signs.

Chronic Infections

• Occur in animals >1 month of age; *S.* Dublin occurs in animals >8 weeks of age.
• These animals fail to thrive; stools may be pudding-like to diarrheic.
• The animals' body temperature may be normal to slightly elevated; animals have poor hair coats and are undersized.

CAUSES AND RISK FACTORS

• Gram-negative facultative intracellular organism.
• *Salmonella enterica* subsp. *enterica* containing 2,500 serovars.
• *Salmonella* Dublin is host adapted to cattle and *S.* Arizonae and *S.* Abortusovis (uncommon in North America) to sheep.
• The most frequently isolated serotypes from cattle include *Salmonella enteric* subsp. *enterica* serovars Typhimurium, Montevideo, Dublin, Newport, and Cerro.
• *Salmonella enterica* subsp. *enterica* serovars Typhimurium, Dublin, and Arizonae are frequently isolated serotypes of sheep and goats.
• Inadequate colostral transfer of immunoglobulins resulting in agammaglobulinemia or hypogammaglobulinemia.
• Birthing areas contaminated with fecal material containing *Salmonella* spp.
• Crowding and poor sanitation increases pathogen concentration and decreases host immunity.
• Use of common feeding and treatment equipment without proper cleaning and disinfection between uses.
• Late gestation, parturition, and induction of lactation are physiologic stressors.
• Factors which reduce immunity or cause alterations in microbial gut flora—transportation, concurrent disease, anesthesia, surgery, feed changes, antimicrobial therapy, and withholding food and water.

SALMONELLOSIS (CONTINUED)

• Herd introductions, especially from multiple sources.
• Wild birds having access to feed and water supplies, especially water fowl.
• Feeding high protein supplements, by-pass proteins and calcium-phosphorus supplements from animal sources as these are often contaminated with the organism.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Diarrhea may be caused by a variety of infectious agents as well as nutritional causes.
• *Clostridium perfringens* type C and *E. coli* occur during the first week of life.
• Cryptosporidia, rotavirus, and coronavirus are disease agents that cause diarrhea during the first 4 weeks of life.
• Coccidiosis occurs after 3 weeks of age and often associated with tenesmus.
• Salmonellosis develops after 2 weeks of age (generally) and is usually associated with a fever while the other agents generally are not associated with a fever.
• Pasteurellosis and mycoplasmosis in animals exhibiting pneumonia.
• Differential diagnoses in animals >1 month of age include dietary changes, indigestion, lactic acidosis, toxicosis, BVDV, and winter dysentery.

CBC/BIOCHEMISTRY/URINALYSIS

• CBC: Hemoconcentration, a slight anemia may exist but is masked by dehydration. A degenerative left shift with neutropenia and band neutrophilia is commonly observed. Plasma proteins are increased initially due to dehydration; however, plasma protein levels decrease due to decreased albumin levels as a result of malnutrition and protein losing enteropathy.
• Serum chemistry: Metabolic acidosis with low plasma bicarbonate. Cattle with nonfatal diarrhea do not develop significant acidosis. Electrolyte values will be low depending on severity of diarrhea and may appear normal but are deficient on a whole-body basis. BUN and creatinine levels are increased due to prerenal azotemia and acute nephrosis due to septicemia and endotoxemia.
• Urinalysis: Depending on state of dehydration, urine will be concentrated, resulting in an increased specific gravity.

OTHER LABORATORY TESTS

• Isolation of the organism from feces in live animals and tissues, bone marrow, and lymph nodes in dead animals along with clinical signs consistent with salmonellosis is confirmatory.
• Samples for bacterial culture should be collected and placed in Cary Blair Transport Media for shipment to the laboratory.
• Fecal PCR can be performed.

PATHOLOGIC FINDINGS

Peracute Infections

• Result in nonspecific gross lesions.
• Petechial hemorrhages on the serosal surfaces of the intestine and in epicardium.
• The lungs are congested.
• Intestines are distended with fluid. The presence of mucosal hemorrhage and necrosis in the intestines is variable.

Acute Infections

• May result in the following gross changes. The abdominal cavity contains increased peritoneal fluid and fibrin tags; the intestines are congested and distended with fluid containing a mixture of mucus and fluid feces along with frank blood, blood clots, pieces of sloughed mucosa, fibrin and mucosal casts; the spleen is enlarged and the liver swollen; lymph nodes are edematous and hemorrhagic; lungs may be congested with evidence of pneumonia.

Chronic Infections

• Result in thickened intestines with evidence of catarrhal enteritis in the distal small intestine, cecum, and colon.
• The mesenteric lymph nodes are hyperplastic and the gall bladder may be thickened containing fibrin.
• Chronic infections associated with *Salmonella* Dublin are exhibited by arthritis, osteomyelitis, and meningitis along with pneumonia.

TREATMENT

THERAPEUTIC APPROACH

• Fluid therapy is needed to correct dehydration, circulatory impairment, and electrolyte and metabolic imbalances. Fluid deficit should be calculated as well as maintenance requirement, 80–100 mL/kg body weight, and estimated fluid loss to determine volume of fluids needed during a 24-hour period.
• Fluid may be administered orally or intravenously. Commercial oral electrolyte solutions containing glucose and an alkalinizing agent (acetate if on whole milk) are recommended for neonates capable of nursing.
• Oral electrolytes are approximately 60% absorbed due to enterocyte pathology and absorption capacity. Neonates without a suckle response need IV fluids. IV administration of 0.9% NaCl is adequate if animals are not severely acidotic.
• With severe acidosis, isotonic sodium bicarbonate solution (1.3%, 13 of sodium bicarbonate to 1 litre of distilled water) may be used. Dextrose solutions (2.5–5%) are indicated in cases of hypoglycemia.
• With hypoglycemia and an unknown electrolyte and acid-base status, a 2.5% dextrose and 0.45% saline solution has been recommended.

MEDICATIONS

DRUGS OF CHOICE

• Florfenicol 20 mg/kg IM q48h (extra-label usage).
• Ceftiofur 2.2 mg/kg IM/SC q12h for 4–7 days (extra-label usage).
• Flunixin meglumine 0.5 mg/kg IV q12h first day, then q24h (extra-label usage).

CONTRAINDICATIONS

• Do not use kaolin and pectin as use may increase electrolyte loss.
• Do not use hypertonic saline.
• Do not use flunixin if renal disease is evident.

PRECAUTIONS

Meat and milk withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Prognosis is dependent on the virulence of the serovar and the host's immune status.
• Animals will have diarrhea or loose stools for approximately 7–10 days.
• Poor weight gains can be expected for 2–3 weeks after clinical signs resolve.
• Some acute infections will become chronic infections.
• Animals may shed the organism in feces for up to 6 months post-recovery.
• Because the organism can survive for months in the environment, outbreaks may recur during periods of animal stress.
• Most outbreaks last 2 weeks, unless the infection becomes endemic, in which case, animals brought into the environment may develop signs over an extended time period.

POSSIBLE COMPLICATIONS

• Endotoxic shock and death.
• Pneumonia and dry gangrene of the distal extremities in calves.
• Retained placenta and metritis in animals that abort.

PATIENT CARE

• Monitor attitude, suckling response and/or appetite, fecal color and consistency, and hydration status.
• Neonates with a suckle response should be left with the dam and allowed to nurse.
• Animals being reared artificially should remain on their diet or switched to whole milk or colostrum. If the diarrhea becomes worse or the calf becomes depressed, removal from the dam or milk is warranted. In the case of hand-fed neonates that are depressed

(CONTINUED) SALMONELLOSIS

and not interested in sucking, or neonates not nursing the dam, neonates should receive a high-energy electrolyte solution at a rate of 10% of body weight divided into a minimum of 4 feedings.
• Calves should also receive 5% of their body weight in electrolyte solutions spacing 2 hours before or after milk feedings. Milk should not be withheld longer than 24 hours and can be given via an esophageal feeder. No more than 1 liter should be tubed at a time.
• Milk and electrolyte solutions can be altered as described previously with a minimum of 10% body weight of fluid per day.
• Oral electrolytes containing bicarbonate should not be fed when calves are receiving milk as milk digestion may be disrupted.
• Ruminating animals should be provided a forage-based diet.
• Force feeding alfalfa meal and electrolytes in a water solution to inappetant animals is helpful.

PREVENTION
• Cleanliness is the basis of prevention. Clean and disinfect animal holding facilities between groups of animals.
• Do not overcrowd animals.
• Equipment should be cleaned and disinfected with iodine, chlorine, or phenolic compounds. Drying and exposure to sunlight increases pathogen die-off.
• Reduce manure build-up.
• Control bird and rodent populations as both may carry *Salmonella* organisms.
• Avoid run-off ponds as water sources.
• Vaccination with a LPS core antigen vaccine will not prevent infection but will reduce clinical signs.
• Sanitary storage and delivery of feedstuffs; keep feeding equipment free of manure.
• Quarantine new additions for 30 days.
• Those handling sick animals should practice biosecurity measures to reduce exposure to healthy animals, wash hands and disinfect boots, maintain clothes free of fecal material.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Acute infections may result in a chronic state.
• Depending on the virulence of the specific serotype and immune status of the host, the organism may be contained within the intestinal tract or invade the circulatory system resulting in multiple organ pathology.
• Clinical signs are often associated with the release of endotoxins and the development of endotoxemia.

AGE-RELATED FACTORS
• Most cases are 2 weeks to 2 months of age.
• All ages are susceptible.
• Infections in young animals are most often a result of contaminated environments.
• Outbreaks in adults are associated with stress and exposure to a virulent serovar.

ZOONOTIC POTENTIAL
• During outbreaks within animal populations, it is not uncommon for animal caregivers to become infected and develop clinical signs.

PREGNANCY
Abortions are common

BIOSECURITY
• Clients should be made aware of the potential for fecal shedding of *Salmonella* organisms by both clinically ill as well as convalescent animals into the environment.
• Isolation and biosecurity procedures to keep organisms from spreading throughout the environment should be developed and instituted.
• Potential for zoonotic spread should be addressed.

PRODUCTION MANAGEMENT
Avoid risk factors by implementing appropriate management and disinfectant procedures.

ABBREVIATIONS

SARCOCYSTOSIS

BASICS

OVERVIEW
Sarcocystosis is a zoonotic disease caused by an intracellular protozoan parasite, *Sarcocystis* spp.

INCIDENCE/PREVALENCE
• In humans, worldwide incidence of intestinal infection is estimated to be 6–10%.
• Ruminants are very prone to sarcocystosis, with an estimated prevalence of 10–100%.

GEOGRAPHIC DISTRIBUTION
Distribution is worldwide. Particular species vary with specific geographic locations.

SYSTEMS AFFECTED
• Hemolymphatic
• Musculoskeletal
• Cardiovascular
• Nervous
• Reproductive

PATHOPHYSIOLOGY
• *Sarcocystis* spp. Have a two-host life cycle involving humans and multiple species of animal. The definitive host is usually a predator or scavenger which is infected through its respective prey, the intermediate host.
• The definitive host is infected after ingesting muscle tissue infected with sarcocysts. The cysts develop into microgametes and macrogametes to an unsporulated oocyst and finally to sporulated oocysts which, after one week, are shed in feces for several months.
• The intermediate host ingests sporocysts during grazing or drinking and they release several sporozoites. The parasite invades the arteries and develops to a first-generation schizont into merozoites I, second-generation schizonts into merozoites II, and finally to third-generation schizonts which are then released in the bloodstream. Schizonts are then circulated to the intermediate host's muscle and nerve cells and form cysts. Infective zooites develop within the sarcocysts in 2–3 months.
• Clinical disease in the intermediate host may occur at two stages in the developmental cycle.
• The first stage occurs at 3–5 weeks after the initial infection and can last for 6–8 weeks. This stage corresponds with the formation of endothelial schizonts with fever, petechiation of mucus membranes, edema, icterus, and macrocytic hypochromic anemia.
• The second stage corresponds to the entry of schizonts into muscle tissue where extensive fiber degeneration and enzyme release can occur. The enlargement of the cysts in massive infestations can cause muscle pain and lameness. After about 100 days, maturation of the cysts occurs, and tissue reactions subside along with clinical signs.
• This recovery from clinical disease may explain the past impression that sarcocystosis was an innocuous condition. In cattle, *S. cruzi* seems to be the only species capable of causing significant clinical disease. In sheep, *S. tenella* can be very pathogenic to lambs.

HISTORICAL FINDINGS
N/A

SIGNALMENT
• Dogs, cats, mammalian wildlife, birds, reptiles, and humans are definitive hosts.
• Intermediate hosts include cattle, sheep, goats, and buffalo in addition to many nonruminant species (pigs, horses, poultry, birds, dogs, cats, rodents, rabbits).

PHYSICAL EXAMINATION FINDINGS
• Usually infection is asymptomatic.
• In ruminants infection can cause fever, anorexia, wasting, weakness, muscle spasms, decreased milk production, diarrhea, pneumonia, sloughing of the tip of the tail, hemorrhages, anemia, icterus, prostration, CNS signs, and death. Pregnant cows may abort.

S

Table 1

Different *Sarcocystis* species

Species	Definitive (final) hosts	Intermediate hosts
S. hominis, S. suihominis	Humans, primates	Cattle
S. cruzi	Dogs, wolves, coyotes, racoons, foxes, hyenas	Cattle
S. hirsuta	Cats	Cattle
S. medusiformis, S. moulei, S. gigantea	Cats	Goats
S. hircicanis, S. capracanis, S. tenella	Cats	Sheep
S. fusiformis, S. buffalonis	Cats	Water buffalo
S. fayeri, S. bertrami	Dogs	Horses
S. leporuum, S. cuniculi	Cats	Rabbits
S. muris, S. cymruensis	Cats	Rodents

GENETICS
N/A

CAUSES AND RISK FACTORS
• *Sarcocystis* spp.
• Dogs, cats, humans, and other carnivores are infected by consuming uncooked tissues of infected animals.
• Ruminants become infected with sporocysts shed in the feces of definitive hosts while grazing on contaminated pastures.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Gastrointestinal parasitism
• Toxicity
• Brucellosis
• Leptospirosis
• Enzootic bovine abortion
• White muscle disease
• CNS diseases: rabies, spongiform encephalopathy, scrapie

CBC/BIOCHEMISTRY/URINALYSIS
• Hypergammaglobulinemia
• Elevations of muscle enzyme activities (creatine kinase, aspartate aminotransferase) and beta and gamma globulin concentrations.

OTHER LABORATORY TESTS
• Immunofluorescent antibody (IFA) test
• PCR-RFLP resolved by agarose gel electrophoresis
• Definitive (final) hosts – visualization of sporocysts in feces.
• Intermediate hosts – gross or microscopic visualization of cysts in muscle tissue (skeletal, cardiac, and esophageal).

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Sarcocysts are evident in stained sections of relevant muscle tissue.

PATHOLOGIC FINDINGS
• Visible cysts of *S. gigantea* are found in sheep tissue and microscopic cysts are detected in the esophagus, diaphragm, heart, and other muscle. However, *S. gigantea* are mildly pathogenic.
• Massive infestation of *S. cruzi* in cattle forms visible lesions leading to carcass condemnation at slaughter.
• Severely affected animals may appear cachectic, or have hemorrhage of the visceral and myocardial serosa.

TREATMENT

THERAPEUTIC APPROACH
Therapeutic treatment is ineffective.

(CONTINUED) SARCOCYSTOSIS

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Pharmacologic treatment is not generally practiced. Experimentally, amprolium administered at 100 mg/kg body weight per os once daily prophylactically for 30 days seemed to reduce the severity of illness in exposed sheep and calves. Except for calves, this is extra-label use.
• Anti-inflammatory medications or vitamin E and immunomodulators may be used as supportive therapy.

CONTRAINDICATIONS
• Do not use amprolium in animals producing milk for human consumption. Do not use in calves to be processed for veal.

PRECAUTIONS
• Amprolium can promote signs of thiamine deficiency (polioencephalomalacia) in ruminants, particularly if overdosed.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• In cattle, only *S. cruzi* has the potential to cause significant clinical disease, which can range from muscle pain, to abortions, to death. Full recovery is seen after 100 days when cysts mature. Sarcocysts will remain in the muscle and can result in carcass condemnation at slaughter.
• *S. tenella* has been associated with high morbidity and mortality in lambs.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
See "Prevention"

PATIENT CARE
N/A

PREVENTION
• Keep definitive carnivore hosts off pasture by means of fencing and other deterrents.
• Ionophore and coccidiostat drugs may help reduce incidence.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Other intestinal parasites
• Meningoencephalitis or encephalitis, hepatitis, and generalized coccidiosis

AGE-RELATED FACTORS
Clinical disease is seen primarily in calves, lambs, and kids.

ZOONOTIC POTENTIAL
• *S. bovihominis*: Humans are the primary host, and generally no clinically significant disease has been documented in humans or cattle in natural infections.
• In experimental infections, some humans experienced transient abdominal pain and diarrhea 10–14 days after exposure, and shed sporocysts in their feces for 5–12 days.
• Other *Sarcocystis* spp. have created rare cases of muscular weakness and pain, periarteritis and subcutaneous tumefaction, indicating humans can potentially serve as intermediate hosts as well. But a causal association has not been established. Immunosuppressed individuals may be at increased risk of clinical disease. It is thought that nearly half of the muscular cysts worldwide in bovines and swine are caused by *S. bovihominis* and *S. suihominis*.

BIOSECURITY

SCHMALLENBERG VIRUS

BASICS

OVERVIEW

• Schmallenberg virus (SBV) is a Bunyaviridae that causes malformations in newborn ruminants in Europe.
• It was first detected in Germany and other parts of Europe during the autumn of 2011.
• SBV infections are often asymptomatic; acute signs included a drop of milk yield, diarrhea, and fever.
• In pregnant animals, thee were abortions and congenital malformations in the parturition period. Besides cattle, sheep and goats, SBV infection was detected in a bison and in alpacas.

INCIDENCE/PREVALENCE

• Seroprevalence in naïve herds varies from 71% to 90%.
• The incidence of reproductive disease (abortion and congenital defects) morbidity and mortality is <3%.

GEOGRAPHIC DISTRIBUTION

• SBV infection was found in numerous European countries including Germany, the Netherlands, Belgium, United Kingdom, Italy, France, Spain, Luxembourg, Denmark, Ireland, Northern Ireland, and Switzerland and antibodies to SBV were detected in animals originating from Austria, Poland, Sweden, Finland, and Norway.
• SBV was discovered by metagenomic analysis of blood samples of cows from a farm in North Rhine-Westphalia in Germany. SBV belongs to a group of teratogenic arthropod-borne viruses, including Akabane virus (AKV).
• The virus infects primarily sheep, goats, and cattle and is supposed to be transmitted by *Culicoides* biting midges including *Culicoides obsoletus* complex, *C. dewulfi, C. scoticus,* and *C. chiopterus*.

SYSTEMS AFFECTED

• Reproductive
• Nervous
• Musculoskeletal

PATHOPHYSIOLOGY

• Arthropod transmission results in viremia.
• Neurons in the brain seem to be the major target for viral replication in the developing fetus. Sheep fetuses seem to be susceptible to SBV infection at 28–50 days of gestation which coincides with the development of the blood brain barrier (BBB). In sheep the BBB starts to develop between days 50 and 60 of gestation and reaches full development by day 123. Thus, the virus may gain easy access to the brain of the fetus during a short period of time: from day 28 of gestation when the placentomes develop until day 50 when the BBB starts to develop. This would explain why disease in adult animals, that have an intact BBB, is mild with no apparent development of lesions in the CNS. SBV inhibits the interferon beta (INF-β) innate immune response of host. The lack of production of IFN-b transcripts, which in cells infected with wild type SBV indicating that the inhibition of IFN production occurred at the level of transcription. The SBV NSs protein is able to modulate at least indirectly the host innate immune response. Thus, the NSs protein of SBV acts as a virulence factor. Importantly, we also found SBV to replicate in neurons of in utero infected calves and lambs.
• In fetal sheep, SBV infection can result in cavitation of the white matter of the cerebrum, cerebellar hypoplasia, mild lymphohistiocytic perivascular encephalitis, and small glial nodules scattered throughout the brain. Thus, the cavitary lesions observed in naturally SBV infected lambs and calves appear to be the natural progression of vacuolar changes within the white matter.
• The malformations and deformities observed in SBV-infected lambs and calves are accompanied by muscle hypoplasia and demyelination. SBV infect the neurons of the gray matter of the spinal cord, which would suggest that muscular hypoplasia and muscular defects observed in SBV infected lambs and calves are mostly secondary to damage of the central nervous system (CNS).

HISTORICAL FINDINGS

Outbreak of aborted, stillborn, and malformed newborns.

SIGNALMENT

Aborting cattle, sheep (most susceptible), and goats

PHYSICAL EXAMINATION FINDINGS

• Mild transient disease can occur in adult ruminants.
• Severe fetal malformation, abortion, and stillbirth.
• The teratogenic effects due to SBV are mostly reported to affect the musculoskeletal system; arthrogryposis, hydranencephaly, brachygnathia, scoliosis, kyphosis, or lordosis were malformations frequently reported during the epidemic.
• Morphologically normal SBV infected animals may present central nervous system alterations, mostly porencephaly.

CAUSES AND RISK FACTORS

• SBV is an enveloped, negative-sense, segmented, single-stranded RNA virus. The three-segmented genome of Bunyaviridae creates a potential for reassortment, which may lead to emergence of new virus strains. Reassortment is a form of genetic recombination in RNA viruses. As with RNA recombination, reassortment requires that a cell be infected with more than one virus. Phylogenetic analysis indicated that Schmallenberg virus might be a reassortant, with segments from Sathuperi virus and Shamonda virus.
• SBV is transmitted by *Culicoides* spp.
• SBV has also been detected in semen of bulls naturally infected with SBV.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Acute symptoms (high fever, diarrhoea, milk reduction and abortion)
  ◦ Bluetongue virus
  ◦ Epizootic hemorrhagic disease virus of deer (EHD)
  ◦ Foot and mouth disease (FMD)
  ◦ Bovine viral diarrhea (BVD)
  ◦ Border disease virus
  ◦ Bovine herpesvirus 1
  ◦ Rift Valley fever
  ◦ Bovine ephemeral fever
• Congenital symptoms
  ◦ Bovine viral diarrhea virus
  ◦ Akabane virus
  ◦ Bluetongue virus
  ◦ Cache Valley virus
  ◦ Nairobi sheep virus
  ◦ Rift Valley Fever virus
  ◦ Other orthobunyaviruses

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

ELISA, indirect immunofluorescence and virus neutralization tests are available to detect SBV antibodies.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Real-time quantitative reverse transcription PCR (RT-qPCR) test for rapid detection of Schmallenberg virus.

PATHOLOGIC FINDINGS

• Gross lesions: The most common gross lesions were arthrogryposis, vertebral malformations, brachygnathia inferior, and malformations of the central nervous system, including hydranencephaly, porencephaly, hydrocephalus, cerebellar hypoplasia, and micromyelia.
• Histologic lesions: The most common histologic lesions are lymphohistiocytic meningoencephalomyelitis in some cases, glial nodules mainly in the mesencephalon and hippocampus of lambs and goats, and neuronal degeneration and necrosis mainly in the brainstem of calves. Micromyelia was characterized by a loss of gray and white matter, with few neurons remaining in the ventral horn in calves. The skeletal muscles had myofibrillar hypoplasia in lambs and calves. The lesions of SBV-associated abortion and perinatal death are similar to those attributed to Akabane virus and other viruses in the Simbu group of bunyaviruses. In fetal sheep, SBV infection can result in cavitation of the white matter of the cerebrum,

cerebellar hypoplasia, mild lymphohistiocytic perivascular encephalitis, and small glial nodules scattered throughout the brain.

TREATMENT

N/A

MEDICATIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• In cattle, the disease is usually acute in form with visible clinical manifestations of fever, reduced milk yield, and diarrhea that subsides, with the animal recovering in 2–3 weeks.
• In sheep and goats, SBV infection is almost asymptomatic with transplacental transmission to fetuses in pregnant animals, causing abortions, stillbirths, and a variety of congenital malformations.

POSSIBLE COMPLICATIONS

N/A

CLIENT EDUCATION

Report any increase in abortion or neonatal abnormalities.

PATIENT MONITORING

Animals with congenital defects will have permanent neurologic deficits.

PREVENTION

• Control the *Culicoides* vectors by employing methods such as the application of insecticides and pathogens to habitats where larvae develop; environmental interventions to remove larval breeding sites; controlling adult midges by treating either resting sites such as animal housing or host animals with insecticides; housing livestock in screened buildings; and using repellents or host kairomones to lure and kill adult midges.
• The treatment of livestock and animal housing with pyrethroid insecticide combined with the use of midge-proofed housing for viremic or high-value animals and reduction of local breeding sites are the best options currently available. However, application of pour-on insecticides has been unsuccessful, with no noticeable reduction in the density of biting midges in highly challenged areas.
• There is an inactivated vaccine available in Europe.

MISCELLANEOUS

ASSOCIATED CONDITIONS

The other orthobunyaviruses have similar clinical outcomes but can be differentiated by serology.

AGE-RELATED FACTORS

Fetus is the most susceptible.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

In pregnant animals, abortions and congenital malformations in the following parturition period occur in <3% of cases.

BIOSECURITY

Midge-proofed housing for viremic or high-value animals and reduction of local breeding sites are the best options currently available.

PRODUCTION MANAGEMENT

The timings of breeding or insemination of female animals can be selected such that the vulnerable stage of pregnancy (analogously to Akabane virus: 4–8 weeks in sheep and approximately 8–14 weeks in cattle) does not lie within the vector active area.

SCRAPIE

BASICS

OVERVIEW

• Scrapie is a nonfebrile, progressive neurodegenerative disease of sheep and goats that costs the sheep industry in the United States an estimated $20 million a year in lost productivity and potential export markets.
• Also referred to as "classical scrapie," scrapie is the oldest known agent in the family of transmissible spongiform encephalopathies (TSEs). Other examples of TSEs include chronic wasting disease (CWD) in cervids, bovine spongiform encephalopathy (BSE), and Creutzfeldt-Jakob disease (CJD) in humans.
• Contamination of the environment and oral exposure to placenta shed from infected dams are major sources for horizontal transmission.
• Transmission via the milk, colostrum, blood, and saliva has also been demonstrated.
• Scrapie has a long incubation period, clinical signs most common between 2–5 years of age.
• Clinical signs vary but can include altered behavior, incessant scratching, weight loss despite normal appetite, ataxia, and ultimately death.
• Scrapie is a reportable disease in the US and is subject to the National Scrapie Eradication Program (NSEP).
• Gold standard diagnosis is by immunohistochemistry (IHC) on formalin-fixed tissues. Biopsy of the rectoanal mucosa or nictitating membrane of the third eyelid are approved antemortem samples, whereas samples of the obex, retropharyngeal lymph node, and tonsil are preferred for postmortem testing.
• Relative genetic scrapie susceptibility testing, especially of prion protein codons 136 and 171, is an effective tool for controlling risk of infection in sheep.
• Scrapie has never been linked to disease in humans who consume sheep muscle.

INCIDENCE/PREVALENCE

• Scrapie was first diagnosed in the US in 1947 in a flock of Suffolk sheep in Michigan. The first US case of scrapie in a goat was reported in 2002.
• For the period April 2003 until February 2017, the Regulatory Scrapie Slaughter Surveillance (RSSS) program has tested just over one-half million culled small ruminants and confirmed 471 cases of classical scrapie (including 41 goats) and 9 cases of Nor98-like scrapie in US sheep.
• In the US, scrapie is most commonly diagnosed in black-faced sheep of which the Suffolk breed predominates. The annual incidence of scrapie in black-faced cull sheep tested at slaughter has steadily dropped from approximately 0.15% in 2003 to 0.004% in 2015, a 98% decrease.

GEOGRAPHIC DISTRIBUTION

Scrapie has been diagnosed in all regions of the continental US and is endemic in many regions of the world. Current and historical infection status and monitoring efforts of each country is tracked and reported by the World Animal Health Organization (OIE).

SYSTEMS AFFECTED

Nervous

PATHOPHYSIOLOGY

• The infectious agent of scrapie is termed a prion and is thought to be primarily comprised of misfolded isoforms of the prion protein (PrP).
• Encoded by the host's prion protein gene (*PRNP*), the normal "cellular" form (PrP^{C}) is expressed as a glycoprotein linked to the surface membrane of many types of host cells, especially those of the nervous and lymphoreticular systems. PrP^{C} is rich in alpha helixes and is susceptible to degradation by proteases.
• In association with scrapie infection, PrP^{C} becomes misfolded to isoforms (PrP^{Sc}) with increased beta sheet content that renders PrP^{Sc} partially resistant to protease degradation and prone to self-aggregation and formation of characteristic scrapie-associated fibrils (SAFs).
• PrP^{Sc} slowly accumulates in the nervous system and typically also in lymphoid follicles and placental cotyledons. While accumulation in peripheral tissues does not cause significant dysfunction, accumulation of PrP^{Sc} in the central nervous system causes neurologic dysfunction and spongiform degeneration.
• Strains of prions are thought to arise from subtle differences in the conformation and aggregation of PrP^{Sc}. Typical or "classical" forms of scrapie are naturally transmissible between genetically susceptible small ruminants and are the primary focus of this chapter. Atypical forms include Nor98 (discovered 1998 in Norway) and Nor98-like scrapie strains, which may be sporadic forms of small ruminant TSE given the evidence to date suggesting poor or no transmission under natural conditions.

SIGNALMENT

• Sheep and goats.
• Most breeds of domestic sheep are affected but in the US, black-faced sheep, especially Suffolk, have been more likely to test positive for scrapie than white- or mottle-faced sheep.
• Diagnosis is much less common in goats but includes both meat and dairy type breeds.
• Scrapie is commonly diagnosed in animals 2–5 years of age, whereas Nor98-like strains are more common in sheep 5 years of age and older.
• No sex predilection.

GENETICS

• Major determinants of susceptibility and disease phenotype are the amino acid sequence of the host's PrP^{C} and the strain of scrapie present.
• Relative genetic scrapie susceptibility testing has been effectively utilized to control infection risk in sheep; research to identify susceptibility genotypes in goats continues. No *PRNP* genotype has been identified that is completely resistant to all prion strains.
• *PRNP* codon 171: Amino acid changes at codon 171 have a large effect on scrapie susceptibility. Virtually no sheep homozygous for arginine (171RR) have been identified with scrapie. (*Note:* 171RR sheep are not protected from developing atypical disease associated with Nor98 and Nor98-like strains. Fortunately, transmission of these atypical strains appears to be inefficient and not likely to occur under natural conditions.)
• *PRNP* codon 136: While sheep homozygous for alanine at codon 136 (136AA) are more resistant than are sheep homozygous for valine (136VV) or heterozygous (136AV), all three genotypes are considered susceptible to scrapie infection for regulatory purposes.

PHYSICAL EXAMINATION FINDINGS

• Incubation period is prolonged and >1 year.
• Signs vary among individuals but often develop insidiously and progress slowly over weeks to months.
• Signs may be singular or multiple and include abnormal behavior (confusion, separation from the group, somnolence, or hyperexcitability), weight loss despite normal appetite, pruritus (incessant scraping which may induce lip smacking behavior), fine head and neck tremors, limb ataxia (commonly symmetric), or general weakness progressing to recumbency.
• In addition, goats may be more likely to nibble at feet and limbs or trunk, removing hair in more-or-less vertical and sometimes bilaterally symmetric patterns.
• Infection is ultimately fatal. Occasionally death may occur without observation of clinical signs or coincident with stressful events such as shearing.

CAUSES AND RISK FACTORS

• Newborn lambs and kids are the most susceptible to infection. The mostly likely modes of transmission are spread from infected dams to offspring and to other lambs and kids through contact with the placenta

(CONTINUED) SCRAPIE

and placental fluids, but also may occur via ingestion of infected colostrum or milk and exposure to a contaminated environment.
• Transmission risk is lower from infected sires to dams and offspring, from infected adult to other adult small ruminants, and from a contaminated environment to adult small ruminants.
• There is a risk of iatrogenic transmission through injection of contaminated materials (e.g., blood components).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Neurologic Signs: Sheep

• Brain abscess (caseous lymphadenitis—CLA/*Actinobacillus*)
• *Clostridium perfringens* type C
• Cobalt deficiency
• Copper deficiency
• Hypocalcemia
• Hypomagnesemia
• Inner ear infection
• Listeriosis
• Louping ill
• Mycotoxins
• *Parelaphostrongylus* (meningeal worm migration)
• Polioencephalomalacia/thiamine deficiency
• Pregnancy toxemia
• Rabies
• Swayback
• Tetanus
• Tick paralysis
• Uremia
• Vitamin A deficiency

Neurologic Signs: Goats

• Bacterial: Botulism, brain abscess, inner ear infection, *Listeria* infection, meningoencephalitis, tetanus
• Congenital: Hydranencephaly, hydrocephalus, progressive paresis
• Nutritional/metabolic: Cobalt deficiency, enzootic ataxia/swayback/copper deficiency, hypovitaminosis A, polioencephalomalacia/thiamine deficiency, pregnancy toxemia, uremia
• Parasitic: *Parelaphostrongylus tenuis*, tick paralysis
• Toxic ingestion
• Pyrethrin/organophosphates
• Salt toxicity
• Trauma
• Viral: Border disease, Borna disease, caprine arthritis encephalitis virus (CAE), louping ill, maedi-visna, pseudorabies, rabies

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• Diagnostic application of common serologic methods is not possible since an immune response to PrP^{Sc} is not a feature of scrapie.
• Development of a blood- or secretion-based antemortem test utilizing novel detection methodologies continues to be an active area of research.

OTHER DIAGNOSTIC PROCEDURES

• Conclusive diagnosis of scrapie is by detection of accumulated PrP^{Sc} by immunohistochemistry (IHC) staining of the obex, retropharyngeal lymph nodes, and tonsils of sacrificed sheep and goats.
• Antemortem testing is possible utilizing biopsy samples of the lymphoid follicles associated with the rectoanal mucosa or nictitating membrane of the third eyelid.

PATHOLOGIC FINDINGS

While immunohistochemical detection of PrP^{Sc} in brain or lymphoid tissues is the gold standard of diagnosis, central neuropathologic lesions may include bilaterally symmetric neuronal vacuolation, microcystic vacuolation (spongiform change) of the gray matter neuropil, astrocytosis, cerebral amyloidosis (rare), and the presence of scrapie-associated fibrils (SAF) as identified by negative-stain EM.

TREATMENT

There is no known treatment for scrapie.

MEDICATIONS

There is no treatment for scrapie.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Scrapie is a reportable disease. Clinical suspect animals >12 months of age should be reported to state or federal regulatory officials.
• A slowly progressive but ultimately fatal clinical course.

PREVENTION

• The National Scrapie Eradication Program (NSEP) is a joint state, federal, and industry supported program that employs both passive and active surveillance, animal identification, case management, and education measures in an effort to eradicate scrapie in the US.
• Participation in the Scrapie Flock Certification Program (SFCP): A voluntary program aimed at helping owners significantly reduce the risk of introducing scrapie into flocks.
• Breeding for genetic resistance in sheep.
• Lambing and kidding in a clean environment. Removing fetal membranes and contaminated bedding to prevent additional exposure.

MISCELLANEOUS

AGE-RELATED FACTORS

• Susceptibility to infection is greatest in neonates.
• Clinical signs are commonly observed in small ruminants between 2 and 5 years of age but rarely in animals <18 months of age.

ZOONOTIC POTENTIAL

Scrapie has never been linked to disease in humans who consume sheep muscle.

PREGNANCY

N/A

BIOSECURITY

• Lambing in a clean environment and removing fetal membranes and contaminated bedding to prevent additional exposure will also reduce exposure and disease risk.
• Scrapie prions have also been detected in milk and colostrum, and components of the blood.

PRODUCTION MANAGEMENT

SEGMENTAL APLASIA OF THE REPRODUCTIVE TRACT

BASICS

OVERVIEW
• Segmental aplasia refers to lack of development of part of one or more of the structures that are derived from the embryonic mesonephric (Wolffian) or paramesonephric (Müllerian) duct systems.
• In males, the mesonephric duct system differentiates into the epididymis, vas deferens, and accessory sex organs. The epididymis and vas deferens are the most commonly affected.
• In females, the paramesonephric duct system differentiates into the uterine tube, uterus, cervix, and vagina. All these structures may be affected by segmental aplasia.

INCIDENCE/PREVALENCE
• The prevalence in ruminants is very low.
• Relatively frequent in SAC.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Segmental aplasia conditions are congenital and represent a developmental error.
• The specific mechanisms have not been elucidated but a hereditary basis is often suspected.
• Segmental aplasia is often unilateral but both sides may be affected.
• Complete aplasia is rare and may represent a separate pathologic process.
• In males, the right side seems to be more frequently affected than the left side. Occlusion of the body or head of the epididymis results in testicular swelling and subsequent degeneration due to fluid backpressure.
• In females, the tubular genitalia may be affected at any level along its anatomy but the most commonly reported conditions are:
  ◦ Uterus unicornis (absence of one uterine horn).
  ◦ Segmental aplasia of a uterine horn resulting in an isolated distal segment.
  ◦ Segmental vaginal aplasia or a persistent hymen.
• Cervical aplasia is possible but rare.

HISTORICAL FINDINGS
• Infertility is the most common presenting complaint.
• In unilateral cases, males are usually fertile.
• In females, unilateral affection may present as infertility, failure to accept the male, or recurrent pregnancy loss. Some cases may present for anestrus.

SIGNALMENT
• Although segmental aplasia can occur in all species, it is particularly well described in cattle and SAC.
• Historically, white Shorthorn cattle were considered at greater risk for paramesonephric disorders (hence, white heifer disease), but up-to-date breed prevalence data is lacking.

PHYSICAL EXAMINATION FINDINGS
• In most cases there are no outwards clinical signs.
• Vaginal aplasia and persistent imperforated hymen may be accompanied by variable degrees of vaginal prolapse, dysuria, and intermittent straining.

GENETICS
• Numerical chromosomal aberrations (e.g., XXY) have been identified as a risk factor.
• A hereditary basis is suspected in some cases.

CAUSES AND RISK FACTORS
Chromosomal abnormalities and specific genes have been implicated.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• In males:
  ◦ Small cystic structures derived from either embryonic duct system can occur adjacent to the ampullae, vas deferentia, and head of the epididymis. These generally have no clinical significance.
  ◦ Spermiostasis, sperm granuloma, epididymitis, epididymal neoplasia testicular degeneration.
  ◦ Orchitis and epididymitis.
• In females:
  ◦ Normal pregnancy
  ◦ Pyometra and mucometra
  ◦ Hydrometra in the doe

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
• In the male, the head and tail of the epididymis as well as the pelvic accessory sex organs are readily assessed by ultrasonography. The complete absence of any expected structure provides a presumptive diagnosis of segmental aplasia.
  ◦ In the bull, the rete testis is a narrow (5–6 mm) and hyperechoic (white) linear structure located in the center of the testis parenchyma. In cases of segmental aplasia in postpubertal bulls, the rete is often distended with hypoechoic (dark) fluid.
• In the female, transrectal ultrasonography shows fluid accumulation in the segment of the tubular tract distal to the aplastic area. This may lead to a mistaken diagnosis of pregnancy but the absence of a fetus and placenta is readily determined by ultrasonography. Transabdominal ultrasonography may be used in small ruminants and SAC.
• Vaginoscopy is used to diagnose aplasia caudal to the cervix.

OTHER DIAGNOSTIC PROCEDURES
• Palpation of a very small or absent epididymal tail is suggestive of the condition. The epididymal head may be enlarged due to distension with semen. If the defect is located in the vas deferens, the epididymal tail may be enlarged.
• Semen collection and evaluations: Bilaterally affected males (epididymal segmental aplasia) are azoospermic.
• Palpation per rectum is a common diagnostic procedure in the cow. Absence of a positive sign of pregnancy leads to a diagnosis of pathologic fluid accumulation. Segmental aplasia is confirmed by identifying a missing portion of the uterine horn.
• Exploratory laparotomy or laparoscopy confirms the diagnosis of segmental aplasia of the uterus.

TREATMENT

THERAPEUTIC APPROACH
• No treatment is recommended for affected animals.
• Unilaterally affected females may be fertile. Females with uterus unicornis continue to cycle and may become pregnant and deliver normally if ovulation occurs on the ovary ipsilateral to the normal side.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Unilateral ovariectomy (affected side) or partial hysterectomy for cows with segmental aplasia of the uterus. Removal of the ovary on the affected side at the same time will solve the problem with infertile ovulation.
• Segmental aplasia of the vagina can be easily corrected if the aplastic segment is very short (<1 cm). This is especially true when fluid accumulates in the cranial vagina, resulting in a caudal bulging of the aplastic area.
• Nonetheless, the standing recommendation should be to cull all affected animals. Veterinarians should consider the ethical implications of surgically altering breeding animals, especially when those animals or their progeny may be sold without full disclosure.

SELENIUM TOXICITY

BASICS

OVERVIEW

• Selenium (Se), an essential trace element, plays a vital role in various physiologic processes including immunity, reproduction, and productivity.
• It has a narrow margin of safety but is required in the diet to prevent deficiencies as seen with white muscle disease.
• Selenium is the only essential nutrient that does not have a GRAS (generally regarded as safe) status and so the FDA regulates Se supplementation in animals as if it were a drug.
• Selenium toxicosis can occur naturally, by the consumption of selenium-accumulating plants, or by human errors from over-supplementation of selenium in the diet and/or accidental overdosing (parenteral/oral).
• Organic forms of selenium such as selenomethionine and Se-methyl selenocysteine are the major selenium-containing compounds found in plants, whereas inorganic forms of selenium such as sodium selenite are the common supplemental/dosing form.
• Acute selenosis may occur at oral doses ≥2.2 mg Se/kg body weight.
• Chronic selenosis has been reported to occur in animals fed >5–40 ppm Se in feed.
• The toxic effects of the organic and inorganic forms of selenium are similar but, in most cases, the toxic dose of the inorganic form is greater than the organic form.
• Clinical signs involve the respiratory, cardiovascular, hematologic, and gastrointestinal systems.
• The fetus can concentrate Se in the liver at concentrations up to three times higher than the dam.
• Chronic selenosis or "alkali disease" causes hoof deformities and hair loss. The term "blind staggers" is a misnomer for selenium toxicosis.

INCIDENCE/PREVALENCE

• Seleniferous areas with alkaline soil
• Sporadic incidences resulting from accidental overdoses

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

• Cardiovascular
• Digestive
• Hemolymphatic
• Musculoskeletal
• Nervous
• Urinary
• Reproductive
• Respiratory
• Integument

PATHOPHYSIOLOGY

• Selenium replaces sulfur in amino acids leading to loss of disulfide bridges which results in weakening of keratin and disruption of hair, hoof, and horn integrity. Se also causes abnormal maturation of keratinocytes in the stratum spinosum which may give rise to degeneration and necrosis. Alopecia results from atrophy of primary hair follicles.
• In the hoof, cells on the coronary papillae produce dyskeratotic debris that accumulates in the horn tubules and distorts the normal architecture of the hoof wall.
• Cytotoxic effects of Se are the result of denaturation of critical protein thiols. Selenite and SeCys react with tissue thiols to produce ROS.
• Selenium has been reported to decrease erythrocytic volume by reducing hemoglobin synthesis, which may result in anemia.

HISTORICAL FINDINGS

• Recent administration of parenteral or oral selenium products.
• History of dietary changes with over-supplementation of selenium or grazing of selenium-accumulating plants when feed is limited.

SIGNALMENT

• Young animals are more susceptible to selenosis as a result of an underdeveloped rumen. Rumen microflora can reduce bioavailable forms of selenium to unavailable, elemental forms.
• No breed or sex predilections have been described in the literature.

PHYSICAL EXAMINATION FINDINGS

Acute Effects

• In some cases, there is acute death with few clinical signs.
• Generally, clinical signs include anorexia, depression, reluctance to move, and respiratory distress. Grinding of teeth, diarrhea, bloat, and abdominal pain may also be present.
• Elevated heart rate and respiratory rate and a weak pulse may be evident. Fever, polyuria, and hemolytic anemia have been reported in some cases.
• Death usually occurs within 12–48 hours of acute exposure, otherwise the animal usually recovers.
• Once clinical signs such as dyspnea and ataxia appear, animals generally succumb within the hour.
• A garlicky smell to the breath may be present, especially during the first 16 hours post-exposure.

Chronic Effects (Alkali Disease/Bobtail Disease)

• Clinical signs associated with chronic selenosis include depression, weakness, emaciation, anemia, bilateral alopecia (neck and tail), swelling of the coronary band, and hoof deformities that may result in separation and sloughing of the hoof wall.
• Reproductive performance may be reduced at concentrations ranging from 5–10 ppm Se in the total diet, although no outward clinical signs are present; may be the result of the interference with absorption and retention of copper.
• Blind staggers has been described in cattle and sheep but its causal link with selenium intoxication is questioned.
• Bovine—even in the absence of clinical alkali disease in cattle, elevated Se concentrations may adversely affect both pregnancy and immune response. Se administered as sodium selenite at 25 ppm (0.6–1 mg Se/kg BW) for 1 month or 15 ppm (0.4–0.6 mg Se/kg BW) for 6 months caused chronic selenosis.
• Sheep—chronic selenosis may result in death—without observing clinical signs. Unlike other ruminant species, wool loss and hoof lesions are not commonly identified, although wool production is known to decrease. Sheep fed diets containing 0.5–1 mg Se/kg BW (about 17–33 ppm in the diet) reportedly was lethal when exposed for 2.5–6 months. See Table 1.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Vitamin E-deficient animals are more susceptible to acute selenosis.
• Se toxicosis has been reported to increase with concomitant cobalt deficiency.
• Signs of Se deficiency resemble those of selenium toxicosis.
• Primary (obligate) selenium accumulators such as *Astragalus, Machaeranthera, Xylorhiza,* and *Haplopappus* spp. can contain >1000 ppm selenium. Secondary (facultative) accumulators such as *Aster, Atriplex, Grindelia, Gutierrezia,* and *Castilleja* spp. can also contain toxic amounts of selenium. Most of the plants that have the ability to accumulate large amounts of selenium are unpalatable and are only eaten by animals when there is nothing else to eat.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Pneumonia, cardiotoxic plant exposure, ionophore overdose, thallium toxicosis, vitamin E and selenium deficiency, and endotoxemia

CBC/BIOCHEMISTRY/URINALYSIS

• Usually unremarkable in acute cases.
• In chronic exposure, the liver enzymes may be elevated as a result of liver damage.

OTHER LABORATORY TESTS

IMAGING

N/A

SELENIUM TOXICITY (CONTINUED)

Table 1

Comparative Selenium Toxicosis in Cattle and Sheep

	Se as sodium selenite (inorganic) (orally)	*Se as selenomethionine (organic) (orally)*
Cattle	• 7 mg Se/kg BW—no effect • 10.1 mg Se/kg BW—anorexia and low milk production for 5 days • 9–11 mg Se/kg BW—anorexia, dyspnea, garlicky breath, followed by death within 2 days • Oral MLD at 9.9–11 mg Se/kg BW • 15 ppm Se in diet for 231 days—decreased weight gain, sore foot, cracked hooves, excitability in 1 of 5 heifers	• 2.2 mg Se/kg/day (*A. pectinatus*) for 6–16 days caused blind staggers in steers. • 3.4 mg Se/kg/day (*A. bisulcatus*) for 7 days caused blind staggers in steers. • 25 ppm Se (*Astragalus hay*) for 46 days caused joint stiffening and cracking of hooves in 4 weeks. By the end of 4 months, sloughing of the hoof started. • 9 out of 11 bullocks showed stiffness and lameness in all four legs, pale mucosa, and slow but gradual sloughing of the hoof. Mean concentrations of Se in the herbage was 37 ppm.
Sheep	• 1.7 mg Se/kg BW—35% mortality within 12–16 h • 2.2 mg Se/kg BW—35% mortality within 12–48 h • 6.4 mg Se/kg BW—pulmonary cong., 95% mortality in 15 days • Hyperpnea, salivary frothing, hydrothorax, pulmonary edema, hepatic and renal degeneration • 1 mg Se/kg BW—no weight loss in 72 days • 0.5–1 mg Se/kg BW—several deaths between 78–178 days • Oral LD_{50}–1.9 mg Se/kg BW	

OTHER DIAGNOSTIC PROCEDURES

• For most ruminants, normal Se in blood (0.08–0.5 ppm) and liver (0.25–1.0 ppm).
• In acute cases, liver and kidney Se levels are useful for diagnosis. In general, concentrations >1 ppm are suggestive of overexposure, and concentrations >5 ppm are suggestive of toxicosis.
• In chronic cases, liver selenium may range from 2 ppm to 7 ppm and the hair/hoof Se may range from 1.5 ppm up to 45 ppm. Generally, hair Se >5 ppm indicates excessive exposure. Hair samples must be taken from hair that was actually growing at time of intoxication to be diagnostic. Blood Se and blood GPx activity have also been used for diagnostic purposes.

S

PATHOLOGIC FINDINGS

Acute Selenosis

• Gross lesions include edematous, congested, and/or hemorrhagic lungs. Bloody froth may be present in the trachea, bronchi, and bronchioles. Congestion and hemorrhages are also observed in the liver, kidneys, and GIT. Petechiations of the epicardium may also be seen with or without edema.
• Histologic lesions are minimal if the clinical course is brief. Otherwise, histopathology reveals endocarditis, myocarditis, and myocardial necrosis. Hydropic degeneration of myocardium is seen along with petechial hemorrhages. Focal areas of necrosis are seen in the liver with occasional vacuolation of the hepatocytes. In kidneys, parenchymous and tubular degeneration with casts is a common finding. Mild hyaline or granular degeneration of skeletal muscle fibers may be present. Variable necrosis of the lymphoid cells may also be present.

Chronic Selenosis

• Gross lesions include edematous and congested lungs, atrophied and cirrhosed liver with discoloration, enlargement of spleen and pancreas, anemia, atrophy of lymphoid tissue, atrophy and dilation of the heart, and erosion of articular surfaces.
• Histopathology indicates congestion and thickening of the alveolar walls in the lungs, hepatic fibrosis, myocardial degeneration, glomerulonephritis, and mild gastroenteritis. Areas primarily affected in the CNS include ventral horns of the cervical and lumbar vertebral segments, with lesser damage in brainstem nuclei. The microscopic appearance of the affected spinal cord includes vacuolation of the neuropils and sometimes within the cytoplasm of the neurons. Neuronal chromatolysis, axonal swelling, multifocal hemorrhage, and endothelial cell swelling and proliferation are also usually present. The white matter has minimal changes.

TREATMENT

THERAPEUTIC APPROACH

No proven therapy for acute selenium toxicity. For chronic selenium toxicity:
• Remove from selenium-containing diet.
• Increase protein and carbohydrate in diet.
• Increase sulfur in the diet.
• 40 ppm arsenic salt or 50–100 ppm arsanilic acid has provided benefit to calves. Arsenic compounds can increase the biliary excretion of selenium.
• Oral administration of 4–5 g naphthalene daily for 5 days, resting for 5 days, and then repeating has been successfully used in the past in mature cattle.

SURGICAL CONSIDERATIONS AND TECHNIQUES

N/A

MEDICATIONS

DRUGS OF CHOICE

• No specific drug/antidote available.
• Analgesics and NSAIDs may be used for pain relief.

CONTRAINDICATIONS

N/A

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

(CONTINUED) SELENIUM TOXICITY

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Guarded prognosis with acute selenosis
- Prolonged recovery with chronic selenosis

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
It is important to educate clients on the risks of selenium administration and proper dosing when providing selenium-containing products for on-farm use.

PATIENT CARE
N/A

PREVENTION
- Avoid excess/further selenium exposure.
- Keep the total dietary concentrations within the recommended limits.
- Prevent access to seleniferous plants.
- Monitor selenium status in the blood.
- Avoid selenium supplementation in seleniferous areas.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Blind staggers (misnomer)
- Polioencephalomalacia

AGE-RELATED FACTORS
Preruminants and young ruminants are considered to be more susceptible to selenosis because the undeveloped rumen is unable to significantly reduce the amount of bioavailable selenium to a non-bioavailable form.

PREGNANCY
- Infertility, abortions, stillbirths, or weak/lethargic calves.
- No teratogenic effects described.
- Hypoplasia of reproductive organs has been observed in lambs from seleniferous areas.

PRODUCTION MANAGEMENT
Analysis of selenium in feed or whole blood for regular monitoring of the overall status

SYNONYMS
- Alkali disease
- Bobtail disease

ABBREVIATIONS
- CNS = central nervous system
- FDA = Food and Drug Administration
- GIT = gastrointestinal tract
- GPx = glutathione peroxidase
- GRAS = generally regarded as safe
- LD_{50} = the estimated dose at which 50% of the population is expected to die
- MLD = minimum lethal dose

SELENIUM/VITAMIN E DEFICIENCY

BASICS

OVERVIEW

• Deficiency of selenium is encountered in many regions of the world, as it is present only in small quantities and is unevenly distributed on the earth's crust. Vitamin E tends to be plentiful in fresh green forages, but can be low in conserved forages and grains.
• The best understood biologic function of selenium involves its role in the antioxidant enzyme glutathione peroxidase (GPx). The consequences of deficiency can thus in part be explained through oxidant damage to cells. Vitamin E also acts as an antioxidant, mainly at the level of the cell membrane. Although selenium and vitamin E requirements are related, the relationship has not been quantified.
• The toxicity of selenium is a recognized clinical problem, while vitamin E is one of the least toxic vitamins.
• Selenium is an essential trace element for animals, whose deficiency has been associated with a range of diseases in ruminants including abortion, infertility, retained placenta, stillborn or weak calves, and calves that fail to thrive. Animals with the greatest growth and production demands will manifest selenium deficiency first.
• An impaired immune response has been associated with selenium and vitamin E deficiencies, with links to mastitis and respiratory diseases.
• Calves and growing heifers are most commonly affected by selenium deficiency. Signs of white muscle disease (WMD) or nutritional myodegeneration (NMD) can be observed in deficient herds.
• Reduction in the activity of selenium-dependent GPx, with an increase in free-radical-induced cellular damage, is associated with muscle damage in the myocardium and skeletal muscle. Immunosuppression around calving leading to mastitis in first-calving heifers is also linked to low selenium intake before calving.
• The reduction in peroxidation is the rationale for feeding increased selenium and vitamin E for cattle in critical periods, such as growing, late gestation, beginning of lactation, and peak of milk yield.

INCIDENCE/PREVALENCE

In regions where selenium deficiency is a concern, the incidence of selenium-responsive disorders in cattle can be higher compared to other regions. Vitamin E deficiency may be common when conserved forages are widely used for feeding cattle.

GEOGRAPHIC DISTRIBUTION

Principally New Zealand, northern Europe, China, the northern part of the United States, eastern Canada, and southern Chile are recognized as having selenium concentrations in soil insufficient to meet livestock requirements.

SYSTEMS AFFECTED

• Musculoskeletal
• Multisystemic

PATHOPHYSIOLOGY

• Selenium exerts its biologic function as a component of selenoproteins. Vitamin E is a lipid-soluble antioxidant essential for protecting cell membranes from oxidative damage by allowing for its own oxidation.
• Several isoenzymes of selenium-dependent GPx have been identified. These reduce hydrogen peroxide and organic hydroperoxides to stop peroxidation of other cytosolic and membrane constituents.
• If peroxidation is uncontrolled, it can initiate chain reactions of reactive oxygen species (ROS) generation, causing tissue damage. WMD is evidenced at slaughter or necropsy by whitish appearance of striated muscle tissue, which is due to bleaching by peroxides and hydroperoxides.
• Selenium deficiency causes an impairment of the phagocytic function of leukocytes, the release of cytokines, and on the response of leukocytes to cytokines. Therefore, infectious diseases (e.g., mastitis) appear as a consequence of the effects of selenium deficiency on the immune response.
• Selenium-dependent iodothyronine deiodinase catalyzes the deiodination of T4 to T3, reverse T3 from T4, and reverse T3 to T2. These enzymes can activate or inactivate the thyroid hormone thyroxine.
• Thioredoxin reductases are dependent upon selenium. Reduced thioredoxin is critical for several redox systems, including those for transcription factors and reductases for DNA synthesis. They have been established as critical for regulating cell growth, prevention of apoptosis, and prevention of embryonic mortality.

SIGNALMENT

• Potentially all ruminant species are affected. Sheep are more susceptible than cattle, and goats are more susceptible than sheep.
• Young, rapidly growing animals are most commonly affected, including newborns, which can be affected prenatally. Older animals are rarely affected by WMD, but are still susceptible to other selenium-responsive diseases such as mastitis, infertility, and retained placenta.
• Both sexes are susceptible to either selenium or vitamin E deficiency.

HISTORICAL FINDINGS

• Rapidly growing animals are most frequently affected with NMD and this can develop either before or after parturition. Older animals have also been reported to be affected by NMD.
• NMD has been reported in goat kids, and suckling and weanling lambs with adequate selenium status but deficient in vitamin E, possibly suggesting inadequate colostrum intake, low colostrum vitamin E concentrations, or inadequate postnatal vitamin E supplementation.
• Other signs that may be associated with deficiency include poor weight gain in young animals, high incidence of retained fetal membranes, high somatic cell counts (SCC) in milk around calving, or a high incidence of clinical cases of mastitis.

PHYSICAL EXAMINATION FINDINGS

• The clinical consequences vary widely within and between species, and likely reflect cellular vulnerability to oxidative stress. A generalized picture of a selenium-deficient herd would include a range of disorders in cows and their calves.
• NMD is characterized by generalized leg weakness and stiffness accompanied by difficulty rising and standing. Impaired suckling ability due to dystrophic tongue muscles, heart failure, and paralysis are also typical.
• In adults, secondary infections such as mastitis and pneumonia are frequently observed. Polypnea may develop in these animals, which can be accompanied by heart disorders.
• An increased incidence of retained placenta, stillborn or weak calves that die soon after birth, and calves that fail to thrive are typical of herds affected by selenium deficiency. Decreased overall calving rates due to subfertility and abortion may be present. Calves will often have diarrhea, and mortality can be high.
• Reduced sperm production and testicular degeneration have been associated with selenium deficiency. Thioredoxin reductase is a testicular selenoprotein that may underlie the defect in spermatogenesis or maturation associated with testicular atrophy in selenium-deficient bulls. This defect is likely due to disruption of ribonucleotide reductase and alteration in the regulation of transcription factors. This may also explain the lower embryo survival noted in selenium-deficient cows.

GENETICS

N/A

CAUSES AND RISK FACTORS

• The general selenium requirement has been established at 0.30 mg/kg ration DM. A dietary selenium concentration less than 0.1 mg/kg DM has been associated with an increased incidence of selenium-responsive disorders.
• The National Research Council recommends about 20 IU of vitamin E/kg DM for lactating cows, and can be as high as 80 IU/kg DM for dry cows and heifers when fed with conserved and stored forages in the last 60 days of gestation. Plasma serum α-tocopherol concentrations >7.0 μmol/L are

(CONTINUED) SELENIUM/VITAMIN E DEFICIENCY

considered adequate in adult cattle. Clinical white muscle disease is common when α-tocopherol levels are <4.6 μmol/L.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• The diagnosis may present considerable difficulties since the clinical signs are not specific.
• Nutritional deficiency of copper, cobalt, and iodine may confound the diagnosis.
• Other metabolic causes of immunosuppression and thyroid disorders as well as musculoskeletal disorders in young stock.

CBC/BIOCHEMISTRY/URINALYSIS

• Muscle damage may lead to elevated aspartate aminotransferase, creatine kinase, and lactic dehydrogenase.
• Myoglobinuria can be observed in selenium- or vitamin E-deficient cattle.

OTHER LABORATORY TESTS

• Criteria for establishing selenium adequacy are variable among countries. However, responses to selenium supplementation in terms of milk production and reproductive performance are observed when herd blood selenium concentrations are <0.13 μmol/L. Responses in animal performance are less likely to occur when mean herd blood selenium concentrations are >0.25 μmol/L.
• The blood activity of GPx has been used as a biomarker for selenium status; however, supplementation based on marginal GPx levels does not guarantee a clinical or economical response to supplementation.
• Bulk tank milk selenium concentration has been used as an indicator of herd selenium status, with a concentration >0.28 μmol/L considered adequate. Note that provision of organic forms of Se tends to increase Se concentration in milk when compared to inorganic forms.
• Selenium deficiency affects the thyroid metabolism, causing lowered circulating T3.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

The best diagnosis is always afforded by a positive response to selenium supplementation.

PATHOLOGIC FINDINGS

• Usually, lesions of NMD are localized in those most actively exercised muscles, suggesting that free radical production is higher in such muscles.
• Postmortem lesions are usually dominated by mineralization of necrotic skeletal and/or cardiac muscles; white foci of calcification and "chicken flesh" appearance with edema are commonly seen in severely affected animals.

TREATMENT

THERAPEUTIC APPROACH

• Selenium and vitamin E injections can dramatically reduce the severity of disease in deficient herds experiencing clinical symptoms; however, lesions are nonreversible when anatomic dysfunction is present.
• Routine supplementation of selenium and vitamin E in the ration, incorporated into salts, meals, grain mixes or total mixed rations, will prevent disease (Table 1).
• Ruminal selenium boluses are also efficacious in prevention of deficiency for at least a year in many cases.

MEDICATIONS

DRUGS OF CHOICE

See Table 1 below

CONTRAINDICATIONS

N/A

PRECAUTIONS

• Oversupplementation of selenium is possible and the margin between the requirement and toxicity is narrow.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

• Arsenic, mercury, cadmium, and copper, molybdenum, and sulfur have been suggested to alter selenium metabolism.
• Oxalate can decrease selenate transport in sheep and the sulfur amino acids will alter selenium metabolism.
• Dietary protein and sulfur amino acids may limit availability of seleno-amino acid incorporation into proteins. Methionine in the diet will directly influence the proportion of selenomethionine incorporation into proteins; selenomethionine availability for incorporation into GPx can be reduced when methionine is limiting. Increased dietary methionine allows for increased availability of selenomethionine to selenocysteine conversion for incorporation into selenium-specific proteins.
• Other factors influencing retention of selenium are phosphorus and the selenium content of the diet. Multiple factors affect absorption and retention of selenium, with high dietary protein tending to increase absorption while increasing urinary loss.

Table 1

Methods and sources for selenium supplementation in adult cattle.

Method	*Source*	*Dose rate*		*Duration (months)*
Discontinuous				
Oral drench	Sodium selenate	0.05	mg/kg BW	1
Parenteral injection	Barium selenate	1		12
	Sodium selenate	0.1		1.5
	Sodium selenite	0.05–1.00		2–3
Ruminal pellets	Elemental Se (10%)	6	g	12
Continuous				
Drench	Sodium selenate	1–8	mg/head/d	
Mineral mixes	Sodium selenate/selenite	1–8	mg/head/d or	
	Se yeast*	0.10–0.15	mg/kg of DM	
Indirect				
Fertilizers	Sodium selenate	5–10	g/Ha	12
	Selenium granules	5–10		24[6]

*Used as feed additive, mg/kg of complete feedstuff.

SELENIUM/VITAMIN E DEFICIENCY (CONTINUED)

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Affected animals should have an improvement of gait and growth within weeks of supplementation.

POSSIBLE COMPLICATIONS
• Severely affected recumbent animals will require euthanasia. Animals with intercurrent infectious disease will have a greater likelihood of dying because of their immunosuppression.
• Decreased growth rates.

CLIENT EDUCATION
Taking the time to help your clients better understand nutritional requirements and their effects on growth, reproduction, and health will greatly aid in reducing preventable disease.

PATIENT CARE
• Ensuring adequate nutritional monitoring for all nutrients in the recovery phase is important for repair of muscle damage and prevention of additional damage.
• Ensuring adequate bedding and access to water and feed is critical for recumbent animals.

PREVENTION
• Dietary supplementation when feeds contain <0.3 mg Se/kg DM and 20 IU vitamin E/kg DM.
• Monitoring maternal selenium and vitamin E status is prudent in deficient areas.
• Screening tests for blood GPx activity are relatively simple and cost-effective.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Secondary infectious disease is common in affected herds.

PREGNANCY
Selenium or vitamin E deficient dams will not provide sufficient selenium or vitamin E to the fetus or from colostrum to allow for adequacy in their offspring. It is important that cattle be fed adequately in the last 2 months of gestation to allow offspring to be born without causing nutritional insufficiency.

PRODUCTION MANAGEMENT
Dietary assessment and intervention should be a routine part of management to avoid nutritional disorders related to selenium and vitamin E.

SYNONYMS
• Nutritional myodegeneration (NMD)
• White muscle disease (WMD)

ABBREVIATIONS
DM = dry matter
GPx = glutathione peroxidase
NMD = nutritional myodegeneration
ROS = reactive oxygen species
SCC = somatic cell count
WMD = white muscle disease

SEE ALSO
• Arsenic Toxicosis
• Copper Deficiency and Toxicity
• Iodine Deficiency and Toxicity
• Molybdenum Toxicity
• Sulfur Toxicity

SEMINAL VESICULITIS

BASICS

OVERVIEW

• The paired vesicular glands are the major accessory sex glands in the bull, buck, and ram.
• The vesicular glands are absent in camelids.
• The vesicular glands contribute volume, nutrients, and buffers to the ejaculate but these contributions are not absolutely essential for fertility.
• The vesicular glands have a lobar structure and are found on the floor of the cranial pelvic cavity. Normal glands in the bull are about 2–4 cm wide and 10–15 cm long.
• Seminal vesiculitis is an inflammation of either or both vesicular glands.
• The condition is most commonly described in the bull but this may be due to the accessibility of the pelvic organs in the bull to palpation per rectum as compared to the buck and ram.

INCIDENCE/PREVALENCE

• The prevalence is reported to be between 1% and 10% in bulls.
• The prevalence is significantly higher (10–30%) in young, peripubertal bulls intensively housed and fed high-energy diets.
• The prevalence is also higher in aged bulls (>9 years).
• Clinical diagnostic criteria may significantly underestimate the true disease prevalence, especially in small ruminants where physical examination of the pelvic accessory sex glands is difficult to accomplish and is not routinely performed.

GEOGRAPHICAL DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• Bacteria are the most commonly incriminated infectious etiologic agents but viral, fungal, and protozoal agents have been isolated. The most commonly isolated organisms include *Trueperella pyogenes, Histophilus somni,* and where not eradicated, *Brucella abortus.*
• The precise mechanism of infection and pathology is not known and ascending, descending, or hematogenous routes of infection are all considered possibilities.
• Primary infections elsewhere in the body, especially chronic ones, may cause seminal vesiculitis by the hematogenous route. Young males on high-energy diets may experience ruminal acidosis, rumenitis, and bacteremia, which potentially explains the higher incidence of seminal vesiculitis in this population.
• Urogenital anomalies may contribute to malfunctioning of the vesicular gland openings on the colliculus seminalis and increase the risk of seminal vesiculitis.
• Retrograde ejaculation or urine reflux into the vesicular gland may predispose to infection or cause a sterile inflammation of the glands.
• Bilateral and unilateral involvement of glands is equally likely.
• In ruminants, seminal vesiculitis is often found as part of a seminal vesiculitis syndrome with concurrent orchitis, epididymitis, ampulitis, bulbourethral adenitis, or prostatitis.

HISTORICAL FINDINGS

• Breeding bulls may have a history of sterility or subfertility but often have acceptable levels of fertility.
• AI sires may have a history of producing semen with poor motility and post-thaw viability along with the presence of white blood cells in the ejaculate.

SIGNALMENT

• Most commonly found in bulls but does affect rams and bucks as well.
• *Bos taurus* and *Bos indicus* bulls are equally affected.
• Most commonly found in peripubertal bulls (10–15 months) and older bulls (>9 years).

PHYSICAL EXAMINATION FINDINGS

• Clinical signs are often completely lacking.
• Unilateral or bilateral enlargement of the glands and loss of lobulations on palpation per rectum are the most common findings.
• In chronic cases, abscess formation and adhesions to adjacent abdominal or pelvic structures may occur.
• Rarely, bulls may show signs of abdominal pain, pain during mounting and thrusting, or pain when semen is collected by electroejaculation.
• Most physical examination findings are normal.
• The finding of infectious or inflammatory lesions anywhere in the genital tract of male ruminants should suggest the possibility of a concurrent seminal vesiculitis.

GENETICS

No known genetic influence or breed distribution

CAUSES AND RISK FACTORS

• Seminal vesiculitis has been attributed to a variety of infectious and noninfectious causes.
• *Mycobacterium tuberculosis, M. avium* subsp. *paratuberculosis*, *Brucella abortus*, *B. ovis,* and *B. melitensis* are potential agents of special concern either for their zoonotic potential or local reporting requirements or both.
• In areas free of brucellosis, *Trueperella pyogenes* is the bacterium most commonly isolated from clinical cases.
• *Streptococcus* spp., *Staphylococcus* spp., *Pseudomonas aeruginosa, E. coli, Tritrichomonas foetus, Chlamydophila* spp., *Ureaplasma* spp., *Mycoplasma* spp., and *Haemophilus* spp. have all been reported to cause seminal vesiculitis in bulls.
• A wide variety of bacteria have been isolated from cases of ovine epididymitis and should be considered potential causes of seminal vesiculitis in this species as well.
• Bovine herpesvirus-1 and other viruses have been incriminated as causes of vesiculitis.
• Sperm entering the gland during ejaculation may initiate an autoimmune reaction and subsequent vesiculitis.
• Infections at other body sites (e.g., orchitis, epididymitis, urethritis, rumenitis, pneumonia, omphalophlebitis, or traumatic reticulopericarditis) or congenital anomalies of the urogenital system (e.g., uterus masculinus or malformation of the colliculus seminalis) may predispose to developing seminal vesiculitis.
• High-density housing systems and high-concentrate diets commonly found in bull test stations appear to increase the risk of seminal vesiculitis as well.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Differential diagnoses for enlargement or asymmetry of the vesicular glands are segmental aplasia, hypoplasia, or accessory vesicular glands.
• The presence of a dilated or infected uterus masculinus may mimic seminal vesiculitis.
• Differentials for white blood cells in the semen include infections or inflammation anywhere along the urogenital tract including the prepuce and penis.
• Urinary calculi should be considered, especially in rams and bucks.
• Primary infectious diseases of special concern in cases of seminal vesiculitis include brucellosis, tuberculosis, and paratuberculosis.

CBC/BIOCHEMISTRY/URINALYSIS

• The CBC will usually be normal.
• Certain semen biochemistry values are altered but these have limited clinical relevance.
• Urinalysis may be normal or show an elevated white blood cell count.

OTHER LABORATORY TESTS

• Semen evaluation may reveal an elevated pH, lower sperm motility, increased catalase activity, and lower fructose concentration.
• Leukocytes are not normally seen in ruminant ejaculates but are generally present with seminal vesiculitis. Neutrophils are most commonly seen, but lymphocytes may predominate in some cases.

SEMINAL VESICULITIS (CONTINUED)

• Many bulls with seminal vesiculitis have semen quality problems, typically sperm with poor motility, or morphologic abnormalities are found.
• Changes in sperm morphology may actually be the result of a concurrent orchitis or epididymitis as part of the seminal vesiculitis syndrome, rather than the direct result of seminal vesiculitis.

IMAGING
• Transrectal ultrasonography is useful for imaging the vesicular glands.
• A 5 MHz transrectal probe with a rigid extension can be used for pelvic examination in small ruminants.
• Affected glands are larger and may have a more or less echoic parenchyma with a relatively hyperechoic appearance to the stromal and ductular network.
• Abscessed glands will show a loss of normal lobar architecture with globoid areas of variable echo-density.

OTHER DIAGNOSTIC PROCEDURES
• Culture and antibiotic sensitivity testing are used to confirm cases with a bacterial etiology and to select appropriate treatment.
• Quantitative culture of an ejaculate collected by artificial vagina or electroejaculation may suffice if large numbers of the infectious agent are being secreted in the ejaculate but contamination with urethral, penile, and preputial microflora is unavoidable and may confuse the diagnosis.
• Noncontaminated samples require that the bull be sedated, and the penis be exposed, disinfected, and catheterized followed by transrectal massage of the vesicular glands and collection of fluid.
• Aerobic, anaerobic, and special (e.g., *Mycoplasma, Ureaplasma, T. foetus*, and fungi) cultures should be performed.
• Routine semen evaluation will usually show hypercoagulation of sperm cells and Diff-Quik staining of semen will confirm pyospermia.

PATHOLOGIC FINDINGS
• Gross findings are consistent with the physical examination findings.
• Histologically, the lesions consist of variable leukocytic infiltration of the interstitial and alveolar areas (microabscessation) along with fibrotic and other degenerative changes throughout the glands.
• Spermatozoa are frequently seen in the ductular or alveolar regions of the gland.

TREATMENT

THERAPEUTIC APPROACH
• Medical treatment with antibiotics, local injection of antibiotics or sclerotic agents, have all been attempted but with limited success.
• Medical treatment is usually done on the farm or at the AI center.
• Given the prolonged duration of most medical therapy, the bull will usually be lost for at least the current breeding season.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Surgical ablation of the vesicular glands (vesiculectomy) may be considered in valuable bulls and usually requires hospitalization.
• Surgery is performed on the standing bull so restraint of the patient is critical.
• Both a perirectal ischiorectal fossa and a ventral pararectal approach to vesiculectomy are described.
• Limited success has been reported following surgery.

MEDICATIONS

DRUGS OF CHOICE
• Antibiotics based on culture and sensitivity for a minimum of 2–4 weeks and potentially for as long as 6–8 weeks.
• Most antibiotics fail to achieve inhibitory concentrations in the seminal vesicles at label dosages. Tulathromycin (2.5 mg/kg IM) and tilmicosin (10 mg/kg SC, q48h for 3 treatments) are reported to more effectively penetrate the seminal vesicles and may offer the potential for more effective and shorter-duration treatment.
• Nonsteroidal anti-inflammatory agents may improve the response to antibiotics in acute cases and reduce the risk of adhesions.

CONTRAINDICATIONS
Appropriate meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
No drugs available in the United States are labeled for treatment of seminal vesiculitis, so all therapies represent extra-label drug use and require a determination of appropriate withdrawal times before slaughter.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Guarded to poor prognosis, and recovery may be temporary, so semen from valuable bulls should be collected and frozen as soon as it receives a normal evaluation.

POSSIBLE COMPLICATIONS
Postsurgical abscess formation and peritonitis

CLIENT EDUCATION
It is imperative that clients understand that there is a guarded to poor prognosis for recovery; therefore, only very valuable bulls should be considered candidates for treatment.

PATIENT CARE
• Sexual rest is recommended during medical therapy and for at least 6 weeks after surgical therapy.
• Repeat a BSE every 6 weeks for up to 6 months.
• Examine the semen carefully for the presence of pyospermia.

PREVENTION
Avoid crowded and unsanitary conditions that may increase the general risk of infectious diseases, especially those caused by *T. pyogenes.*

MISCELLANEOUS

ASSOCIATED CONDITIONS
Seminal vesiculitis can occur in association with primary infections in other organs or as part of the seminal vesiculitis syndrome.

AGE-RELATED FACTORS
• Spontaneous recovery is probably the rule for most young bulls affected with seminal vesiculitis, and treatment of these bulls will often seem to be successful.
• Older bulls are less likely to respond favorably to treatment and have a more guarded prognosis for recovery.

ZOONOTIC POTENTIAL
Brucellosis and tuberculosis can cause seminal vesiculitis in ruminants.

PREGNANCY
N/A

BIOSECURITY
• All males to be used as breeding animals should be subject to the same parasite control and vaccination procedures as the females in the herd or flock except that bulls should not be routinely vaccinated for brucellosis.
• Bulls or bull calves destined for sale to AI centers should be vaccinated only as specifically requested by the AI facility.
• All breeding males entering a herd or flock should undergo a breeding soundness examination and an appropriate period of quarantine followed by reexamination.

PRODUCTION MANAGEMENT
• Animals affected with seminal vesiculitis have the potential to reduce the reproductive efficiency of food and fiber production systems.
• This reduction occurs most often as a result of the decreased fertility of the affected males but may also involve disease transmission to the females.
• Males with evidence of subfertility or infectious or hereditary diseases should be eliminated from the breeding population.

(CONTINUED) **SEMINAL VESICULITIS**

SYNONYMS

SENNA SPECIES

BASICS

OVERVIEW

• Annual or perennial herbs or shrubs that cause musculoskeletal problems in ruminants.
• These plants are members of the Fabaceae (legume) family.
• Between 200–300 different species exist in the Senna genus, primarily located in temperate and tropical regions of the world.
• *Senna occidentalis* (common name coffee senna) and *Senna obtusifolia* (sickle pod) are the two most common species in North America.
• Other less-common species found in the south central United States and Mexico include *S. roemeriana* (twin-leaf senna, two-leaf senna) and *S. lindheimeriana* (Lindheimer senna).
• *S. occidentalis* and *S. obtusifolia* are often found in poorly-maintained pastures, along roadsides, in ditches and fence rows. They may also be found in cultivated fields of corn, sugar cane and other row crops. *S. occidentalis* prefers partial shade and *S. obtusifolia* prefers sandy soil.
• The Sennas are erect, commonly growing up to 8 feet in height.
• They possess alternate, pinnately compound leaves with 4–8 pairs of obovate leaflets.
• Flowers are yellow, 1–2 cm.
• Pods on *S. obtusifolia* are sickle-shaped, almost four-sided, 10–20 cm in length with the ends pointing downward.
• *S. occidentalis* has pods that are more flattened, 10–20 cm in length, and straighter with the tips extending upward.
• Seeds are dark brown.
• The plants may contaminate grains, soybean crops, silage, green chop, and hay.
• Ruminants also become intoxicated by eating the plant in the field.

INCIDENCE/PREVALENCE

• Relative to the availability of the plants.
• The plants are reported to be unpalatable.
• Most intoxication occurs in the fall after a frost damages the plants. The author has seen intoxication after plants were wilted subsequent herbicide treatment. One explanation for this increased consumption of dead or wilting plants may be due to sugars concentrating in the plants as they are dying.
• *S. roemeriana* is more likely a problem in the spring.
• Disease associated with *Senna* spp. is usually limited to a few animals unless plants are inadvertently fed in contaminated silage, hay, etc. This may be due in part to the unpalatable nature of the plants.
• 0.5–3.0% body weight of green plant consumed daily over 5–7 days or overnight fill on *S. occidentalis* will produce toxicity.

GEOGRAPHIC DISTRIBUTION

• Worldwide distribution.
• *S. occidentalis* and *S. obtusifolia* are most common in the Gulf Coast region but are found from Pennsylvania to Texas.
• *S. roemeriana* and *S. lindheimeriana* are found in the south central US and Mexico.

SYSTEMS AFFECTED

• Anthraquinones cause damage to the gastrointestinal tract.
• Other systems affected by *Senna spp.* include skeletal and cardiac muscle and the hepatic system.

PATHOPHYSIOLOGY

• Poorly understood.
• Toxic principles are numerous anthraquinones (obtusin, obtusifolin, emodin, and others). They are known to produce gastrointestinal effects, and are thought to inhibit electron transport of mitochondria, causing myodegeneration, myopathy, and muscular weakness. However, the exact cause of the muscle damage has never been proven.

SIGNALMENT

All ruminants are susceptible, although cattle are most commonly intoxicated.

PHYSICAL EXAMINATION FINDINGS

• Diarrhea (moderate to severe), is seen shortly after consumption and is usually the first observed sign.
• Anthraquinones are known to cause gastrointestinal upset, resulting in depressed appetite and diarrhea.
• Progressive muscular weakness indicated by tremors in rear limbs, ataxia, weakness, and eventual inability to rise occurs later in the course.
• Animals are generally afebrile.
• Cattle are often referred to as "bright-eyed downers" as they will often continue to eat, drink, and remain alert.
• In contrast, some affected animals become lethargic and anorectic.
• The urine is usually dark due to myoglobinuria from muscle degeneration.
• Most animals do not survive once recumbency occurs and death occurs within 1–7 days.

CAUSES AND RISK FACTORS

• Anthraquinones are the toxic principles in *Senna* species. The entire plant is considered toxic when green or dry.
• Mature plants are more toxic than younger specimens.
• Seeds are more toxic than foliage and contain the highest concentration of anthraquinones.
• *Senna* species are not generally very palatable and are more likely consumed in the late summer and fall when other food sources become scarce.
• *S. occidentalis* is more toxic than *S. obtusifolia*.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• White muscle disease associated with deficiencies of vitamin E and selenium
• Acute copper poisoning in sheep
• Dallisgrass staggers
• Other causes of "downer" animals

CBC/BIOCHEMISTRY/URINALYSIS

• Marked elevations in serum enzymes AST and CK are commonly noted, reflecting muscle necrosis and degeneration. CK levels may be elevated 10-1000× above normal.
• AST is often elevated 10× above normal levels.
• Myoglobinuria is commonly noted. It may be mistaken for hemoglobinuria (hemoglobin is visible in plasma, whereas myoglobin is not).
• The elevation in AST and CK reflects acute muscle degeneration.

OTHER LABORATORY TESTS

Evidence of plant consumption

PATHOLOGIC FINDINGS

• Signs of toxic myopathy as evidenced by severe muscle necrosis.
• Pale streaking to almost white discoloration of muscle, adjacent to normal muscle may be seen in the shoulder and pelvic limbs, especially in the quadriceps femoris, semimembranosus, and semitendonosus.
• Hyperemia of the mucosa of the stomach and small intestine.
• Mild hepatic necrosis and renal tubular necrosis may be seen microscopically.
• The heart may also contain pale streaking and hemorrhages.

TREATMENT

THERAPEUTIC APPROACH

• Primarily supportive treatment of symptoms as there is no specific therapy available.
• Intravenous fluids to assist maintenance of renal function if myoglobinuria is present.
• Treatment is usually unrewarding after recumbency develops with most animals dying in 1–7 days.

MEDICATIONS

DRUGS OF CHOICE

• Activated charcoal: 2–5 g/kg body weight given orally to control absorption of toxins from the gastrointestinal tract (1 g charcoal per 5 mL water).
• Mineral oil administered orally to more rapidly transport plant materials from gastrointestinal tract.

• Generally, it is considered best to use either activated charcoal or mineral oil, but not both at the same time.

CONTRAINDICATIONS

The use of vitamin E and selenium is contraindicated as their use will increase myodegeneration and mortality.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Clinical course may last up to 7–10 days.
• Once recumbency occurs, few animals recover.

PREVENTION

• Prevent animal access to *Senna* spp.
• Maintain appropriate level of nutrition.
• Closely monitor livestock for increased interest in *Senna* species after a frost or herbicide treatment since this may increase plant palatability.

MISCELLANEOUS

AGE-RELATED FACTORS

The author has noted both calves and adult cattle consuming *Senna* species in sufficient amounts to result in death.

PREGNANCY

Experimentally, fetal deaths have been reported in pregnant animals fed Senna. See Suggested Reading.

ABBREVIATIONS

• AST = aspartate transaminase
• CK = creatine kinase

Author Matt G. Welborn
Consulting Editor Christopher C.L. Chase

SHEEP AND GOAT POX

BASICS

OVERVIEW

• Sheep and goat pox caused by separate host-specific capripoxviruses, sheep poxvirus (SPV) and goat poxvirus (GPV). Most strains host-specific for either sheep or goats; some can recombine with other strains causing lesions in one or both species and result in a wide variety of clinical signs.
• Disease is characterized by fever and generalized pox lesions on the skin and mucus membranes. A bronchopneumonia can also be noted in infected animals.
• Transmitted primarily by aerosol from close contact with infected animals. Other methods of viral transmission are abrasions of the skin or mucosa coming into direct contact with dried scabs or contaminated fomites. *Stomoxys calcitrans* is an efficient mechanical vector.
• Disease has not been detected in wild sheep/goat populations.

INCIDENCE/PREVALENCE

• Morbidity and mortality vary with the breed of the animal, its immunity to capripoxviruses, and the strain of the virus.
• Mild infections are common among indigenous breeds in endemic areas, but more severe disease can be seen in young or stressed animals, animals with concurrent infections, or animals from areas where pox has not occurred for some time. Reported morbidity rates in indigenous breeds range from 1% to 75% or higher.
• Although the mortality rate is often <10%, case fatality rates of nearly 100% have been reported in some young animals.
• Imported breeds of sheep and goat usually develop severe disease when they are moved into an endemic area. The morbidity and mortality rates can approach 100% in newly imported, highly susceptible flocks.

GEOGRAPHIC DISTRIBUTION

Endemic in Africa (countries north of the equator), Middle East, India/Pakistan, and most of Asia; recently observed in Southern and Eastern Europe.

SYSTEMS AFFECTED

• Integument
• Ophthalmic
• Respiratory

PATHOPHYSIOLOGY

• The virus enters through the oral, nasal, or respiratory epithelium or via the skin dermis or epidermis. Local viral replication occurs in these affected epithelial tissues.
• Infected macrophage type cells are thought to transport the virus to the regional lymph nodes, where further viral replication takes place. There is a marked proliferative response in the affected lymph nodes, which greatly increase in size.
• A strictly cell-associated viremia then occurs, which introduces infected cells (probably macrophages) throughout the body. The virus then replicates further in the epithelial tissues of the skin, lungs, endothelium, muscle and, more rarely, in nervous tissue.
• The basic lesions in the various affected tissues are due to a vasculitis, thrombosis, and the resulting necrosis. The balloon degeneration of epithelial cells results in the occasional vesicular-type lesions seen with smallpox, but with sheep and goat pox the lesions are necrotic, scabbed epithelium and dermis, with full skin thickness lesions often leaving deep scarring of the hide.

SIGNALMENT

• Severity is influenced by age, sex, breed, and nutritional status of the animal.
• Mortality rate in naïve animals can approach 50–90%. Mortality rate of native sheep from endemic areas can vary from 5% to 10%.
• Young are severely affected with morbidity/mortality approaching 85–95%. Neonates may have a mortality rate of 100%.

PHYSICAL EXAMINATION FINDINGS

• Clinical disease may range from mild to severe.
• Incubation period 4–14 days with the disease lasting up to 6 weeks. Various stages of the pox lesions may be observed at the same time. Complete recovery may take up to 3–4 months.
• Fever, 104–106°F (40–41°C), and depression with conjunctivitis and rhinitis common.
• Pox lesions are soon noted in haired and hairless areas of the body. Swelling of the muzzle, nares, and lips are usually noted first. Macules and papules develop on the muzzle, nares, lips, eyelids, perineum, scrotum, axillary/inguinal regions, and udder.
• Lesions first appear as circular, raised, erythematous areas (macule) that progress to raised blanched regions with a central region of fluid (papule). Papules rupture leaving circular umbilicated lesions that scab over and slowly heal. Associated dermis is thickened, hard, and edematous. Lesions leave deep scars.
• Papules on the eyelid can be very painful and cause blepharitis and mucopurulent discharge.
• Nose, nasal passages, and tracheal lesions cause respiratory distress and mucopurulent discharge. Virus is present in secretions.
• Pneumonia results in severe labored breathing/cough; secondary bacterial infections common. Animals often remain in poor body condition.
• The lesions scab over forming deep slow-healing ulcers in the skin.

CAUSES AND RISK FACTORS

• The poxviruses of sheep and goats (capripoxviruses) are closely related, both antigenically and physicochemically. They are also related to the virus of lumpy skin disease.
• Naïve and young animals are highly susceptible.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Bacterial pneumonia
• Bluetongue virus
• Contagious ecthyma (orf)
• *Dermatophilus congolensis* (streptothricosis)
• Insect bites
• Photosensitization
• Psoroptic mange

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY FINDINGS

• Virus detected from scabs, vesicle fluid, and oral/nasal secretions.
• Polymerase chain reaction (PCR) assays and sequencing can detect capripoxvirus genomes in tissue samples or cultures, and identify whether the virus is SPV or GPV
• Agar gel immunodiffusion (AGID) test cross reacts with other pox viruses.
• Virus neutralization tests, indirect fluorescent antibody tests and indirect ELISA tests used for antibody measurements for exposure to the viruses.

OTHER DIAGNOSTIC PROCEDURES

Electron microscopy is often used to identify typical large brick-shaped poxvirus particles covered by short tubular elements and measuring 265–295 nm. Viral particles can be difficult to differentiate from orthopoxviruses.

PATHOLOGIC FINDINGS

• Gross lesions include thickened and edematous dermis and epidermis. Lymph nodes draining these areas are often swollen and edematous.
• Pox lesions (circumscribed macules, papules, vesicles, and deep circular ulcerated lesions with scabs in later resolving cases) noted on the muzzle, nares, hairless areas of the axillary and inguinal regions, vulva, prepuce, udder, teats, eyelids, sclera, lips, oral cavity, esophagus, and rumen.
• Lung lesions are randomly distributed throughout the lungs due to hematogenous spread of the virus. Lesions are discrete, hard, gray-white to hemorrhagic nodules that are easily identified in the lungs. The pulmonary parenchyma adjacent to these areas often becomes atelectic due to the affected bronchiole constriction. Secondary bacterial pneumonias are often sequelae to the infection.
• Histologic lesions include acanthosis of epidermis with ballooning degeneration of keratinocytes. Necrosis and microvesiculation of the stratum spinosum occurs as the lesion progresses.
• Eosinophilic intracytoplasmic inclusion bodies are noted in the swollen keratinocytes.

• Dermis is edematous with some hemorrhage and neutrophilic infiltrates.
• Macrophages accumulate in the affected dermis with some becoming enlarged and swollen with eosinophilic intracytoplasmic inclusion bodies and large vacuolated nuclei with marginated chromatin (*cellules claveleuses* or sheep pox cells). Fibrocytes and fibroblasts can also become infected and develop intracytoplasmic inclusions.
• Necrosis of the affected dermis and epidermis is due to a severe necrotizing vasculitis that develops in the affected dermis affecting arterioles and venules with thrombosis of affected blood vessels.
• Lung lesions characterized by a proliferative bronchopneumonia with hyperplasia and necrosis of the bronchiolar epithelium. Alveolar septal walls and associated peribronchiolar connective tissue are thickened by edema and hemorrhage. Some type II pneumocyte hyperplasia is noted in alveoli. Variable numbers of macrophages and neutrophils are present in the affected areas with scattered "sheep pox cells" present.
• Eosinophilic intracytoplasmic inclusions can be present in the "sheep pox cells" and type II pneumocytes.
• Mononuclear infiltrates containing "sheep pox cells" can be noted systemically in the heart, kidney, adrenal glands, liver, thyroid, and pancreas.

TREATMENT

THERAPEUTIC APPROACH
• Reportable disease, one should consult with regulatory veterinarians before treatment.
• Treating affected animals is difficult. Supportive treatment should be considered.

MEDICATIONS

DRUGS OF CHOICE
• The administration of antipyretic to make the animal feel better so it will eat and drink are important.
• Antibiotics for secondary bacterial skin or pulmonary disease may be helpful in the survival of the animal.

PRECAUTIONS
If treated for secondary bacterial infections or given antipyretics, appropriate meat and milk withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Animals living in endemic areas usually have some innate immunity; susceptible adult animals can have a significant mortality.

POSSIBLE COMPLICATIONS
Secondary bacterial infections in the skin and lung are possible.

PATIENT CARE
Animals should be monitored for secondary bacterial infections.

PREVENTION
• Scabs remain infective for months. If reintroducing animals, vaccination would be an appropriate preventive measure.
• Virus shed in body secretions (particularly nasal and ocular). Virus can remain viable in the environment; passage to other sheep by contact with fomites (including contaminated herdsmen) can occur.
• Live attenuated vaccines are available; confer good immunity lasting up to 2 years. New capripoxvirus vector vaccines for sheep/goat pox and lumpy skin disease is currently being developed.
• The ability of the vaccine to protect already exposed /infected animals is questionable. However, good protection can be expected in vaccinated noninfected animals.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Bacterial pneumonia

AGE-RELATED FACTORS
Neonatal lambs and kids can have significant mortality.

ZOONOTIC POTENTIAL
Several suspected human cases of goat pox have been described. However, no virus was isolated from these individuals.

PREGNANCY
• Pregnant animals may abort, probably due to the high fever observed and systemic infection.
• Fetal infections have not been recorded.

BIOSECURITY
• Vaccinate and quarantine new stock entering a flock or herd.
• In an outbreak, vaccinate all animals to develop some immunity to the virus.
• Vector control to decrease insect populations, particularly *Stomoxys calcitrans*, may not help in control.

PRODUCTION MANAGEMENT
• Disease is transmitted by direct contact with virally contaminated dried scabs.
• Respiratory and oral secretions from sick animals and virally contaminated fomites (i.e., clothes, hands and boots of herdsmen, feed, and other equipment) can spread the disease.

ABBREVIATIONS
• AGID = agar gel immunodiffusion
• ELISA = enzyme-labeled immunosorbent assay
• GPV = goat poxvirus
• PCR = polymerase chain reaction
• SPV = sheep poxvirus

SEE ALSO
• Bluetongue Virus
• Dermatophilosis
• Orf (Contagious Ecthyma)

SMALL RUMINANT DERMATOLOGY

BASICS

OVERVIEW
• Skin diseases of sheep and goats may be contagious, zoonotic, and/or detrimental to production.
• Common skin diseases of sheep and goats include dermatophytosis, tick and mite infestations, lice, keds and flystrike, contagious ecthyma, and staphylococcal infections.
• Some specific skin diseases of small ruminants, or specific diseases with cutaneous manifestations, may also be reportable to veterinary regulatory authorities.

INCIDENCE/PREVALENCE
Varies with specific conditions, some of which can be endemic in herds or flocks or occur in outbreak fashion.

GEOGRAPHIC DISTRIBUTION
Occur worldwide in areas where sheep and goats are raised; specific diseases will vary in their distributions based on climate, management factors and other influences.

SYSTEMS AFFECTED
Integument

PATHOPHYSIOLOGY
See specific disorders of interest in this text.

HISTORICAL FINDINGS
See specific disorders of interest in this text.

SIGNALMENT
• Skin disease is a common complaint of both sheep and goats.
• Some disorders may have specific signalment associations; for example, contagious ecthyma is more likely to affect juvenile sheep.

GENETICS
N/A

CAUSES AND RISK FACTORS
See specific disorders of interest in this text.

S

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Differential diagnoses can be determined based upon the characteristics of the dermatologic lesions in question, or based upon the area of the body affected by the problem.
• Determination of the primary lesion (pustules, papules, vesicles, wheals, nodules, or presence of a parasite) can be very helpful to establish a differential list. It should also be considered if the observed lesions are secondary to, and a result of, a primary lesion, such as crusts from a concomitant bacterial infection that is secondary to a primary cause.
• Differential diagnoses for small ruminants with specific dermatologic lesions are listed below:

Pustular/Papular/Vesicular Lesions
• Impetigo caused by *Staphylococcus*
• Contagious ecthyma
• Pemphigus foliaceus
• Capripox
• Foot and mouth disease
• Caprine herpesvirus
• Bluetongue
• Peste des petits ruminants

Nodules With or Without Ulcers
• Demodicosis
• Staphylococcal dermatitis
• Mycetoma (fungal tumors)
• Abscesses (caseous lymphadenitis)
• Cutaneous papillomas
• Squamous cell carcinoma
• Melanoma
• Tuberculosis

Pruritus
• Lice
• Sheep keds
• Fleas
• Ticks
• Mites: *Psoroptes* (ear mange), *Sarcoptes*, *Chorioptes*
• Migrating helminths (*Metastrongylus* and *Parelaphostrongylus tenuis*)
• Flies: *Musca* (bush fly), *Stomoxys calcitrans* (stable fly), *Culicoides* (biting midges), *Tabanus* (March flies)
• Scrapie

Crusting and Scaling
• Dermatophytosis
• Dermatophilosis
• *Malassezia* dermatitis
• Protozoa: *Toxoplasma* spp., *Besnoitia* spp.
• Hypothyroidism
• Contagious ecthyma
• Zinc deficiency
• Selenium deficiency and undetermined vitamin E uptake
• Pemphigus foliaceus
• Capripox
• Mites
• *Pelodera* (*Rhabditis*) *strongyloides*

Hair Loss
• Hypothyroidism
• Dermatophytosis
• Contact dermatitis
• Atopic dermatitis
• Mites
• *Pelodera*
• Selenium deficiency and undetermined vitamin E uptake

Erythema
• Sunburn
• Photosensitization

Sloughing of Affected Area
• Frostbite
• Ergotism
• Chemical burns
• Second or third degree burns
• Photosensitization

Differential diagnoses for small ruminants with dermatologic lesions on specific body parts are listed below.

Lips, Face, and Neck
• Contagious ecthyma
• Capripox
• Staphylococcal dermatitis/folliculitis
• Dermatophytosis
• Dermatophilosis
• Demodecosis
• Peste des petits ruminants (morbillivirus)
• Sarcoptic mange
• Pediculosis
• Zinc deficiency
• Selenium deficiency
• Pemphigus foliaceus
• Bluetongue (primarily sheep)
• Urine scald in breeding bucks
• Photosensitization
• Sunburn
• Squamous cell carcinoma
• Contact dermatitis
• Actinobacillosis
• Elaeophoriasis ("sore head")

Ears
• Dermatophytosis
• Dermatophilosis
• Sarcoptic mange
• Ear mites
• Photodermatitis
• Frostbite
• Pemphigus foliaceus
• Squamous cell carcinoma
• Sunburn
• Ergotism
• Fescue toxicosis

Body
• Scrapie
• *Parelaphostrongylus tenuis*
• Dermatophilosis (lumpy wool disease)
• Psoroptic mange
• Goat/sheep pox
• Contagious viral pustular dermatitis
• Vitamin/nutrient deficiency such as:
  ◦ Vitamin A
  ◦ Vitamin C responsive dermatitis
  ◦ Copper deficiency
  ◦ Selenium deficiency
  ◦ Zinc deficiency
• Anagen defluxion (wool break, sheep)
• Follicular cyst
• Fleece rot
• Contact dermatitis
• Ulcerative dermatosis (sheep)
• Pediculosis

Feet
• Contagious ecthyma
• Foot and mouth disease
• *Staphylococcus* folliculitis
• Interdigital fusiform infection

(CONTINUED) SMALL RUMINANT DERMATOLOGY

- Dermatophilosis
- Sarcoptic mange
- Chorioptic mange
- Ergotism
- Fescue toxicosis
- *Besnoitia* dermatitis
- Zinc deficiency
- Contact dermatitis
- Pemphigus foliaceus
- Bluetongue

Udder

- Contagious ecthyma
- Staphylococcal dermatitis or folliculitis
- Zinc deficiency
- Hyperpigmentation from exposure to sun
- Cutaneous papillomas in white Saanens

Perineum

- Contagious ecthyma
- Caprine herpesvirus
- Staphylococcal dermatitis
- Ticks
- Neoplasia
- Squamous cell carcinoma
- Urine scald

CBC/BIOCHEMISTRY/URINALYSIS
Usually of limited value unless cutaneous signs relate to a more significant systemic disorder.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
- Skin scrapings, particularly useful for diagnosing mite infestations
- Dermatophyte culture
- Potassium hydroxide preparation for the diagnosis of dermatophytosis
- Woods lamp examination
- Cytologic evaluation and impression smears of lesions
- Bacterial culture and sensitivity testing
- Skin biopsy

PATHOLOGIC FINDINGS
See specific disorders of interest in this text.

TREATMENT

THERAPEUTIC APPROACH
- Treatment should always be based on reasonable diagnosis, which can be derived from a thorough historical assessment and physical examination, and from information garnered through selected diagnostic procedures.
- Treatment recommendations vary depending on the disorder in question, but key tenets of therapy include preventing further damage, improving comfort, resolving lesions, and preventing relapses by identifying triggering or influencing factors.

SURGICAL CONSIDERATIONS AND TECHNIQUES
NA

MEDICATIONS

DRUGS OF CHOICE
See specific disorders of interest in this text.

CONTRAINDICATIONS
Corticosteroids should be avoided in pregnant animals.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
See specific disorders of interest in this text. In general, unless associated with significant systemic disease, or refractory to treatment, most dermatologic disorders have a good prognosis for survival and complete recovery.

POSSIBLE COMPLICATIONS
- Secondary bacterial infection of abnormal skin.
- Severe self-trauma with pruritic conditions.
- Opportunistic infection of abnormal skin or wounds with blow flies or screw worm fly.
- Dehydration and protein loss if large areas of skin are inflamed and exudative (such as with extensive burns).

CLIENT EDUCATION
Many dermatologic disorders of small ruminants are infectious or relate to management factors, so targeted client education is often a critical means of decreasing prevalence of skin disorders within groups.

PATIENT CARE
Focus on reducing discomfort and further damage to the skin, and providing appropriate treatment for lesions and monitoring response.

PREVENTION
See specific disorders of interest in this text. Prevention of most skin disorders relies on factors related to management and biosecurity.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
See specific disorders of interest in this text.

ZOONOTIC POTENTIAL
Dermatophytosis, orf, and several other skin disorders of small ruminants are caused by zoonotic agents, or can be contracted through similar means in a variety of species. Care should be exercised during handling of animals and during the collection and evaluation of samples.

PREGNANCY
Corticosteroids should be avoided in pregnant animals.

BIOSECURITY
- Quarantine new animal arrivals to prevent disease or parasite transmission to the herd or flock.
- Some disorders with cutaneous manifestations are considered reportable or exotic in specific regions or countries.

PRODUCTION MANAGEMENT
- Dermatologic diseases may have a deleterious effect on production through a variety of mechanisms, including animal comfort, systemic effects, and thriftiness.
- Specific disorders may be managed through vaccination (e.g., contagious ecthyma).

SYNONYMS
See specific disorders in this text.

ABBREVIATIONS
N/A

SNAKEBITE

BASICS

OVERVIEW

• Pit vipers are responsible for the majority of venomous snakebites in North America.
• The snakes are named for the fossa in the loreal area between the eye and nostril on either side of the head. The loreal pits are external openings to a pair of extremely sensitive infrared-detecting organs which help snakes find prey.
• Pit vipers include rattlesnakes (*Crotalus* spp.), pygmy rattlesnakes, cottonmouths (water moccasins), copperheads (*Agkistrodon* spp.), and massasaugas (*Sistrurus* spp.). These snakes are identifiable by a triangular head, elliptical pupils, keeled scales, and the presence of rattles in adults. Young rattlesnakes have a blunt tip on the tail until it is broken off.
• Pit vipers can be aggressive (depending upon type) and inject a neurotoxic or hemotoxic venom designed to incapacitate or predigest its prey with a small, potent dose.
• Venom is delivered through hinged, hollow, retractable fangs in a rapid stabbing motion. Mature snakes can control the amount of venom injected, while juvenile snakes tend to inject a maximum amount of venom. Older snakes possess more potent venom, and larger snakes are frequently capable of storing larger volumes of venom.
• Coral snakes (*Micruroides euryxanthus* and *Micrurus* spp.) are nocturnal and are rarely responsible for venomous bites to farm animals. They bite with short, fixed fangs and hold on, delivering a neurotoxic venom by chewing.
• Envenomation in all victims is potentially fatal and is a medical emergency.

INCIDENCE/PREVALENCE

Unknown in large animals

GEOGRAPHIC DISTRIBUTION

• Pit vipers are widely distributed throughout North America (United States and parts of Canada), except Alaska, Hawaii, and Maine.
• Pit vipers are also found in Mexico, South America (except Chile), and Australia.
• True vipers are found in Africa, South America, India, and in tropics.
• Coral snakes inhabit the southern US from Arizona to Florida and are found worldwide in the tropics.

SYSTEMS AFFECTED

• Cardiovascular
• Hemolymphatic
• Integument
• Musculoskeletal
• Nervous
• Respiratory

PATHOPHYSIOLOGY

• The composition and mechanism of action of the various components of snake venom continue to be elucidated.
• Venom is classified as hemotoxic or neurotoxic depending upon the predominant physiologic effects.
• Both venoms contain enzymatic proteins that aid in tissue degradation and digestion
  ◦ Metalloproteases
  ◦ Hyaluronidase
  ◦ Collagenase
• Hemotoxic venom affects hemostasis (plasmin-like protease, thrombin-like protease, and kallikrein-like protease); hydrolyze second messengers like cAMP, (phosphodiesterases) and potent, nonenzymatic polypeptides, all of which result in pain, massive swelling, tissue necrosis, and coagulation abnormalities.
• Neurotoxic venom has significantly less local tissue destruction and pain, but has profound effects on both pre- and postsynaptic skeletal and nonskeletal muscle, neuromuscular junction sites including muscarinic and neuronal receptors, and potassium, sodium, and calcium ion channels. Phopholipase A_2 causes membrane disruption and mediates many neurotoxic and cardiotoxic biochemical changes. Numbness, muscle fasciculations, paralysis, and respiratory collapse can be the result.

HISTORICAL FINDINGS

Usually one animal is affected at a time, but several animals may be affected over the course of a season.

SIGNALMENT

All species are susceptible.

PHYSICAL EXAMINATION FINDINGS

• Rapid regional swelling with severe pain, edema, ecchymosis, and petechiation.
• Bleeding and puncture wounds may or may not be apparent.
• Tissue necrosis, inspiratory dyspnea, and epistaxis are common (especially if bite is near or on the muzzle).
• Increased salivation, dysphagia, and anorexia.
• Lethargy, weakness, reluctance to move, muscle fasciculations, paresis, and paralysis.
• Raised temperature, tachycardia, cardiac arrhythmias, shock, numbness, and respiratory collapse.
• Central nervous system signs: Obtundation, seizures, and coma.

CAUSES AND RISK FACTORS

Snakebite with envenomation

Snake

• Size, age, nutritional status, and species of snake (aggressive species such as the Mojave rattlesnake are more likely to strike).
• Amount of venom injected: 25% of bites are "dry" bites with no injection of venom.
• Toxicity of venom, which varies between species: Rattlesnake > water moccasin > copperhead.
• Toxicity of venom will vary within species and within individual snake as it ages or as the size of prey changes.

Victim

• Depends upon the bite and location (tongue, muzzle, face, body wall, or directly into a large vessel pose the greatest risk).
• Age and size of victim (younger animals are more likely to sustain bites resulting in fatality).
• Preexisting conditions that compromise immune response.
• Victim's susceptibility to venom and time to medical treatment.
• Animals often survive the initial bite only to succumb to infection later due to delayed recovery and treatment.
• Activity after the bite also increases the distribution of venom.

Location/Habitat/Time of Year

• Animals that crowd into shaded areas in hot summer months especially adjacent to watering holes, wood piles, rocky outcroppings, overgrazed pastures, and during drought.
• April through October when snakes are most active.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Trauma
• Insect envenomation
• Abscessation
• Lizard bite (Gila monster)

CBC/BIOCHEMISTRY/URINALYSIS

• Hemoconcentration
• Thrombocytopenia
• Hypoalbuminemia
• Leukocytosis
• Echinocytosis
• Elevated creatinine kinase
• Elevated aspartine aminotransferase
• Elevated cardiac troponin I
• Myoglobinuria, hematuria, proteinuria, glucosuria

OTHER LABORATORY TESTS

• Serial coagulation profiles
• Thromboelastography (TEG)
• Fibrinogen
• Serum antibodies to venom
• Detection of venom in serum

IMAGING

• Ultrasound or radiography to rule out traumatic injury or puncture
• Echocardiography: Cardiac function

OTHER DIAGNOSTIC PROCEDURES
• Marking leading edge of swelling along with circumferential measurements of limb or muzzle may give an indication of progression.
• Electrocardiograph: Arrhythmias.

PATHOLOGIC FINDINGS
• Gross findings are variable.
• Swelling, serous exudation, tissue necrosis, sloughing.
• Hemorrhage especially at bite site.
• Passive congestion of all organs.
• Hemorrhagic icterus.
• Histopathologic findings are highly variable.

TREATMENT

THERAPEUTIC APPROACH
• Maintenance of airway, preplacement of nasal tubing prior to occlusion or tracheostomy if necessary.
• Intravenous fluid support, polyionic fluids for hypotensive cases.
• Keep animal calm, restrict movement.
• Wash wound to remove topical debris.
• Do not infuse fluid into wound.
• Wound care and debridement as necessary.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Debridement as necessary

MEDICATIONS

DRUGS OF CHOICE
• Antivenin is the treatment of choice. Recommendations for human bite victims are for treatment with multiple vials, but 1–2 vials may be sufficient to improve outcome for animals.
• Administration of antivenin as early as possible after envenomation may preclude the need for treatment with additional vials later.

Antivenin
• Antivenin: CroFab Crotalidae Polyvalent Immune Fab (Ovine) (BTG Specialty Solutions Center, West Conshohocken, PA 19428, USA).
  ◦ Composed of four antivenins: *Crotulas atrox* (Western diamondback rattlesnake), *Crotalus adamenteus* (Eastern diamondback rattlesnake), *Crotalus scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus* (cottonmouth or water moccasin). A study in dogs has been conducted with good results utilizing 1–2 vials of antivenin.
• Antivenin (Crotalidae) Polyvalent (ACP) equine origin (Pfizer New York, NY 10017).
  ◦ Composed of four antivenins: *Crotalus adamanteus* (Eastern diamondback rattlesnake), *Crotalus atrox* (Western diamondback rattlesnake), *Crotalus durissus terrificus* (tropical rattlesnake, Cascabel), and *Bothrops atrox* (fer-de-lance).
• Antivenin (*Micrurus fulvius*) equine origin (Pfizer, New York, NY 10017).
  ◦ Will neutralize the venom of *Micrurus fulvius tenere* (Texas coral snake) but will not neutralize venom of *Micruroides euryxanthus* (Arizona or Sonoran coral snake).
• Antivenin (Crotalidae) Polyvalent, equine origin (Boehringer Ingelheim, Saint Joseph, MO 64506). Labeled for use in dogs; studies have shown typical 1–2 vials utilized in dogs.
  ◦ Composed of four antivenins: *Crotalus adamanteus* (Eastern diamondback rattlesnake), *Crotalus atrox* (Western diamondback rattlesnake), *Crotalus durissus terrificus* (Central and South American rattlesnake, Cascabel), and *Bothrops atrox* (fer-de-lance).
• Current use is extra-label in ruminants.
• Be prepared to treat for an allergic reaction.

Other Treatments
• Treatment with broad-spectrum antimicrobials
• Nonsteroidal anti-inflammatory medication for pain
• Revaccinate with tetanus and *Clostridium* toxoids

PRECAUTIONS
• Use caution when and if handling a dead snake. Reflex bites do occur.
• Treatments used previously that have been shown to be detrimental or ineffective are incision, suction, infusion of fluids into wound area in an attempt to dilute toxin, application of hot or cold compress, tourniquets, or electric shock.
• Controversial: Use of corticosteroids in the treatment of venomous snakebites in veterinary medicine.
  ◦ Corticosteroids delay healing and may, although not proven, interfere with effects of antivenin.
  ◦ No studies have shown increased survival rate with use of corticosteroids.
  ◦ Can be used for treatment of allergic reaction associated with antivenin administration.
• Colloid therapy may increase risk of bleeding diathesis, complicate interpretation of coagulation profiles, or cause anaphylaxis. Use with caution.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
Corticosteroids may interfere with antivenin.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Depends on bite location, age and size of victim.
• Depends on size, age, nutritional status, and species of snake, and amount and toxicity of the venom.

PATIENT CARE
• Restrict activity and movement.
• Food and water should be readily accessible and feed should be easy to swallow.
• Serial monitoring of coagulation profiles, complete blood count, biochemistry panel, and urinalysis, and cardiac parameters should be performed as often as warranted by the clinical condition, especially in the first 48 hours.
• Tissue destruction may not peak for several days. Swelling resolves in 3–7 days in most cases that survive.
• Recurrent coagulopathy may occur 1–2 weeks after administration of antivenin due to short persistence of antivenin in the blood compared to venom.

PREVENTION
Crotalus Atrox Toxoid (rattlesnake venom) vaccines are licensed for dogs and horses. There are no vaccines licensed for ruminants and vaccine efficacy is not well established.

MISCELLANEOUS

AGE-RELATED FACTORS
• Young animals are more at risk due to their inquisitive nature.
• A snakebite with envenomation is more likely to result in mortality due to smaller body size.

ZOONOTIC POTENTIAL
• Wear gloves to protect hands with skin abrasions when treating wounds.

PREGNANCY
• Fetal death as a result of venomous snakebite has been reported in humans.
• The safety of antivenin treatment during pregnancy in animals has not been established.

SNAKEBITE (CONTINUED)

ABBREVIATION
• TEG = thromboelastography

SODIUM DISORDERS: HYPERNATREMIA

BASICS

OVERVIEW
Definition—a serum sodium concentration [Na^+] exceeding the upper limit of normal ruminants, usually >152 mmol/L.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
• Cardiovascular • Musculoskeletal • Nervous • Respiratory • Multisystemic

PATHOPHYSIOLOGY
• Hypernatremia—deficit of water in relation to the body's sodium stores. • It can result from a net water loss or a sodium gain. • Sodium is the major extracellular fluid (ECF) cation. Plays a vital role in maintaining the cell membrane potential, ECF volume and osmolality. • Sodium affects water shifts between the ICF and ECF, with hypernatremia and hyperosmolarity leading to a shift of free water from the ICF to the ECF, which results in brain cell shrinkage, vascular rupture, and neurologic deficits in severe cases. • Source of sodium is primary dietary intake. • Renal is the primary route of excretion (~99% reabsorbed in renal tubules). • Cardiovascular effects of hypernatremia—decreased left ventricular contractibility. • Hepatobiliary system—impaired gluconeogenesis and lactate clearance. • Musculoskeletal effects—muscle weakness, cramps, rhabdomyolysis.

SIGNALMENT
All species of ruminant

PHYSICAL EXAMINATION FINDINGS
• Lethargy • Muscle twitching • Hyperreflexia • Spasticity • Coma • Seizures and death

CAUSES AND RISK FACTORS

Sodium Gain
• Salt poisoning. High Na^+ in the diet with inadequate access to water. • Hypertonic fluid. Administration of hypertonic saline or bicarbonate solutions (IV or oral). • Inadequately mixed milk replacer. • High salinity (>1,000 ppm) of water used to prepare milk replacer.

Water Losses
Can be caused by either renal or extrarenal mechanisms.
• Renal—osmotic diuresis (hyperglycemia, mannitol or loop diuretics). • General—pyrexia. • Respiratory—hyperventilation. • Gastrointestinal. Diarrhea, if compensatory water intake has not yet occurred.

Pseudohypernatremia
• Sodium salts of EDTA, fluoride, and heparin. • Decreased plasma protein and/or lipid concentration.

Risk Factors
• Inadequate water intake. • "Salt intoxication" occurs if salt-restricted animals are allowed access to salt (ad libitum consumption).

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Meningitis • Polioencephalomalacia • Lead poisoning • Rabies

CBC/BIOCHEMISTRY/URINALYSIS
• Hypernatremia. • Hyposthenuria is associated with diabetes insipidus. • Electrolytes imbalances of K^+, Cl^-, Ca^{2+}, Mg^{2+}.

OTHER LABORATORY TESTS
• Fractional excretion of Na [FE_{Na}]. Suspect extrarenal losses if [FE_{Na}] <1% and dehydration; suspect renal losses if [FE_{Na}] >1% and dehydration. • Plasma osmolality can be elevated. • Urine glucose and osmolality increases with osmotic diuresis.

OTHER DIAGNOSTIC PROCEDURES
• History, physical examination, and laboratory evidence. • Determine the cause of hypernatremia (sodium gain or water losses).

PATHOLOGIC FINDINGS
• Marked congestion and edema of the brain and meninges. Petechiae and ecchymoses within the gray and white matter of the brain.

TREATMENT

THERAPEUTIC APPROACH
• Addressing the underlying cause (e.g., diarrhea; fever, hyperglycemia and correcting the feeding preparation) and correcting the prevailing hypertonicity. • Acute hypernatremia (developed over a period of hours). Reduction of serum [Na^+] by 1 mmol/L/h is appropriate. • Chronic hypernatremia or unknown duration. Reduction of serum [Na^+] at a maximal rate of 0.5 mmol/L/h. It prevents cerebral edema and convulsions during treatment. • The goal of treatment is to reduce the serum [Na^+] to 152 mmol/L.

MEDICATIONS

DRUGS OF CHOICE
Only hypotonic fluids are appropriate.
• Pure water or 5% dextrose (provide 0 mmol/L of [Na^+]) • 0.2 % sodium chloride in 5% dextrose solution (provide 34 mmol/L of [Na^+]) • 0.45 % sodium chloride (provide 77 mmol/L of [Na^+]). • Because the risk of cerebral edema increases with the volume of the infusate, the volume should be restricted to that required to correct hypertonicity.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Clinical course and prognosis vary and are associated with the underlying disease condition.

POSSIBLE COMPLICATIONS
Neurologic deficits

PATIENT CARE
Monitoring hydration status, acid-base and electrolyte balance.

PREVENTION
• Isotonic saline (0.9%) is unsuitable for correcting hypernatremia. • Salt intake should be gradually increased to salt-deprived animals. • Do not give salt supplementation when cattle are dehydrated or have been starved. • Unlimited access to water can minimize adverse effects of high salt intake.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Renal diseases and diarrhea

PREGNANCY

SODIUM DISORDERS: HYPONATREMIA

BASICS

OVERVIEW
Definition: A serum sodium concentration ($[Na^+]$) less than the lower limit of normal ruminants, usually <132 mmol/L.

INCIDENCE/PREVALENCE
Unknown.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Cardiovascular • Nervous

PATHOPHYSIOLOGY
• Hyponatremia—excess of total body water relative to extracellular sodium. • Sodium is the major extracellular fluid (ECF) cation. Plays a vital role in maintaining the cell membrane potential, ECF volume, and osmolality. • Sodium affects water shifts between the ICF and ECF. • Source of sodium is primary dietary intake. • Renal is the primary route of excretion (~99% reabsorbed in renal tubules). • Effects of hyponatremia include cerebral edema. Noncardiogenic pulmonary edema can occur, resulting in hypoxemia that can worsen the severity of brain edema.

SIGNALMENT
All ruminant species

PHYSICAL EXAMINATION FINDINGS
• Disorientation, weakness, depression, ataxia, blindness, seizures. • If hyperkalemia is present, it increases the risk of cardiac dysrhythmias (i.e., uroabdomen).

CAUSES AND RISK FACTORS
Hypovolemic Hyponatremia
Decreased total body water and serum $[Na^+]$, but $[Na^+]$ are proportionally lower than body water.
• Diarrhea, third spacing sequestration (i.e., pleuritis, peritonitis, ascites, uroabdomen), intestinal torsion. • Renal disease and/or renal losses (i.e., diuretics including thiazide, furosemide). • Adrenal insufficiency.
• Postobstructive diuresis.

Euvolemic or Dilutional Hyponatremia
Total body water volume does not change but serum $[Na^+]$ decreases.
• Syndrome of inappropriate antidiuretic hormone (SIADH). • Psychogenic polydipsia.
• Iatrogenic—glucose or mannitol administration. • Oral administration of hypotonic fluids. • Diabetes insipidus, if it is compensated with water intake.

Hypervolemic Hyponatremia
Total body water increases but serum $[Na^+]$ does not change.
• The hallmark of these conditions is the presence of edema or ascites. • Heart, liver or renal failure. • Severe hypokalemia in which sodium will shift intracellularly.

Pseudohyponatremia
• Hyperlipidemia or hyperglobulinemia.
• Mannitol can cause pseudohyponatremia.

Risk Factors
• Diarrhea • Administration of diuretics
• Inappropriate fluid therapy • Heart, liver or renal failure

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Severe hypoglycemia • Metabolic acidosis
• Meningitis • Polioencephalomalacia

CBC/BIOCHEMISTRY/URINALYSIS
• Hyponatremia. Serum $[Na^+]$ <120 mmol/L is considered severe hyponatremia. • Other electrolyte imbalances depend on the underlying causes.

OTHER LABORATORY TEST
• Fractional excretion of Na^+ [FE_{Na}]: suspect renal losses if [FE_{Na}] >1%. • Plasma osmolality is low in hyponatremia.

OTHER DIAGNOSTIC PROCEDURES
• History and physical examination to determine the causes of hyponatremia.
• Evaluation of volume status, and analysis of serum and urine sodium levels and osmolality.

PATHOLOGIC FINDINGS
Central pontine myelinolysis can occur after rapid treatment of chronic hypernatremia.

TREATMENT

THERAPEUTIC APPROACH
• Addressing the underlying cause (i.e., diarrhea, pleuritis, uroabdomen, correcting feeding preparation). • Consider if the animal has signs or symptoms of cerebral edema, time frame for the development of the hyponatremia. • Consider whether the animal has risk factors for developing neurologic complications from hyponatremia or its treatment. • Hyponatremia that has developed <48 hours. Correct rapidly by increasing serum $[Na^+]$ to 125 mmol/L over 6 hours. • The amount of $[Na^+]$ needed to increase serum $[Na^+]$ to 125 mmol/L can be calculated with the following formula: 125 – measured $[Na^+]$ (mmol/L) × 0.6 × body weight (kg). Hypertonic saline 3% is the solution recommended for correction of hyponatremia. • Furosemide can be given to increase excretion of dilute urine. • The serum $[Na^+]$ should be checked q2h and the rate of the infusion adjusted accordingly.
• Hyponatremia that has developed >48 hours. Correct gradually. Increase serum $[Na^+]$ to 125 mmol/L. Correct no more than 8–10 mmol/L/24h initially.

MEDICATIONS

DRUGS OF CHOICE
Recommended fluid is 3% saline solution with loop diuretic (e.g., furosemide).

PRECAUTIONS
Central pontine myelinolysis can occur after rapid treatment of chronic hypernatremia or may be directly caused by hyponatremia. It has been described in dogs and humans but not in ruminants.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Clinical course and prognosis vary and are associated with the underlying disease condition.

POSSIBLE COMPLICATIONS
Neurologic deficits can occur.

PATIENT CARE
Close monitoring of electrolytes and neurologic status during correction of hyponatremia.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Diarrhea • Heart, liver, or renal failure

PREGNANCY

SOLE LESIONS IN DAIRY CATTLE

BASICS

OVERVIEW

• Lameness is common in dairy cows, with most lesions affecting the sole.
• The most significant lesions of the sole are white line disease and sole ulcers.
• An initial insult to the corium primarily affects the laminar region, and that corium damage increases, with the resulting alteration in the physical forces on the sole.
• The risk of sole lesions is related to stage of lactation, individual cow factors, and farm characteristics.
• Ninety percent or more of lameness in dairy cattle involves the foot. Of that involving the foot, most involves rear feet, particularly the lateral claw.
• Cows most at risk for sole lesions are those with low body condition scores.
• Farms most at risk are those with high stall curbs, long standing times during milking, automatic alley scrapers, and abrasive flooring surfaces or flooring imperfections (e.g., holes in concrete). In pasture based systems, long walking distance to the parlor and rough lane surfaces increase risk.

INCIDENCE/PREVALENCE

• Incidence is influenced by a variety of farm-level factors and varies widely between operations.
• Surveys have suggested that the incidence may be as high as 55 cases per 100 cows per year.
• Another survey estimated an incidence rate of 30 cases per 100 cows per year, a fatality rate of 2%, an increase in days open of 28 days, and costs for treatment and additional labor of $23 per case, estimating an annual cost of $9000 per 100 cows.

GEOGRAPHIC DISTRIBUTION

Worldwide depending on the environment

SYSTEMS AFFECTED

Musculoskeletal

PATHOPHYSIOLOGY

See "Causes and Risk Factors"

HISTORICAL FINDINGS

• Cows with white line disease typically present with severe acute lameness.
• Cows with sole ulcers typically suffer from a low-grade lameness that often progresses to a more severe lameness over time.

SIGNALMENT

Sole ulcers are seen almost exclusively in housed, lactating dairy cattle.

PHYSICAL EXAMINATION FINDINGS

• The site of the lesion can generally be determined by using hoof testers around the periphery of the abaxial wall. Using a hoof knife, the sole should be cleaned and a thin layer of horn removed. The key indicator of a problem is a dark necrotic area within the white line at the site identified with the hoof testers. This is most likely the site at which the lesion is forming.
• Lesions are most commonly seen in the lateral hind claw at the heel-sole junction. The sole of the claw may appear normal on initial examination; however, using hoof testers, an area of pain is typically identified approximately two-thirds of the way back from the toe and toward the axial wall.
• As the sole is trimmed with a knife, it is common to find evidence of an old hemorrhage within the horn of the sole at this site. Eventually, a portion of horn will be removed to reveal a full-thickness defect of the sole with granulation tissue protruding from the underlying corium.
• In complicated cases, a cellulitis develops and spreads to involve articular and soft tissue structures.

GENETICS

N/A

CAUSES AND RISK FACTORS

• The flexible junction between the sole and wall horn, colloquially known as the "white line," is the weakest portion of the sole. Even in a normal animal, it is common to see a small amount of debris impacted into this area.
• Dairy cattle are prone to a subclinical laminitis-like syndrome as a result of being fed diets rich in highly fermentable carbohydrate and low in long-stem fiber. Laminitis is known to make the white line weaker and predispose to white line disease.
• The horn of the white line is formed by the laminar corium which is also the suspensory apparatus of the third phalanx (P3). Conditions such as laminitis which interfere with the vascular supply to the corium are likely to reduce the quality of white line horn produced by the laminar corium, which is believed to increase the potential for white line separation. Areas of hemorrhage may also be visible within the horn in the region of the white line. One thought is that prolonged standing, particularly during the transition period around calving when the suspensory apparatus is weaker and more susceptible to mechanical stresses, may result in inflammation of the suspensory tissues during the time at which it is forming horn of the white line. It is speculated that inflammation of these tissues while they are concurrently forming the horn of the white line would result in hemorrhage and weaker white line horn when it reaches the weight-bearing surface. A weakened white line is more likely to be softer and defective thereby predisposing to the impaction of organic matter within the white line. Should contaminated debris breach the white line and reach the corium, an abscess will form. Such abscesses cause extreme pain as they enlarge due to the great pressures developed between the base of P3 and the hoof capsule, neither of which are flexible.
• Abscesses in both cattle and horses will enlarge and migrate beneath the wall of the hoof and burst out at the coronary band, or they may track caudally below the sole and burst out in the region of the heel.
• The same subclinical laminitis syndrome described above can result in a weakening of the attachments between the laminae of the wall and sinking of P3 within the hoof capsule. This results in the ventral surface of P3 compressing the corium of the sole against the horn of the sole. This compression appears to be most marked in the region of the deep flexor process of P3.
• In addition to changes within the hoof, there are important changes seen in the morphology of the dairy cow's hoof. In the hindlimb, the lateral claw is under asymmetric stress when compared to the medial claw. This overloading of the lateral claw tends to result in hypertrophy of the sole horn, which further overloads the claw.
• In most dairy cows, overgrowth of the claw is characterized by a disproportionate overgrowth of the toe. This, combined with the commonly seen erosion of the heel horn, results in weight bearing by the claw being transferred from the toe back toward the heel region.
• When all these factors are combined, it is apparent that the heel region of the lateral hind claw is under a great deal of stress. As P3 sinks within the hoof capsule, the corium is compressed between the flexor process and the sole. This initially results in a contusion of the corium exhibited as a hemorrhage in the heel-sole junction. The blood is incorporated into the horn and may be seen in the sole as bruising. As the condition progresses, the corium undergoes pressure necrosis and horn formation in the area is halted. This results in a defect in the sole that grows from the inside to the external environment. When the defect is full thickness, a sole ulcer has formed, exposing the underlying corium.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Digital dermatitis
• Lacerations
• Thin soles
• Foreign bodies
• Fractures
• Foot rot—easily distinguished on examination of the foot
• Abscesses secondary to penetrating wound

SOLE LESIONS IN DAIRY CATTLE (CONTINUED)

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Radiology of the distal limb may be of benefit in cases where there is concern that infection may have spread to either the navicular bursa, distal and/or proximal interphalangeal joints, and the flexor tendon sheaths.

OTHER DIAGNOSTIC PROCEDURES
• Lesions are diagnosed on the basis of the characteristic clinical signs. All that is necessary is close examination of the foot.
• In cases where the infection has spread to the deeper tissues of the foot, it is common to identify that the foot is grossly swollen. The swelling seen in such cases may be distinguished from simple foot rot on the basis that the swelling is asymmetric and centered on one claw.
• The swelling is typically found in either the heel region or around the cranio-lateral aspect of the coronary band.

PATHOLOGIC FINDINGS
See "Causes and Risk Factors"

TREATMENT

THERAPEUTIC APPROACH
• White line abscesses require drainage to provide pain relief and promote healing of the lesion. Having identified the suspected site of the abscess, a hoof knife should be used to resect the wall horn and to follow the lesion to the corium and drain the abscess. Once the abscess is open, the extent of the abscess should be determined using a blunt probe. The entire defect should be opened and all underrun horn removed.
• Care should be taken to avoid leaving any jagged or underrun edges, which would allow foreign material to impact in the lesion.
• When dealing with a sole ulcer, it is important to first trim the foot to normalize weight bearing between the medial and lateral claws as well as adjusting the plane of the sole to prevent excessive weight bearing in the heel region. Next, all undermined sole should be removed from around the ulcer, taking care to not traumatize the corium. The heel of that claw should be lowered (cut deeper than the opposite heel) to prevent any weight bearing in the region of the flexor process. Finally, a wooden or composite block should be placed on the opposite claw to transfer weight bearing away from the affected claw.
• The area of the sole ulcer should be trimmed with great care to remove any underrun horn tissue.
• Bandaging the lesion left by an abscess or sole ulcer is of no value as the dressing simply becomes contaminated with fecal material. The lesions should be left open to heal.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• In chronic cases with severe soft tissue involvement, surgical intervention may be necessary (e.g., lateral wall resection, claw amputation, tenotomy, etc.).
• A number of surgical procedures have been described to salvage the claw, but due to the expense involved, many clinicians opt to amputate the affected digit.

MEDICATIONS

DRUGS OF CHOICE
• Antibiotics are not indicated in the treatment of simple uncomplicated white line disease abscesses or sole ulcers. They are indicated only when infection has spread to the deeper structures of the foot.
• Some clinicians may elect to use NSAIDs to provide analgesia in severe cases.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

CONTRAINDICATIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Simple uncomplicated white line disease abscesses and sole ulcers typically resolve in 4–6 weeks. On occasion, severe lesions may require additional time.
• The prognosis for infections that involve the deep structures of the hoof is always guarded. Since many of these cases typically present late in the disease course, the infection is well established and there is already significant pathology.
• Aggressive antibiotic therapy is warranted when deep structures of the hoof are involved, but success is limited. Surgery is generally required. Euthanasia may be the only option in some cases where it is not possible to control suffering and the animal is not showing improvement.
• Studies have shown that the life expectancy for a dairy cow following amputation of a digit is <1 year.

POSSIBLE COMPLICATIONS
Spread of infection to soft tissue structures of the distal limb

CLIENT EDUCATION
Prompt attention to lame cattle is not only warranted for welfare purposes but will greatly improve outcomes and minimize losses.

PATIENT CARE
• The majority of animals will show immediate relief after trimming of the lesion and application of an orthopedic block. If the animal fails to have significant improvement after placement of the block, or the lameness is noted to be more severe following treatment, the animal should be reevaluated for another cause of lameness or possible incorrect block placement.
• Animals that remain lame after 3–4 days should be reexamined.
• Orthopedic blocks should always be removed or rechecked within 30 days of application to determine the need for block replacement or permanent removal. Block wear varies according to the distance cows walk and the type of flooring surface. At this time, it is also appropriate to perform a minor hoof trim to encourage complete resolution of the lesion.

PREVENTION
• Attention should be paid to the dairy cow ration to ensure that it always contains sufficient long-stem fiber to prevent ruminal acidosis.
• Since peripartum hormonal changes and metalloproteinase activity are more likely during the transition period (from 2–3 weeks pre-calving to 4 weeks post-calving) it is important to assure the maximum in cow comfort (i.e., no overcrowding, maintain stocking rates at no more than 80%, maximize stall comfort with properly designed and well-maintained stalls, etc.).
• Dairy cows should have their feet trimmed on a regular basis to prevent overloading of the lateral hind claw.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Lameness, decreased milk production, loss of profit

AGE-RELATED FACTORS
Sole ulcer lesions are most common in mid to late lactation multiparous cattle.

PRODUCTION MANAGEMENT
• Body condition scoring should be performed routinely to target high-risk low body condition animals.
• Evaluating barn layout and the cows' time allocation to minimize high steps or stall curbs, long standing times during milking and

abrasive flooring or flooring imperfections (e.g., holes in concrete). Automatic alley scrapers are also a risk that must be managed.
• Attention should be paid to the design of the dairy barn to ensure that cows can always lie down in comfort. Cows at pasture typically lie down for two-thirds of the day. When the animal is recumbent, the feet do not bear weight and therefore the diseases cannot develop.
• In pasture-based herds, cows will ideally walk minimal distances to the parlor during higher risk periods (i.e., very hot or wet conditions) and the need for lane way resurfacing should be assessed annually.

ABBREVIATION

• NSAIDs = nonsteroidal anti-inflammatory drugs

SQUAMOUS CELL CARCINOMA

BASICS

OVERVIEW

Squamous cell carcinoma (SCC) is a malignant tumor of epidermal cells. In cattle, ocular squamous cell carcinoma (OSCC) is the most common ocular tumor. It can also affect the skin, gastrointestinal tract, and genitourinary tract of ruminants.

INCIDENCE/PREVALENCE

When recording incidence, typically preneoplastic and early neoplastic lesions (plaques, papillomas, and carcinoma in situ) are included in the affected group.

Cattle

• The incidence of OSCC varies between countries. In the United States, estimates of the incidence ranged from 0.8% to 5%, whereas in Australia it is been reported to be as high as 10–20% and in the Netherlands as low as 0.04%. This is consistent with reports that in regions with abundant sunlight the prevalence can be as high as 40%. OSCC is more common in older cattle with a peak around 7–8 years.
• Bladder SCC is very rare except in endemic areas, where the incidence of bladder neoplasia may range from 15% to 25%. Cows with bladder SCC may have more than one type of tumor in their bladder.

Small Ruminants

Most commonly SCC is diagnosed in Merino sheep and older animals (>4 years old) with a reported peak incidence of up to 12% in older animals. Areas that are affected more frequently are the face, ears, and vulva. In goats the perineum appears to be most commonly affected due to their high and short tail which exposes the area to UV light.

Camelids

Overall the second most common malignant tumor in camelids, with half of SCC originating in the skin and the remainder occurring in the GI tract. SCC is the most commonly reported primary neoplasm affecting the GI tract in camelids, usually the first gastric compartment (C1), with potential metastasis seen throughout the abdominal and pleural cavities. In the skin, all regions can be affected with the face, prepuce and perineum most commonly involved.

GEOGRAPHIC DISTRIBUTION

Generally the development of SCC/OSCC is associated with an increase in altitude and mean annual hours of sunlight and with decreases in latitude.

OSCC

• Most OSCC in the United States occurs in the South and Southwest.
• Australia and some regions in Africa also experience a significant number of cattle afflicted with OSCC.

SCC

• SCC of the upper intestinal tract and bladder are most common in regions where bracken fern, containing the cofactor for tumor development, exists along with the presence of infection with bovine papilloma virus 4 (BPV-4). This combination of factors resulting in SCC of the upper intestinal tract was initially reported in Scotland, but additional reports from Europe, Africa, and South America have been published.
• In Australia SCC of the muzzle, ears, and perineal region is a significant problem in sheep.
• In South Africa, lesions on the udder and teats of Saanen and Angora goats have been found.

SYSTEMS AFFECTED

• Integument
• Digestive
• Urinary
• Ophthalmic

PATHOPHYSIOLOGY

The pathogenesis of squamous cell carcinoma is multifactorial and includes extrinsic and intrinsic factors. Factors that have been suggested to play a role in the development of SCC in ruminants include:
• Exposure to solar radiation (ultraviolet light, UV).
• Papillomavirus infection causing precursor lesions that then undergo neoplastic transformation.
• Exposure to carcinogens in bracken fern (*Pteridium aquilinum*) can result in malignant transformation of papillomas of the upper gastrointestinal tract and bladder. In addition, induced immunosuppression can prevent rejection of early neoplastic lesions.
The tumors develop in all species through a series of premalignant stages which progress over time to squamous cell carcinoma. At the same time neoplastic lesions can arise without noticeable precursor stages, and spontaneous regression has been described.

OSCC

Ocular squamous cell carcinomas (OSCC) arise from the epithelial surface of the conjunctiva or cornea. For OSCC the combination of lack of pigmentation in the periocular tissues in the corneoscleral region and exposure to high levels of UV light are linked to an increased prevalence. In addition, it has been found that up to 63.4% of cases with OSCC show an abnormal expression of p53, a tumor suppressor gene that is associated in humans and horses with OSCC development. Abnormal expression is thought to be associated with UV light exposure.

HISTORICAL FINDINGS

Depends on type of SCC. See "Physical Examination Findings" for more details.

SIGNALMENT

• SCC/OSCC of all types is seen primarily in cattle, but has been reported in sheep and less commonly in goats.
• It has also been described as one of the most common tumors in camelids with more reports in llamas than in alpacas.
• In the US, Hereford and Hereford-cross cattle are most likely to be affected with OSCC.
• Other breeds in which OSCC is reported include Simmental, Holstein Friesians, and rarely in other breeds.
• The mean age of cattle with OSCC is 7–8 years, with a decreasing mean age in areas of highest UV light exposure.
• SCC of the upper intestinal tract and bladder is typically found in cattle between 6 and 12 years of age.
• In sheep SCC is most commonly seen in animals >4 years of age.
• The age range in which SCC is seen in camelids is 5–10 years or older, with most camelids that develop SCC of the first gastric compartment >10 years.
• Predominant sex: Although most afflicted cattle are female, that simply reflects the fact that most herds are made up primarily of cows, and bulls are kept in fewer numbers. The same is true of ewes and rams.

PHYSICAL EXAMINATION FINDINGS

OSCC

• Signs depend on the anatomic location, tissues involved, as well as stage of malignancy.
• Precancerous lesions are usually either papilloma-like structures or small, white, elevated, hyperplastic plaques.
• Malignant tumors are more irregular, pink, erosive, and often show signs of necrosis.
• In cattle the most common site is the lateral limbus, followed by the eyelids, nictitating membrane, and medial canthus.
• Invasive OSCC of the palpebrae and medial canthus metastasize more commonly than do OSCC arising from the globe; in advanced stages local invasion of bony structures may be observed.
• Mild to moderate purulent ocular discharge can be present as well as secondary conjunctivitis.

SCC

• Signs depend highly on the location and extent of the lesion.
• SCC of the upper intestinal tract can result in bloat, regurgitation of ruminal contents, loss of condition, painful abdomen, and difficulty swallowing.
• Cutaneous SCC: Horny outgrowths of skin or scales that are painful on manipulation, occurring on unpigmented or lightly pigmented skin in the sacral region, dorsum, and escutcheon as well as mucocutaneus junctions (e.g., vulva).
• SCC of the bladder is typically associated with hematuria.

(CONTINUED) SQUAMOUS CELL CARCINOMA

• Clinical signs associated with distant metastasis are rarely seen.

Camelids

• SCC lesions of the skin (face, prepuce, and perineum): Usually proliferative with some degree of surface ulceration; chains or clumps of nodules may be seen.
• SCC of the GI tract (first gastric compartment, C1): Gradual weight loss with progressive anemia, signs of colic, hypoproteinemia, lethargy and anorexia, abdominal distention or respiratory difficulties due to ascites or pleural effusion, occasionally melena and/or diarrhea.

GENETICS

The high incidence of OSCC seen in Hereford and Hereford-cross cattle was once believed to be associated with a heritable component. Since then, studies have shown that a strong genetic trait for a white face, as well as their use as range animals, predisposes these breeds to the development of OSCC. Selective breeding for more pigmentation around the eyes greatly reduces tumor occurrence.

CAUSES AND RISK FACTORS

Ophthalmic and skin:
• Exposure to ultraviolet light
• Lack of pigmentation
• Infection with bovine papillomavirus
• Correlations with high plane of nutrition
Upper gastrointestinal tract and bladder:
• Infection with BPV-4 and/or BPV-2
• Ingestion of bracken fern or other carcinogenic and immunomodulatory compounds
• Trauma

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Papillomas
• Keratoancanthomas
• Carcinoma in situ
• Dermoid cyst
• Fibroma, fibrosarcoma
• Granulation tissue
• Conjunctival follicular hyperplasia

CBC/BIOCHEMISTRY/URINALYSIS

• OSCC and SCC of the upper intestinal tract—results are usually normal.
• SCC of the bladder—anemia, hematuria.

OTHER LABORATORY TESTS

N/A

IMAGING

Radiology:
• Skull radiographs might be indicated if local invasion of bony structures around the orbit can not be ruled out otherwise.
• Thoracic or abdominal radiographs may be used to identify potential metastasis to determine prognosis prior to possible surgical intervention.
Ultrasound:
• Abdominal ultrasound may be helpful to identify additional lesions (metastasis) and for the diagnosis of bladder tumors.
• May also help to determine the extent of locally invasive masses and involvement of underlying structures.

OTHER DIAGNOSTIC PROCEDURES

• Cytologic evaluation of samples obtained by aspiration or scraping followed by Giemsa or Wright's staining may reveal abnormal epithelial cells suggestive of SCC/OSCC.
• A biopsy specimen for histopathology of a suspicious lesion can be used to establish a diagnosis and in 85–90% of cases agrees with the diagnosis made by cytologic examination.
• A biopsy or an aspirate of a local lymph node may help determine presence of metastatic disease (occurrence of metastasis is approximately 10%).

PATHOLOGIC FINDINGS

OSCC

• Invasion into local tissues, including bone and along the optic nerve, may be seen.
• Metastasis to the ipsilateral parotid and lateral retropharyngeal lymph nodes may be seen and on rare occasions they may extent into the thoracic or abdominal organs with approximately 5% of cattle with OSCC having lung metastasis at slaughter.

SCC of the Skin, Upper Gastrointestinal Tract, and Bladder

• Individuals affected with upper GI SCC may have multiple lesions in the oral cavity and throughout the upper and lower GI tract.
• Camelids—usually the first gastric compartment (C1) is involved with potential metastasis throughout the abdominal and pleural cavities. Ascites or pleural effusion can also be present.
• Small ruminants—SCC of the skin can be accompanied by cutaneous papillomas of the udder and teats.
• Findings on histopathology include epidermal hyperplasia, hyperkeratosis, parakeratosis, acanthosis, accentuation of the epidermal rete, and keratinocyte dysplasia.
• Extending into the dermis are cords and islands of neoplastic cells demonstrating a variable degree of epithelial differentiation, sometimes including "keratin pearls."

TREATMENT

THERAPEUTIC APPROACH

• There are currently no treatment options for tumors located in the gastrointestinal tract and bladder.
• OSCC
  ◦ Early detection of OSCC is important in order for treatment to be effective. Up to 75% of small lesions (<5 mm in diameter) will regress spontaneously.
  ◦ Multiple treatment modalities can be used successfully on early lesions.
• Surgical excision
  ◦ *En bloc* resection is best performed for smaller lesions (10–20 mm) for which adequate margins can be obtained. This method is also indicated for lesions of the third eyelid. Nerve blocks are used to facilitate anesthesia of the area (e.g., auriculopalpebral nerve block, retrobulbar or Peterson nerve block) with or without additional infiltration of local anesthetic (e.g., lidocaine 2%).
  ◦ Third eyelid removal—The third eyelid is grasped and clamped off using two long tissue forceps in a triangular pattern. The entire third eyelid is then removed using a scalpel blade or scissors and the forceps are left in place for a few minutes to facilitate hemostasis. It is important to ensure that the complete cartilage is removed since a remaining stump can cause chronic irritation and potentially incite further OSCC development. The wound edges can be sutured using a simple interrupted or continuous pattern, or left to heal by second intention.
• Cryosurgery: Can be used alone or in combination with surgical excision. Utilizing two freeze/thaw cycles (freezing to −30°C, a quick freeze and slow thaw cycle appears to result in maximum cryodestruction) has been reported to result in a 97% complete regression rate. The animal again is restrained and local anesthesia is facilitated by nerve blocks and/or local infiltration of local anesthetic (lidocaine 2%). The tissue peripheral to the lesion is protected against freezing by using petroleum jelly. A Styrofoam wedge can be applied to protect the cornea. Frozen tissue sloughs off over the next 7–14 days and is gradually replaced by granulation tissue. A study with more complete follow-up data demonstrated that approximately 71% of lesions treated with cryosurgery had complete regression without recurrence up to 3.5 years.
• Radiofrequency hyperthermia: Raising the temperature in the tumor to 50°C for 30 sec/cm^2 of tumor surface has resulted in complete regression in 90.8% of tumors treated after one or multiple applications. This regression lasted at least for 5.5 months in all animals, and for a year in the cattle available for monitoring at that time in one study. This technique can be used in smaller lesions and after initial debulking. Hyperthermia penetrates 5–10 mm of tissue. Multiple applications may be necessary for larger lesions.
• Radiation therapy: Administered with implants of gamma-emitters such as cobalt-60, gold-198, or cesium-137, this technique has been quite effective at

SQUAMOUS CELL CARCINOMA (CONTINUED)

controlling OSCC; however, these methods are quite costly and are not widely available.
• Immunotherapy: This includes methods to enhance the individual's immune system to induce tumor regression. Different approaches to immunotherapy have been made (e.g., autogenous vaccines made from tumor tissue, infection with Bacillus Calmette Guerin (BCG), and systemic and peri- and intralesional injections of interleukin-2 (IL-2)) with moderate success. Injections of IL-2 for 10 consecutive days resulted in 50–69% regression rates depending on the concentration used and the location of the tumor, with tumors on the third eyelid and limbus being the most responsive.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• See "Therapeutic Approach" for details.
• Surgical removal of OSCC and precursor lesions is only moderately successful in controlling the disease, with recurrence rates of 37–48% reported.
• *En bloc* excision of the tumor (e.g., enucleation, exenteration) and regional lymph nodes can be performed to salvage valuable animals, but is not cost effective in most instances.

MEDICATIONS

DRUGS OF CHOICE

N/A

CONTRAINDICATIONS

The use of intralesional chemotherapeutics (e.g., cisplatin) is not permitted in food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Untreated, OSCC will invade normal tissues (potentially including the CNS) and ultimately metastasize to the regional lymph nodes and lungs. Extensive disease can result in carcass condemnation and thus financial loss.
• With surgical excision (enucleation or mass resection), local recurrence is common (37% in one report), but may allow salvage of the animal for slaughter depending on local regulations.
• Cryosurgery, with a two-freeze cycle, will result in a 77–97% complete response rate. Approximately 71% of responding tumors did not recur in one study following cryosurgery.

POSSIBLE COMPLICATIONS

• Premature loss of breeding cows.
• Carcass condemnation at slaughter due to metastasis or multiple SCC.

CLIENT EDUCATION

• Lesions may recur locally so treated animals should be examined periodically (every 3–4 months) for evidence of recurrence.
• Cryosurgery or hyperthermia can result in hair loss and regrowth of white hairs at the treated site.

PATIENT CARE

All cattle should be examined on a regular basis for OSCC, at least three times a year (including once in the summer months) during routine maintenance health treatments.

PREVENTION

• Breeding cattle for pigmentation in the periocular tissues as well as for pigmentation of the corneoscleral junction will decrease the incidence of OSCC.
• Routine evaluation of all eyes, with cryosurgery or surgical removal of lesions that are enlarging and >5 mm in diameter, greatly decreases the development of lesions that would result in financial loss to the herdsman (through carcass condemnation and premature loss of breeding stock).

MISCELLANEOUS

ASSOCIATED CONDITIONS

Infection with bovine papilloma viruses is thought to cause the initial precancerous lesion.

AGE-RELATED FACTORS

• OSCC are typically diagnosed in animals >4 years of age.
• In camelids, skin and GI lesions are most often diagnosed in older animals (>5 years).

PRODUCTION MANAGEMENT

Routine evaluation of all eyes in a herd allows early detection and treatment of lesions in the epithelium that may be early SCC or premalignant changes.

ABBREVIATIONS

• BPV = bovine papilloma virus
• CNS = central nervous system
• GI = gastrointestinal
• IL-2 = interleukin 2
• OSCC = ocular squamous cell carcinoma
• SCC = squamous cell carcinoma
• UV = ultraviolet

ST. JOHN'S WORT TOXICITY

BASICS

OVERVIEW

• St. John's wort is an erect perennial herb that stands 1–3 feet tall. Its leaves are opposite, dotted, with many yellow flowers.
• Hypericin is the active ingredient. It is a red florescent pigment found in a semisolid state in the black dots that are scattered over the surface of the leaves, stems, and petals and is present in the plants at all times.
• Hypericin is a naturally occurring naphthodianthrone derivative in the plant species *Hypericum perforatum*. The hypericin concentration in the plant may vary depending on the place of growth, state of plant material, and part of the plant—whole herb concentration 0.00095%–0.466% and flowers up to 0.086%.
• The hypericin concentration in a broadleaf biotype varies from a winter minimum of <100 ppm to a summer maximum approaching 3,000 ppm. In contrast, the narrow-leaf biotype increases from similar winter values to summer maxima approaching 5,000 ppm.
• Consumption causes primary photosensitization, which leads to increased sensitivity of the skin to subsequent light exposure.
• There appears to be an absolute requirement for exposure to bright sunlight before any effects of hypericum will develop.
• St. John's wort is found in dry soil, roadsides, and pasture ranges.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Potentially worldwide, depending on species and environment

SYSTEMS AFFECTED

• Cardiovascular
• Digestive
• Integument
• Urinary
• Multisystemic

PATHOPHYSIOLOGY

• The mechanism of action is unresolved.
• One study suggested that hypericin was an inhibitor of rat brain mitochondrial monoamine oxidase (MAO).
• Serotonin receptors may be involved in the pharmacologic action of hypericum extracts.
• Another study found that hypericum extract inhibits serotonin uptake by rat synaptosomes derived from rat embryo neurons. Other investigators reported that serotonin receptor expression in neuroblastoma cells was reduced by hypericum extracts.
• When animals ingest the plant, the hypericin is absorbed from the intestinal tract and goes into the circulation. Hypericin is a photodynamic agent able to cause cellular damage and sunburn.

SIGNALMENT

• Cattle, sheep most commonly affected. Goats are very resistant to toxicity.
• Potentially all ruminant species are affected.

PHYSICAL EXAMINATION FINDINGS

• Extreme hyperesthesia to touch and to contact with cold water.
• Restlessness and discomfort. Animals tend to rub their ears, eyelids, and muzzle.
• Photophobia and/or photosensitization. In sheep with heavy fleece, lesions occur on head and coronary band, but in shorn sheep lesions can occur on the back. Sheep can also have extensive head edema. Onset of lesions may just take hours and initially include erythema and edema followed by blisters, exudation, necrosis, and sloughing of necrotic tissue. In cattle, lesions occur on areas of the body that are nonpigmented and on the teats, udder, perineum, and nose.
• Hyperthermia when exposed to sunlight.
• Diarrhea and tachycardia.
• Seldom lethal. But can markedly affect production of meat, milk or wool and can cause the animal considerable distress.
• Exposure of the tongue to sunlight while licking can cause glossitis with ulceration and deep necrosis.
• Congested mucus membranes and hyperemia of exposed skin on tail and legs. Edema of eyelids and ears, exudation of serum from ears.
• Loss of eyelashes, corneal opacity, and blindness after 5–7 days with high levels of ingestion.
• Animals with pigmented skin and those that remain in subdued light suffer few effects.
• Hemolytic anemia.
• Kidney and liver dysfunction may occur with severe exposure.

CAUSES AND RISK FACTORS

• Hypericum is the toxic principle.
• Severity of effects increases with duration of exposure, but not with dose.
• A single dose of hypericum remains potentially effective for up to 4 days.
• Induces hepatic cytochrome P450 and approximately doubles its metabolic activity.
• Plasma concentration of concomitant medication using cytochrome P450 enzymes will be reduced.
• Rectal temperature rise in affected sheep is a reliable indicator of the early development of an adverse clinical effect.
• There appears to be an absolute requirement for exposure to bright sunlight before any effects of *H. perforatum* will develop.
• A single dose of *H. perforatum* remains potentially effective for up to 4 days.
• In a small group of Merino sheep tested, a tolerance level for *H. perforatum*, eaten at the flowering stage, of <1% (plant wet weight) of body weight and a tolerance level for hypericin of <2.65 mg per kg live weight were demonstrated.
• Sheep develop restlessness, photophobia, tachycardia, tachypnea, congested mucus membranes, diarrhea, and hyperthermia. Skin lesions include redness of the tail, eyelid edema, and auricular edema. One week later, salivation, perioral and periauricular alopecia, keratoconjunctivitis, corneal opacity, and blindness may be evident.
• Another study found the minimal dose of dried whole hypericum to cause symptoms to be 3 g/kg in calves weighing 100–120 kg. Calves that receive this dose and were exposed to sunlight developed pyrexia and tachypnea 3–4 hours later. The animals became restless, passed soft feces, and developed perinasal and perioral erythema. Calves receiving the same dose but not exposed to sunlight only developed soft feces. Calves receiving 5 g/kg developed similar but more severe symptoms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Hepatogenous photosensitivity as a result of phylloerythrin accumulating in the blood. Phylloerythrins are formed from the anaerobic breakdown of chlorophyll by microorganisms in the forestomach of ruminants.
• Endogenous photosensitizing agent from aberrant metabolism of hemoglobin.
• Antibiotic-associated photosensitization (sulfonamides and tetracyclines).
• Phenothiazine-induced photosensitization (phenothiazine sulfoxide is the metabolite).
• Plants that can cause sunburn either by contact or ingestion—vetches, various clovers, and buckwheat (*Fagopyrum* spp.)—have caused sunburn and skin scald in animals.

CBC/BIOCHEMISTRY/URINALYSIS

• Elevated serum BUN, Na, K, and bilirubin (total and direct) concentrations.
• Lower than normal serum in Hb, RBC count, PCV, TP, glucose, cholesterol, triglycerides, and serum alkaline phosphatase concentrations.
• Serum sorbitol dehydrogenase, GGT, concentrations within normal limits.
• Transaminases, CPK, sodium, and potassium increase and the BUN may increase up to ninefold. Glucose and hemoglobin decrease, while WBC level does not change.

PATHOLOGIC FINDINGS

• Skin changes typically are limited to the lesser pigmented areas or to the head in sheep. Depending upon the amount of plant material eaten, the changes range from minimal reddening and blister-like effects to extensive areas of sloughing.
• In more severe cases, the skin will be thickened with a gelatinous appearance extending down into the deeper corium.

ST. JOHN'S WORT TOXICITY (CONTINUED)

Crusty and ulcerative or proliferative areas may be present, especially around the face.
• Microscopically, the edema of the skin will be accompanied by necrosis and a polymorphonuclear infiltrate in the deeper corium.

TREATMENT

THERAPEUTIC APPROACH

• Remove animal from source.
• Affected animals should be given full shade or preferably housed and allowed out to graze only during darkness.
• Corticosteroids given parenterally in the early stages may be useful.
• Secondary skin infections and suppuration should be treated with a topical broad-spectrum antibiotic.
• Flystrike should be prevented.
• Emergency evacuation of the gastrointestinal tract is not required since the toxin takes several days to build up in the body and cause signs.

MEDICATIONS

DRUGS OF CHOICE

• 1.1 mg/kg/day prednisone or prednisolone PO for 10 days.
• Depending on the severity of the lesions, antibiotics and anti-inflammatory medications may be indicated.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Condition seldom causes death and soon clears once the plant source is removed.
• The prognosis and the eventual productivity of the animal are related to the site and severity of the primary lesion and to the degree of resolution.

PREVENTION

• Weed management—mowing and hand removal.
• Animals will avoid St. John's wort if more palatable forage is available.

MISCELLANEOUS

PREGNANCY

Can cause decreased litter size and reduced body size at birth

PRODUCTION MANAGEMENT

If the pasture contains large stands of St. John's wort, removal is indicated. Mow, spray, and/or reseed to improve the pasture quality.

SYNONYM

Klamath weed

STARVATION

BASICS

OVERVIEW
Starvation is defined as the insufficient intake of energy and nutrients, or the inability to obtain food for an extended period of time.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
N/A

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• Many physiologic changes occur as an animal attempts to satisfy its energy requirements in a starvation situation. At the cellular level, catabolism continues to supply the substrates required for anabolism and vital functions. Reserve stores of nutrients are utilized to compensate for the lack of nutritional intake.
• The most readily usable material, glycogen, is utilized first primarily from liver stores and is exhausted in a few hours. Next, stored fat from various subcutaneous deposits (near the kidney, mesentery, and omentum) is utilized. Following this use, fat deposits in the parenchymal organs are utilized, followed by fat deposits in the bone marrow. The final source of energy available to the animal is cell cytoplasm, which is primarily protein. Prolonged catabolism of muscle cells results in muscle atrophy.
• Ketosis is commonly seen.
• Nitrogen excretion rises due to the protein catabolism. The animal eventually reaches a point where it dies because of insufficient blood glucose necessary for brain function and the occurrence of hypoglycemic shock.
• Inadequate food intake, especially in ruminants, results in a rapid decrease in the number of bacteria and protozoa and in the level of volatile fatty acids present in the rumen.
• Nearly 70% of the energy available to ruminants is from fatty acids, thus further impacting on energy availability.
• Decreased microbial populations also diminish the animal's ability to digest fiber.
• Prolonged food deprivation is known to cause a fall in the core body temperature.
• If the animal is subjected to low environmental temperatures with inadequate shelter and/or nutrition then thermoregulation is lost and death by cardiac arrest occurs. This may occur before the loss of significant muscle mass.
• Muscle weakness accompanied by low muscle mass results in prolonged recumbency. This results in lowering of the core body temperature, inability to get up, and eventually asystole, cardiac arrest, and death.

HISTORICAL FINDINGS
• Food unavailability or shortage, wild animals seen by humans more frequently, significant loss in animal body weight.
• Ongoing drought or persistent cold environmental temperatures.

SIGNALMENT
• Thin animals are most susceptible to starvation because of decreased energy stores and environmental tolerance.
• Young and old animals have the highest nutritional demands and the lowest positions in the social environment with respect to food access.
• Young growing animals and pregnant or lactating animals have much higher energy and protein requirements than do dry stock.

PHYSICAL EXAMINATION FINDINGS
• Lethargic, unsteady, listless, unafraid of humans.
• Dehydration, rough hair coat, thin body condition with loss of palpable or visible fat on the ribs or brisket, muscle atrophy, visibility of individual muscle groups especially in the hindquarters.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Inability to ingest, digest, absorb, or utilize food
• Injury, poor teeth, parasitism, chronic disease, foreign bodies, neoplasia
• Inadequate supply of or access to food (competition or overcrowding)
• Insufficient energy and nutrient intake
• Extreme parasitism
• Harsh environmental conditions (drought, deep snow)
• Increased energy demands (pregnancy, lactation, growth)
• Predator stress
• Lack of adequate shelter

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Malnutrition, parasitism, neoplasia

CBC/CHEMISTRY/URINALYSIS
• Anemia
• Hypoproteinemia, hypoglycemia, hypocalcemia, high anion gap; increased AST, SDH, GGT, and CK
• Proteinuria, ketonuria possible

OTHER LABORATORY TESTS
• Starvation is best diagnosed by gross examination or necropsy (see "Pathologic Findings").
• Femur or mandibular bone marrow fat analysis can be grossly examined in older animals. Some laboratories offer a femur marrow compression method, ether-extract method, kidney fat index, and wet weight-dry weight method.

PATHOLOGIC FINDINGS
• Changes are many and varied. The most striking is the lack of fat in the subcutaneous, visceral, and bone marrow locations.
• Muscle atrophy is generally significant. Serous atrophy of fat is common. The internal organs are generally smaller than normal.
• The digestive tract is generally void of any material and is often shrunken. The gallbladder is generally distended and bile staining may be present. Rumen ulcers may be present and rumen materials are scant and dry. Villous atrophy may be seen in the rumen. Abomasal or duodenal ulcers may be present.
• Femoral bone marrow will be red or yellow in color, transparent and gelatinous.

TREATMENT

THERAPEUTIC APPROACH
• Generally ruminants will not eat large quantities of food when sudden access to unlimited food occurs.
• If food is not provided until late stages of starvation, the animal will likely die. It may take up to 2 weeks for a ruminant to adjust to the new diet and change into a positive energy balance.
• Care must be given to provide a good-quality palatable feed containing readily available carbohydrates, roughage, minerals, and vitamins.
• Moderate quality hay or grass is the safest starting feed along with unlimited access to clean water.
• Treat pre-existing health conditions.
Deficiencies that must be corrected, in order of importance, are:
• Energy.
• Rumen-digestible protein (or alternative nitrogen and sulfur equivalent) required by rumen bacteria to produce energy and protein from low-quality feed.
• High-quality protein required for growth, pregnancy, and lactation.
• Minerals, particularly phosphorus, calcium, and magnesium.
• Vitamins associated with the lack of fresh green feed, particularly vitamins A, D, and E.

MEDICATIONS

DRUGS OF CHOICE
Directed at specific treatments of underlying disease conditions

PRECAUTIONS
N/A

STARVATION (CONTINUED)

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Will vary greatly depending on chronicity and underlying cause of starvation.

POSSIBLE COMPLICATIONS
The animal is prone to acidosis if a sudden shift of microbial population occurs and the only feed provided is high in carbohydrates, so avoid that practice.

CLIENT EDUCATION
Owners should be educated on appropriate animal husbandry and nutritional requirements.

PATIENT CARE
See "Therapeutic Approach"

PREVENTION
Appropriate animal care and husbandry

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Malnutrition.
- Metabolic diseases.
- Mineral deficiencies and imbalances.
- Hypocalcemia.
- Hypomagnesemia.
- Reduced fertility in males and females.
- Abortions, stillbirths, birth of underweight offspring, poor growth of neonates due to inadequate lactation in dams.
- Grain toxemia/acidosis:
  - Any factor that causes variation in intake (e.g., inclement weather, or palatability of feed) or changes in the availability of the carbohydrate (e.g., a change in grain type, or grain processing) may cause digestive upsets at any time, not just in the period of grain introduction.
- Urea poisoning if excessive amounts of protein supplements are fed during recovery.
- Urinary calculi due to mineral imbalances and dehydration.
- Plant poisoning- hungry animals may consume toxic plants, including shrubs and trees, which they would normally avoid.
- Blue-green algae toxicosis:
  - Blooms of blue-green algae are more likely to appear in warmer months during drought.

PREGNANCY
It is common for pregnant animals to abort their fetus during times of starvation. Stillbirths are also common. A fetus that survives will often be small and have an increased chance for mortality. Dams may not allow nursing or may abandon their young.

PRODUCTION MANAGEMENT
- Once pasture is inadequate, cattle should be confined and fed. Confined cattle need significantly less energy for maintenance than do those that are left in the paddock to wander in search of feed.
- Free choice hay, water, and minerals should be available after animals start to eat again.
- Animals should be separated into smaller feeding groups based on age, body condition, and body size.
- The pastures should be left in a condition where they can recover quickly when a drought breaks.
- Any change in feed (especially grain) should be introduced gradually—failure to do this is probably the major cause of illness seen in recovery from drought/starvation.

ABBREVIATIONS
- AST = aspartate aminotransferase
- CK = creatine phosphokinase
- GGT = gamma glutamyl transferase
- SDH = sorbitol dehydrogenase

STRONGYLOIDIASIS

BASICS

OVERVIEW

• Strongyloidiasis refers to infection of a variety of mammals, including ruminants, with specific species of *Strongyloides*, a free-living nematode. Other genera of free-living nematodes can also infect mammals, creating a variety of clinical signs depending on the route of infection and organs affected in the host.
• Three genera of the order Rhabditida (free-living soil nematodes) can parasitize ruminants, including *Rhabditis* (*Pelodera*) *strongyloides, Halicephalobus gingivalis* (also known as *Micronema deletrix* or *Halicephalobus deletrix*), and *Strongyloides.*
• *R. strongyloides* can create pruritic dermatitis in cattle by penetrating the skin of animals in contaminated environments.
• *H. gingivalis* is a rare and highly pathogenic parasite creating neurologic disease in humans and horses; it has been linked to meningoencephalomyelitis in a small group of dairy calves in Denmark.
• *S. papillosus* affects calves, lambs, and particularly goat kids, with infection occurring via skin penetration and transmammary transmission to nursing neonates. Clinical signs of infection include dermatitis, diarrhea, and coughing.

INCIDENCE/PREVALENCE

Unknown, but increased prevalence with permissive management factors such as confinement, crowding, and poor sanitation are likely.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Digestive
• Integument
• Nervous
• Respiratory
• Reproductive

PATHOPHYSIOLOGY

• The life cycle of *Strongyloides* is unique because it has alternate free-living and parasitic generations. The males of this species are not parasitic.
• The parasitic, parthenogenic female is embedded primarily in the mucosa of the proximal small intestine; eggs are laid into the mucosa, develop rapidly, and are embryonated when they are passed in the feces 1–3 weeks after infection.
• On pasture, eggs hatch and develop within 24–48 hours to infective third-stage (filariform) larvae, or alternatively, develop into free-living males or females that can mate to produce infective larvae.
• Grazing hosts ingest infective larvae, or infective larvae penetrate the host skin, typically between the claws of the foot.
• In older animals, larvae accumulate in the subcutaneous tissues and migrate to the mammary gland during impending lactation. Neonates are subsequently infected via ingestion of milk, and egg-laying females may be present in the intestine from about 1 week after birth.
• In young animals, infective larvae penetrate the skin and spread hematogenously to the lungs where they break into the alveoli, migrate up the airways, and/or are coughed up the trachea into the pharynx and swallowed, to develop into mature females 2–3 weeks after ingestion.
• *R. strongyloides* achieves infection by penetrating skin in contact with contaminated surfaces, ground or bedding, particularly the neck, flank, abdomen, and udder, resulting in irritation and inflammation of the skin.
• *H. gingivalis* is thought to penetrate skin and mucus membranes, and appears to display neurotropism in the host, but the life cycle, mode of infection, and risk factors associated with this parasite are poorly understood.

HISTORICAL FINDINGS

Relate to the presence of permissive management factors for *Strongyloides* infection, such as recent births of vulnerable neonates, overcrowding, and confined, poorly sanitized environments.

SIGNALMENT

• Young calves, particularly dairy stock.
• Neonatal and weaned goat kids and lambs.
• Adult ruminants carry a degree of immunity to intestinal infection with this parasite.

PHYSICAL EXAMINATION FINDINGS

• *R. strongyloides*: Dermatitis reflected by marked alopecia of the neck and flank with flaking, thickening and wrinkling of the skin, pruritus, and exudation of serum in severe cases. Pustules may be noted on the ventral abdomen and udder. Cattle in tropical environments can display otitis externa and chronic wasting.
• *H. gingivalis*: Granulomatous encephalomyelitis in calves results in impaired proprioception, central nervous signs, uveitis, and recumbency within the first few weeks of life.
• *Strongyloides* has been studied under natural and experimental conditions, and infection can result in a variety of clinical signs as follows:
  ◦ Natural infections can result in clinical signs related to the GI tract (intermittent diarrhea, blood and mucus in feces, anorexia and weight loss); respiratory tract (coughing and tachypnea); and integument of the interdigital space (lameness, stamping, biting at or rubbing feet and legs, increased susceptibility to foot rot) or of the body (pustular, erythematous dermatitis).
  ◦ In sheep and lambs, initial skin invasion by *S. papillosus* larvae may not induce any inflammation but subsequent exposures cause a pustular, erythematous dermatitis. Concurrent enteritis and pulmonary hemorrhage may occur in lambs.
  ◦ Adult animals seldom show clinical signs of a *Strongyloides* burden unless stressed, diseased, or exposed to heavy infestation, in which case bulls can show balanoposthitis, and sheep and goats may show unthriftiness, diarrhea, weight loss, and moderate anemia. Tiny white worms may be visible in feces of small ruminants. Reinfection can result in bouts of coughing.
  ◦ Experimental infection in kids, lambs and calves has created pallor, coughing, diarrhea, weight loss, neurologic signs and sudden death due to hepatic rupture in some kids, and cardiac arrest in lambs and calves.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Most common when animals are kept confined in a wet, dirty environment.
• Dams that are parasitized at the time of parturition are the major source of *Strongyloides* infection for neonates.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Contact dermatitis or irritation from dirty, wet bedding
• Infectious and noninfectious causes of diarrhea
• Foot rot
• Trombiculidiasis
• Cutaneous larval migrans
• Chorioptic mange
• Dermatophytosis

CBC/BIOCHEMISTRY/URINALYSIS

Anemia in heavily infested animals

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

• Fecal flotation identifies colorless, small, thin-shelled oval embryonated eggs (40–60 × 20–25 µm). The female is not fecund and therefore a dozen or more eggs in a sample can represent a large load of adults.
• Free-living adults frequently develop from cultures of feces from *Strongyloides* infected animals.
• Skin biopsy identifies pustular dermatitis characterized by edema, inflammatory infiltration (neutrophils, eosinophils, lymphocytes, and giant cells), and destruction of larvae.
• Necropsy: Adults (3–6 mm) may be evident in the small intestine or in scrapings of the intestinal mucosa. Minced tissue can be

STRONGYLOIDIASIS (CONTINUED)

placed in a Baermann isolation device to identify immature parasites.
• Serum ELISA may be useful.

PATHOLOGIC FINDINGS
• Catarrhal enteritis with petechiae and ecchymoses may be evident, especially in the duodenum and jejunum.
• Microscopically, larvae establish tunnels in the epithelium of the small intestine at the base of the villi and persist in that location. Villus atrophy can occur, associated with mixed mononuclear inflammatory cell infiltrate into the lamina propria. The epithelium of the crypts of Lieberkuhn is hyperplastic and larvae may be evident in the crypts.
• Embryonated or larvated ova may be retained in the epithelial tunnels and help to distinguish *Strongyloides* from *Trichostrongylus* or other parasitic species.

TREATMENT

THERAPEUTIC APPROACH
• Soiled bedding should be removed and bedding should be kept clean and dry to eliminate moist, warm, habitats for free-living nematodes and larvae.
• Spontaneous recovery may occur if the source of infection is removed and management changes made.
• Anthelmintics can be used which are approved for the ruminant species in question and for the production status of the animal in which it is to be used.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• If giving oral medication, reduce feed intake 24 hours before treatment. This has the greatest impact on the benzimidazole class, but can improve other drug classes.
• Albendazole: Goat 10 mg/kg; sheep 7.5 mg/kg body weight PO
• Eprinomectrin: Goat/sheep 0.5 mg/kg PO
• Febantel: Goat/sheep 5 mg/kg PO
• Fenbendazole: Goat/sheep 20 mg/kg PO
• Ivermectin: Goat 0.4 mg/kg; sheep 0.2 mg/kg PO
• Levamisole: Goat 8–12 mg/kg PO
• Morantel: 10 mg/kg PO
• Moxidectin: Goat 0.5 mg/kg PO
• Oxfendazole: Goat 10 mg/kg PO; sheep 5–10 mg/kg PO

CONTRAINDICATIONS
Albendazole should be avoided in pregnant ruminants, particularly within the first 3 months of gestation.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Parasite resistance to anthelmintics is a serious growing danger, so all possible management steps should be favored over anthelmintic use, particularly for parasites such as *Strongyloides* which have relatively limited pathogenicity.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Spontaneous recovery is likely, and rapid response to appropriate anthelmintic treatments is expected.

POSSIBLE COMPLICATIONS
Secondary infection of inflamed skin or secondary bacterial bronchopneumonia.

CLIENT EDUCATION
Focus on management strategies to reduce *Strongyloides* infestation.

PATIENT CARE
Provide clean, dry bedding that is replaced at appropriate intervals.

PREVENTION
• 30–35% of animals carry the majority of nematodes and create pasture contamination.
• To avoid resistance, some of these animals need to remain untreated, so the herd or flock should be managed via targeted selective treatment versus general deworming.
• This ensures a refugia (a population not selected by anthelmintic treatment) of susceptible nematode larvae is maintained on the pasture, to help dilute out resistant genes from resistant nematodes.
• Use of the FAMACHA system can identify clinically anemic animals in need of deworming, leaving healthier animals to host the refugia.
• Similarly, select young animals with poor weight gain for treatment and leave normally growing animals untreated to promote refugia.
• Animals should be kept on "safe pastures"—those where pasture contamination is low and significant reinfection takes longer. This can be a pasture not grazed by the species of interest in 3–6 months, or pastures that have been tilled, burned, or replanted.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Secondary mild bacterial bronchopneumonia

AGE-RELATED FACTORS
Neonates and young animals are more susceptible than adults.

ZOONOTIC POTENTIAL
Cutaneous larval migrans can occur in humans with *S. papillosus*; however, other parasites are more likely to initiate this problem (such as canine hookworms).

PREGNANCY
Routine deworming of dams late in gestation decreases transmammary transmission to neonates.

BIOSECURITY
• In general, to aid parasite control, place all new arrivals in a secure dry lot where they are fed, cleaned, and cared for in order to minimize any contact with herd.
• Perform fecal examination for the presence of nematode eggs.
• Within 2–3 days of arrival, consider treating with three different classes of anthelmintics on the same day, for example, administer a milbemycin (moxidectin), benzimidazole (fenbendazole), and membrane depolarizing agent (levamisole).
• Perform second fecal examination 10–14 days after deworming to check for presence of nematode eggs; if results are negative, repeat the fecal examination in 5–7 days.
• Allow only animals with negative findings on two separate tests to be placed in the herd or flock.

PRODUCTION MANAGEMENT
• Infestation may result in decreased milk production and meat production, pruritic dermatitis may result in damage to the wool and hide, and severe infections in young animals may lead to poor condition, reduced growth, or death.
• Routine deworming of dams in late gestation decreases transmammary transmission of *Strongyloides* to the neonate.
• Early deworming of neonates born to affected untreated dams.
• Provide a clean, dry environment with adequate clean bedding in stalls and rest areas.
• Pasture management to reduce host exposure to parasites by manure removal and rotational grazing.
• Select for parasite resistance by culling animals with chronic, heavy parasite loads.
• Avoid bringing resistant parasites onto properties by isolating new ruminants until fecal egg counts have been performed and deworming performed if needed.

STRYCHNINE POISONING

BASICS

OVERVIEW
• Toxin derived from seeds and bark of tree *Strynos nux-vomica* that is native of southeast Asia.
• Strychnine is used in rodenticide baits.

INCIDENCE/PREVALENCE
• Occurs where strychnine grain baits are used. They contain 0.5–1% strychnine alkaloid. Some formulations may contain higher strychnine concentrations. Most baits are used to control rodent populations with below-ground use of these products.
• The lethal oral dose of strychnine for cattle is reported as 0.5 mg/kg body weight. Strychnine is rapidly absorbed from the GIT and metabolized by hepatic enzymes. Strychnine is widely distributed in the body with a small portion excreted unchanged into the urine.

SYSTEMS AFFECTED
Nervous

GEOGRAPHIC DISTRIBUTION
Worldwide

PATHOPHYSIOLOGY
• Strychnine is a selective antagonist in blocking the inhibitory effects of glycine at the glycine receptors of the postsynaptic membrane.
• May also increase levels of glutamic acid.
• End result is neuronal excitation of motor neurons.

HISTORICAL FINDINGS
History of exposure to rodenticide baits that contain strychnine.

SIGNALMENT
All species are susceptible.

PHYSICAL EXAMINATION FINDINGS
Signs can occur within minutes of ingestion.
• Restlessness
• Muscle twitching
• Contracture of skeletal muscles
• Convulsions
• Death

CAUSES AND RISK FACTORS
• Exposure to rodenticide baits that contain strychnine.
• Poor management of rodenticide baits.
• Malicious intent may be cause of exposure.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Botulism
• Metaldehyde or lead toxicosis
• Organophosphorus, carbamate, or chlorinated hydrocarbons
• Sodium ion toxicity
• Tremorgenic mycotoxins
• Tetanus

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic changes

OTHER DIAGNOSTIC PROCEDURES
Detection of toxin in bait, blood, GIT, urine, liver, or kidney using chromatography or mass spectrometry.

PATHOLOGIC FINDINGS
No specific lesions are noted; however, necrosis of the cerebral cortex and brainstem have been reported in humans poisoned with strychnine.

TREATMENT

THERAPEUTIC APPROACH
• Supportive treatment
• Sedation

MEDICATIONS

DRUGS OF CHOICE
None

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Most cases result in death; there have been a few reports of recovery.

PREVENTION
Keep rodenticides away from feedstuffs and livestock.

MISCELLANEOUS

BIOSECURITY
• Monitor all use of rodenticides, particularly around feedstuffs. Keep rodenticides away from livestock.
• Malicious intent may be cause of exposure.

PRODUCTION MANAGEMENT
Keep rodenticides away from livestock and facilities.

ABBREVIATION
GIT = gastrointestinal tract

SULFUR TOXICITY

BASICS

OVERVIEW

• Sulfur (S) occurs in nature as free S or combined with other elements in sulfides and sulfates. The most common form in water is the sulfate (SO_4^{2-}) ion, although some sulfurous wells may contain relatively high concentrations of dissolved sulfides. The most common naturally occurring forms in feedstuffs are S-containing amino acids (e.g., methionine).
• S is an essential macro element, and, in fact, comprises about 0.15% of the total body in mammals. It is a constituent of the amino acids methionine, cysteine, cystine, homocysteine, cystathionine, taurine, and cysteic acid. It is also a component of biotin, thiamine, estrogens, ergothionine, fibrinogen, heparin, chondroitin, glutathione, coenzyme A, and lipoic acid. Unlike monogastrics, ruminants can synthesize their own organic forms of S from inorganic S.
• S is highly toxic if consumed in excess amounts.
• High doses of S may cause sudden death or polioencephalomalacia (PEM). Somewhat smaller doses can impact productivity (weight gain, reproduction) via its effect upon copper metabolism, and other, poorly understood, chronic effects.

INCIDENCE/PREVALENCE

In 1997, 11.5% of 454 pairs of forage/water samples collected from around the United States yielded dietary S concentrations potentially hazardous for cattle; 37% of these elevated pairs originated from the western United States.

GEOGRAPHIC DISTRIBUTION

S toxicity on western rangelands most commonly results from water-borne SO_4. However, in confinement feeding operations, especially in the mid-west, it is more likely to be associated with feeding ethanol by-products.

SYSTEMS AFFECTED

• Hemolymphatic
• Nervous
• Reproductive
• Respiratory

PATHOPHYSIOLOGY

• The first step in ruminal synthesis of S-amino acids from inorganic S is reduction of the latter to H_2S. Under normal circumstances, the reactive sulfide ion is combined with carbon by rumen microflora to create methionine, homocysteine, cystathionine, cysteine, and other S-amino acids. Under conditions of excessive S intake, however, significant quantities are reduced to H_2S, and the very toxic gas escapes from the rumen into the systemic circulation, resulting in sudden death or polioencephalomalacia.
• Smaller concentrations of ruminal sulfide react with Cu and/or Mo to form biologically unavailable Cu compounds.
• Chronic exposure to H_2S may impair innate respiratory immunity (phagocytosis and the mucociliary elevator).

HISTORICAL FINDINGS

Acute Toxicity

• Sudden death within 1–2 days of a major change in diet or water supply.
• Cortical neurologic signs within a few days to 2–3 weeks of a major change in diet or water supply.

Chronic Toxicity

• A veterinarian faced with poor conception rates, poor response to vaccine, or increased incidence of respiratory disease should *consider* chronic S toxicity as a possible differential.

SIGNALMENT

• Potentially all ruminant species are susceptible, but cattle seem to be the most sensitive.
• In general, animals need a functional rumen to be affected, thus adults are more likely to be affected than neonates.

PHYSICAL EXAMINATION FINDINGS

• Sudden death with no premonitory signs and no lesions.
• Circling, head-pressing, star-gazing, muscle fasciculations, and convulsions.
• Increased infectious disease with poor response to vaccination and treatment, possibly related to impaired immune function.
• Decreased reproductive efficiency, especially in the first trimester, as a result of Cu deficiency.
• Signs suggestive of cortical neurologic damage, including blindness, tremors, and convulsions.

CAUSES AND RISK FACTORS

Sources

• Naturally occurring S in common forages ranges from 0.17% to 0.48%. This concentration may be drastically altered by human activity.
• Ethanol production by-products, such as DDG, *may* contain S concentrations many times higher than natural feedstuffs.
• The predominate form of S in drinking water is the SO_4^{2-} ion. Concentrations vary widely with the local geosphere. In general, waters from alkaline, arid regions, such as the Great Plains and Intermountain West, tend to contain much higher concentrations of S than other regions of North America.

Toxicity

• Ruminants are more susceptible to S toxicity than nonruminants. All ruminants are susceptible.
• Although there are no experimental side-by-side comparisons of S toxicity in various ruminant species, in the author's experience cattle seem to be more sensitive than sheep and goats. Bison and elk are somewhat intermediate.
• Since S toxicity depends upon generation of the sulfide ion, which may be influenced by a host of other dietary and environmental factors, and because the dose of S received is the sum of the S content of all dietary components including water, it is difficult to settle upon a single number that consistently guarantees safety. The NRC recommends that "the sulfur content of cattle diets be limited to the requirement of the animal, which is 0.2% dietary sulfur for dairy and 0.15% in beef cattle and other ruminants."

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Lead poisoning
• Nitrate or cyanide poisoning
• Poor nutrition or trace element deficiencies
• Sodium ion toxicity
• Thiamine deficiency
• Thromboembolic meningoencephalitis

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• Rumen gas cap H_2S concentrations will be higher than background concentrations in some, but not all, acute cases. This is a somewhat exotic test that must be performed on a live or freshly dead animal.
• Analysis of blood or liver for lead and brain for sodium will possibly eliminate two major differentials.
• Hepatic Cu concentration is often depressed in cases of ill-thrift due to chronic S toxicity.

OTHER DIAGNOSTIC PROCEDURES

Analysis of feedstuffs and water for S. All components of the diet must be analyzed and the total dose calculated.

TREATMENT

THERAPEUTIC APPROACH

• Remove animals from source of high dietary S.
• *Massive* doses of parenteral thiamine may provide some improvement in early cases of PEM.
• Dexamethasone may also help with early cases of PEM.
• Switching rations from high carbohydrate (if on them) to high roughage may prevent new cases.

SULFUR TOXICITY (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE

• Thiamine administration at a dosage of 10 mg/kg body weight q6–8h for cattle or small ruminants. The first dose is administered slowly IV; otherwise, the animal may collapse. Subsequent doses are administered IM for 3–5 days.
• Administration of dexamethasone at a dosage of 1–2 mg/kg, IM or SC, to reduce cerebral edema.

CONTRAINDICATIONS

Ionophores increase H_2S production in vitro. The clinical significance of this has not been proven.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Prognosis is guarded for animals showing signs of PEM.

PREVENTION

Avoid sudden changes in diet or water source, especially during summer months, and allow animals time to adapt to any new combination of feed and water.

MISCELLANEOUS

PRODUCTION MANAGEMENT

• Test each new batch of ethanol by-products before feeding.
• On rangelands with potentially high SO_4 waters, test water before introducing cattle, especially if they are accustomed to low SO_4 waters.

ABBREVIATIONS

• DDG = dry distillers' grains
• IM = intramuscular
• IV = intravenous
• PEM = polioencephalomalacia
• SC = subcutaneous

SEE ALSO

• Cyanide Toxicosis
• *Histophilus somni* Complex
• Lead Toxicosis
• Nitrate and Nitrite Toxicosis
• Sodium Disorders: Hypernatremia

SWEET CLOVER POISONING

BASICS

OVERVIEW

• Three members of *Melilotus* species are a concern within the United States:
  ◦ White sweet clover (*Melilotus alba*) ◦ Sour clover (*Melilotus indica*) ◦ Yellow sweet clover (*Melilotus officinalis*)
• Herb with 3 blade leaflets that are obovate to linear. • Flowers are small and yellow or white. • Coumarin scent (vanilla like) when dried. • Used as hay and silage forage.
• Toxicity occurs when fungi grow in the stems of harvested plants because the plants are not completely dried for hay.

INCIDENCE/PREVALENCE

• Typically, morbidity is low (10–15%) and the case fatality rate high (>50%). • The most devastating episodes occur following surgery, dehorning, and castration. • Disease problems are more likely to appear in winter when animals are fed hay put up in large round bales during a wet summer.

GEOGRAPHIC DISTRIBUTION

This herb is found throughout the US.

SYSTEMS AFFECTED

Hemolymphatic

PATHOPHYSIOLOGY

• Dicoumarol is formed from the interaction of fungal growth in the partially dried or fermented stems with the already present coumarin within the herb. • Coumarin already present in the stems has a relatively low toxicity. • Dicoumarol interferes with vitamin K function, which is needed for activation of coagulation factors II, VII, IX, and X. • Depletion of coagulation factors is seen with dicoumarol concentrations of 10 ppm. • Toxicity effects are seen clinically at 20–30 ppm.

HISTORICAL FINDINGS

• Exposure to sweet clover hay or silage.
• Typically occurs with 4–5 weeks of consumption of toxic hay.

SIGNALMENT

• Although all animals are at some risk, this hemorrhagic disease occurs primarily in cattle.
• Sheep are less susceptible than are cattle.

PHYSICAL EXAMINATION FINDINGS

• Anemia and hemorrhage may be problems in the newborn in the absence of overt signs other than prolonged prothrombin time in the dam. • Subcutaneous hemorrhage. • Body cavity hemorrhage. • Intractable bleeding following surgery or medical procedures.
• Spontaneous bleeding. • Tachycardia, tachypnea. • Weakness. • Death.

CAUSES AND RISK FACTORS

• Dicoumarol is the toxic principle.
• Exposure to plant that has been improperly cured for hay or fermented for silage. • These conditions of large bales and moist plants make curing of the tougher stems more difficult and more likely to have fungal growth. • Silage is less often a problem, but it is still a risk, especially in dairy cattle. • There may be no indication prior to surgery of the animal's predisposition for clotting problems, but following surgery, it may be seemingly impossible to stop the bleeding. • Handling animals in squeeze chutes or similar types of facilities also predisposes trauma and subsequent development of subcutaneous hemorrhage.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Blackleg • Warfarin rodenticide toxicity

CBC/BIOCHEMISTRY/URINALYSIS

Anemia

OTHER LABORATORY TESTS

• Coagulation
  ◦ Prolonged prothrombin time ◦ Increased whole blood clotting time

OTHER DIAGNOSTIC PROCEDURES

• History of exposure to the plant • Clinical signs of bleeding or hematomas • Analysis of hay for dicoumarol

TREATMENT

THERAPEUTIC APPROACH

• Severe cases may need blood transfusion.
• Vitamin K_1. • Remove from source and supplement with forage with good quality alfalfa hay.

MEDICATIONS

DRUGS OF CHOICE

• Vitamin K_1 1–5 mg/kg body weight administered IV, IM, or SC depending on severity of the case. • Repeat dose of vitamin K_1 as needed. • Vitamin K_3 has been used at double the dose of vitamin K_1 with some success. • Oral Vitamin K_3 is ineffective.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• If found and treated, many recover • Death

PATIENT CARE

• PCV • Prothrombin time

PREVENTION

If to be used for forage, must be sown heavily to result in thin stems from dense growth. Cut early while stems are thin, dry thoroughly for hay and pack well for silage.

MISCELLANEOUS

PREGNANCY

• Of special concern is the potential for hemorrhage during parturition or in the newborn calf. • As sheep are more resistant, there is little likelihood of problems at lambing and in newborn lambs.

PRODUCTION MANAGEMENT

• Suspicious sweet clover hay may be fed if it is alternated with good alfalfa hay every 10–14 days. • Pregnant cows should not be fed hay or silage containing *Melilotus* unless these forages have been evaluated for dicoumarol content. • It would be prudent to forgo feeding sweet clover at least 1 month prior to calving. • Cultivars of sweet clover low in coumarin and safe to feed (e.g., Polara) have been developed.

ABBREVIATIONS

• IM = intramuscular • IV = intravenous • PCV = packed cell volume • SC = subcutaneous

SEE ALSO

• Clostridial Disease: Muscular • Rodenticide Toxicity

Sweet Potato Poisoning

BASICS

OVERVIEW
• Sweet potatoes (*Ipomoea batatas*) produce several toxins in response to injury or mold (*Fusarium solani*) and parasitic infection. • Feeding of sweet potatoes not suitable for human consumption to livestock is the most common exposure.

INCIDENCE/PREVALENCE
• Often seen in the spring when spoiled sweet potatoes are most likely to be fed; however, the disease can occur anytime spoiled sweet potatoes are fed. • Morbidity rates in cattle fed moldy sweet potatoes can be as high as 75% and mortality is usually <10% but can be as high as 30%.

GEOGRAPHIC DISTRIBUTION
Throughout the United States but primarily in the southeast where it is a common practice to feed spoiled sweet potatoes to livestock.

SYSTEMS AFFECTED
Respiratory

PATHOPHYSIOLOGY
• Toxins produced by the sweet potato include 4-ipomeanol, 1-ipomeanol, 1,4-ipomeanol, and ipomeanine • These toxins cause destruction of type 1 pneumocytes and epithelial cells leading to proliferation of type 2 pneumocytes. • Bioactivation of a pneumotoxin, primarily in Clara cells and macrophages of the lung rather than in cells in the liver, results in formation of reactive metabolite intermediates such as 3-methylindole (3-MI). • These reactive metabolites bind to proteins in the lungs and cause tissue destruction, especially of type 1 pneumocytes and epithelial cells. Type 1 pneumocytes are responsible for gas exchange within the alveoli. • Under the stimulus of factors released by macrophages, type 2 pneumocytes proliferate to replace lost type 1 cells and in the process cause formation of foci with massive increase in cellularity. • During this period of proliferation, the ability of type 2 cells to synthesize and secrete functional surface-active phospholipids (surfactants) is decreased. Surfactant produced no longer effectively lowers surface tension. This compromises lung function. • This results in atypical interstitial pneumonia (AIP).

SIGNALMENT
Bovine (most common), ovine, and caprine

HISTORICAL FINDINGS
History of exposure to sweet potatoes

PHYSICAL EXAMINATION FINDINGS
• Labored breathing often open-mouth • Coughing • Salivation • Extended head and neck • Animals may be belligerent

CAUSES AND RISK FACTORS
Consumption of moldy sweet potatoes containing 4-IP

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Perilla mint toxicity • DL tryptophan toxicity (fog fever) • Lungworm infection • Irritant gasses inhalation

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic changes

OTHER LABORATORY TESTS
Detection of toxin in rumen samples thru gas chromatography/mass spectrometry

OTHER DIAGNOSTIC PROCEDURES
Sweet potato residue in rumen contents

PATHOLOGIC FINDINGS
• Gross pathology finds distended lungs that fail to collapse with prominent edema and fluid and foam oozes from cut surface. • Histopathologic examination will reveal proliferation of type 2 pneumocytes and alveolar lumens filled with fibrinous exudate.

TREATMENT

THERAPEUTIC APPROACH
• No specific treatment. • Keeping animals as calm as possible is important. • If stressed, animals often become anoxic and die. • Remove animals from etiology (i.e., purple mint, moldy sweet potatoes, or lush pasture).

MEDICATIONS

DRUGS OF CHOICE
• No specific drugs are effective. • Symptomatic treatment such as corticosteroids, atropine, diuretics, antihistamines, and antibiotics. • Supportive treatment: Bronchial dilators. • Weigh the value of therapeutic pharmacology versus the stress involved with handling and treatment.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Depending on the amount of lung damage, very guarded early prognosis as death may occur within 12–24 hours. • Clinical course may last 2–3 weeks. • If animals survive 2 or 3 days and are not stressed, prognosis improves. • Even severely affected animals may return to normal in 2–3 weeks when the type 2 pneumocytes resolves to type 1.

CLIENT EDUCATION
Danger associated with feeding moldy sweet potatoes

PREVENTION
Avoid feeding spoiled sweet potatoes

TEASER PREPARATION

BASICS

OVERVIEW
• Estrus detection is an essential part of any artificial breeding program (AI or ET) in ruminant production systems.
• Heat detection inefficiency is one of the major contributing factors to poor reproductive performance, particularly in dairy animals.
• Teaser animals are used to aid in estrus detection.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Preparation of teaser aims to increase heat detection efficiency without risk of impregnation.
• Although male sexual behavior may be obtained in females and castrated males through injection of testosterone (i.e., androgenized heifers or steers), this technique is being abandoned to reduce use of hormones in production animals.
• When intact males are used, pregnancy is prevented by eliminating the possibility of full erection, intromission, or ejaculation of viable spermatozoa.
• Vaginal intromission can be prevented mechanically by the use of aprons (small ruminants) or surgically by translocation of the penis and prepuce (penile deviation), penectomy, or penopexy. Erection may also be prevented by injecting an acrylic substance into the corpus cavernosum muscle or creation of a preputial stenosis.
• Ejaculation of viable spermatozoa is eliminated by vasectomy, epididymectomy, or intratesticular injection of a sclerotic agent.
• The combination of vasectomy and penile translocation is the most recommended technique in order to prevent disease transmission and eliminate the risk of pregnancy associated with accidental vaginal intromission.

HISTORICAL FINDINGS
N/A

SIGNALMENT
• Young postpubertal male with good libido.
• Hormone-treated animals can be heifers (usually freemartin), cull cows, or steers.

PHYSICAL EXAMINATION FINDINGS
Animal should be healthy with normal reproductive development.

DIFFERENTIAL DIAGNOSES
N/A

CBC/BIOCHEMISTRY/URINALYSIS
Total protein and packed cell volume should be determined prior to anesthesia (penile translocation).

OTHER LABORATORY TESTS
Testing for contagious diseases

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Hormone-treated heifers and steers
  ◦ Testosterone enanthate 500 mg IM and 1,500 mg SC, then 1,000 mg every 2 weeks (estrus detection varies 40–60%).
  ◦ Synovex H implants (200 mg testosterone propionate and 20 mg estradiol benzoate, one implant per 100 lb body weight), response rate about 80% and lasts about 6 months.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Epididymectomy
  ◦ Performed on standing animal in the chute for bulls and in sitting position for sheep and goats.
  ◦ Sedation is not necessary in bulls but is helpful in small ruminants.
  ◦ Local block is applied at the skin incision site. There are two variants of the technique based on the site of skin incision, which can be at the base of the scrotum over the tail of the epididymis or higher with the testis pushed dorsally to expose the tail of the epididymis.
  ◦ A 3 cm incision is made through the scrotal skin and the vaginal tunic to expose the cauda epididymis.
  ◦ The proper ligament of the epididymis is identified and absorbable suture material is passed through in such a way that the tail of the epididymis is ligated at two sites 2 cm apart and the section is transected.
  ◦ The skin incision may be left open.
• Translocation of the penis and penis
  ◦ The technique can be performed in the field under injectable anesthesia. The animal is placed in slightly tilted dorsal recumbency with the left side slightly extended.
  ◦ The ventral abdomen from the umbilicus to the scrotum and the left lower flank is clipped and prepared for surgery. Care must be taken to thoroughly clean the preputial cavity with dilute iodophor.
  ◦ A catheter is placed as deep as possible within the prepuce and held with towel clamps at the preputial orifice.
  ◦ A 4 cm circular skin incision is made around the preputial orifice and extending caudally on midline to the sigmoid flexure. Mark the proximal part of the preputial orifice with a stay suture to avoid disorientation.
  ◦ The penis within its prepuce is dissected away from the body wall using combined blunt dissection and incision with scissors after ligation of any major blood vessels. It is important to dissect just enough to allow separation of the prepuce and avoid formation of a large dead space.
  ◦ A circular skin incision, slightly smaller than the removed preputial orifice skin, is made just above the flank fold. The site for the incision can be gauged by deviating the dissected prepuce at a 45° angle.
  ◦ The circular flank incision is joined to the midline incision near the base of the penis by tunneling under the skin with a long forceps (Knowles cervical forceps).
  ◦ A sterile sleeve is passed through the formed tunnel and the prepuce is passed through it such that the preputial orifice is brought to the circular skin incision and sutured in place in a simple interrupted pattern.
  ◦ The ventral midline incision is sutured using a Ford interlocking pattern.
• Preputial stenosis
  ◦ This technique is not as common as the previously described techniques and consists of creating a stenosis of the prepuce by placing a purse-string suture circumventing the prepuce and burring it subcutaneously, or by placing a stainless steel ring around an isolated section of the prepuce.
• Penile fixation
  ◦ The surgery is done with the animal sedated, placed in lateral recumbency, and local anesthesia is performed at the surgical site.
  ◦ A 10 cm longitudinal incision through the skin, subcutaneous tissue, and cutaneous trunci muscle is made midway between the preputial opening and the base of the scrotum at the junction of the sheath and the body wall.
  ◦ Blunt dissection is required to locate the dorsal surface of the penis.
  ◦ The penis is exteriorized and its elastic tunics from its dorsal surface are cleared from the preputial reflection to approximately 10 cm caudal.

TEASER PREPARATION (CONTINUED)

◦ The linea alba should then be cleared of all loose connective tissue.
◦ At least three simple interrupted sutures 1–2 cm apart are then placed through the tunica albuginea on the dorsal surface of the penis and the linea alba using nonabsorbable suture material. Care should be taken to avoid the urethra during suture placement.
◦ The skin incision is then closed with nonabsorbable suture material.

MEDICATIONS

DRUGS OF CHOICE
• Sedation and analgesia: Xylazine (0.1 mg/kg body weight IV for bulls; 0.1 mg/kg IM for goats; 0.2 mg/kg for sheep) and ketamine (0.2 mg/kg for bulls; 3–5 mg/kg IM in sheep and goats) and local infiltration of lidocaine or bupivacaine.
• Postsurgical anti-inflammatories: Flunixin meglumine.
• Antibiotic therapy: Procaine penicillin G, 22,000 IU/kg for 5 days) is recommended following penile deviation or fixation.

CONTRAINDICATIONS
Appropriate meat withdrawal times should be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Animal should be fasted (small ruminant 24 hours, bulls 24–48 hours) prior to surgery
• Suture are removed 14 days after surgery.
• Vasectomized or epididymectomized males should undergo semen collection and evaluation 2–3 weeks after surgery to make sure that there are no viable spermatozoa in the ejaculate.
• Teasers may be used 4 weeks after penile translocation.

POSSIBLE COMPLICATIONS
• Local infection, adhesions, and formation of sperm granuloma are possible after caudectomy.
• Seroma, abscess, and dehiscence of the surgical site in penile translocation if aseptic technique is not observed.
• Urine accumulation and preputial eversion may occur in penile deviation if preputial swelling is excessive.
• Insufficient retraction or suture breakdown may be experienced after penile fixation technique.

CLIENT EDUCATION
• Welfare issues regarding some techniques.
• Some animals (small ruminants in particular) may still be able to penetrate after penile translocation, particularly if the surgery is performed at young age.
• The duration of service of a teaser animal varies.

PATIENT CARE
• Sexual rest for 3 weeks
• Antibiotic and anti-inflammatory therapy as indicated
• Semen collection and evaluation prior to use for heat detection

PREVENTION
Vaccination against clostridial diseases or administration of tetanus antitoxin and tetanus toxoid at the time of surgery.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
• Males to be used as teasers should be free of contagious diseases and selected from known herds or flocks.
• It is preferable to use animals from within the herd.

PRODUCTION MANAGEMENT
• The useful life of the teaser male is longer with vasectomy and penile deviation in the author's experience.
• Performance of the teaser should be monitored as some procedures are associated with loss of libido.
• Bulls used as teasers should not be kept for a long time as they become more and more difficult to handle, particularly in a dairy operation.

SYNONYMS
• Gomer bull, marker
• Estrus detector male

ABBREVIATIONS
• IM = intramuscular
• IV = intravenous
• SC = subcutaneous

SEE ALSO

TEAT LACERATIONS

BASICS

OVERVIEW

• Teat lacerations are most often a result of step-on injury by the animal herself or an adjacent animal.
• The prognosis for laceration repair depends on whether the laceration is partial thickness or full thickness, involving the streak canal, teat sinus, or gland sinus. Prognosis also depends on location, size, and direction of the laceration, degree of tissue loss, age of laceration, and degree of contamination.
• Longitudinal lacerations have a more favorable prognosis because the blood supply flows from the base of the teat towards the apex. Proximal lacerations heal better because perfusion is better closer to the base of the teat.
• Improper healing of teat injuries can result in scar tissue formation, teat obstruction, teat fistulas, and ultimately loss of the quarter.
• Mastitis is a common sequela of teat laceration especially if it is full thickness.
• The teat is composed of five layers: internal mucosa, submucosa, connective tissue and blood vessels, muscular layer (circular and longitudinal layers), and external squamous epithelium.
• The teat cistern is contained within the teat, the distal opening of which is the rosette of Furstenberg, which leads to the streak canal and teat sphincter. If the streak canal or gland sinus is involved in the laceration, the prognosis for adequate return to function is guarded.
• The teat in general has good blood perfusion so the age of the laceration is not as critical. Lacerations up to 12 hours old are candidates for primary repair. For older lacerations delayed primary closure should be considered.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

• Integument
• Mammary

PATHOPHYSIOLOGY

Wound healing can be divided into three phases: inflammation, proliferation, and maturation/remodeling. The first phase involves influx of white blood cells and inflammatory mediators as well as fibrin clot formation. Proliferation involves granulation tissue formation and epithelialization. Wound remodeling begins after 2 weeks, which is the final stage.

HISTORICAL FINDINGS

History of trauma. Duration is important in determining primary vs. secondary closure.

SIGNALMENT

• Any female ruminant (cattle, sheep, and goats can be affected).
• Dairy cows more likely to be affected than beef cows.
• Animals with large or pendulous udders more commonly affected.

PHYSICAL EXAMINATION FINDINGS

• Teat edema
• Teat hemorrhage
• Milk leakage through teat wall
• Pain
• Bloody milk
• Mastitis

GENETICS

Dairy cattle and goats with poor udder conformation and high milk production will be predisposed to teat lacerations due to their pendulous udder.

CAUSES AND RISK FACTORS

• Self-trauma
• External trauma
• Pendulous or large udders

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Mastitis can cause swelling of the teat and/or discoloration, bloody milk without obvious external trauma.
• Teat spiders, webs, and scar tissue can cause swelling and obstruction, but do not have associated bleeding or laceration.
• Teat fistulas cause leaking milk, but without associated traumatized tissue.
• Gangrenous mastitis causes swelling, discoloration, and bleeding, but is progressive and often generalized.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• California Mastitis Test (CMT) may indicate increased somatic cell count if mastitis is present.
• Milk culture may show bacterial growth if mastitis is present secondary to laceration.

IMAGING

Ultrasound of teat may be helpful to differentiate laceration from other causes.

OTHER DIAGNOSTIC PROCEDURES

Theloscopy can be used to locate and differentiate lesions inside the teat.

PATHOLOGIC FINDINGS

N/A

TREATMENT

THERAPEUTIC APPROACH

• Surgical repair is recommended for a good prognosis.
• Teat must be thoroughly cleaned and evaluated for tissue viability, blood supply, extent of injury.
• Systemic administration of antibiotics is rarely indicated.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• The wound margins should be carefully debrided and rinsed with physiologic saline solution. Any necrotic tissue should be meticulously debrided, but due to the small quantity of the teat tissue, preservation of as much tissue is encouraged to facilitate laceration closure.
• After adequate sedation, an anesthetic ring block with 2% lidocaine around the base of the teat (avoiding the circumferential vein and the teat and gland cistern) should be performed. Alternatively, a caudal epidural can be performed in lieu of the ring block or in addition to it.
• The animal is easiest to work on when restrained in lateral or dorsal recumbency. A tourniquet may be placed around the base of the teat to reduce bleeding and milk flow into the lacerated area during repair. The repair should be performed as aseptically as possible.
• Surgical repair of full thickness lacerations should be in three layers. The submucosa and intermediate layers are closed separately with a continuous horizontal mattress pattern that does not perforate the mucosa. A 3-0 or 4-0 absorbable monofilament suture on a swaged-on tapered needle should be used. The skin should be closed with a 3-0 or 4-0 monofilament suture using a simple interrupted suture pattern.
• Partial thickness lacerations are closed in two layers similar to full thickness repair outlined above, with omission of the first layer in the submucosa.
• Passive drainage using a teat cannula is recommended every other day followed by infusion of intramammary antibiotics every 4 days for 10 days in total. Refer to AMDUCA and FARAD for regulations and withholding times related to off-label use of antimicrobials in food-producing species.
• Tissue adhesives and glue should be avoided in repair due to the inflammatory reaction they can elicit.

TEAT LACERATIONS (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE

- Sedation with acepromazine
  - Cattle and goats: 0.05–0.1 mg/kg IV
  - Sheep: 0.03–0.05 mg/kg IV
- Xylazine can be used to sedate ruminants at the following doses:
  - Goats: 0.05 mg/kg IV or 0.1 mg/kg IM
  - Sheep 0.1–0.2 mg/kg IV or 0.2–0.3 mg/kg IM
  - Cattle 0.1 mg/kg IV or 0.2 mg/kg IM
  - Recumbency will be induced for approximately 1 hour. Low dose xylazine (0.015–0.025 mg/kg IV or IM) will provide sedation without recumbency in ruminants.
- Flunixin meglumine (1.1–2.2 mg/kg IV) can be used at the time of repair, but is rarely necessary after the initial dose.

CONTRAINDICATIONS

- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
- Acepromazine has been reported to cause sloughing of the tail if inadvertently administered into the coccygeal artery, and therefore care should be taken when administering in the coccygeal vein.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- Healing should be complete in 10–14 days.
- Prognosis is better with partial thickness lacerations than full thickness lacerations.
- See "Overview" for more details regarding prognostic factors.

POSSIBLE COMPLICATIONS

- Teat fistula formation can occur anywhere along the repair line. Fistulas should be allowed to heal for 3–4 weeks before surgical repair is attempted. Full thickness repair should be performed again in the region of the fistula, following resection of the fistula.
- Mastitis is likely, and should be treated appropriately, avoiding intramammary infusions if possible.

CLIENT EDUCATION

Instill the importance of prompt attention to teat lacerations to dairy workers so that wounds will have a better outcome. Also work with management on culling decisions due to poor udder conformation.

PATIENT CARE

- Laceration should be monitored daily for signs of repair breakdown.
- Suture removal at 7–10 days after surgery.

PREVENTION

- Avoid overcrowding cows or other ruminants.
- Ensure good footing for the animals.
- Animals with pendulous udders may require separate housing or culling.
- Ensure that free stalls are wide enough for easy rising.
- Monitor the length of the medial dew claw(s) as overgrowth can result in teat or udder injury.

MISCELLANEOUS

ASSOCIATED CONDITIONS

None

AGE-RELATED FACTORS

Older cows and does may be more prone due to increased udder size and pendulous nature.

ABBREVIATIONS

- AMDUCA = Animal Medicinal Drug Use Clarification Act
- CMT = California Mastitis Test
- FARAD = Food Animal Residue Avoidance Databank (FARAD) (see www.fiveminutevet.com/ruminant)
- IV = intravenous

TEAT LESIONS

BASICS

OVERVIEW
• Teat lesions result from traumatic, milking machine, environmental, infectious, or chemical insults that injure teat skin, dermis, or mucosa resulting in lactation difficulties.
• Mastitis may result if there is penetration and compromise of the teat sinus or external sphincter.

INCIDENCE/PREVALENCE
• More common in animals with the genetic characteristics described under "Genetics."
• Increased incidence can be seen with infectious epidemics, abrupt milking system malfunction, or changes in milking practices.
• Higher prevalence with adverse environmental conditions (close confinement, freezing temperatures, traumatic rough terrain, flies) and higher parity.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Integument
• Mammary

PATHOPHYSIOLOGY
• Teat lesions damage the physiologic barriers of the teat skin, wall, and sphincter.
• Loss of barrier integrity can cause the teat and gland sinuses to leak milk and/or allow entry of pathogens into the mammary sinuses resulting in mastitis.
• Teat end lesions usually do not contribute to mastitis unless the lesions are severe.

HISTORICAL FINDINGS
• Reluctance to be nursed or milked.
• Poor milk letdown and reduced production.
• Known trauma, mastitis event, or recent environmental changes may be noted.

SIGNALMENT
Lactating animals

PHYSICAL EXAMINATION FINDINGS
• Teat inflammation (swelling, edema, redness).
• Fever, anorexia, recumbency (secondary mastitis, bacterial sepsis).
• Vesicles, papules, or scabs.
• Bleeding or laceration.
• Teat end hyperkeratosis or sphincter eversion.
• Stamping of feet, brushing udder with hind legs.
• In chronic cases, there is mammary gland atrophy.

GENETICS
• Traits associated with teat lesions include cylindrical teat shape (opposed to funnel-shaped), long teats, disk-shaped external sphincter shape (opposed to round), large and pendulous udders, teat placement and angle of the udder (teats more easily stepped on), and suspensory ligament breakdown.
• Slow milkers and high-producing animals also have higher incidence of teat lesions.

CAUSES AND RISK FACTORS
Environmental
• Blunt trauma (stepped-on teats)
• Laceration (wire, brambles, other sharp objects)
• Cold (frostbitten and chapped teats)
• Photodermatitis (sunburn)
• Chemicals (defective or inappropriate teat dips or lime from floors and stalls)
• Milking machine trauma (overmilking and excessive vacuum pressure)
• Insects (teat atresia from *Haematobia irritans irritans*—the horn fly)

Infectious Agents
• Pseudocowpox
• Vesicular stomatitis
• Foot and mouth disease virus
• Bovine viral diarrhea
• Bovine malignant catarrhal fever
• Cowpox
• Bovine herpes virus 2
• Vaccinia virus
• Bovine papillomavirus

Mycotoxins
• *Aspergillus* spp.
• *Fusarium* spp.
• *Anacystis* spp.
• *Pithomyces chartarum*

Corpora Amylacea Photosensitization Plants
• *Ammi majus* (bishop's weed, greater ammi)
• *Cooperia pedunculata* (rain lily)
• *Cymopterus watsonii* (spring parsley)
• *Fagopyrum esculentum* (buckwheat)
• *Heracleum mantegazzianum* (giant hog weed)
• *Hypericum perforatum* (St. John's wort)
• *Thamnosma texana* (Dutchman's breeches)
• *Brassica* spp. (kale)
• *Lantana camara* (lantana)
• *Senecio* spp. (ragwort)
• *Amsinckia* spp. (fiddleneck)
• *Panicum* spp. (millet)

Chemicals
• Phenothiazines
• Thiazides
• Acriflavines
• Rose Bengal
• Methylene blue
• Sulfonamides
• Tetracycline

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Pseudocowpox, vesicular stomatitis, foot and mouth disease, bovine viral diarrhea, bovine malignant catarrhal fever, cowpox, bovine herpes virus 2, bovine papillomavirus, environmental causes (see "Causes and Risk Factors/Environmental"), and photosensitization from ingestion of various plants, chemicals, or mycotoxins.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Endoscopy and ultrasonography may be useful to assess cause and prognosis of milk flow hindrance.

OTHER DIAGNOSTIC PROCEDURES
• Dependent upon visualization and palpation.
• Milk culture prior to antibiotic treatment may be helpful to combat secondary mastitis.

PATHOLOGIC FINDINGS
• Lacerations, swelling, hemorrhage, sphincter eversion, teat end hyperkeratosis, vesicles, papules, necrotic skin, and/or cracks.
• Scarring with lumen narrowing.

TREATMENT

THERAPEUTIC APPROACH
Milking
• Discontinuing machine milking of affected teat(s) will speed healing by reducing manipulation-associated trauma (milk retrieved with a cannula).
• Culling may be considered in severe cases with refractory mastitis.

Chapped or Sunburned Teats
• Provide shade and apply topical emollients approved for use in lactating cattle (mineral oil, glycerin, or lanolin).
• Teats should be dried after milking.

Frostbite, Virus Infection, and Teat End Trauma
• Preventing mastitis while keeping the teat duct patent may require teat dilators, cannulas, and intramammary or parenteral antimicrobials.
• For teat end lesions caused by the above conditions, using teat dips containing antiseptics such as chlorhexidine, iodophors, and bleach can reduce secondary mastitis.
• Keep teats dry and cows comfortable.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Lacerations
• Surgical correction is appropriate depending on the severity and post-trauma interval.
• Fresh lacerations (<12 hours) with adequate blood supply may be closed with two-layer everting mucosa and skin/muscle sutures.
• Older lacerations warrant cleansing and removal of the skin flap followed by second intention healing with granulation.
• Teats should be bandaged if feasible.

TEAT LESIONS (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE

Antibiotics

• Systemic antibiotics are generally not warranted. Care must be taken in regard to milk contamination if a topical antibiotic is used.
• Refer to specific mastitis pathogen chapters for treatment protocols in the case that mastitis develops secondary to teat lesions.

Teat Dips

• Iodophor solutions: 0.5–1% available iodine
• Hypochlorite solutions: 4% free chlorine
• Chlorhexidine solutions: 0.3%

Emollients

• Glycerin: 15–30%
• Mineral oil
• Lanolin

CONTRAINDICATIONS

N/A

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Common adverse sequelae of severe lesions are teat sphincter scarring and obstruction with integrity loss and resultant mastitis.

POSSIBLE COMPLICATIONS

• Loss of quarter and decreased milk production for permanently damaged teat
• Mastitis
• Reduced milk intake in suckling offspring

CLIENT EDUCATION

• Severe acute teat end lesions are serious injuries with resultant mixed-pathogen mastitis and granulation/canal stenosis.
• Aseptic technique, canal dilation, and appropriate antimicrobial withdrawal times will benefit the patient.

PATIENT CARE

• Aseptic milking techniques will reduce the incidence of mastitis.
• House animals on clean, dry bedding and away from suckling calves and other sources of teat trauma.
• Teat sphincter integrity should be monitored as inflammation subsides and possible granulation ensues.
• Monitoring body temperature, milk consistency, CMT testing, and milk cultures for mastitis.

PREVENTION

• House cows in clean areas with ample space and protection from the elements.
• Practice sound milking hygiene techniques.
• Keep lots, pastures, and fences well maintained and free of debris.
• Use approved fly control.
• Genetically select for desirable udder and teat conformation.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Mastitis, contact dermatitis, loss of productivity

AGE-RELATED FACTORS

Teat lesions increase with parity

ZOONOTIC POTENTIAL

• No zoonotic potential unless caused by cowpox or pseudocowpox virus.
• Gloves should be worn when dealing with suspect or infected animals.

ABBREVIATION

CMT = California Mastitis Test

SEE ALSO

• *Brassica* spp. Toxicity
• Mastitis (specific chapters)
• Photosensitization
• Pseudocowpox

TERATOGENS

BASICS

OVERVIEW

• A teratogenic is an agent that, on fetal exposure, can alter fetal morphology or subsequent function.
• Teratogens include chemicals, infectious agents, nutritional deficiencies, toxic plants, or physical condition.
• The effects of exposure are not limited to concentration. The timing of exposure during gestation, length of exposure, and concentration of teratogen are all important.
• Teratogenicity depends upon the ability of the agent to cross the placenta.

INCIDENCE/PREVALENCE

• Specific incidence is difficult to determine.
• Occurrence follows seasonal patterns associated with growth characteristics of toxic plants or population dynamics of vectors.

GEOGRAPHIC DISTRIBUTION

Worldwide for some common teratogens. Others are limited to specific regions.

SYSTEMS AFFECTED

• Cardiovascular
• Musculoskeletal
• Nervous
• Ophthalmic
• Reproductive
• Urinary

PATHOPHYSIOLOGY

• The zygote is particularly resilient to the effects of teratogens.
• The embryo is most susceptible to teratogenic agents during periods of rapid differentiation. This susceptibility declines with time, as the embryo becomes more developed. The same trend is seen throughout fetal development (the more developed the fetus, the more resilient it is to the effects of teratogens). While this is generally true, certain structures differentiate relatively late in fetal development. These structures include the cerebellum, palate, and parts of the urinary and reproductive system, which are prone to congenital defects.
• Teratogens affect fetal development by causing abnormal differentiation or specific lesions in developing organs or by limiting fetal development through other mechanisms, such as reduction of motion (e.g., lupine toxicosis).

HISTORICAL FINDINGS

• Increased incidence of pregnancy loss or abortion
• Increased incidence of fetal or neonatal abnormalities
• Stillbirth or neonatal mortality
• History of exposure to teratogen
• Previous occurrence in the herd associated with specific pasture or reproductive management (breeding season).

SIGNALMENT

• Pregnant cows, ewes, and does of any age and breed with a history of exposure to a teratogen.
• Neonates, stillborn or aborted fetuses with developmental abnormalities.

PHYSICAL EXAMINATION FINDINGS

• Physical examination of the dam is often unremarkable.
• Examination of live neonates may show various abnormalities. The most obvious are hydranencephaly, microphthalmia, and arthrogryposis.

GENETICS

Teratogen susceptibility can vary among genotypes within the same species, and possessing certain genes may make the developing animal more susceptible to the effect of a teratogen.

CAUSES AND RISK FACTORS

Nutritional

• Vitamin A deficiency—defects in eye development or harelip.
• Vitamin E/selenium deficiency—white muscle disease in neonates (rarely a cause of abortion), deficiency must be severe to induce white muscle disease in fetus.
• Vitamin D deficiency—neonatal rickets.
• Copper deficiency—dystrophic myelination of spinal cord (enzootic swayback in lambs).
• Iodine deficiency—congenital goiter.

Endocrine

• Polycyclic aromatic hydrocarbons—formed from incomplete combustion of organic material, these compounds have a steric resemblance to steroids. They have been shown to affect serum progesterone (P4), estrogen (E2), prolactin, and luteinizing hormone (LH) and are teratogenic in rats. Livestock are exposed via contaminated water, air, soil, and forages.
• Polychlorinated biphenyls—PCBs are used in hydraulic fluid, plastics, and lubricants. They accumulate in the environment and in fatty tissues and act as synthetic endocrine disruptors with high affinity for estrogen receptors. They may impair normal ovulation and blastocyst implantation. In an experimental rabbit model, PCB exposure induced embryo toxicity and pregnancy loss. Animals may become exposed by ingesting contaminated feed and water.
• Organochlorines (DDT)—chlorinated hydrocarbon used as an insecticide. It can persist for long periods and can be absorbed orally or topically. It is an endocrine disruptor with estrogenic like effects resulting in impaired fertility and pregnancy losses.
• Zearalenone—abnormal fetal development due to estrogenic properties of zearalenone.
• Phytoestrogens—biologically active nonsteroidal plant compounds that are similar in structure to mammalian estrogen and can compete for estrogen receptors. They are found in legumes (alfalfa, soybeans, red clover, subterranean clover, white clover, and alsike clover). Concentrations in plants may increase under cool and wet condition or with stressors such as fungal infection or insect infestation. High concentrations of phytoestrogens can cause cystic ovaries, infertility, and impaired pregnancy maintenance. Also cause decreased lambing rates in ewes due to decreased ovulation rates.
• Bisphenol-A/Bisphenol-S (BPA, BPS)—endocrine disruptor effect results in intrauterine growth restriction, also may negatively affect Leydig cell production of insulin like peptide 3 (INSL3) which is required for testicular descent and therefore may play a role in cryptorchidism.

Drugs

• Acepromazine—fetal CNS depression near term.
• Aminoglycosides—nephrotoxicity in fetus.
• Antifungals—deformation of facial bones, eye, and CNS in cats and rats.
• Atropine—may produce fetal tachycardia.
• Corticosteroids—fetal articular cartilage defects and increased incidence of cleft palate.
• Diazepam—associated with congenital defects in humans, rats, and mice in the first trimester.
• Dimethylsulfoxide (DMSO)—teratogenic in laboratory animals, not advised for use in pregnant animals.
• Sulfonamides—congenital defects reported in rats and mice. Long-acting sulfonamides may antagonize folate (required for neural tube development) and also induce bone marrow suppression.
• Tetracyclines—can induce bone and teeth malformations as well as dental staining in the fetus.

Plants

• *Veratrum californicum* (cyclopamine)—cyclopic malformation in lambs when exposed at day 14 of gestation. Pituitary hypoplasia and prolonged gestation. Embryo death when exposed at days 19–21. Cleft palate when exposed on gestational days 24–30. Metacarpal and metatarsal defects at gestational days 28–31. Ingestion by cows during days 12–30 may cause cleft palate, brachygnathia, syndactyly, decreased number of coccygeal vertebrae.
• *Astragalus* spp. and *Oxytropis* spp. (toxin not identified)—brachygnathia, contracture or overextension of joints, limb rotations, osteoporosis.

TERATOGENS (CONTINUED)

• Lupines (anagyrine and ammodendrine)—maternal ingestion at days 40–70 of gestation results in fetal malformations ("crooked calf syndrome") including arthrogryposis, scoliosis, torticollis, lordosis, kyphosis, or palatoschisis (cleft palate).
• Poison hemlock (*Conium maculatum*; piperidine alkaloids, esp. coniine). Maternal ingestion at days 40–70 of gestation results in fetal malformations including arthrogryposis, scoliosis, torticollis, lordosis, kyphosis, palatoschisis (cleft palate), and excessive flexure of carpal joints.
• Tobacco (*Nicotiana* spp.; piperidine alkaloid, anabasine). Maternal ingestion at 30–60 days of gestation can induce fetal skeletal malformations including arthrogryposis, palatoschisis, torticollis, lordosis, and kyphosis.

Viruses

• Border disease (Pestivirus)—cerebellar hypoplasia, hydrocephalus, hydranencephaly, porencephaly, aberrant hair growth (hair instead of wool) in lambs (may also affect kids).
• Akabane virus (Bunyaviridae)—causes fetal malformations in cattle, sheep, and goats. Arthrogryposis, hydranencephaly, porencephaly, hydrocephalus, cerebellar hypoplasia.
• Schmallenberg virus (Orthobunyavirus)—teratogenic effects in cattle, sheep, and goats include scoliosis, hydrocephalus, arthrogryposis, cerebellar hypoplasia, and an enlarged thymus.
• Bovine viral diarrhea virus—midgestation infections (3–6 months) can cause congenital defects including microophthalmia, microencephaly, brachygnathia, cerebellar hypoplasia, hydranencephaly, hydrocephalus, thymic hypoplasia, cataracts, retinal dysplasia, and optic neuritis.
• Bluetongue virus (Orbivirus)—most severe in sheep but affects many wild and domestic ruminants. Exposure at 40–60 days of gestation usually results in abortion but may see hydranencephaly and retinal dysplasia if fetus survives. Infection at 60–100 days of gestation, exposure results in porencephaly.
• Cache Valley virus (Bunyavirus)—mostly affects sheep. Arthrogryposis, scoliosis, torticollis, hypoplastic musculature, hydranencephaly, hydrocephalus, porencephaly, microencephaly, cerebellar and cerebral hypoplasia.
• Wesselbron virus (Flavivirus)—affects sheep and goats. Neurotropic virus causing necrosis of fetal CNS. Segmental aplasia of spinal cord, hydranencephaly, hydrocephalus, porencephaly, cerebellar hypoplasia, arthrogryposis, brachygnathia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Numerous causes and risk factors (see "Causes and Risk Factors") can result in similar developmental malformations. Differential diagnosis is established by epidemiologic, laboratory investigation.

CBC/BIOCHEMISTRY/URINALYSIS
May be indicated in the dam depending on teratogen exposure.

OTHER LABORATORY TESTS
• Virus isolation (dam), precolostral serology in neonates
• Feed/Water analysis
• Liver biopsy for toxins

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Clinical signs, history of exposure/ingestion, finding evidence of exposure/ingestion can be key to diagnosis.
• Epidemiologic data and records analysis.

PATHOLOGIC FINDINGS
Developmental malformations associated with the causes and risk factors can be seen and evaluated on necropsy.

TREATMENT

THERAPEUTIC APPROACH
Live affected neonates with severe abnormalities should be humanely euthanized.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE

CONTRAINDICATIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Most cases are discovered after the fact (abortion or birth of fetuses with multiple defects).
• Some infectious causes may require culling of animals that may become potentially shedders.
• If multiple animals are affected, a proper investigation protocol, involving several specialists and laboratory backup, should be set.
• Some infectious diseases are notifiable.

POSSIBLE COMPLICATIONS
• Severe fetal abnormalities may result in abortion or dystocia.
• Developmental malformations/birth defects may result in death or poor quality of life.

CLIENT EDUCATION
• Report abnormalities, stillbirths, and abortions to attending veterinarians.
• Recognize the major regional toxic plants and monitor pastures.

PATIENT CARE
• Remove from source of toxin.
• Neonates with severe developmental abnormalities may need to be euthanized.

PREVENTION
• Limit exposure to teratogens during pregnancy.
• Appropriate adjustment of nutrition to address deficiencies.
• Pasture management or modification of the breeding season to avoid exposure at critical times of pregnancy in cases of toxic plants.
• Biosecurity and preventive measures for infectious causes.

TESTICULAR DISORDERS: BOVINE

BASICS

OVERVIEW

• Diseases of the bovine testis are often devastating in terms of future reproductive performance but only rarely do they affect the general health of a bull.
• Testicular disorders can be of congenital, inflammatory, or degenerative nature.
• The most common inflammatory disorders are orchitis and epididymitis. These are discussed in detail in a separate chapter, Orchitis and Epididymitis. The focus here is on a more general approach to diagnosis and treatment of testicular disorders in the bull.

INCIDENCE/PREVALENCE

• Studies on the incidence of various testicular disorders are scarce.
• Congenital testicular defects are relatively rare, probably because of the selection pressure through breeding soundness examination (BSE).
• Reported incidence of cryptorchidism is 0.17% with majority (69%) being left-sided.
• Testicular degeneration and small testicular size are common reasons for classification of bulls as unsatisfactory breeders.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

Congenital Disorders

• Cryptorchidism is the most common congenital testicular disorder of domestic animals. Fortunately, it is relatively uncommon in bulls, probably as the result of aggressive selection for normal testicular descent. Although considered hereditary, the mode of inheritance in cattle has not been established adequately.
• Monorchism and polyorchism are rarely seen.
• Hypoplasia of the testis is rare in ruminants and a hereditary predisposition is suspected in most cases.
• While not associated with clinical disease, the appendix epididymis (mesonephric duct remnant) is a vestigial structure present near the head of the epididymis. The appendix epididymis may become cystic and can be detected by ultrasonography or palpation as it enlarges. It is an incidental finding.

Acquired Disorders

• Acquired diseases of the testes can be classified using the traditional DAMNIT system.
• Testicular degeneration is common in bulls. The specific etiology is rarely apparent in clinical cases, likely due to the lag between insult and testis response. Among the conditions known to cause degenerative lesions are heat, toxins, nutritional disorders, obstructive lesions, and ischemia. The initial lesion is a reduction in germ cells number followed by spermiostasis and calcification of the straight tubules near the rete testis. The end stage is characterized by fibrosis and absence of any germinal cells.
• Autoimmune disorders are not commonly reported in ruminants though the bull is capable of producing antisperm antibodies. The true significance of this disorder awaits a reliable commercial test for antisperm antibodies in serum and seminal plasma.
• Neoplastic disorders of the testis are uncommon in bulls. Interstitial cell tumors, seminomas, and sustentacular (Sertoli) cell tumors are the primary testis tumors. Secondary tumors include lymphoma and mesothelioma and are extremely rare.
• Infectious and inflammatory conditions elsewhere (see chapter, Orchitis and Epididymitis).
• Trauma to the testes often results from fighting or crushing injuries from other bulls. Bulls may spontaneously recover from minor trauma but massive trauma can rupture the tunics and result in large hematomas. Bulls seldom recover from this level of insult and the danger exists that scrotal inflammation and antibody production will compromise sperm production in the undamaged testis.
• Inguinal hernia may occur spontaneously or immediately after mating. Congenital inguinal hernia may be hereditary. Excessive fat deposition in the vaginal tunics during puberty has been associated with acquired inguinal hernia. The size of the vaginal ring also seems to be a predisposing factor.

HISTORICAL FINDINGS

• Most testicular abnormalities will be discovered at the time of castration for calves or during BSE.
• Breeding bulls may present with sudden or progressive enlargement of the scrotum or a history of infertility.

SIGNALMENT

• Congenital abnormalities are usually seen in calves at the time of castration or young virgin bulls presenting for BSE.
• Acquired abnormalities are seen in mature breeding bulls.

PHYSICAL EXAMINATION FINDINGS

• Signs vary with the specific disease condition but infertility or subfertility are common findings.
• Most testicular abnormalities are not accompanied by systemic signs of illness except for the case of severe trauma (testicular hemorrhage), inflammatory disorders (epididymitis and orchitis), and possibly incarcerated hernias.

GENETICS

• Sex chromosome aneuploidy and chimerism (degeneration).
• Genetic (hypoplasia).
• Polled Herefords and Shorthorns have reportedly higher incidence of cryptorchidism.

CAUSES AND RISK FACTORS

• Group housing of bulls predisposes them to traumatic injuries.
• Nutrition: Obesity is considered to be one of the leading causes of testicular degeneration in bulls.
• Other systemic diseases.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Diagnosis of testicular disorders requires a thorough history and physical examination.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• Serum hormone concentrations
• Scrotal palpation and measurement
• Microbial culture of the ejaculate
• Testicular biopsy (histopathologic assessment)
• BSE (semen collection and evaluation)

IMAGING

• Ultrasonographic evaluation of the scrotum is an essential diagnostic procedure for assessing testicular disorders in valuable bulls.
• Abnormalities that can be detected by ultrasonography because of variation in echotexture of the parenchyma include calcification, fibrosis, rete testis dilation, and nodules. Cystic dilation of the epididymis may be visualized in cases of segmental aplasia.

OTHER DIAGNOSTIC PROCEDURES

• Transrectal palpation may be helpful in the diagnosis of some pathologies (e.g., inguinal hernia).
• Laparoscopy or laparotomy may be considered for valuable animals.

PATHOLOGIC FINDINGS

• Cryptorchidism: The testis may be retained in the inguinal canal or abdominal cavity. It is generally smaller than the descended testis and has no spermatogenic activity.
• Testicular hypoplasia: Testis is smaller than normal. Histologically, the seminiferous tubules are small, round with no lumen and no spermatogenic activity.
• Testicular degeneration: The testes are usually smaller than normal. Fibrosis and calcification may be evident on the cut surface of the parenchyma. Histologically, the seminiferous tubules present various degrees of vacuolization and collapse.

(CONTINUED) TESTICULAR DISORDERS: BOVINE

TREATMENT

THERAPEUTIC APPROACH
Treatment for testicular disorders is often unrewarding.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Hemicastration with parenteral antibiotic and NSAID therapy may improve the prognosis for bulls with severe, unilateral disease.
• Hemicastration should only be considered if the condition is acquired or if the bull is to be used in a terminal cross.

TESTICULAR DISORDERS: CAMELID

BASICS

OVERVIEW

• Testicular disorders are the most common cause of subfertility in camelids.
• Testicular disorders can be categorized into congenital and acquired conditions.
• Congenital disorders warrant elimination of the male from breeding due to their possible hereditary nature and association with poor fertility in daughters.
• Breeding males with acquired unilateral testicular disorders are often managed by unilateral castration.
• Testicular degeneration is the most common acquired disorder resulting in reduced or loss of fertility.

INCIDENCE/PREVALENCE

• Examination of 3,015 alpacas showed the following incidence of various congenital abnormalities
  ◦ Testicular hypoplasia: 9.9% (5.9% bilateral)
  ◦ Cryptorchidism: 5.7% (3.5% unilateral left)
  ◦ Ectopic testes: 2.5% (1.7 unilateral left)
• In camels, there are very few clinical observations on incidence of testicular disorders. Orchitis and testicular degeneration seem to be the most common.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• Congenital testicular disorders in camelids include:
  ◦ Cryptorchidism: Normal testicular descent in camelids occurs late in fetal life. Camelids are born with descended testes in the scrotum. Cryptorchidism is suspected to be hereditary. Unilaterally affected males are fertile if the descended testis is normal. Monorchism is possible but rare. Monorchism has been associated with unilateral renal agenesis in alpacas.
  ◦ Testicular hypoplasia is common in SAC. It is characterized by small, hard testes, poor or lack of development of the seminiferous tubules, and reduced or absent spermatogenesis. Affected males have normal libido but various degrees of infertility due to reduced sperm production and quality.
  ◦ Rete testis cysts are commonly found in SAC. They are believed to be due to tubili recti occlusion. Their effect on fertility depends on their size.
  ◦ Epididymal cysts are due to epididymal segmental aplasia and can result in total sterility if bilateral.
  ◦ Ectopic testicles refers to an abnormal location of the testis. The testis is usually located in the abdominal region lateral to the prepuce or in the medial surface of the hind leg in the femoral canal or crural canal. Because of abnormal thermoregulation, ectopic testes are devoid of any spermatogenic activity.
  ◦ The left testis is more often affected than the right.
• Acquired testicular disorders are suspected due to sudden or progressive change in testicular size or subfertility.
  ◦ Decreased testicular size is generally due to testicular degeneration or atrophy which may be the result of a direct insult to the testis, aging, nutritional deficiencies, or heat stress. Use of testosterone or anabolic steroids (racing camels) downregulates the hypothalamo-pituitary axis resulting in testicular degeneration.
  ◦ Increased scrotal or testicular size may be due to:
    ▪ Hydrocele: The accumulation of fluid in the vaginal cavity and results from heat stress and circulatory disorders. It is rarely a cause of infertility but may contribute over time to testicular degenerative changes.
    ▪ Orchitis and epididymitis: Often result from hematogenous bacteremia. The most common isolates are *Brucella* spp. and *Streptococcus zooepidemicus*. Other bacteria may be introduced directly by puncture wounds or trauma.
    ▪ Testicular hemorrhage: Often the result of biting wounds sustained during a fight with another male.
    ▪ Testicular neoplasia: Seminoma is the most common.
• Infertility is due to poor sperm production, poor motility, and increased sperm abnormalities resulting from loss of seminiferous tubules or epididymal function. The degree of infertility varies depending on whether the condition is unilateral or bilateral and the amount of tissue affected.

HISTORICAL FINDINGS

• Poor libido or infertility.
• Observed increase or decrease in testicular size. In SAC, this is often noticed at the time of shearing.
• Inflammatory or traumatic disorders may be noticed as reluctance to breed or abnormal gait.

SIGNALMENT

• Young animal presented for BSE.
• Adult breeding males with observed external abnormalities or poor fertility.

PHYSICAL EXAMINATION FINDINGS

• Usually normal except for the observed changes in behavior and size of the scrotum.
• Testicular trauma may present as an emergency due to swelling and lameness.

GENETICS

Cryptorchidism and testicular hypoplasia are suspected to be hereditary.

CAUSES AND RISK FACTORS

• Genetics for congenital disorders
• Testicular degeneration: Poor nutrition, heat stress, systemic disease, administration of androgens
• Orchitis, epididymitis: *Brucella abortus*, *Brucella melitensis*

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Differential diagnosis between congenital and acquired testicular disorders is very important from legal and ethical perspectives.
• Reproductive history and prior BSE results are important.
• Testicular ultrasonography and biopsy should be considered in order to refine the diagnosis.

CBC/BIOCHEMISTRY/URINALYSIS

• May be indicated in cases of suspected orchitis and epididymitis.
• Indicated before unilateral castration.

OTHER LABORATORY TESTS

• Testing for brucellosis
• Bacteriology of aspirated fluid from the testis
• Semen collection and evaluation

IMAGING

Testicular ultrasonography: Testicular degeneration and fibrosis is characterized by increased echogenicity of the parenchyma. Rete testis cysts are visualized as an anechoic area of variable size in the mediastinum testis. This modality allows differentiation between traumatic lesions, abscesses, and neoplasia.

OTHER DIAGNOSTIC PROCEDURES

Testicular biopsy under heavy sedation using one of the following techniques:
• Wedge incisional or open biopsy: The scrotum is prepared for surgery. A 0.5 cm incision is made through the skin, parietal vaginal tunic, and the exposed tunica albuginea, avoiding vascular areas. Testicular tissue that protrudes from the rent in the tunica albuginea is ablated with a scalpel blade. The tunica albuginea, parietal vaginal tunic, and the scrotal skin are closed with absorbable suture.
• Trucut (self-firing needle): The scrotal skin is blocked with lidocaine. A 4 mm stab incision is made through the skin and vaginal tunic after surgical preparation. A 14–18 gauge self-firing biopsy needle is inserted through the tunica albuginea.
• "Core" biopsy. After surgical preparation of the scrotal skin, a 1 and $\frac{1}{2}$ inch 16 gauge needle is introduced into the testicular parenchyma and redirected by a gentle push-pull movement into two sites. The needle is retracted from the tissue while a finder is placed over the hub to maintain the core sampled. A direct smear is prepared from the sample obtained.

• Fine-needle aspirate: Testicular tissue is aspirated with a 20 gauge needle and 12 mL syringe, making sure not to include the epididymis. Cytologic smears stained with DiffQuik® are interpreted based on the different types of spermatogenic cells.

PATHOLOGIC FINDINGS

• Gross and histologic evaluation of the testis after castration confirm the diagnosis.
• Testicular hypoplasia: Small diameter seminiferous tubules without evidence of spermatogenesis.
• Seminiferous tubules are evaluated for spermatogenic activity and presence of degenerative changes (vacuolization, loss of architecture). Inflammatory and neoplastic changes can be evaluated more thoroughly. Atypical spermatogenic cells are associated with testicular neoplasia.

TREATMENT

THERAPEUTIC APPROACH

Males with traumatic or inflammatory injuries should be managed to reduce risk of infection and decrease inflammation.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• Males with congenital and possibly hereditary testicular disorders should be castrated.
• Unilateral castration is recommended for all unilateral acquired conditions, particularly if the interstitial tissue of the affected tests is still functional.

MEDICATIONS

DRUGS OF CHOICE

• Xylazine and ketamine for anesthesia
• Anti-inflammatories: Flunixin meglumine
• Antibiotherapy: Procaine penicillin G, 22,000 IU/kg body weight for 5 days) is recommended postoperatively.

CONTRAINDICATIONS

Appropriate meat withdrawal times should be followed for all compounds administered to food-producing animals.

PRECAUTIONS

N/A

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Semen collection and evaluation should be performed 60 days following unilateral castration.
• Frequency of use of the male should be adjusted based on sperm production ability.

POSSIBLE COMPLICATIONS

• Infection and adhesions are possible after trauma.
• Inflammation may affect spermatogenic activity of the remaining testicle.

CLIENT EDUCATION

• Proper housing and management of breeding males to avoid accidents.
• Maintain proper breeding records.
• Maintain a good herd health preventive program.
• Regular examination of the external genitalia.

PATIENT CARE

• Sexual rest for 4 weeks
• Antibiotic and anti-inflammatory therapy as indicated

TESTICULAR DISORDERS: SMALL RUMINANT

BASICS

OVERVIEW
Common testicular abnormalities in small ruminants include hypoplasia/testicular degeneration, varicocele, orchitis, epididymitis, sperm granulomas, and cryptorchidism.

INCIDENCE/PREVALENCE
• Cryptorchidism is more common in bucks compared to other ruminants. This condition has an increased incidence in intersex goats.
• The incidence of cryptorchidism depends on selection pressure against the trait. It has been reported as having a 2% incidence in commercial herds, but having a higher incidence in intersex goats.
• Varicocele occurs sporadically in rams.
• Testicular degeneration is associated with other testicular disorders. This can also occur as a result of heat stress and systemic illness (fever).
• Orchitis/epididymitis is more common in rams than in bucks.

GEOGRAPHIC DISTRIBUTION
Worldwide

PATHOPHYSIOLOGY
• Several processes can affect testicular function. Bilateral affection usually results in infertility or sterility.
• Congenital disorders:
  ◦ Cryptorchidism is a failure of one or both testicles to descend into the scrotum.
  ◦ Testicular hypoplasia is caused as a result of a genetic abnormality. It is commonly seen in intersex goats and with chromosomal abnormalities in rams.
  ◦ Sperm granulomas are localized swellings that occur as a result of spermatozoa exposure outside of the immune-privileged tubular duct system of the male reproductive tract. This is caused by misaligned or blind-ended efferent ducts that normally drain into the caput epididymis.
  ◦ Inguinal hernia.
• Infectious processes:
  ◦ Orchitis is caused by trauma or an extension of infection from the epididymis.
  ◦ Epididymitis is a common finding in rams: In older rams, contagious epididymitis due to *Brucella ovis* is common is some regions. In ram lambs several bacterial pathogens (*Histophilus*, *Actinobacillus*, and *Haemophilus*) have been incriminated.
• Degenerative processes:
  ◦ Testicular degeneration may be due to nutritional deficiencies, poor health, or age.
  ◦ Varicocele is a localized swelling and thrombosis of the pampiniform plexus in the spermatic cord. This condition is more common in rams.
• Neoplastic processes: Testicular neoplasms are rare but seminoma has been reported.
• Trauma and accident: Testicular hemorrhage and scrotal herniation are the most common traumatic injuries.

SYSTEMS AFFECTED
Reproductive

HISTORICAL FINDINGS
• Infertility
• Abnormal appearance of the scrotum
• Sudden increase in scrotal size

GENETICS
Conditions that are considered heritable include cryptorchidism, varicoceles, and granuloma/epididymal aplasia.

SIGNALMENT
• Congenital disorders: Young rams and bucks around the time of puberty or at the first breeding soundness examination.
• Acquired disorders: Incidental findings at BSE or specific complaints in older rams. Testicular degeneration is typically discovered in older animals or following severe systemic disease, poor health and nutrition.
• Sperm granulomas were discovered in males >1 year of age.

PHYSICAL EXAMINATION FINDINGS
• Testicular hypoplasia: Smaller than normal testis. Usually hard on palpation. It can be difficult to assess out of the breeding season.
• Testicular degeneration: Testis is more elongated and the parenchyma can palpate either harder or softer versus the normal. Calcification of testicular parenchyma may be present and affect semen quality.
• Varicocele: The spermatic cord palpates as a fluctuant swelling. It is common for rams to display an abnormal rear limb posture with this condition.
• Orchitis: One or both testicles show significant enlargement and increased temperature. Pain may be elicited on palpation of the affected testicle(s). Systemic illness may result in some severe cases. Libido may be decreased.
• Epididymitis: Characteristic swelling and fibrosis of the epididymis. This condition can lead to the formation of sperm granulomas if the integrity of the epididymis is compromised and haploid cells exit from the immunologically privileged environment.
• Cryptorchidism will be evident on inspection and palpation of the scrotum. It can be unilateral or bilateral. Affected animals have normal masculine characteristics and behaviors. Bilateral cases are azoospermic while unilaterally affected animals are fertile.
• Sperm granulomas: Presence of a localized swelling and inflammation of the epididymis. This condition is most commonly found at the caput epididymis.

CAUSES AND RISK FACTORS
• Testicular hypoplasia is a genetic abnormality that is considered heritable.
• Testicular degeneration can be due to aging or a sequela to many other factors such as extremes in environmental temperatures, scrotal insulation from fat, systemic disease, malnutrition, and parasitism. Blockage of the excurrent duct system can also lead to degeneration.
• Varicocele has an unknown etiology in small ruminants, but some authors suspect a genetic cause.
• Orchitis/epididymitis is an infectious process.
  ◦ Virgin ram lamb epididymitis is caused by several organisms such as *Histophilus*, *Actinobacillus*, *Haemophilus* spp. and occasionally *Corynebacterium pseudotuberculosis*. It is common to diagnosis this condition in young rams that are housed together.
  ◦ Mature ram epididymitis and orchitis are due to *B. ovis* infection. Other bacterial infections are also possible.
  ◦ *B. melitensis* infection in goats.
• Sperm granulomas are caused by a blockage in the excurrent duct system.
• Cryptorchidism is likely a heritable defect.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• An inflamed or enlarged scrotum could be orchitis/epididymitis, hydrocele, hematocele, varicocele, sperm granulomas, inguinal herniation, or neoplasia.
• An abnormally small scrotum or testicle could be testicular hypoplasia or testicular degeneration.
• The absence of one or both testicles in the scrotum could be cryptorchidism or a previous castration.

CBC/BIOCHEMISTRY/URINALYSIS
• An inflammatory leukogram in severe cases of epididymitis/orchitis.
• Leukocytes may be discovered on urinalysis.

OTHER LABORATORY TESTS
• Spermiogram
  ◦ Poor motility and morphology due to abnormal thermoregulation (hydrocele, hematocele, varicocele).
  ◦ Decreased concentration and increased sperm abnormalities in cases of testicular degeneration or testicular hypoplasia.
  ◦ Increased abnormalities and presence of numerous polymorphonuclear neutrophils.
• Culture of semen or urine if ram lamb epididymitis and mature ram epididymitis is suspected.

IMAGING
• Ultrasonography is useful in diagnosing abnormalities in the testicle, epididymis, and spermatic cord.
  ◦ Atrophy, inflammatory and degenerative changes results in a heterogeneous

T

appearance of testicular parenchyma. Comets tails are seen in the parenchyma in case of calcification.
◦ Increased fluid content in the vaginal cavity suggests presence of hydrocele (anechoic), pyocele or hematocele (echogenic). Strands of fibrin and adhesions may also be visualized.
◦ Presence of intestinal loop within the scrotum confirms inguinal/scrotal hernia.
◦ Transabdominal ultrasound may be useful in locating the retained testicle(s).
• Thermography can be useful in diagnosis of problems in the testicle.

OTHER DIAGNOSTIC PROCEDURES
Serologic testing and bacterial culture of semen for infectious causes of epididymitis and orchitis in rams.

PATHOLOGIC FINDINGS
• Testicular hypoplasia and testicular degeneration are characterized histologically by seminiferous tubules lined by one layer of cells with lack of spermatogenic activity. In testicular hypoplasia, the tubules are small, round and often devoid of a lumen.
• Necrosis, edema, and infiltration of inflammatory cells are characteristic of orchitis.
• Varying degrees of fibrosis may be present between seminiferous tubules.

TREATMENT

THERAPETUTIC APPROACH
N/A

SURGICAL CONSIDERATIONS AND TECHNIQUES
Unilateral castration may be considered in unilateral acquired noncontagious conditions for valuable males.

MEDICATIONS

DRUGS OF CHOICE
Culture and sensitivity results from seminal fluid are the basis for antibiotic treatment of infectious causes of testicular disease in small ruminants.

CONTRAINDICATIONS
Meat withdrawal times must be followed.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Antibiotic therapy is often unrewarding in cases of epididymitis/orchitis.
• Hemicastration of affected testicles can result in near normal semen production in the contralateral testicle if there is not damage to the germinal epithelium. Prognosis for return to breeding soundness is guarded.
• Treatment of testicular degeneration is unrewarding and the prognosis is poor.
• All males with congenital abnormalities should be culled.

POSSIBLE COMPLICATIONS
• Infertility
• Death (inguinal herniation)

CLIENT EDUCATION
• All males should undergo BSE.
• Testicular hypoplasia and cryptorchidism are considered heritable conditions. Affected animals should be culled from breeding.
• Valuable males should be submitted for semen cryopreservation.

PATIENT CARE
Animals should be submitted for BSE to determine response to treatment or to monitor the progression of testicular degeneration.

PREVENTION
• Biosecurity measures and serologic testing for *Brucella ovis.*
• Ram/buck management should include an adequate nutritional, parasite control, and vaccination program.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Testicular degeneration is common in old males.

ZOONOTIC POTENTIAL
B. melitensis

PREGNANCY
Brucellosis results in poor pregnancy rates, abortions, stillbirths, and weak lambs.

BIOSECURITY
• Surveillance and strict isolation protocols for new additions to the herd or flock.
• Testing of outside males.
• A diagnosis of brucellosis should be reported to the state veterinary office.

PRODUCTION MANAGEMENT
Regular BSE on all breeding animals

SYNONYMS
N/A

ABBREVIATION
BSE = breeding soundness examination

SEE ALSO
• Breeding Soundness Examination: Small Ruminant
• Brucellosis

THELAZIASIS

BASICS

OVERVIEW
• Ophthalmic infection by the nematode *Thelazia* spp. eyeworms. • Species include *T. gulosa, T. skrjabini,* and *T. rhodesii.* • Additional species can also infect sheep, goats, deer, buffalo, and dromedaries.

INCIDENCE/PREVALENCE
Varies with geographic location and may be decreasing due to extensive use of macrocyclic lactone endectocides in cattle. Prevalence decreased in England from 41.9% in 1978 to 1.5% in 2005.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Ophthalmic

PATHOPHYSIOLOGY
• *Thelazia* spp. of ruminants requires muscid flies as intermediate hosts; the genus *Musca* is the most important vector in North America. • Adult *Thelazia* live in the lacrimal ducts of the nictitating membrane, in the conjunctival sacs, or under the eyelids and nictitating membranes. Females pass first-stage larvae into ocular secretions where they are ingested by flies during feeding. These develop into infective third-stage larvae in 9–49 days and are deposited on the eye of the host as the fly feeds. • The prepatent period is 2–6 weeks, which is species dependent. • Lesions are caused by the serrated cuticle of the parasite; most lesions are associated with the movement of the active young adults. • Mechanical irritation and inflammation can lead to conjunctivitis, blepharitis, keratitis, and other corneal damage. Inflammation of lacrimal glands/ducts leads to reduced tear production. • Asymptomatic infections may also occur.

HISTORICAL FINDINGS
Asymptomatic to chronic conjunctivitis and keratitis

SIGNALMENT
• *T. rhodesii*: Cattle, buffalo, goats, sheep, and deer in North America, Europe, Africa, Middle East, Asia • *T. gulosa* and *T. skrjabini:* cattle in North America, Europe

PHYSICAL EXAMINATION FINDINGS
• Quite variable, from asymptomatic incidental finding to severe signs. • Conjunctivitis, epiphora, blepharitis, and photophobia. • Keratitis possibly with ulceration, perforation, or scarring. • Visible worms on surface of eye, under eyelids or nictitating membranes.

GENETICS
N/A

CAUSES AND RISK FACTORS
Cause: *Thelazia* spp. infection

Risk factors: Presence of face flies in an endemic area

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Chronic bacterial conjunctivitis • Viral conjunctivitis/keratitis • Corneal laceration • Foreign body

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Gross examination of conjunctival sacs and underlying nictitating membranes. Topical anesthesia may be necessary to aid the manipulation of the third eyelid. • Microscopic examination of lacrimal fluids for larvae.

PATHOLOGIC FINDINGS
May see the parasite emerging from the conjunctival sac or deposited on the skin/hair around the eye of moribund species.

TREATMENT

THERAPEUTIC APPROACH
Administration of an effective anthelmintic has replaced manual removal under local anesthetic.

MEDICATIONS

DRUGS OF CHOICE
• Ivermectin or doramectin at 200 µg/kg body weight given subcutaneously can be 99–100% effective for *T. rhodesii* in cattle. • Levamisole at 5 mg/kg given subcutaneously or administered as a 1% topical aqueous solution is also effective but off-label.

CONTRAINDICATIONS
Do not treat lactating animals producing milk for human consumption with ivermectin or doramectin.

PRECAUTIONS
Appropriate meat and milk withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Full recovery in about 2 months although long-term persistence of areas of corneal opacity may occur.

POSSIBLE COMPLICATIONS
Scarring of cornea or loss of eye secondary to perforation of cornea is possible in rare severe cases.

CLIENT EDUCATION
N/A

PATIENT CARE
N/A

PREVENTION
• Control of face flies. • Dry, open pastures and less intensely confined conditions help reduce fly numbers.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Corneal ulceration. • Mechanical irritation and inflammation can lead to lesions involving the lacrimal glands and ducts, conjunctivitis, blepharitis, keratitis, and other corneal damage.

ZOONOTIC POTENTIAL
Reports of other species (*T. californiensis, T. callipaeda*) in humans.

PRODUCTION MANAGEMENT
• Control of face flies. • Dry, open pastures and less intensely confined conditions help reduce fly numbers.

SYNONYM
N/A

ABBREVIATIONS
N/A

TICK PARALYSIS

BASICS

OVERVIEW
• A lower motor neuron (LMN) paralysis resulting from the bite of female ticks of species including *Dermacentor* spp. and *Amblyomma* spp. in the United States and *Ixodes holocyclus* in Australia.
• The potential for inducing paralysis has been suspected in 64 species of tick belonging to the *Ixodid* and *Argasid* genera.
• The tick injects a neurotoxin that causes progressive motor paralysis, respiratory depression, and death in animals that have no immunity to the toxin.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
• Common in Australia, human and animal cases reported throughout the US (particularly in the Rocky Mountains and Pacific Northwest), and worldwide.
• Distribution patterns reflecting tick populations.
• Exposure to environments favorable to tick infestations such as brushy, woody areas.

SYSTEMS AFFECTED
• Nervous
• Digestive
• Respiratory
• Cardiovascular
• Hemolymphatic
• Musculoskeletal

PATHOPHYSIOLOGY
• Exact pathology is not certain. Signs are caused by a protein neurotoxin possibly produced by the tick itself, by a microbial organism associated with the tick, or by a toxic metabolite resulting from the interaction of tick saliva with host tissue.
• There is a reduction of acetylcholine release and a resulting blockage of neurotransmission at neuromuscular junctions.
• Interference with presynaptic nerve terminal depolarization and acetylcholine release produces a neuromuscular blockade. This manifests primarily as an ascending flaccid paralysis varying from paraparesis to quadriplegia.

HISTORICAL FINDINGS
The owner is not usually aware of the presence of a tick and animals usually present with weakness and ataxia.

SIGNALMENT
• Sheep, goats, cattle.
• Other species such as dogs may be affected.
• All ages potentially are at risk, and both sexes are equally affected.

PHYSICAL EXAMINATION FINDINGS
• Initially, ataxia and weakness in hindlimbs.
• Progression to paralysis of hindlimbs then ascending, symmetrical, flaccid tetraplegia.
• Afebrile.
• Hyporeflexia of the superficial and deep tendons.
• Nystagmus.
• Dyspnea, dysphagia, inability to regurgitate cud normally, weak facial muscles.
• Flaccid tail and anus.
• Disease may progress further and cause respiratory muscle paralysis resulting in death.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Exposure to environments favorable to tick infestations such as brushy, woody areas.
• Seasonal incidence may change in geographic regions where tick populations vary based on ambient temperatures.
• Antitoxic immunity can occur 2 weeks after primary tick exposure and lasts a few weeks. Immunity may be boosted in subsequent infestations.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Botulism
• Acute polyradiculoneuritis
• Spinal cord compression
In early stages:
• Rabies
• Trauma
• Myelopathy
• Metabolic disorders
• *Parelaphostrongylus tenuis* migration

CBC/BIOCHEMISTRY/URINALYSIS
• Results are usually normal.
• Mild metabolic acidosis and dehydration develop. Other changes include increases in blood glucose and cholesterol, and a decrease in blood potassium.
• Increased serum levels of creatine kinase (CK) in tick paralysis caused by *D. andersoni* and *I. holocyclus.*
• Phosphate levels increased in later stages of paralysis caused by *I. holocyclus.*

OTHER LABORATORY TESTS
CSF is normal.

IMAGING
May be useful to rule out other causes of paralysis or to examine degree of lung compromise (e.g., pulmonary edema, aspiration) secondary to respiratory paralysis.

OTHER DIAGNOSTIC PROCEDURES
Examination for the presence of ticks or tick craters on affected animals.

PATHOLOGIC FINDINGS
None specific to the disease, death occurs due to respiratory paralysis.

TREATMENT

THERAPEUTIC APPROACH
• Timely removal of attached ticks, either manually or by using a suitable acaricide. It may be necessary to shave long-haired animals to effectively locate all ticks.
• A canine-derived *Ixodes holocyclus* antivenom (hyperimmune serum) is available in Australia and has been used in lambs and kids. The intravenous route is recommended at a dose of 1 mL/kg body weight. Anaphylactic reactions are possible and treated animals should be monitored closely.
• Supportive therapy—monitor for respiratory paralysis and hypoxia.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Acaricidal dips
• Antivenom

CONTRAINDICATIONS
Steroids should not be used in pregnant animals.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Incubation period is usually 5–7 days.
• Depending on the species of tick involved, prognosis is good to excellent if ticks are removed promptly. Recovery usually occurs within 1–3 days.
• Animals infested with *Ixodes holocyclus* (Australian paralysis tick) may continue to worsen despite removal of all ticks and frequently die within 1–2 days without treatment.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
Educate clients on tick prevention strategies and proper removal technique for ticks.

PATIENT CARE
Significant nursing care is required for recumbent animals.

PREVENTION
• Ectoparasite sprays or dips to kill ticks on the animals.

TICK PARALYSIS (CONTINUED)

• Environmental control to reduce tick populations is recommended.
• Cattle and sheep have been shown to develop antibodies to *Dermacentor* and were not susceptible to paralysis after active or passive immunization to tick-specific antigens.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
N/A

ZOONOTIC POTENTIAL
The same ticks can cause tick paralysis in humans. Animals with the disease cannot transmit the disease to humans.

TOBACCO TOXICOSIS

BASICS

OVERVIEW
Definition: Intoxication and/or adverse consequences after ingestion of plants of the genus *Nicotiana.* They are members of the nightshade family, Solanaceae.

INCIDENCE/PREVALENCE
• Varies with geographic location • *N. tabacum*—cultivated tobacco • *N. trygonphylla*—wild or desert tobacco in the dry areas of southwest United States • *N. attenuata*—wild or coyote tobacco also in the dry areas of southwest US • *N. glauca*—tree tobacco, an evergreen shrub of low elevation areas of Arizona and California

GEOGRAPHIC DISTRIBUTION
Worldwide; southwestern US and anywhere tobacco is cultivated

SYSTEMS AFFECTED
• Digestive • Musculoskeletal • Nervous • Reproductive

PATHOPHYSIOLOGY
• Two primary toxic compounds are responsible for the adverse effects of tobacco ingestion—nicotine and anabasine.
• Nicotine—a potent pyridine alkaloid has poor palatability, but animals will eat it if forage is scarce. It can cause a direct contact irritation to gastrointestinal mucosa. Pharmacologically, it mimics acetylcholine at the autonomic ganglia and myoneural junction acting as a neuromuscular blocking agent. • Anabasine—a piperidine-pyridine alkaloid, a teratogen.

HISTORICAL FINDINGS
Access to *Nicotiana* spp. where forage is poor, pasturing on land where tobacco is cultivated, and ingestion of tobacco products or tobacco-tainted water.

SIGNALMENT
• Potentially any animal can be affected.
• Among domestic ruminants, cattle, sheep, and goats have had documented cases.

PHYSICAL EXAMINATION FINDINGS
Neurologic Symptoms
Salivation, vomiting, diarrhea, excitement, increased respiratory rate, twitching, trembling, stiff and uncoordinated gait leading to respiratory paralysis, weakness, bloat, blindness, collapse, and death.

Teratogenic Effects
Calves exhibit arthrogryposis of the forelimbs and spondylosis identical to that seen in lupine toxicity. In sheep, carpal flexure and cleft palate can be seen.

DIAGNOSIS
History of potential exposure to *Nicotiana* spp. and compatible clinical signs.

DIFFERENTIAL DIAGNOSES
• Other toxic plant causes of sudden death—blue-green algae, cyanogenic plants, death camas, larkspur, laurels, lupine, milkweed, oleander, water hemlock. • Other teratogenic causes should be investigated such as bluebonnet, locoweed, and poison hemlock.

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic changes

OTHER LABORATORY TESTS
As an aid to diagnosis, urine or tissues may be analyzed for alkaloid content using GC-MS.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• In cases of sudden death, no specific lesions may be seen, except the finding of *Nicotiana* spp. in the digestive tract. • Pale mucus membranes, poorly oxygenated blood, myocardial hemorrhage, pulmonary hemorrhages, cerebral congestion, and foam in the trachea are occasionally seen but there are no distinctive pathologic changes.
• Teratogenic lesions in calves or lambs as listed above might be seen.

TREATMENT

THERAPEUTIC APPROACH
• No specific treatment except to prevent further ingestion. • Administering activated charcoal and cathartics might be helpful and intravenous fluids may be needed. • Seizures can be treated with diazepam. • Bradycardia can be treated with atropine. • If practical, artificial respiration and supplemental oxygen can be provided in extremely valuable livestock.

MEDICATIONS

DRUGS OF CHOICE
No specific antidote.

CONTRAINDICATIONS
Steroids should not be used in pregnant animals.

PRECAUTIONS
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
If the animal survives acute toxicity, the prognosis is good.

PREVENTION
Prevent access to and consumption of *Nicotiana* spp., especially in forage-scarce areas.

MISCELLANEOUS

PREGNANCY
Teratogenic—prevent access to *Nicotiana* spp. by ruminants.

PRODUCTION MANAGEMENT
Access to *Nicotiana* spp. where forage is poor, pasturing on land where tobacco is cultivated, and ingestion of tobacco products or tobacco-tainted water should be denied to livestock.

ABBREVIATION
• GC-MS = gas chromatography-mass spectrometry

SEE ALSO
• Blue-Green Algae Poisoning • Cyanide Toxicosis • Death Camas • Lupine Toxicity
• Milkweed (*Asclepias* spp.) Toxicosis

TONGUE TRAUMA

BASICS

OVERVIEW

• Acute or chronic oral ulceration, bruising, and or necrosis may be due to a virus (vesicular stomatitis, bluetongue, epizootic hemorrhagic disease, bovine viral diarrhea virus, malignant catarrhal fever, Seneca valley virus), trauma or irritant (chemical irritants, coarse plants/feed) or oral foreign bodies.
• Abscesses may occur due to actinobacillosis or "woody tongue."
• Because of the tongue's important role in feed prehension and the eating habits of ruminants, tongue trauma is often acutely evident (salivation, blood mixed with saliva, tongue extended from mouth, dysphagia).

SYSTEMS AFFECTED

• Digestive
• Musculoskeletal

PATHOPHYSIOLOGY

• Dependent upon inciting cause.
• *Actinobacillus lignieresii* is a commensal organism of the GI tract and therefore may colonize oral ulcerations.
• Feeding coarse, dry feeds containing goathead (*Tribulus terrestris*) stickers and plant awns (*Hordeum* spp., *Bromus* spp., *Alopecurus* spp., *Setaria* spp.) may result in damage to oral mucosa and colonization of deeper tissues with organisms.
• Oral foreign bodies such as wire may lacerate the tongue or be swallowed such that it is retained by the lingual frenulum leading to salivation, hemorrhage, and eventually infection.

HISTORICAL FINDINGS

Dependent on etiology. History of weight loss may be the first noticeable sign in subtle cases.

SIGNALMENT

• Tongue trauma is more common in younger animals due to their predisposition to suckle on environmental objects (wire, thorns, etc.).
• Vesicular stomatitis in dairy cattle results in large ulcerations of the tongue with lesions evident on teats and coronary bands.
• Bluetongue virus in susceptible sheep results in tongue and dental pad erosions along with other signs compatible with vasculitis.
• Malignant catarrhal fever (cattle) and Rinderpest (cattle sheep and goats) generally manifest as erosive stomatitis not limited to the tongue.

PHYSICAL EXAMINATION FINDINGS

Salivation, blood in saliva, dysphagia, reluctance to allow examination of head, anorexia, weight loss, dehydration, foul odor to breath, nasal discharge.

CAUSES AND RISK FACTORS

Early weaning, less than optimal housing conditions, salt or water seeking behavior (lack of salt/trace minerals or suitable source of clean water) resulting in consumption of irritant substances (chlorinated naphthalenes). Feeding coarse, dry feeds containing stickers and plant awns may result in damage to oral mucosa and colonization of deeper tissues with organisms. Oral foreign bodies such as wire may lacerate the tongue during prehension leading to hemorrhage and eventually infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

A complete oral examination should be performed to rule out foreign bodies, abscesses and other disorders. Caution should be practiced during the examination to prevent injury to the examiner (proper animal restraint). Lingual trauma, oral or pharyngeal infection or abscesses should not present with other lesions (coronary bands of feet, teat lesions, generalized vasculitis, CNS signs, disseminated GI disease).

OTHER LABORATORY TESTS

Culture and sensitivity testing is indicated if an infective agent is suspected.

IMAGING

May be helpful with foreign body or fracture.

PATHOLOGIC FINDINGS

Dependent on etiology

TREATMENT

THERAPEUTIC APPROACH

Dependent on underlying management or disease factors

SURGICAL CONSIDERATIONS AND TECHNIQUES

Surgical correction may involve glossectomy or partial glossectomy with consideration of the importance of the tongue to prehension of feed.

MEDICATIONS

DRUGS OF COICE

Will vary depending on etiology.

FOLLOW-UP

Patient outcomes and preventive management plans will vary depending on etiology.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Weight loss and potential culling

PRODUCTION MANAGEMENT

Control of risk factors inlcuding keeping all caustic chemicals away from livestock access.

ABBREVIATION

GI = gastrointestinal

TOXICOLOGY: HERD OUTBREAKS

BASICS

OVERVIEW
• Food animal practitioners are commonly required to attend toxicologic incidents affecting single or multiple livestock.
• Toxicologic events are usually emergencies occurring day or night, year round.
• Larger herd sizes within certain agriculture sectors (i.e., dairy, calf raisers, and beef feedlots) create the potential for increasingly severe incidents.
• The risk to animals kept on confined feeding operations is more concerning as their sole source of nutrition is the ration and water provided by the farmer.
• Rations can unknowingly become contaminated with toxic weeds included with forage. Ration concentrates can be included at toxic levels due to mixing errors. Components can contain residue contamination from the feed mill as a result of previously produced batches.
• Emotions are strained, whether it is a client's club project or a large operation involving hundreds of animals. One's empathic capabilities can be central to obtaining the owner's cooperation and trust.
• The rapidly deteriorating state of affected livestock requires immediate supportive treatment and care while simultaneously attempting to construct a plan for a diagnosis.
• Smartphones are a very powerful field tool able to provide immediate contact with offsite expertise, internet access, picture documentation and sharing.

INCIDENCE/PREVALENCE
• Toxic events are estimated to be responsible for as much as 3–5% mortality among livestock species (horses, large and small ruminants) in 17 states in the western United States.

SYSTEMS AFFECTED
N/A

PATHOPHYSIOLOGY
N/A

SIGNALMENT
• Poisonings occur in all species, sexes, ages, and production classes of livestock.
• Occasional age-related distinctions may develop such as mature cows being affected by toxic forage while the suckling calves at their side are unaffected.

PHYSICAL EXAMINATION FINDINGS
• Signs associated with a toxicologic event are commonly vague.
• In some instances, signs only become apparent weeks to months following initial exposure.
• Sudden death is commonly the client's only sign in an acute or peracute incident. Poor performance such as slow growth or low milk production can be associated with chronic toxic exposures.

CAUSES AND RISK FACTORS
• An indepth discussion of the causes and risk factors associated with a toxic event can be found in titles listed under "Suggested Reading."
• Generally speaking, specific toxin sensitivity differences between livestock species have been well documented.
• Some livestock species can adapt to exposure to moderate levels of specific toxins.
• Livestock's level of production or physiologic state (pregnant, ill) can alter an animal's toxin susceptibility.
• Plant stage of maturity as well as growing conditions can alter toxin levels within a given species of plant.
• Certain toxins have a seasonality, as is the case in late summer algal toxicities.
• Inappropriate pesticide or herbicide storage have been the cause of livestock poisonings.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Vague signs commonly associated with poisonings make it important to first rule out other possible causes of illness and death such as nutritional, viral, bacterial, and parasite etiologies.

CBC/BIOCHEMISTRY/URINALYSIS
• The single most important consultation when approaching a toxicologic incident is with the area diagnostic laboratory and specifically with a toxicologist. The laboratory's assistance can prove invaluable when selecting tissues for submission and the tests to request.
• At the bare minimum feed, serum, urine, ruminal contents, brain, liver, kidney, and skeletal muscle should be considered for submission.

OTHER LABORATORY TESTS
Toxins may not be equally distributed throughout the feed or water, therefore submit multiple samples to increase chances of inclusion of offending feed.

OTHER DIAGNOSTIC PROCEDURES
Examination of GIT contents may aid in diagnosis.

PATHOLOGIC FINDINGS
There are few pathognomonic findings for specific toxicologic agents.

TREATMENT

THERAPEUTIC APPROACH
• Largely ineffective as the time elapsed from exposure to diagnosis negates effectiveness of treatment efforts.
• The immediate removal of the toxic source is imperative.
• Many toxic agents require common treatments such as slowing absorption from the GI tract (activated charcoal) or skin (soap and water).
• More specific treatments may include the use of pH modifiers, vegetable oil, or emulsifiers to alter ruminal absorption.
• Palliative treatments such as the use of atropine for parasympatholytic effects or the use of IV fluids for cardiovascular support.
• As with any therapy used in food-producing animals in the USA it is imperative that the treatment falls within AMDUCA. Consultation with FARAD may prove useful for extra-label uses.
• Salvage or euthanasia can be considered under some instances.

MEDICATIONS

DRUGS OF CHOICE
Rarely any specific drug for treatment

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Varies greatly depending on the toxic principle.

POSSIBLE COMPLICATIONS
• Severity of complications are multifactorial and influenced by livestock species, toxin, time exposed, and amount of exposure. Some events result in irreversible, permanent damage to the livestock. Recovery and return to full production can occur in some instances; however, the time required for recovery has to be weighed against the salvage value of the patient and purchase of a replacement animal.
• Carcass disposal issues can be a very important and costly complication depending on local, state, or federal regulations. Improper carcass disposal has resulted in secondary wildlife fatalities.

PATIENT CARE
Dependent on species involved, toxic cause, facilities, and owner capabilities. Large numbers of affected livestock might be economically unfeasible.

PREVENTION
• Sample statistically significant number of feed samples to be analyzed for the commonly occurring toxic weeds growing at the forage origin.
• Regular communication with county agriculture extension service for up-to-date regional information.
• Regular surveillance of pastures (especially roadside fence lines, waterways) to identify

TOXICOLOGY: HERD OUTBREAKS (CONTINUED)

species in pastures as well as removal of noxious volunteers.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Varies greatly depending on the toxic principle.

AGE-RELATED FACTORS
Varies greatly depending on the toxic principle.

ZOONOTIC POTENTIAL
The importance of determining any public health concerns cannot be overemphasized. Primary toxin exposure can occur to animal handlers. Secondary exposure can occur to consumers of the milk, meat, or eggs produced from affected livestock.

PREGNANCY
Many toxic compounds can be abortifacients. As there are many infectious causes of abortion it is important to rule out their involvement beforehand.

BIOSECURITY
- Intentional poisonings have occurred.
- Biosecurity measures described and utilized to counter infectious agents such as foot and mouth disease can also be useful against intentional poisonings.

PRODUCTION MANAGEMENT
- Promote open dialog between nutritionist, veterinarian, hay broker, feeders.
- Document standard operating procedures addressing proper feed sampling and storage, chemical, pesticide and herbicide storage and use, carcass disposal, product (milk, eggs) disposal, biosecurity.
- Work with processors to establish procedures addressing adulterated product handling.

ABBREVIATIONS
- AMDUCA = Animal Medicinal Drug Use Clarification Act
- FARAD = Food Animal Residue Avoidance Databank (FARAD) (see www.fiveminutevet.com/ruminant)
- GIT = gastrointestinal tract
- IV = intravenous

TRACHEAL EDEMA ("HONKER") SYNDROME

BASICS

OVERVIEW
• Tracheal edema ("honker") syndrome is a potentially life-threatening condition seen sporadically in feedlot cattle.
• Characterized by severe edema and hemorrhage of the dorsal wall of the trachea from the mid-cervical region to the tracheal bifurcation, resulting in partial to complete occlusion of the tracheal lumen.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
Canada and the United States; potentially worldwide

SYSTEMS AFFECTED
• Respiratory
• Musculoskeletal

PATHOPHYSIOLOGY
• The etiology of the syndrome is unknown.
• Possible causes may include viral or bacterial infection, trauma to the trachea from feed bunks, passive congestion and edema due to fat accumulation at the thoracic inlet, hypersensitivity, and mycotoxicosis.
• Postulated that marked intratracheal pressure changes due to frequent coughing could be the underlying cause of the tracheal lesions.

HISTORICAL FINDINGS
• Seen more often in warm weather. Possible exacerbation due to heat and dust.
• Typically seen during the last half of the feeding period.
• History varies, and can range from subclinically affected animals to those found dead.

SIGNALMENT
• Feedlot beef cattle, similar syndrome reported in pigs
• There appears to be no age or sex predilection.

PHYSICAL EXAMINATION FINDINGS
• Subclinical disease is possible. Tracheal lesions have been demonstrated at slaughter in cattle that did not have clinical signs.
• Typical signs include an acute onset of dyspnea with an increased inspiratory effort, coughing, and a loud, guttural stertor leading to the colloquial term "honker."
• Clinical signs can progress to open-mouth breathing with head and neck extended, cyanosis, belligerence, recumbency, and death.
• Some animals are found acutely dead with no premonitory signs.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Clinical signs are seen predominantly in warm weather and are often brought on by increased movement or exercise.
• The etiology of the syndrome is unknown. Hypothetical causes include viral or bacterial infection, trauma to the trachea from feed bunks, passive congestion and edema due to fat accumulation at the thoracic inlet, hypersensitivity, and mycotoxicosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Necrotic laryngitis (calf diphtheria)
• Pharyngeal trauma
• Atypical interstitial pneumonia
• Laryngeal/tracheal foreign body, abscess, granuloma, neoplasia
• Previous severe arytenoid chondritis resulting in permanent narrowing of the rima glottis
• Laryngeal paralysis

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
Tracheal endoscopy may be helpful in making a definitive diagnosis.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Gross findings include severe submucosal edema and hemorrhage of the dorsal trachea seen from the midcervical trachea to the tracheal bifurcation. On cross section, the lumen of the trachea may be >50% occluded.
• On histopathology, the tracheal mucosa is hyperemic and hyperplastic with focal erosions and loss of cilia. The submucosa is markedly thickened by hemorrhage and edema and infiltrated by white blood cells. The trachealis muscle is separated from the surrounding connective tissue by hemorrhage and edema with swelling and vacuolation of the myocytes.

TREATMENT

THERAPEUTIC APPROACH
• Calm and minimal handling is imperative as asphyxiation and death can ensue if the animal becomes overly excited.
• The provision of shade and cooling with a water spray may be helpful in hot weather.
• Due to the distal location and extent of the typical lesions, temporary or permanent tracheostomy will likely be of no benefit unless an endotracheal tube is placed to the point of the tracheal bifurcation.
• Many cases will relapse, therefore salvage should be considered if the animal can be stabilized and transported comfortably.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Corticosteroids: Dexamethasone 0.05 mg/kg body weight IM or IV or prednisolone 1–2.2 mg/kg IM or IV daily.
• Broad-spectrum antimicrobials may be indicated but results vary.

CONTRAINDICATIONS
If salvage is a better decision from an animal welfare (avoiding chronic or repeated worsening respiratory distress events) and management perspective, then antimicrobials should be withheld.

PRECAUTIONS
Appropriate milk and meat withdrawal times should be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Prognosis for full recovery is guarded to poor as relapse often occurs.

POSSIBLE COMPLICATIONS
Poor response to therapy and relapse may require early slaughter or euthanasia.

PATIENT CARE
• Calm and minimal handling is imperative as asphyxiation and death can ensue if the animal becomes overly excited.
• The provision of shade and cooling with a water spray may be helpful in hot weather.

PREVENTION
Movement and exercise of cattle late in the feeding period should be avoided during warmer months and restricted to early morning hours when unavoidable.

MISCELLANEOUS

PRODUCTION MANAGEMENT
• Causes may include viral or bacterial infection, trauma to the trachea from feed bunks, passive congestion and edema due to fat accumulation at the thoracic inlet, hypersensitivity, and mycotoxicosis.
• Calm and minimal handling of affected animals is recommended.

TRACHEAL EDEMA ("HONKER") SYNDROME (CONTINUED)

• Provision of shade and cooling with a water spray may be helpful in hot weather.

SYNONYMS

• Honker
• Bovine honker syndrome
• Tracheal stenosis syndrome
• Tracheal stenosis of feedlot cattle

ABBREVIATIONS

• IM = intramuscular
• IV = intravenous

SEE ALSO

• Atypical Interstitial Pneumonia
• Calf Diphtheria/Necrotic Stomatitis

TRAUMATIC RETICULOPERITONITIS

BASICS

OVERVIEW
Traumatic reticuloperitonitis (TRP) is a common disease of cattle but rarely seen in small ruminants. The eating habits of cattle predispose them to the accidental swallowing of metal foreign objects that settle in the rumen or reticulum.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
Potentially worldwide, depending on species and environment

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
• The foreign object may penetrate the reticulum resulting in localized or generalized peritonitis, or only the wall of the reticulum may be involved and this may result in dysfunction due to interference with chemoreceptors or mechanoreceptors.
• The diaphragm, pericardium, and heart are located cranial to the reticulum and the liver is lateral and dorsal. Any of these organs may be penetrated by the foreign body and become involved in the inflammatory process.

HISTORICAL FINDINGS
In the most severe form of TRP, affected cattle may present with a dramatic change in posture, standing with an arched back, total anorexia, and vocalizing with a grunting noise when forced to move or when urinating. A sudden decrease in milk production is commonly reported.

SIGNALMENT
• This disease is seen primarily in cattle consuming processed forages or concentrates. In at least one study, the risk of TRP decreased with increasing parity and was higher when cattle had feet and leg problems.
• Species affected are dairy and beef cattle; however, potentially all ruminant species can become affected.
• There are no breed or age predilections.
• Females are more likely to have this disease because they are the predominant gender on any farm.

PHYSICAL EXAMINATION FINDINGS
• Physical examination of these cattle is characterized by fever, decreased rumen contractions, and an unwillingness to flex ventrally when pinched over the withers. They may have tachycardia, and auscultation of the heart may reveal increased cardiac intensity or may be muffled due to bacterial contamination and subsequent inflammation of the pericardium.
• Chronic cases present a diagnostic challenge due to signs that are subtle and vague. Affected cattle in early lactation may have mild ketosis secondary to their anorexia. Mild bloat and changes in fecal consistency are also common signs. Weight loss, roughened hair coat, and diffuse generalized lameness may be the only signs.

GENETICS
N/A

CAUSES AND RISK FACTORS
The indiscriminate eating habits of cattle are the most likely cause of this disease. Construction in and around their environment will also increase the risk. The care and upkeep of the machinery used to process and provide silage to the cattle also plays a role in risk management.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Abomasal ulcers, diaphragmatic hernia, endoparasitism, heart disease, hepatic abscesses, indigestion, laminitis, lymphosarcoma, or other neoplasia may all be confused with TRP. Clinical signs will assist with ruling out laminitis. Further physical examination findings via rectal palpation may assist in ruling out lymphosarcoma or other abdominal neoplasms.

CBC/BIOCHEMISTRY/URINALYSIS
• The white blood cell count and distribution, plasma proteins, and fibrinogen may be normal in the initial stages of TRP. Total plasma proteins of over 10 g/dL have been shown to have a positive predictive value of 76% for TRP in referral populations.
• Biochemical profiles are not of high value in diagnosing TRP, but may be of benefit in ruling out others on the differential diagnosis list.
• Urinalysis would not be of definitive value in this disease, reflecting only the secondary ketosis that accompanies the anorexia commonly observed.

OTHER LABORATORY TESTS
Analysis and cytology of abdominal fluid showing increased protein and leukocyte count and active neutrophils ± bacteria. All normal bovine peritoneal fluid clots upon exposure to air, so samples are placed in small EDTA tubes.

IMAGING
• Abdominal radiographs with the horizontal beam centered over the reticulodiaphragmatic region in an attempt to confirm the presence of metallic foreign bodies can be done with the cow in that standing position or cast into dorsal recumbency.
• One study in which standing radiographs were taken describes the sensitivity of the procedure in detecting TRP as 83%.
• Ultrasound diagnosis has been utilized as well.

OTHER DIAGNOSTIC PROCEDURES
Abdominocentesis is recommended and may be aided by ultrasonography to obtain fluid. Remember that in normal, nonpregnant, adult cattle the amount of abdominal fluid is small.

PATHOLOGIC FINDINGS
• Peritonitis will occur if the reticulum epithelium is breeched. This may be walled off by the inflammatory response or it may progress.
• Sudden death has occurred as a result of laceration of a coronary blood vessel or puncture of the heart by the foreign body.

TREATMENT

THERAPEUTIC APPROACH
• Conservative treatment is most often attempted first and includes administration of a forestomach magnet, antibiotics, and confinement. Many cattle recover after this therapy with resumption of appetite and motility within 3 days.
• Initially affected animals should be stabled with their forequarters higher than their hindquarters.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Those animals that do not recover in 3 days may require a rumenotomy to remove the foreign body in order to allow them to recover. This becomes an economic challenge for the producer and veterinary surgeon.

MEDICATIONS

DRUGS OF CHOICE
Cattle with diffuse peritonitis have a poor prognosis for return to production or life. Treatment of peritonitis requires systemic antibiotics, possible drainage of the affected area, and surgical correction of the inciting cause.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Cattle with diffuse peritonitis have a poor prognosis for return to production or life.

T

TRAUMATIC RETICULOPERITONITIS (CONTINUED)

POSSIBLE COMPLICATIONS
• Those cattle that seem to recover in the short term may later develop forestomach outflow problems typical of vagal indigestion.
• It is not uncommon for the foreign body to migrate through the diaphragm and penetrate through the pericardium causing pericarditis and/or pleuritis.

CLIENT EDUCATION
See "Production Management"

PATIENT CARE
Return of rectal temperatures to normal values and increasing appetite and rumen motility are key findings in responding animals.

PREVENTION
Some producers will administer prophylactic magnets to all heifers at 6–8 months of age as another means of prevention of TRP. The implementation of this procedure will depend on the risk or known prevalence within the herd, but in most cases is cost effective.

MISCELLANEOUS

PREGNANCY
May exacerbate disease symptoms.

PRODUCTION MANAGEMENT
Most producers now have large magnets in place on feed-handling equipment that eliminates the delivery of sharp metal objects to cattle at the time of feeding. Also, many producers have gone away from upright silos for storage of their corn silage in favor of bunkers. This has eliminated another source of metal contamination of feedstuffs by eliminating the mechanical unloader necessary for old upright silos.

SYNONYMS
• Hardware disease
• Wire disease

ABBREVIATION
• TRP = traumatic reticuloperitonitis

TREMETOL: WHITE SNAKEROOT AND RAYLESS GOLDENROD

BASICS

OVERVIEW
• White snakeroot is an opposite branching, dark green perennial, which grows 1–4 feet tall in damp, open areas of woods and shaded areas along streams.
• Stems are slender, round, and may be purplish.
• Leaves are 3–5 inches in length and have three distinct veins, coarsely toothed margins, and a sharp tip.
• Flowers are white and clustered in groups of 10–40 at the end of branches and bloom in late summer and fall.
• Roots are shallow and fibrous, and twist and turn, giving the plant its name.
• The plant grows in moist areas bordering streams, woodlands, as well as wooded areas with rich basic soil. It may persist in open areas after clearing.

INCIDENCE/PREVALENCE
• Intoxication requires ingestion of 0.5–1.0% of body weight of green plant over 2–3 weeks.
• Consumption of green plant material equivalent to 5–10% of the animal's body weight is required to produce intoxication.
• Because the toxicant's effects are cumulative, small amounts ingested for several weeks may be almost as toxic as a large amount eaten in a few days.
• There is slow loss of toxicity with heat and/or drying of the plant; however, this is variable, but dried plants in hay and even frost-damaged plants are reported to remain toxic for some time.

GEOGRAPHIC DISTRIBUTION
The geographic distribution is mostly eastern North America and grows from the East Coast including Canada, west to Minnesota, and south to east Texas and the Gulf Coast.

SYSTEMS AFFECTED
• Cardiovascular
• Musculoskeletal
• Multisystemic

PATHOPHYSIOLOGY
• Toxicity is most abundant in the foliage of the mature plant, is resistant to frost, and, although decreased, persists in the dried plant.
• The same toxins found in *Ageratina altissima* (white snakeroot) are also found in *Isocoma wrightii* (rayless goldenrod).
• The specific toxin has not been identified, but the unpurified form has been named tremetol.
• Effect of toxin requires microsomal activation and may explain different effects in different species.
• Intoxication is theorized to inhibit citrate synthase causing ketosis detectable by acetone smell of breath and urine.
• Intoxication in animals is often called trembles.
• Nursing young are clinically affected by high concentration in milk.
• Causes muscle damage and weakness.
• Causes hepatic necrosis.
• May cause photosensitization of small ruminants if animal survives acute disease.
• The toxin is cleared in milk and may cause signs in offspring or humans if ingested.

HISTORICAL FINDINGS
• Disease usually seen in late fall or early winter.
• Animals die soon after becoming recumbent.
• History of weight loss.

SIGNALMENT
• Seen most frequently in sheep, dairy cows, and goats, but all species ingesting the plant are at risk.
• Goats may be at a greater risk.

PHYSICAL EXAMINATION FINDINGS
• Ketosis causes acetone breath
• Afebrile
• Clinical signs different between species

Cattle and Sheep
• Reluctance to move.
• Stiff movements or ataxia.
• Severe trembles after exercise.
• Depression.
• Recumbency.
• Sudden death.
• Dyspnea, salivation, constipation, regurgitation may occasionally occur.
• Clinical signs may appear 3 days to 3 weeks after ingestion.

Goats
• Goats typically show signs of liver failure.
• Depression.
• Weakness.
• Head pressing.
• Icterus.
• Slight tremors with exercise.
• Recumbency.
• Sudden death.
• Photosensitization if animal survives acute disease.
• Clinical signs may appear 1–5 days after ingestion.

CAUSES AND RISK FACTORS
• The specific toxic principle in snakeroot is unknown.
• Moving naïve animals to contaminated pastures when there is inadequate forage (i.e., fall and winter).
• Lactating animals are more resistant due to rapid excretion of toxin in milk, putting nursing animals at high risk for clinical signs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Selenium/Vitamin E deficiency
• Ionophore toxicosis
• Other causes of liver disease in small ruminants
• Gossypol intoxication
• Botulism in cattle
• Organophosphate intoxication
• CNS trauma
• Other tremorgenic toxicities

CBC/BIOCHEMISTRY/URINALYSIS
• Muscle enzymes (CK, LDH, ALP, AST, troponin) are elevated.
• Animals have ketoacidosis.
• May have myoglobinuria.
• Goats may have elevations in bilirubin.

OTHER DIAGNOSTIC PROCEDURES
• Evidence of plants in rumen
• Evidence of plant exposure

PATHOLOGIC FINDINGS
• Centrolobular hepatic degeneration and necrosis
• Skeletal muscle necrosis
• Cardiac abnormalities reported primarily in horses
• Extreme congestion of liver, kidney, abomasums, brain, and spinal cord
• Extreme fat degeneration of liver and kidney

TREATMENT

THERAPEUTIC APPROACH
• Correct any electrolyte and acid-base abnormalities.
• Ketosis is refractory to treatment.

MEDICATIONS

DRUGS OF CHOICE
• Activated charcoal (AC) (2–5 g/kg PO in a water slurry).
• Evidence in other species of recycling through gastrointestinal system; repeat doses of AC may be beneficial.
• Laxatives.

CONTRAINDICATIONS
• Any drug promoting hepatic microsomal enzymes is contraindicated.
• Any drug inhibiting hepatic microsomal enzymes may be helpful.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Animals exhibiting clinical signs have grave prognosis.

T

TREMETOL: WHITE SNAKEROOT AND RAYLESS GOLDENROD (CONTINUED)

PATIENT CARE
Monitor electrolytes.

PREVENTION
• Prevention of white snakeroot intoxication is possible—monitor pasture and hay for white snakeroot.
• Selective use of herbicides or manual removal of plants may help to diminish problem.

MISCELLANEOUS

AGE-RELATED FACTORS
Nursing animals may show clinical signs before other animals in the herd.

ZOONOTIC POTENTIAL
• During colonial time period hundreds of people were poisoned by milk from affected animals.
• As organic farming becomes more popular, the risk to humans may become more significant. Because the toxin is fat soluble, butter is also toxic.

PREGNANCY
N/A

PRODUCTION MANAGEMENT
Imperative to prevent access to plants during the growing season.

SYNONYMS
• River fever
• Swamp sickness
• Trembles

ABBREVIATIONS
• AC = activated charcoal
• ALP = alkaline phosphatase
• AST = aspartate aminotransferase
• CK = creatine kinase
• LDH = lactate dehydrogenase
• PO = per os, by mouth

SEE ALSO
• Brain Assessment and Dysfunction (see www.fiveminutevet.com/ruminant)
• Clostridial Disease: Gastrointestinal
• Clostridial Disease: Muscular
• Clostridial Disease: Nervous System
• Fungal Tremorgens
• Gossypol Toxicosis
• Liver Abscesses
• Organophosphate Toxicity
• Selenium/Vitamin E Deficiency

TRICHOMONIASIS

BASICS

OVERVIEW

• Trichomoniasis is a bovine venereal disease caused by an extracellular flagellated protozoan, *Tritrichomonas foetus*.
• The disease is asymptomatic in bulls but causes severe economic loss due to early embryonic loss and abortion.
• Trichomoniasis is a reportable disease in many countries. In the United States, some states require all bulls to be tested.
• *T. foetus* has been isolated from camels but its role in infertility and abortion in this species is not yet clear.

INCIDENCE/PREVALENCE

• Prevalence has been studied in several countries including Argentina, Australia, Spain, Switzerland, and the US.
• Prevalence varies from one country to another. In the US herd prevalence varies from 5% to 15% and up to 5% of bulls tested may be positive.
• The disease is more prevalent in beef herds, particularly in the southern and western US.
• Outbreaks have been reported in dairies using natural service.

GEOGRAPHIC DISTRIBUTION

Worldwide, particularly where natural service is the main method of breeding.

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• Bulls are generally infected if they breed a carrier female.
• The protozoan colonizes the epithelium of the prepuce, penis, and occasionally the urethral orifice of infected bulls.
• Infected bulls are asymptomatic. The parasite is restricted to the mucosal surface and is incapable of invading deeper tissues. The only histologic finding in infected bulls is a lymphocytic and plasmocytic infiltration of the epithelium and subepithelial layer.
• Older bulls (>3 years) become chronically infected whereas younger bulls (<2 years) seem to clear the infection.
• There are no effects on semen quality in infected bulls.
• Cows become infected if they are mated to carrier bulls or inseminated with cryopreserved semen from infected bulls.
• The parasite has cytotoxic and hemolytic activity resulting in an inflammatory response (salpingitis, endometritis, and cervicitis). Pregnant cows experience fetal death in the first trimester and more rarely abortion later in gestation. The pregnancy loss ranges from 5% to 30%. Most abortions occur before 5 months of gestation but later abortions have been observed.
• Pregnancy loss occurs generally 7–9 weeks after infection. Aborting cows show a high number of organisms in the chorioallantois and fetal stomach.
• A high proportion of infected cows may have a pyometra.
• Infected cows develop a local vaginal antigen-specific antibody response (IgG1 and IgA) but this immunity does not always prevent reproductive loss.
• Cows clear the infection within 6–18 weeks.

HISTORICAL FINDINGS

Herds experiencing an outbreak of trichomoniasis share several historical findings including:
• Introduction of open or late calving cows in the herd
• Introduction of nontested bulls
• Use of communal grazing and co-mingling during the breeding season with unknown or untested herds
• Keeping older bulls or open cows from previous season
• Large number of cows returning to estrus
• Low pregnancy rate
• Reduced calving rate or a prolonged calving season

SIGNALMENT

N/A

PHYSICAL EXAMINATION FINDINGS

• Infected bulls do not show any clinical signs.
• Infected aborting cows may show vaginal discharge.
• Clinical suspicion in the herd is made at the time of pregnancy diagnosis. The proportion of open cows varies depending on whether the herd practices early (<90 days) or late (>90 days) pregnancy diagnosis. Overall pregnancy rate may be as low as 70% with a highly variable gestational stage.
• Up to 5% of the open cows may be diagnosed with pyometra (fluid-filled uterus with no positive signs of pregnancy and presence of a corpus luteum).

GENETICS

N/A

CAUSES AND RISK FACTORS

• *Tritrichomonas foetus* is an extracellular flagellated protozoan. The parasite is spindle shaped and measures 8–12 µm by 15–20 µm with three anterior flagellae and a recurrent flagellum (undulating membrane).
• The main risk factor for the disease is the introduction into the herd of carrier bulls.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Other causes of infertility or early pregnancy loss that may present in the same manner as trichomoniasis are nutritional deficiencies and campylobacteriosis.
• Nutritional deficiencies, in particular, poor energy intake, may result in poor reproductive performance due to anestrus, delayed puberty, poor conception rates, and increased early embryo loss. Nutritional deficiencies are suspected based on historical findings, BCS at calving or at breeding, heifer growth performance, and general health of the herd. Ration analysis should provide more information on the nutritional state of the herd.
• Campylobacteriosis due to *Campylobacter fetus* subsp. *venerealis* has the same herd presentation but without the increased rate of pyometra.
• Less commonly, *Histophilus somni* (*Haemophilus somnus*), *Chlamydophila* spp., and *Ureaplasma* spp. may cause outbreaks of venereally transmitted infections resulting in early pregnancy loss. However, these are generally accompanied by clinical genital lesions.
• Use of poor fertility bulls may also results in poor pregnancy rates and a prolonged calving season.

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

• In bulls, the most common diagnostic test is culture or culture and PCR from the smegma obtained by preputial scraping.
  ◦ The bull is restrained in a chute and the preputial orifice is cleaned. A sterile plastic-covered, 22-inch uterine infusion pipette attached to a 12 mL syringe is introduced deep into the fornix. The plastic cover is pulled back and the pipette is vigorously rubbed against the preputial mucosa while applying a negative pressure with the syringe to allow collection of a good amount of smegma.
  ◦ It is important not to contaminate the sample with too much blood or fecal material.
  ◦ Other techniques for sampling use preputial scraping devices (Tricamper®, Trichit®) which claim better samples and less blood contamination.
  ◦ In the US, several states require training and certification in *T. foetus* sampling before accepting samples from veterinarians.
  ◦ The smegma is placed into commercially available special culture media (Diamond's TYM medium or InPouch®; Biomed Diagnostic, San Jose CA, USA).
  ◦ Samples are incubated at 37°C (98.6°F) and examined 1, 3, 5, and 7 days after sampling.
  ◦ The protozoan is easily identified at 200× to 400× magnification under light microscopy by its wave-like, rapid and irregular rolling and jerky movement.
  ◦ Sensitivity of culture for detection of *T. foetus* ranges from 84% to 96% and may be lower under field conditions. Therefore, a culture/PCR test is recommended and improves significantly the sensitivity and specificity. Some states require that the

TRICHOMONIASIS (CONTINUED)

culture and PCR be performed in an approved or certified laboratory.
• In cows, direct microscopic evaluation of the uterine content from the pyometra reveals the presence of parasite. The fluid may be submitted for culture and PCR.
• The parasite is also isolated from abomasal content of aborted fetuses and can be identified with dark field microscopy.
• Immunohistochemistry using polyclonal and monoclonal antibodies are effective methods for detection of *T. foetus* in fetal and placental tissues.
• In non-autolyzed placentae, the parasite may be identified in the stroma of hematoxylin and eosin stained sections.

IMAGING
Transrectal ultrasonography is not necessary but can confirm palpation diagnosis of pyometra.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• There are no obvious lesions in bulls. Immunohistochemistry may reveal *T. foetus* and/or its surface antigen adhered to the surface of the preputial and penile squamous epithelium.
• In cows, cervicitis and endometritis have been described in cases of *T. foetus* infection. However, these conditions are not common in natural infection. Pyometra is the most commonly found condition. Histologic lesions include mild to moderate infiltration of neutrophils and eosinophils in the stratum compactum and the stratum spongiosum of the endometrium. Many females show aggregations of mononuclear cells in the stratum spongiosum resembling lymphoid follicles, 6–9 weeks after infection.
• There are no gross lesions in the abortus except placental edema in some cases. The fetus may be in a variable state of autolysis. Fetal lung may show bronchopneumonia with neutrophilic and macrophage exudate. On histology, trichomonads may be seen in alveoli and airways along with Langhans and/or foreign body giant cells.

T

TREATMENT

THERAPEUTIC APPROACH
Treatment is illegal in several countries. Although *T. foetus* may be sensitive to nitro-imidazole drugs, these drugs should not be used.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
N/A

CONTRAINDICATIONS
N/A

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Economic losses vary greatly but are expected to be significant.
• Bulls and open cows should be culled and disposed of according to local/state regulations.
• Trichomoniasis is a reportable disease in several countries. In the US, there are no federal trichomoniasis regulations currently. However, some states have specific regulations. Some states require three consecutive negative tests one week apart before an animal is deemed negative.
• Sample pooling may reduce cost of testing. However, not all states accept results from pooled samples.
• It is important for practitioners to check the protocol for testing with the state veterinarian or other regulating agency.
• The practitioner, producer, and state veterinarian should develop a trichomoniasis elimination program for the herd.
• Positive cows may be maintained in a separate herd and bred by artificial insemination from clean bulls.
• Vaccination of females twice, one month apart, just prior to bull exposure has been suggested as an additional method of control in infected herds.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
• Know the risk factors and economic losses for trichomoniasis.
• Understand the limitations of testing protocols.
• Develop a quarantine and testing program, particularly for bulls.
• Develop a prevention and eradication program with their veterinarian.

PATIENT CARE
Positive animals should be culled from breeding.

PREVENTION
• Prevention of trichomoniasis is based primarily on biosecurity measures including testing of all new bulls and avoiding co-mingling with other herds.
• Use of virgin bulls should be part of any preventive measure.
• A commercial killed whole cell vaccine is available. Experimental studies have shown that vaccination of bulls helps prevent or clear infection in bulls. Vaccination of females has been shown to reduce reproductive losses after mating to infected bulls. However, recommendation for widespread use of vaccination as the sole method of control of the disease is controversial.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Abortion, infertility

AGE-RELATED FACTORS
Older bulls (>3 years of age) are more likely to become persistent carriers.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Early pregnancy loss and abortion

BIOSECURITY
• Test all newly introduced bulls.
• Avoid introduction of open or late calving cows.
• Avoid co-mingling with other herds.

PRODUCTION MANAGEMENT
• Cull all open cows and test all bulls.
• Use artificial insemination with cryopreserved sperm from controlled sources.

SYNONYM
Trichomonosis

ABBREVIATIONS
• BCS = body condition score
• IgA = immunoglobulin A
• IgG1 = immunoglobulin G1
• PCR = polymerase chain reaction

TRYPANOSOMIASIS

BASICS

OVERVIEW
• Caused by protozoa of the genus *Trypanosoma* that live in the blood and body fluids of their hosts.
• Results in anemia, emaciation of animals, and loss of condition.
• Transmission is by vectors (tsetse flies—*Glossina morsitans, G. palpalis, G. fusca,* and vampire bats) and through mechanical vectors of the genus *Tabanus.* Hematogenous equipment, such as needles and surgical instruments, can also transmit trypanosomes.
• Ruminants are widely known to be active reservoirs.
• Infections with trypanosomes result in diseases such as nagana, surra, Chagas' disease, and African sleeping sickness.

INCIDENCE/PREVALENCE
Unknown

GEOGRAPHIC DISTRIBUTION
Found in the subtropical and tropical areas of Africa, Asia, and South and Central America.

SYSTEMS AFFECTED
• Cardiovascular
• Digestive
• Nervous
• Musculoskeletal
• Hemolymphatic
• Reproductive
• Ophthalmic

PATHOPHYSIOLOGY
• The protozoa multiply in the blood, tissue, or body fluids of the vertebrate host and are transmitted between vertebrate hosts through the saliva of blood-sucking flies as they feed.
• At the site of inoculation, there is a local skin reaction called a chancre.
• From here the trypanosomes reach the bloodstream directly or through the lymphatic system.
• Parasitemia becomes apparent 10–14 days after inoculation.
• Trypanosomes' success lies in their ability to evade the host's immune system by altering the antigenic nature of its surface-coat glycoproteins.

HISTORICAL FINDINGS
Lethargy, depression

SIGNALMENT
• Cattle, sheep, goats, camels, llamas, and buffalo.
• Adult sheep between 1 and 4 years of age with 4 years of age being the norm for susceptibility; lambs are more susceptible to infection if exposed prior to 10 weeks of age.

PHYSICAL EXAMINATION FINDINGS
• There are no pathognomonic signs and the severity of the signs varies depending on the size of the inoculation dose, the species and strain of the trypanosomes, and breed and management of the host.
• Can present as an acute, subclinical, or chronic infection.
• Acute: Anemia, intermittent fever, loss of condition, and abortion may be seen; decrease in milk production; in some cases diarrhea; some become inappetant with a stiff gait and die within a few weeks.
• Chronic: Affected animals are anorexic, apathetic, and emaciated, and have ocular discharge, keratoconjunctivitis, and a dull coat. A marked jugular pulse develops, associated with pale mucus membranes and elevated respiratory and pulse rate. Although the animal continues to eat, it gradually loses weight and death occurs after several months due to heart failure.
• Subclinical: Stress plays a prominent role in the disease process.
• CNS effects include meningoencephalitis, progressive weakness, and ataxia.

GENETICS
Certain breeds of African cattle are considerably more resistant to African trypanosomiasis than others.

CAUSES AND RISK FACTORS
• Nagana or African trypanosomiasis: *Trypanosoma brucei, T. congolense*, *T. vivax,* and *T. simiae*—variety of animals affected. Transmitted cyclically by tsetse flies and mechanically by other biting flies.
• Surra: *T. evansi*—horses and camels affected; transmitted mechanically by biting flies in Africa, Asia, and South and Central America.
• Found in subtropical and tropical locations; the risk factor is being exposed to vectors, such as tsetse flies, biting flies (tabanids), and vampire bats.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Acute anthrax
• Anaplasmosis
• Babesiosis
• Theileriosis
• Hemorrhagic septicemia
• Gastrointestinal helminths (*Haemonchus*)
• Chronic malnutrition

CBC/BIOCHEMISTRY/URINALYSIS
• Decreased packed cell volume, erythrocyte count, and hemoglobin
• Leukopenia, neutropenia, lymphocytosis, and monocytosis
• Hypoglycemia, hypoalbuminemia, hyperglobinemia
• Thrombocytopenia
• Metabolic acidosis

OTHER LABORATORY TESTS
Serology for other infectious diseases

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Microscopic examination (direct)—wet mount of blood slides, thick and thin blood films stained with Giemsa, and stained lymph nodes for visual identification of trypanosomes and exclusion of other blood parasites.
• Indirect method—antigen-detecting ELISA, indirect fluorescent antibody test.
• Molecular test—species-specific DNA probes.
• Subinoculation into experimental animals.

PATHOLOGIC FINDINGS
Most findings are nonspecific but can include serous atrophy of fat, subcutaneous edema, emaciation, petechiation, and enlarged liver, spleen, and lymph nodes. The spleen may also be atrophied or normal in some cases depending on the severity of the disease. Other lesions include necrosis of the kidneys and heart muscle and a sore or chancre at the site of entry.

TREATMENT

THERAPEUTIC APPROACH
• Supportive care
• Blood transfusion from known negative animals

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATION

DRUGS OF CHOICE
• Treating trypanosomiasis is expensive and not always successful. In some countries, there are prophylactic treatments that have been used with some success.
• Diminazene aceturate (Berenil, 3.5–7 mg/kg body weight, IM) for *T. vivax* and *T. congolense*, well tolerated by ruminants but not by horses.
• Homidium bromide (ethidium B, 1 mg/kg IM) and homidium chloride (novidium or ethidium C, 1 mg/kg IM) for *T. vivax* and *T. congolense*. Cattle and small ruminants.
• Isometamidium chloride is another preferred drug to use against *T. vivax* and *T. congolense* in ruminants as a curative (0.25–0.5 mg/kg, IM) and prophylactic dose (1 mg/kg, IM). Pyrithidium bromide is less widely used against *T. vivax* and *T. congolense* as prophylactic at 2 mg/kg body weight.
• Suramin may also be used against *T. brucei* as a curative and prophylactic drug at 10 mg/kg body weight in horses and camels.
• Melarsomine (0.25–0.5 mg/kg, IM or SC). Registered for use against *T. evansi* in camels. Very widely used in the Middle East.

(CONTINUED) TRYPANOSOMIASIS

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
Trypanosomiasis is considered a foreign animal disease in several countries including the US, and should be reported immediately to authorities.

POSSIBLE INTERACTIONS
Sudden death can occur.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Due to the potential for reinfection, prognosis varies depending on the severity of infection and how rapidly it was detected and treated.

POSSIBLE COMPLICATIONS
Abortion, sudden death can occur after treatment in heavily parasitized animals.

CLIENT EDUCTION
Importance of preventive measures

PATIENT CARE
Because reinfection can occur, monitor weight, appetite, temperature, and PCV.

PREVENTION
• Vector control is recommended.
• Trypano-tolerance—certain breeds of African cattle are considerably more resistant to African trypanosomiasis than others. The mechanisms of trypano-tolerance have been extensively studied and it has been established that it has a genetic basis. Certain small ruminant breeds are also more trypano-tolerant than others. Selective breeding for tolerant animals can reduce the need for medication in endemic areas.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Sheep aged 1–4 years of age; lambs <10 weeks of age

ZOONOTIC POTENTIAL
• Chagas' disease—*T. cruzi*—occasionally pigs but mainly in dogs and humans susceptible; transmitted by sucking blood vectors in South and Central America and the southern parts of the United States.
• African trypanosomiasis in humans can be caused by *Trypanosoma brucei gambiense* (central and west Africa), which causes a latent chronic infection, and *Trypanosoma brucei rhodesiense* (southern and east Africa), which causes a more virulent acute infection.

PREGNANCY
• African trypanosomiasis can be transmitted in utero from infected mothers resulting in abortion and perinatal death of the fetus; trypanosomiasis can also cause infertility.

BIOSECURITY
Vector control is important although difficult in endemic areas.

PRODUCTION MANAGEMENT
Economic losses can arise from emaciated animals, mortalities, and the cost of vector control programs.

SYNONYMS
• African sleeping sickness
• Chagas' disease
• Nagana
• Surra
• Trypanosomiasis
• Tsetse disease
• Tsetse fly disease

TUBERCULOSIS: BOVINE

BASICS

OVERVIEW
• Bovine tuberculosis (bovine TB) is caused primarily by the bacterium *Mycobacterium bovis*.
• Bovine TB is a reportable disease in many countries, including the United States, and is found in all parts of the world.
• Bovine TB affects primarily the respiratory system and associated lymph nodes. The disseminated form of the disease can be found in other organ systems including the gastrointestinal tract, reproductive tract, mammary glands, and central nervous system.
• *Mycobacterium bovis* infections have been described in numerous domestic and wild animals including sheep, goats, horses, pigs, deer, antelope, dogs, cats, ferrets, camels, foxes, mink, badgers, rats, primates, llamas, kudu, eland, tapir, elk, elephant, sitatunga, oryx, addax, rhinoceros, opossum, ground squirrel, otter, seal, hare, mole, raccoon, coyote, lion, tiger, leopard, and lynx.
• Most species other than cattle are considered to be dead-end hosts; however, some species can serve as reservoir hosts. Known reservoir hosts include brush-tailed opossums in New Zealand, badgers in the United Kingdom and Ireland, deer in the United States, bison in Canada, and greater kudu, common duiker, African buffalo, warthog, and Kafue lechwe in Africa.
• Bovine TB can be transmitted either by the respiratory route or ingestion.
• *Mycobacterium bovis* is a zoonotic agent and is a significant public health concern.

INCIDENCE/PREVALENCE
• In the US where an eradication program has been in place since 1917, the prevalence in cattle is extremely low (0.1 cases per 1 million head). The same is true for many developed countries including New Zealand whose eradication program has been praised.
• In many developing countries prevalence remains high (reports between 3% and 50% in some African countries), with much variability depending on husbandry practices and region.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Respiratory
• Reproductive
• Mammary
• Nervous
• Digestive

PATHOPHYSIOLOGY
• Disease is contracted via inhalation of droplets aerosolized from infected reservoirs and less commonly via ingestion of contaminated milk or water.
• If not cleared by alveolar macrophages, the mycobacteria will proliferate and through a cytokine-mediated hypersensitivity reaction a focus of immune cells will form. Eventual formation of a necrotic, caseous, partially calcified center encased by a fibrous capsule is what constitutes the classic tubercle.
• In cases of disseminated TB, these lesions will be found in surrounding lymph nodes and multiple other organs (see "Systems Affected").

HISTORICAL FINDINGS
Bovine tuberculosis is a chronic debilitating disease, but can occasionally be acute and rapidly progressive.

SIGNALMENT
Bovine TB can affect all ages but prevalence is higher in cattle >2 years old.

PHYSICAL EXAMINATION FINDINGS
• Early infections are often asymptomatic; however, in later stages, common symptoms include progressive emaciation, a low-grade fluctuating fever, weakness, and inappetence.
• Animals with pulmonary involvement have a moist cough that is worse in the morning, during cold weather, or during exercise. These animals may also exhibit dyspnea or tachypnea.
• In some animals, the retropharyngeal or other lymph nodes enlarge and may rupture and drain.
• Greatly enlarged lymph nodes can obstruct blood vessels, airways, or the digestive tract.
• If the digestive tract is involved, intermittent diarrhea and constipation may be seen. Lesions are sometimes found on the female genitalia but are rare on the male genitalia.
• Mammary gland involvement typically results in induration and hypertrophy of the affected gland, and enlargement of the supramammary lymph nodes.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Bovine TB is caused primarily by the bacterium Mycobacterium bovis.
• *M. bovis* can survive for several months in the environment, particularly in cold, dark, and moist conditions.
• The major risk factor for infection with bovine TB is exposure to infected reservoirs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Other causes of chronic respiratory disease—*Mycoplasma bovis*, chronic lung abscesses, aspiration pneumonia.
• Other causes of chronic weight loss and ill thrift—Johne's disease, parasitism, and bovine leukosis.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Caudal fold tuberculin test (CFT)—an intradermal skin test that is used as an initial screening test. In the US, an accredited veterinarian must administer this test.
• Comparative cervical test (CCT)—an intradermal skin test used most commonly as a follow-up to the CFT to differentiate immune responses to *Mycobacterium bovis* and *Mycobacterium avium*. In the US, only a state or federal veterinarian can perform this test.
• *Mycobacterium bovis* gamma interferon assay—an assay used most commonly as a follow-up to the CFT test.

PATHOLOGIC FINDINGS
• The characteristic gross lesion seen in an animal infected with bovine TB is the presence of granulomatous tubercles within the body. A tubercle is a white nodule usually 1 mm to 2 cm in diameter.
• Tubercles may be localized to a single organ or disseminated through many organ systems.
• Bovine TB tubercles are most commonly found in the thoracic cavity and associated lymph nodes.
• The lesion most commonly associated with bovine TB is a granuloma.
• On histology, following acid-fast staining of suspect tissue, bacteria that take up stain, including *Mycobacterium bovis*, will appear as short red or pink rods when examined under a microscope.

TREATMENT

Animals diagnosed with the disease are humanely euthanized and those in the herd of contact are quarantined. Specific regulations will vary depending on country.

MEDICATIONS

DRUGS OF CHOICE
N/A

CONTRAINDICATIONS
N/A

PRECAUTIONS
Proper intradermal administration is necessary for accurate test results when performing the CFT and CCT.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Cattle infected with bovine TB are humanely destroyed. Farms where bovine TB positive animals originate are considered infected and subsequently are quarantined. Disposition of these herds is decided upon by the regulatory authorities governing TB control in that area.

POSSIBLE COMPLICATIONS
- Human infections
- Economic implications based on loss of milk sales and herd culling

PATIENT CARE
N/A

PREVENTION
Bovine TB is considered a herd disease; therefore, emphasis is placed on preventing the introduction of the disease onto a farm. Biosecurity procedures should be put in place that prevent the introduction of cattle at high risk of having bovine TB and to prevent potential wildlife reservoirs from having close contact with cattle, cattle feed, or cattle water.

MISCELLANEOUS

ZOONOTIC POTENTIAL
Mycobacterium bovis is a zoonotic agent that historically was spread primarily through the consumption of unpasteurized milk from infected cows. Other potential routes of zoonotic transmission include consumption of undercooked meat and close contact with infected cows.

PREGNANCY
In cattle with advanced bovine TB, fetal infection can occur, resulting in calves being born infected with bovine TB.

BIOSECURITY
Because this is a disease of high consequence both as a zoonosis and as a potential to cause economic disaster for infected herds, employing standard farm biosecurity measures is extremely important. See chapters, Biosecurity: Beef Cow/Calf and Biosecurity: Dairy.

PRODUCTION MANAGEMENT
Routine herd testing may be required depending on government regulations.

ABBREVIATIONS
- CCT = comparative cervical test
- CFT = caudal fold tuberculin test
- TB = tuberculosis

ULCERATIVE POSTHITIS AND VULVITIS

BASICS

OVERVIEW
• Ulcerative posthitis is an infectious disease of the external genitalia affecting both male and female small ruminants.
• It is most commonly caused by an aerobic, Gram-positive rod-shaped bacterium, *Corynebacterium renale.*
• This bacterium is a normal inhabitant of the skin and external genitalia of small ruminants and can be spread by venereal transmission.
• The bacteria can survive for 6 months in wool and scabs and can survive freezing in exudates.
• *C. renale* proliferates on the genital mucosa in the presence of urea, which increases in the urine of animals fed high amounts of protein and nonprotein nitrogen (NPN) in rations.
• *C. renale* hydrolyzes urea to ammonia, which results in necrosis of surrounding tissues.

INCIDENCE/PREVALENCE
Sporadic, but a significant proportion of animals in vulnerable groups can be affected, such as pre-sale or pre-breeding rams receiving adjusted rations.

GEOGRAPHIC DISTRIBUTION
Worldwide; distribution influenced by production systems

SYSTEMS AFFECTED
• Reproductive
• Urinary

PATHOPHYSIOLOGY
• *C. renale* is a commensal organism of the skin and external genitalia of small ruminants.
• This organism contains urease and can hydrolyze urea to ammonia.
• Provision of a high-protein ration increases rumen ammonia production, which undergoes hepatic conversion to urea for excretion in the urine.
• High concentrations of urea in the urine allow *C. renale* to proliferate and hydrolyze urea; resulting ammonia creates chemical damage to the skin of the prepuce or vulva.

HISTORICAL FINDINGS
• May include risk factors such as grazing of lush green pastures, or introduction of a high-protein ration to pre-sale, pre-breeding, or finishing animals.
• Signs of disease can commence 2 weeks or later after dietary changes.

SIGNALMENT
• Male and female small ruminants may be affected (males much more commonly).
• Castrated males are predisposed.
• Breeding rams, pet wethers, feedlot lambs, show lambs/kids, and wool and fiber production animals are predisposed.
• Merinos and Angoras are commonly affected due to dense wool and fiber.
• Usually animals >6 months old.

PHYSICAL EXAMINATION FINDINGS
• Moist ulcers at the mucocutaneous junction of the prepuce form, then become covered by a thin, brown, malodorous scab.
• Focal swelling of the prepuce and pain on palpation are evident, with malodorous exudate, necrotic tissue, and urine present in the preputial orifice.
• Infection can ascend to create swelling and ulceration along the internal prepuce, and adhesions can form between the penis and prepuce.
• Stenosis of the preputial orifice may be evident.
• Dysuria may be reflected by vocalization during urination (goats) and may relate to stricture of the vermiform appendage.
• Stilted gait can reflect discomfort and weight loss can occur in chronic disease.
• Bucks which transmit the bacteria may be asymptomatic.
• Does and ewes initially have erythema and swelling of the vulva, which progresses to ulcerative and scabbing lesions of the perineum, vulva, and caudal vagina.
• Dysuria can occur if the urethral orifice is affected, and fibrosis and contracture of the vulva can occur in longstanding cases.

GENETICS
Angora goats and Merino sheep predisposed

CAUSES AND RISK FACTORS
• High-protein rations, generally ≥16%, but disease can occur with as little as 12% protein
• Legume pastures
• Alfalfa hay
• Thick wool or fiber in the preputial region
• Wet grasses
• Venereal spread
• Castration

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Caprine herpesvirus-1, *Actinobacillus seminis*, *Ureaplasma* spp., and *Trueperella pyogenes* may also cause ulcerative posthitis lesions.
• Obstructive urolithiasis and/or urethral rupture.
• Preputial trauma.
• Ulcerative dermatosis (poxvirus) lesions look similar, but scab removal creates hemorrhage, and lesions are often also present on the legs, lips, and eyes.
• Contagious ecthyma (orf) causes raised, proliferative lesions that are also present on the face, lips, and udder.

CBC/BIOCHEMISTRY/URINALYSIS
Usually unremarkable; rare cases of urinary outflow obstruction may have azotemia and elevated serum potassium.

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Diagnosis is generally based on physical examination and lesion characteristics; however, lesions can be cultured or biopsy samples obtained for culture, histopathology, or PCR (herpesvirus).

PATHOLOGIC FINDINGS
• Grossly, there is ulceration and swelling of external genitalia.
• Histologically lesions are consistent with acanthosis, parakeratosis, and hyperkeratosis, or mucosal ulceration, suppurative inflammation, and the presence of bacteria.
• Herpesvirus infection would be reflected by acidophilic intranuclear inclusion bodies, and chromatin margination in epithelial cells adjacent to ulcers.

TREATMENT

THERAPEUTIC APPROACH
• Basic management steps may effect a cure if performed early in disease:
  ◦ Isolate affected individuals from other vulnerable animals.
  ◦ Shear the wool or hair around external genitalia to allow drying.
  ◦ Reduce protein or NPN in the ration, e.g., provide grass hay to animals grazing legume pastures.
• Sheath irrigation with antiseptic solutions and antibiotic administration can be performed for more significant clinical disease.
• Treatment of any kind should continue until lesions are dry and the animal is comfortable.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Early treatment obviates the need for surgical intervention; however, lesion cleaning and debridement may speed healing.
• Preputial resection may be required to permit urine flow and possible return to breeding after severe infection is cleared.

• As a salvage procedure, 2–4 cm incisions can be made through the ventral preputial skin to allow drainage and lavage.
• Strictured vermiform appendages may require resection.

MEDICATIONS

DRUGS OF CHOICE
• Topical antibiotic application can be performed; avoid irritating or caustic solutions.
  ◦ Topical mastitis therapy medications and the ointment combination of neomycin, bacitracin, and polymyxin B ("triple antibiotic") have been used but even topical use may require a withdrawal time.
• NSAIDs help decrease pain and inflammation (flunixin, meloxicam).
• Systemic antibiotics are indicated in severe cases (penicillin, ampicillin, tetracycline).

CONTRAINDICATIONS
• Xylazine should not be used in an animal with suspected or known urinary obstruction since it promotes diuresis, which can provoke urinary bladder rupture.
• Avoid iodine-based preparations for sheath lavage as they encourage the formation of adhesions and granulation tissue.

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• If recognized prior to fibrosis/adhesions, animals have a good chance of full recovery with appropriate medical and dietary management.
• Return to breeding soundness is unlikely in severely affected animals, particularly males.

POSSIBLE COMPLICATIONS
• Males:
  ◦ Loss of breeding soundness due to adhesion of penis to prepuce
  ◦ Scarring of preputial orifice
  ◦ Urethral obstruction
  ◦ Urethritis
• Females:
  ◦ Loss of breeding soundness due to impaired vulvar conformation
  ◦ Urine scalding
  ◦ Fibrosis of vulva may be severe enough to cause dystocia
  ◦ Cystitis/pyelonephritis might occur

CLIENT EDUCATION
Largely a disease of management, so make clients aware of causes, risk factors, and methods of prevention.

PATIENT CARE
Patients must be closely monitored to ensure patency of urinary tract and to monitor discomfort.

PREVENTION
• Maintain protein in feeding regimen below 16% when possible.
• Shear at times of high protein intake.
• Isolate affected animals.
• Increase water availability.
• May include ammonium chloride in feed to reduce urine pH.

MISCELLANEOUS

AGE-RELATED FACTORS
Rare in animals <6 months of age.

PREGNANCY
Fibrosis of vulva may be severe enough to cause dystocia.

BIOSECURITY
• Isolation of affected individuals from herd or flock is indicated.
• Separate males and females.
• Burn any fiber and scabs from treated animals to reduce transmission risk.

PRODUCTION MANAGEMENT
• Limit dietary protein to <16%.
• Shear animals at times of high protein intake.

SYNONYMS
• Pizzle rot
• Enzootic balanoposthitis and vulvitis
• Sheath rot

ABBREVIATIONS
• NPN = nonprotein nitrogen
• NSAIDs = nonsteroidal anti-inflammatory drugs
• PCR = polymerase chain reaction

SEE ALSO
• Orf (Contagious Ecthyma)
• Penile Disorders
• Urolithiasis

ULTRASONOGRAPHY: MAMMARY

BASICS

OVERVIEW
• Ultrasonography is an important evaluation modality of udder conformation and health.
• Ultrasonographic evaluation of mammary gland parenchyma and teat provides information that correlates well with presence of inflammatory changes or abnormality of development.
• Mammary ultrasonography should be used along with clinical evaluation by inspection and palpation of the gland, CMT testing, and gross chemical and bacteriologic evaluation of milk.
• Indications include evaluation of milk flow disorders, isolated abscesses, mammary gland hematoma, neoplasia, and detection of foreign objects.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Mammary

PATHOPHYSIOLOGY
• Anatomy and physiology of the mammary gland
  ◦ The mammary gland originates as primary mammary buds from modified sweat glands of the epidermal epithelium.
  ◦ The primary mammary buds push into the underlying dermis, forming the secondary mammary buds, which protrude and continue to develop into a gland by branching and forming a duct system.
  ◦ From birth to puberty the mammary gland grows at the same rate as other tissues (isometric growth). With the onset of puberty, under the influence of cyclic changes, the gland undergoes allometric growth. Branching and diameter of the ducts increase due to estradiol influence, and alveoli develop under progesterone influence.
  ◦ The final development of the gland occurs during pregnancy under the influence of several hormones (estrogen, progesterone, prolactin, adrenal cortical hormones, and placenta lactogens). The alveoli develop into lobules grouped into lobes that open into a common duct. Milk is synthesized in the secretory cells of the alveoli and delivered to the cistern through intra- and interlobular ducts. The teat consists of a teat canal and the teat cistern surrounded by a well-developed circular muscle forming a teat sphincter that helps retain milk. The junction between the teat canal and the teat cistern has longitudinal mucus membrane folds, the rosette of Fürstenberg. Milk ejection is induced by oxytocin which causes contraction of myoepithelial cells surrounding the alveoli.
  ◦ The external pudendal artery provides the main blood supply to the udder. The lymphatic drainage is provided by the superficial inguinal (supramammary) lymph node. The teat base contains an erectile venous plexus (venous ring of Fürstenberg).
  ◦ Species variation of the anatomy:
    ▪ Cow: 4 quarters and 4 teats, one gland, one canal and one cistern per teat
    ▪ Sheep and goat: 2 halves and 2 teats, one canal and one cistern per teat
    ▪ Camelid: 4 quarters and 4 teats, 2 canals and 2 cisterns per teat
• The udder can be affected by traumatic, inflammatory, neoplastic, and developmental disorders resulting in an alteration of the density of the tissues, which can be revealed by ultrasonographic evaluation.
• Congenital defects include glandular hypoplasia, teat cistern agenesis, partial or complete obstruction due to transverse intraluminal membrane, rudimentary teats, short teats, and supernumerary teats and glands.

HISTORICAL FINDINGS
• Abnormal conformation, size, or sensitivity of the udder
• Poor lactation or milk letdown
• Abnormal milk

SIGNALMENT
Postpubertal or lactating female

PHYSICAL EXAMINATION FINDINGS
• Presence of conformation abnormalities or asymmetry.
• Increase size or sensitivity may be seen in clinical mastitis.
• Bloody or purulent discharge from the teat.
• Enlarged lymph node.
• Abnormal milk.

GENETICS
• Mammary gland conformation and aptitude for milk production.
• Some congenital abnormalities may be hereditary.

CAUSES AND RISK FACTORS
• Genetics
• Infection
• Trauma

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
N/A

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• CMT
• Somatic cell count

IMAGING
• Equipment and technique
  ◦ The glandular parenchyma is scanned with a linear transducer 5–7.5 MHz frequency for small ruminants and SAC and 3.5–5 MHz for the bovine and camel.
  ◦ A higher frequency transducer (7.5–10 MHz) is ideal for the evaluation of the teat and superficial lesions.
  ◦ The gland is cleaned. The hair/fiber is clipped to improve contact. Application of a coupling gel greatly improves the quality of images. For evaluation of the teat, images are improved by placing the teat in a water-filled plastic cup. Alternately a standoff gel pad can be used or the transducer may be placed in a latex condom filled with coupling gel.
• Normal echotexture
  ◦ Skin should appear echogenic and smooth.
  ◦ Glandular parenchyma has a homogeneous echogenicity with visible anechoic areas corresponding to vessels. An echogenic line corresponding to a septum is visible between glands.
  ◦ The teat should be scanned vertically as well as in a transverse manner. The gland cistern is anechoic and demarcated by a hyperechoic line corresponding to the mucosal membrane. Large, round, anechoic structures corresponding to the venous ring of Fürstenberg are seen between the gland cistern and the teat cistern. The teat wall shows, from inside to outside, a thin, bright echoic line (mucus membrane), a thicker hypoechoic homogenous layer with several anechoic vessels (muscle and connective tissue), and a hypoechoic line (skin). In the most ventral aspect, the rosette of Fürstenberg is seen as two parallel echoic lines. Measurement of each component of the teat is helpful if serial evaluations are planned.
• Abnormalities
  ◦ Skin lesions may occasionally be detected. Most of these are abscesses and nodules. Their appearance varies in echogenicity but they should stand out from the rest of the glandular parenchyma.
  ◦ Glandular parenchyma
    ▪ Mastitis: Not all types of mastitis produce changes that are visible by ultrasonography. However, acute inflammatory changes may be depicted by increased edema and a more heterogeneous appearance of the parenchyma. The gland may display a comet-tail appearance signaling presence of gas in some Gram-negative bacterial infection. Chronic infection due to *Trueperella pyogenes*, *Klebsiella* spp., and *E. coli* may be detected as round, hypoechoic areas with a hyperechoic center. The milk within the cistern may appear more echogenic.

- Hematomas are initially seen as very echogenic masses that progressively show enlarging anechoic or hypoechoic areas with floating fibrin strands and clots as they become more organized.
- Abscesses, due to infection with *Corynebacterium pseudotuberculosis*, are often found in small ruminants and camelids. They usually present as distinct masses with a thick hyperechoic wall and a central cavity with different degrees of echogenicity.
- Foreign bodies are identified as hyperechoic structures casting shadows.
- Neoplasia is rare but has been diagnosed in goats and camelids. Adenocarcinomas present as multiple anechoic cavitary lesions interspaced by hyperechoic tissues.

◦ Teat
- Traumatic lesions to the teat canal and rosette of Fürstenberg often produce a heterogeneous appearance with echoic mucosal lesions.
- Inflammation of the teat cistern produces a thickened, irregular mucosal membrane with increased heterogeneity due to increased blood flow.
- Lactoliths (milk stones) may be identified as echogenic particles of varying sizes, either free or attached to the mucosal membrane.
- Polyps and papillomas may be detected as proliferative lesions.
- Congenital abnormalities should be suspected in primiparous animals with poor milk letdown. Ultrasonographically visible abnormalities include duplication of the teat (conjoined teat), teat agenesis, presence of septum in the cistern, or obstructing intraluminal membranes.
- Extreme dilation of the teat cistern is a common finding in camels.

UMBILICAL DISORDERS

BASICS

OVERVIEW

• Umbilical disorders can occur in all ruminants, usually in newborn and young animals.
• Umbilical masses can be divided into the following categories:
1. Uncomplicated umbilical hernia
2. Umbilical hernia with superficial infection or abscess
3. Umbilical hernia with umbilical remnant infection
4. Umbilical abscess or chronic omphalitis
5. Urachus rupture or cyst
• Umbilical hernias are the most common umbilical disorders in ruminants and camelids.
• The hernia sac has an inner peritoneal membrane and is covered with skin. These hernias have a genetic component but can also result secondary to an umbilical infection.
• Animals with umbilical hernias larger than 4–5 cm should be considered for surgical correction. Unfortunately, umbilical hernias in cattle rarely close spontaneously.
• The hernia usually contains intestines, i.e., abomasum, omentum (most common), or both. If the hernia is reducible there is a decreased incidence of intestinal strangulation. Chronic hernia can result in an abomasal umbilical fistula leading to loss of chloride and resulting in hypochloremic and hypokalemic metabolic acidosis.
• The presence of a patent urachus is not common in ruminants.

INCIDENCE/PREVALENCE

Umbilical disorders are common in veterinary practice.

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Cardiovascular
• Integument
• Digestive

PATHOPHYSIOLOGY

• At parturition the umbilical cord ruptures and the two umbilical arties retract actively. The urachus is pulled passively by the arteries into the abdomen. The umbilical vein does not retract but collapses due to surrounding smooth muscle contraction. The body wall should close within a few days to a few weeks. Failure of closure of the body wall is referred to as a congenital umbilical hernia.
• Congenital umbilical hernias can have a genetic origin.
• Umbilical hernias may be acquired from infection of the umbilicus in the neonatal period. Bacteria from the environment may seed the umbilical remnants. Less commonly the infection of the umbilical remnants may be hematogenous from a generalized septicemia or bacteremia. Common bacterial isolates in ruminants include *Trueperella pyogenes, E. coli, Proteus, Enterococcus, Streptococcus,* and *Staphylococcus* species.
• Excessive use of iodine or iodine in high concentrations for dipping of the umbilicus can cause necrosis of the remnants and surrounding tissue, increasing the incidence of infection and subsequent disorders.
• Neonates that develop partial or complete failure of passive transfer have an increased risk for umbilical infection and development of hernia due to compromised immunity.

GENETICS

• Umbilical hernias are the most common bovine congenital defect.
• Increased incidence of umbilical hernias in Holstein-Friesian cattle.
• Beef cattle have a lower risk of developing umbilical hernias in comparison to dairy cattle.

HISTORICAL FINDINGS

• Observation of an umbilical mass.
• Abnormal urination.
• Incidental finding during neonatal examination (camelid).
• Some accidents to the umbilicus may follow dystocia.

SIGNALMENT

• Ruminants and camelids.
• Patent urachus is more common in males.

PHYSICAL EXAMINATION FINDINGS

• Swelling
• Pain
• Presence of hernia sac
• Depressed, lethargic, or anorexic (bacteremia or septicemia or metabolic derangement)
• Purulent discharge or drainage
• Dribbling, scalding urine (patent urachus)
• Colic signs (bowel strangulation)
• Joint distension (septicemia or bacteremia)
• Fever

CAUSES AND RISK FACTORS

• Hereditary.
• Environmental contamination leading to infection of umbilical remnants.
• Excessive use of strong iodine or chlorhexidine for umbilical dipping leads to necrosis.
• Calves derived from SCNT pregnancies are at higher risk because of the abnormally large umbilical cord stump associated with large offspring syndrome and abnormal placentation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

• Physical examination, palpation, and ultrasonography of umbilical masses helps differentiate between various conditions of the umbilicus.
• Umbilical hernias have a distinct hernia ring. The hernia may be reducible. Examination of the content by ultrasonography reveals the presence of parts of the gastrointestinal tract.
• Abscesses are usually warm and present typical purulent content which may drain to the surface.
• Patent urachus is diagnosed by observation during urination and by ultrasonographic evaluation of the urachus and bladder.

CBC/BIOCHEMISTRY/URINALYSIS

Hyperfibrinogenemia, hyperproteinemia, neutrophilia, neutrophil-lymphocyte reversal, and mild anemia in cases of infection.

OTHER LABORATORY TESTS

Blood culture: Can be indicated in cases of septicemia.

IMAGING

• Transabdominal ultrasonography of the enlarged umbilical remnants (umbilical arteries, vein, and urachus) may reveal:
  ◦ The nature of the content of the hernia sac
  ◦ Inflammatory changes and abscess formation with thickening of the umbilical remnants
  ◦ Communication between the urachus and the bladder (patent urachus)
  ◦ Uroperitoneum in cases of rupture of the urachus.

OTHER DIAGNOSTIC PROCEDURES

Abdominocentesis: If a large amount of fluid is present in the peritoneal cavity, analysis of the fluid can help differentiate between uroperitoneum and peritonitis. Culture of the fluid provides information on the organism in the case of septic peritonitis.

PATHOLOGIC FINDINGS

• Umbilical hernia: The content of the hernia may become strangulated, leading to inflammatory changes and ischemic necrosis. Occasionally, neonates may be born with a complete failure of the skin to close in the umbilical region and eventration of intestines.
• Omphalophlebitis: The umbilical vessels are enlarged and thickened due to inflammation.
• In cases of large offspring syndrome, the umbilical mass may be 4–10 times the size of a normal umbilical stump.

TREATMENT

THERAPEUTIC APPROACH

Umbilical Hernia

Pinning: Clamps or elastrator bands are useful for closing small hernias (<4 cm in length). With the animal sedated, local anesthetic is placed around the hernia sac. The animal is placed in lateral recumbency, the hernia is reduced, and the procedure performed. The elastrator band is placed as close to the body wall as possible and two metal pins are placed in a crossing fashion to retain the band in

place. This will cause necrosis of the tissue distal to the band and an inflammatory reaction that will hopefully cause the hernia ring to close. If this is performed on lambs they should be given tetanus prophylaxis.

Medical Management of Infection of the Umbilicus or Umbilical Remnants

• Some cases of omphalophlebitis and/or omphaloarteritis respond to medical treatment.
• Prolonged broad-spectrum antibiotic treatment until infection is resolved.
• If medical treatment is proving ineffective, then surgical excision should be suggested to the owner.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Surgical Resection of Umbilical Hernia

• In cases where the hernia is >4 cm in length, it is advisable to perform surgical closure after resection of the hernia sac. This can be performed under local anesthesia or general anesthesia.
• Large calves should be held off feed for 48 hours.
• The umbilicus is clipped and prepared for surgery. An elliptical incision is made around the hernia sac and dissection performed to expose the hernia ring. The abdominal cavity is opened either just cranial or caudal to the hernia sac on the linea alba to allow introduction of a finger into the abdominal cavity. This allows digital palpation of the hernia ring to ensure no viscera is entrapped.
• The hernia is closed using an absorbable suture of a size determined by the size of the animal. A simple continuous pattern can be used in uncomplicated cases. In larger animals or with larger hernias, the middle of the incision can be closed with a near-far-far-near (tension relieving) suture pattern. The defect both cranial and caudal to this suture is then closed in a simple continuous pattern. This usually provides a secure repair that heals rapidly.
• All animals should receive tetanus prophylaxis.
• Animals should have limited exercise postoperatively and should be monitored for signs of sepsis and dehiscence.

Surgical Management of Infection of the Umbilicus or Umbilical Remnants

• The opening of the umbilicus is oversewn to prevent contamination of the surgical site. The prepuce in male animals can also be oversewn to prevent contamination of the site with urine.
• An elliptical incision is made around the umbilicus. The abdominal cavity is opened either just cranial or caudal to the umbilicus on the linea alba to allow introduction of a finger into the abdominal cavity. This allows digital palpation of the infected umbilical remnants. The incision is continued just lateral to the umbilical remnants on either side. Care is taken not to transect the umbilical vein, arteries, or urachus. The remnants are inspected for signs of infection.
• The vein and arteries should be ligated to remove as much infection as possible. If the umbilical vein is affected all the way to the liver, then marsupialization of the vein may need to be performed. The urachus is transected at the apex of the bladder within its healthy limits, and closed with a monofilament, absorbable suture in a two-layer closure (simple continuous oversewn with a Cushing or Utrecht suture pattern). The suture should not enter the lumen of the bladder if possible.
• Several suture patterns can be used to close the linea alba. Simple interrupted, interrupted cruciate, or simple continuous patterns are used most commonly. A monofilament absorbable suture material is the best option for closure.
• If marsupialization of the umbilical vein is indicated because of extensive infection, it can be marsupialized at the cranial aspect of the incision. The lumen of the vein is spatulated and sutured to the muscle and skin prior to closure of the incision. The venous stump should be flushed daily with antiseptic solution (1% chlorhexidine or 0.1% providone iodine). Broad-spectrum antibiotics should be administered for a minimum of 14 days post-surgery. The venous stump usually will close within a month. In very rare cases a second surgery may be needed to resect the infected umbilical vein if marsupialization is unsuccessful.

MEDICATIONS

DRUGS OF CHOICE

• Sedation
  ◦ Acepromazine: Cattle and goats at 0.05–0.1 mg/kg body weight IV and sheep at 0.03–0.05 mg/kg IV.
  ◦ Xylazine: Goats 0.05 mg/kg IV or 0.1 mg/kg IM; sheep 0.1–0.2 mg/kg IV or 0.2–0.3 mg/kg IM; cattle 0.1 mg/kg IV or 0.2 mg/kg IM. Recumbency will be induced for approximately 1 hour. Low dose xylazine 0.015–0.025 mg/kg IV or IM will provide sedation without recumbency in ruminants.
  ◦ Anesthesia with xylazine (0.20 mg/kg) followed by ketamine (4 mg/kg IV) has been used in calves.
  ◦ Lumbosacral epidural (2% lidocaine, 1 mL/10 lb body weight) after sedation with xylazine can be used in calves with simple hernias.
  ◦ In camelids, sedation with butorphanol and gas anesthesia are preferred for umbilical hernia repair or umbilical stump excision.
• Antimicrobials
  ◦ Choice of antibiotics and duration of treatment vary depending on the extent of surgery and risk for septicemia.
  ◦ Ceftiofur, 2.2 mg/kg q24h
  ◦ Oxytertacycline, 20 mg/kg SC q72h
  ◦ Procaine Penicillin G, 22,000 IU/kg
  ◦ Ampicillin/Amoxicillin 10 mg/kg IM q12h
• Anti-inflammatory drugs
  ◦ Flunixin meglumine 1.1–2.2 mg/kg IV can be used at the time of surgery, but is rarely necessary after the initial dose.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS

Acepromazine should not be administered via the coccygeal vein because of the close proximity to the coccygeal artery. Inadvertent infusion into the artery can result in possible loss of the tail.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Uncomplicated umbilical hernia repair carries a very good prognosis for survival and growth.
• Incarcerated umbilical hernias and post-surgical infection may increase the risk for dehiscence.

POSSIBLE COMPLICATIONS

• Suture abscess.
• Seromas.
• Hematomas.
• Incisional dehiscence which may result in evisceration and incarceration of bowel.
• Tetanus.
• Septic peritonitis especially if there is gross contamination of the abdomen at surgery or severe umbilical vein infection extending far cranially or to the liver.
• Uroabdomen secondary to leakage from closure of the apex of the bladder.
• Urolithiasis in small ruminants due to placement of suture material into the lumen of the bladder.

PATIENT CARE

• Animals should be confined post-surgery and closely monitor for signs of incisional infection or dehiscence.
• Close monitoring for signs of anorexia, fever, depression, or recumbency which may indicate development of bacteremia or sepsis.

PREVENTION

• Ensure adequate ingestion of good quality colostrum. Neonates should be exposed to as little stress as possible, especially in the first

UMBILICAL DISORDERS (CONTINUED)

2–3 days of life, to enhance colostrum absorption.
• Judicious care of the umbilicus in neonates. Clean environment and navel dipping with 1% chlorhexidine or 0.1% providone iodine(noncaustic).
• Selective breeding with males who are not genetically predisposed to producing offspring with hernias.

MISCELLANEOUS

UREA TOXICITY

BASICS

OVERVIEW

• Urea/nonprotein nitrogen toxicosis is defined as a condition that occurs when large amounts of urea/nonprotein nitrogen are ingested.
• Urea is considered an economical source of crude protein (CP) in ruminant diets. Other nonprotein nitrogen sources will be metabolized in a similar manner.
• Utilization of urea (CH_4N_2O) by the ruminant animal is initiated by its microbial hydrolysis to two ammonia (NH_3) molecules and one carbon dioxide molecule in the rumen environment. This step is accomplished by urease from specific bacterial species such as *Succinivibrio dextrinosolvens*, *Prevotella ruminicola*, and *Ruminococcus bromii.*
• In the rumen, the NH_3 produced from dietary proteins, urea, or other nonprotein nitrogen (NPN) sources is further utilized for synthesis of bacterial amino acids and bacterial proteins. Utilization of NH_3 for bacterial protein synthesis is dependent upon availability of highly fermentable carbohydrate sources such as dietary starch.
• Excess NH_3 is absorbed through the rumen wall and is transferred to the liver for conversion to urea before excretion in the urine.
• Depending on the CP level of the diet, a variable amount of urea is recycled back to the rumen. This is achieved mainly through saliva and to some extent through diffusion across the rumen wall. Urea recycling is intended to increase NH_3 concentrations in the rumen to meet N requirements of the rumen bacteria.
• When the liver's ability to detoxify NH_3 to urea is exceeded, blood NH_3 concentrations are increased to lethal levels (i.e., urea toxicity).

INCIDENCE/PREVALENCE

• The dietary urea levels required to induce toxic symptoms as well as the blood NH_3 concentrations associated with toxicity vary considerably. The conditions that may protect ruminants from urea toxicity are also quite variable. However, urea administration with the diet is less toxic than when administered separately. Younger ruminants are found to be more susceptible to toxicity than older ones.
• In general, urea is used widely in ruminant diets and intakes >0.45 g urea/kg of body weight are known to decrease feed intake and milk production in dairy cows and can induce toxicity.
• Urea toxicity symptoms occur at blood concentrations >1 mg/100 mL and become more severe at higher levels.
• Urea-induced death usually occurs when blood NH_3-N concentrations are in the range 2–4 mg/100 mL.
• Not unusual to find as high as 5–6 mg/100 mL.

GEOGRAPHIC DISTRIBUTION

Worldwide, depending on species and production management

SYSTEMS AFFECTED

• Digestive
• Musculoskeletal
• Nervous
• Respiratory

PATHOPHYSIOLOGY

• Following ingestion of large amounts of urea, a rapid release of NH_3 occurs.
• This increases the rumen pH to reach alkaline levels, which in turn supports high rates of NH_3 absorption through the rumen wall.
• Blood NH_3 is toxic to animal cells at low concentrations and is responsible for cell death. Additionally, NH_3 is carcinogenic.
• Alkaline rumen environments (pH >7.4), therefore, are considered the most important factor in inducing high blood NH_3 concentrations and toxicity.

HISTORICAL FINDINGS

• Elevated concentrations of rumen NH_3 and the subsequent high concentrations of NH_3 in serum are the key characteristics of urea toxicity.
• Complications due to increased serum NH_3 concentrations include alkalosis, rapid uptake of NH_3 by the brain, and central nervous system damage.

SIGNALMENT

• Potentially all ruminant species.
• Younger ruminants are found to be more susceptible to toxicity than adults.

PHYSICAL EXAMINATION FINDINGS

• Clinical signs are apparent within 20–30 min following ingestion of a toxic urea dose.
• Death can occur within hours after exposure.
• The clinical signs include respiratory difficulties (e.g., rapid and/or labored breathing), nervousness, muscular tremors, incoordination, excessive salivation, loss of ability to stand, bloat (due to reduction in rumen motility), and occurrence of tetany. The main cause of death appears to be respiratory arrest.
• Clinical signs can be similar to hypomagnesemia.
• The clinical signs of urea toxicity have been categorized into the following three stages: (1) The stage of depression and fatigue is associated with serum NH_3 concentrations in the range 0.5–1.0 mg/100 mL. (2) The beginning of the stage of convulsion is associated with serum NH_3 concentrations >2 mg/100 mL. (3) The end of the stage of convulsion is associated with serum NH_3 concentrations in the range 4.0–7.0 mg/100 mL. Damage of the brainstem and paralysis of the respiration center are usually responsible for death.

CAUSES AND RISK FACTORS

• Inadequate mixing of urea or urea-containing supplements with the remaining dietary ingredients may result in consumption of large urea doses at one time and can dispose the animal to urea toxicity.
• Feeding urea to animals that are not adapted to dietary supplementation of NPN such as urea, NH_3, and ammonium salts.
• Allowing free access to palatable sources of high-urea concentrates.
• Feeding poor-quality, forage-based diets.
• Use of urea in low-energy rations.
• Feeding urea-containing diets to cattle that are deprived of feed for extended periods of time (e.g., 24–48 hours).

DIAGNOSIS

Ammonia or NPN poisoning is suggested by signs, lesions, history of acute illness, and dietary exposure.

DIFFERENTIAL DIAGNOSES

• Differential diagnoses include poisonings by nitrate/nitrite, cyanide, organophosphate/carbamate pesticides, raw soybean overload, 4-methylimidazole, lead, chlorinated hydrocarbon pesticides, and toxic gases (carbon monoxide, hydrogen sulfide, nitrogen dioxide).
• Acute infectious diseases; and noninfectious diseases such as encephalopathies (e.g., leukoencephalomalacia, hepatic encephalopathy, polioencephalomalacia), enterotoxemia or rumen autointoxication, protein engorgement, grain engorgement, ruminal tympany, and pulmonary adenomatosis.
• Nutritional and metabolic disorders related to hypocalcemia, hypomagnesemia, and other elemental aberrations should also be considered.

CBC/BIOCHEMISTRY/URINALYSIS

The PCV and serum concentrations of NH_3, glucose, lactate, potassium, phosphorus, AST, ALT, and BUN usually are significantly increased.

OTHER LABORATORY TESTS

• The most accurate indicator of urea toxicity is serum or ocular fluid NH_3 concentrations.
• Specimens for NH_3-N analysis include ruminal-reticular fluid, serum, whole blood, and urine. All specimens should be frozen

UREA TOXICITY (CONTINUED)

immediately after collection and thawed only for analysis; alternatively, ruminal-reticular fluid may be preserved with a few drops of saturated mercuric chloride solution added to each 100 mL of specimen.
• Animals dead more than a few hours in hot ambient temperatures or 12 hours in moderate climates probably have undergone too much autolysis to be of diagnostic value.
• NH_3-N concentrations of ≥2 mg/100 mL in blood, serum, or vitreous humor indicate excess NPN exposure.
• Clinical signs usually appear at ~1 mg/100 mL. The concentration of NH_3-N in ruminal-reticular fluid is >80 mg/100 mL in most cases of NPN poisoning and may be >200 mg/100 mL.
• Acclimated ruminants fed diets high in legume hay, soybean meal, cottonseed meal, linseed meal, fish meal, or milk by-products may have NH_3-N concentrations in rumen fluid approaching 60 mg/100 mL with no apparent toxicity.
• The pH of ruminal-reticular fluid should also be determined; a pH of 7.5–8 (at time of death) is indicative of NPN toxicity.

PATHOLOGIC FINDINGS

• Carcasses of animals dying of NPN poisoning appear to bloat and decompose rapidly, with no specific characteristic lesions.
• Gross brain lesions are not usually reported in NPN-induced ammonia toxicosis, but histopathologic lesions may include neuronal degeneration, spongy degeneration of the neuropil, and congestion and hemorrhage in the pia mater.
• Frequently, pulmonary edema, congestion, and petechial hemorrhages may be seen. Mild bronchitis and catarrhal gastroenteritis are often reported.
• Regurgitated and inhaled rumen contents are commonly found in the trachea and bronchi, especially in sheep.
• The odor of NH_3 may or may not be apparent in ingesta from a freshly opened rumen or cecum.
• A ruminal or cecal pH ≥7.5 from a recently dead animal is highly suggestive of NPN poisoning. The ruminal pH remains stable for several hours after death under most circumstances but continues to rise in NPN toxicosis.

U

TREATMENT

THERAPEUTIC APPROACH

Early Stages

• Oral administration of 5% acetic acid solution to neutralize excess rumen NH_3. This treatment is effective in increasing potential survival of the animal if it is performed prior to the onset of tetany.
• Oral administration of cold water to slow the rate of urea hydrolysis to NH_3 and to dilute its concentration in the rumen.

Late Stages

Rumen lavage to remove the nonprotein nitrogen.

MEDICATIONS

DRUGS OF CHOICE

• Supportive therapy is indicated and includes IV isotonic saline solutions to correct dehydration, and IV calcium gluconate and magnesium solutions IV to relieve tetanic seizures.
• Convulsions may also be controlled with sodium pentobarbital or other injectable anesthetic agents.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Prognosis is grave when severe symptoms are present.

PREVENTION

• Gradual adaptation to urea feeding (e.g., feeding urea to dairy cows at 0.34 g/kg of body weight was achieved after a 6-week adaptation period without inducing negative effects on feed intake, blood composition, milk production, or milk composition).
• Feeding readily fermentable carbohydrate sources (e.g., starch and molasses) in amounts that enable rumen bacteria to capture the released NH_3 for bacterial protein synthesis.
• Uniform mixing of urea with the remaining dietary ingredients.
• Maintaining a regular feeding schedule.
• Feeding urea at rates not exceeding 33% of dietary CP.
• Feeding liquid urea supplements with phosphoric acid to maintain acidic rumen environments and to decrease the rate of NH_3 absorption.
• Coating urea with fat supplements to decrease its rate of hydrolysis to NH_3.
• Extrusion of urea with concentrates such as grains also decreases its rate of hydrolysis.
• Use of urease inhibitors to slow the release of NH_3. These inhibitors include hydroxamic acids, especially caprylohydroxamic acid.
• Urea should not be added to diets that are already meeting the animal's CP requirements.
• The diet should contain sufficient amounts of calcium and phosphorus. The sulfur to N ratio in the diet also should not be less than 1:15. The diet should also contain sufficient amounts of trace minerals, especially cobalt and zinc.
• Feeding low-energy, high-fiber diets, especially poor-quality forages, should be avoided with urea feeding.

MISCELLANEOUS

AGE-RELATED FACTORS

Younger ruminants are found to be more susceptible to toxicity than older ones.

ZOONOTIC POTENTIAL

N/A

PREGNANCY

N/A

PRODUCTION MANAGEMENT

• Urea administration with the diet is less toxic than when administered separately. Younger ruminants are found to be more susceptible to toxicity than older ones.
• In general, urea is used widely in ruminant diets and intakes exceeding 0.45 g urea/kg of body weight are known to decrease feed intake and milk production in dairy cows and can induce toxicity.

SYNONYM

Ammonia toxicosis

ABBREVIATIONS

• AST = aspartate aminotransferase

UREAPLASMA

BASICS

OVERVIEW
• Ureaplasmas are cell-wall deficient bacteria of the Mycoplasmataceae family (phylum Terenicutes) which also includes *Mycoplasma.*
• *Ureaplasma diversum* is found only in cattle, where it is a common inhabitant of the respiratory and genital tract.

INCIDENCE/PREVALENCE
• *U. diversum* is commonly isolated or detected by molecular diagnostic techniques in samples from the reproductive tract of apparently normal female cattle (15–70%), particularly from the vulvar and vestibular regions. Heifers with granular vulvitis lesions are reportedly three times as likely to be PCR positive for *U. diversum* as those without vulvovaginal lesions. It is also more frequently detected in uterine flushings from cows with evidence of endometritis.
• Breeding-age beef heifers tend to have the highest prevalence (30–80%) while *U. diversum* has also been isolated from 1-month-old female calves (21%).
• *U. diversum* is also a common inhabitant of the bull reproductive tract (5% to >70%), particularly within the prepuce and distal urethra. While the prevalence is highly variable, there are reports of it being cultured from frozen semen appropriately extended with recommended antibiotics.
• A recent study in Finland detected *U. diversum* in the respiratory tract of 23% of group-housed dairy calves at 1–2 months of age. Calves with clinical respiratory disease were significantly more likely to harbor *U. diversum.*

GEOGRAPHIC DISTRIBUTION
• First isolated from the urogenital tract of cows in western Canada.
• It has been reported in several other countries: Brazil, France, United States, Australia, Finland and may potentially be present worldwide.

PATHOPHYSIOLOGY
• The frequency with which *U. diversum* is isolated from cattle with apparently normal reproductive function has created controversy about its pathogenic significance for over 40 years. It is often considered a commensal bacterium.
• While specific pathologic mechanisms have not been determined, *U. diversum* is associated with a variety of bovine reproductive pathologies including granular vulvitis, endometritis, salpingitis, abortion, weak or stillborn calves, and infertility in female cattle. In bulls it is reported to cause epididymitis, seminal vesiculitis, and balanoposthitis, as well as alterations of sperm morphology and motility.
• Venereal transmission is considered a major source of new infections but transfer of the organism may also result from contaminated obstetric or breeding equipment, use of a common transrectal palpation sleeve, direct contact, congenital transmission, passage through the birth canal during delivery, and via contaminated sperm, oocytes, and embryos used in assisted reproductive programs (i.e., AI, ET, IVF).

HISTORICAL FINDINGS
• Abortion, usually in the last third of pregnancy
• Stillbirths or weak calves
• Infertility
• Lesions of granular vulvovaginitis

SIGNALMENT
U. diversum is found in all breeds of cattle, but more commonly in younger animals of both sexes.

PHYSICAL EXAMINATION FINDINGS
• Most carriers do not present any clinical signs.
• The most common clinical sign is a granular vulvaginitis.

CAUSES AND RISK FACTORS
• It has been suggested that increased blood urea nitrogen predisposes an animal to infection by providing urea substrate for the growth of *Ureaplasma* spp.
• Risk of transmission is increased by high density of cattle in an enclosure and unsanitary breeding techniques.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Granular venereal disease caused by other organisms, including IBR/IPV virus.
• Infertility caused by vibriosis or trichomoniasis.
• Other causes of mid- to late-term abortion.
• Other causes of genital tract inflammation in bulls.
• Calving or breeding trauma.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Culture is the gold standard for diagnosis but molecular techniques are becoming more common.
• Samples should be taken carefully to avoid contamination.
• The organism is fastidious so culture samples must be collected, stored, and transported in strict compliance with the recommendations of the diagnostic laboratory that will be processing them. Special transport media is usually required for culture.
• Not all diagnostic facilities offer services for detection of *U. diversum*.
• Diagnosis of *U. diversum* as a cause of abortion should be based on isolation from samples collected aseptically from the placenta, fetal lungs, and fetal stomach content.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Fetal necropsy, histopathology

PATHOLOGIC FINDINGS
• *Ureaplasma* infection in female cattle most commonly presents as vestibular hyperemia, usually accompanied by discrete, raised (hence granular) lymphoid cell proliferation with or without mucoid discharge. Granular lesions may progress to a pustular stage. Similar lesions are found on the prepuce and glans penis of affected bulls.
• *U. diversum* is also associated with repeat breeding, abortion, stillbirth, and weak calves.
• Abortion is characterized by a diffuse placentitis and interstitial pneumonia. The amnion is thick and opaque with multifocal areas of hemorrhage, fibrin exudation, necrosis, and fibrosis.

TREATMENT

THERAPEUTIC APPROACH
• Treatment in most cases is considered neither necessary nor practical. Most healthy, well-fed cattle appear to have only brief periods of infertility associated with the organism, so aggressive treatment that would require meat and milk withholding is hard to justify.
• Intrauterine or systemic oxytetracycline has been recommended for granular vulvitis therapy.
• Systemic antibiotic therapy is recommended for salpingitis and seminal vesiculitis when *Ureaplasma* is suspected.
• Eliminating the organism from the vestibulovagina and sheath is difficult.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
U. diversum is usually sensitive to tetracycline, macrolide, aminoglycoside, and fluoroquinolone antibiotics. In humans, there are concerns about *U. urealyticum* tetracycline resistance but little specific information is available regarding *U. diversum* antibiotic resistance patterns in cattle.

(CONTINUED) UREAPLASMA

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Most animals that are otherwise healthy appear to be unaffected by the organism or will spontaneously recover from a temporary infertility.

POSSIBLE COMPLICATIONS
- Salpingitis and seminal vesiculitis, while uncommon, represent potentially serious complications of *U. diversum* genital infections.
- Complications are rare but if fertility is significantly affected for a prolonged period of time, affected animals are at an increased risk of being culled.
- Infected calves may have an increased risk of respiratory disease.

CLIENT EDUCATION
Breeding hygiene

PATIENT CARE
- Repeated swabbing for culture or molecular diagnostics is required to confirm elimination of the organism. There seems to be little justification to this approach.
- Monitoring the reproductive performance of individual animals (BSE, pregnancy diagnosis) or the herd on a regular and ongoing basis is a better method for assessing the significance of the disease.

PREVENTION
- No vaccine is currently available.
- Use of a guarded sheath for AI and ET equipment has been suggested as a way to reduce uterine contamination during these procedures.
- Post-breeding intrauterine infusion of tetracycline has been reported to improve fertility in affected animals, but appropriately controlled studies are lacking and the possibility of spontaneous recovery cannot be ruled out.
- Gentamicin, tylosin, lincomycin, and spectinomycin are usually added to extenders for frozen semen.

MISCELLANEOUS

ASSOCIATED CONDITIONS
- Seminal vesiculitis, balanoposthitis in bulls
- Vaginitis, endometritis, salpingitis, abortion, stillbirth, weak calves in cows

AGE-RELATED FACTORS
Younger cattle seem to be more commonly infected, suggesting the development of immunity over time.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
U. diversum has been implicated in early embryonic loss, mid- to late-term abortion, stillbirth, and birth of low-viability calves.

BIOSECURITY
- The organism appears to be a ubiquitous commensal and there may be no effective way to control exposure. Regardless, routine herd biosecurity protocols should be in place for every farm.
- Semen and embryos should be acquired through reputable, certified sources to minimize the potential for disease introduction.

PRODUCTION MANAGEMENT
- The impact on herd reproductive performance is unclear.
- Routine monitoring of herd reproductive performance should be part of every herd management program.

ABBREVIATIONS
- AI = artificial insemination
- BSE = breeding soundness examination
- ET = embryo transfer
- IBR = infectious bovine rhinotracheitis
- IPV = infectious pustular vulvovaginitis
- IVF = in vitro fertilization

SEE ALSO

UROLITHIASIS

BASICS

OVERVIEW

• Obstructive urolithiasis is a frequent problem in male small ruminants. It can also occur in bovines to a lesser extent.
• Urinary calculi are concentrations of mucus, protein, and minerals in the urinary tract.
• The composition of uroliths varies depending on diet and geography. The most common uroliths are calcium apatite and phosphatic based calculi. These calculi are usually white or gray, usually smooth, radiopaque, and easily broken. Silicate and calcium carbonate uroliths are occasionally seen.
• Calcium based uroliths are common in ruminants grazing lush, rapidly growing clover pastures or being fed alfalfa hay.
• Urethral obstruction is most commonly seen in show or pet goats and lambs that have a high-concentrate and low-roughage diet.

INCIDENCE/PREVALENCE

• Well recognized in sheep wethers and steers maintained in feedlot conditions and fed high-concentrate, low-forage diets.
• Wethers castrated at an early age are more susceptible due to a lack of testosterone driving development of the urethra and urethral process.

GEOGRAPHIC DISTRIBUTION

Silicate calculi are more commonly diagnosed in animals grazed on sandy soil, high in silica, conditions more frequently seen in the western parts of the United States and Canada.

SYSTEMS AFFECTED

• Urinary
• Cardiovascular
• Integument
• Multisystemic

PATHOPHYSIOLOGY

• Diets that are high in concentrate, phosphorus, and magnesium and low in roughage and calcium will predispose to risk of phosphate urolith formation. Urine is normally highly saturated with mineral solutes. Multiple factors can cause these minerals to leave solution and precipitate in the urine.
• Normally, a ruminant will remove phosphorus from its body by excreting it into saliva and through the manure. Diets high in concentrate and low in roughage decrease the production of saliva so phosphorus has to be excreted from the blood via the urinary system.
• The distal sigmoid flexure is the most common site of obstruction in steers and bulls. In sheep and goats the urethral process and the distal sigmoid flexure are the most common site of obstruction.
• Some breeds of sheep (e.g., Texel and Scottish Blackface) may be predisposed to calculi formation because of excretion of phosphorus via the urinary system in preference to via saliva.

HISTORICAL FINDINGS

• Male castrated animals with history of castration at an early age and diet consisting of high concentrate and low forage.
• History of low water consumption, lethargy, inappetance, and straining ± vocalization.
• In steers, owners may notice preputial swelling as the first sign.

SIGNALMENT

• Males more commonly affected.
• All ages are affected but the incidence is greater in younger ruminants.

PHYSICAL EXAMINATION FINDINGS

• Dysuria, stranguria, hematuria, anuria
• Prolonged urination or urine dribbling
• Tachycardia
• Tachypnea
• Vocalization
• Tail flagging
• Abdominal straining (can lead to rectal prolapse)
• Abdominal pain (stretching, kicking at abdomen, flank watching)
• Abdominal distention
• Preputial/perineal edema ("water belly" in cattle; secondary to urethral rupture)
• Bruxism
• Anorexia, weakness, depression

GENETICS

Texel and Scottish Blackface have a high incidence due to their preferred method of phosphorus excretion.

CAUSES AND RISK FACTORS

• High-grain, low-roughage diets.
• Dietary electrolyte imbalances, decreased water consumption/availability, and abnormal urine pH.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

A hair ring present around the penis may cause signs of discomfort and dysuria similar to that seen with obstructive urolithiasis.

Hematuria

• Bladder polyps
• Bracken fern toxicity
• Cystitis
• Infarction of kidney
• Papilloma
• Pyelonephritis
• Trauma
• Urethritis

Dysuria

• Actinomyces
• Cystitis
• Mycoplasma
• Orf
• Photosensitivity
• Sacral fracture
• Spinal cord injury
• Trauma
• Ulcerative balantitis and vulvitis

CBC/BIOCHEMISTRY/URINALYSIS

• A complete blood count may reveal a stress leukogram and mild to severe azotemia depending on duration. Mild hemoconcentration, hyperkalemia, hyperglycemia, hyponatremia, hypochloremia, hypocalcemia, and hypophosphatemia can been seen on biochemistry.
• Hematuria and proteinuria are common findings; crystalluria is a variable finding.
• Pyuria can be present with traumatic urethritis, cystitis, or secondary bacterial infection.

OTHER LABORATORY TESTS

If bladder rupture is suspected, an abdominal fluid to serum creatinine ratio can be performed. The ratio should be < 2:1 and if greater suggests urine leakage into the abdomen.

IMAGING

• An enlarged bladder is often visualized on right-sided abdominal or transrectal ultrasound.
• Echogenic material in the bladder or kidneys is occasionally visualized, but lack of this finding does not rule out the diagnosis. A large amount of free fluid (ascites) may also be visualized in the abdomen if the abdominal portion of the urinary tract is ruptured due to unresolved obstruction.
• Abdominal radiography may allow visualization of the calculi depending on composition.
• Calcium oxalate and calcium carbonate crystals are radiopaque while struvite (magnesium ammonium phosphate), apatite, and silicate crystals are radiolucent. Therefore, lack of radiographic visualization does not rule out the presence of obstructive calculi.
• Infusion of contrast media retrograde through a urethral catheter may allow visualization of calculi; however, urethral rupture/fistula formation or bladder rupture can occur.
• Ultrasonographic examination of the kidneys is indicated in chronic (>24 hours) urethral obstruction. The presence of hydronephrosis with loss of cortical tissue warrants a guarded to poor prognosis for restoring normal renal function.

OTHER DIAGNOSTIC PROCEDURES

• Abdominal palpation in small ruminants.
• Urethroscopy has recently been recognized as a modality for diagnosing urethral obstruction in ruminants.

• Abdominocentesis yielding urine (be aware of inadvertent cystocentesis with enlarged bladder).

PATHOLOGIC FINDINGS

• Single to multiple calculi lodged along the extent of the urinary tract. The tissues will be hyperemic, hemorrhagic, or necrotic depending on duration of disease.
• Bladder or urethral rupture may be present as well as hydroureter and hydronephrosis.

TREATMENT

THERAPEUTIC APPROACH

• Treatment should be aimed at supportive care and correcting the obstruction.
• In cases of bladder rupture, urine can be drained from the peritoneum to reduce the effects of uremia and correct electrolyte imbalances. Drainage should be performed slowly to reduce the risk of circulatory shock, and IV fluids should be given concurrently.
• IV fluids should be given judiciously in cases of complete obstruction. Choice of fluid therapy should be based on electrolyte imbalances. IV fluids containing potassium should be avoided if hyperkalemia is present.

Cattle

Signs are generally seen after rupture of the urethra once preputial swelling is present. A perineal urethrostomy is the treatment of choice and is used as a salvage procedure to allow animal to survive to slaughter.

Small Ruminants

Although most cases benefit from surgical intervention, partial obstructions may be attempted with medical management along with less-invasive surgical techniques (see *urethral process amputation* and *urethral catheterization and retrograde flushing*). Medical management may include repeated administration of diazepam (0.1–0.5 mg/kg body weight IV) or acepromazine maleate (0.05–0.1 mg/kg IV) to promote urethral relaxation. There are limited reports suggesting the use of acidic solutions (hemiacidrin and Walpole's solution) to dissolve struvite stones through retrograde flushing or ultrasound-guided infusion into the bladder.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Urethral Process Amputation

• If the obstruction is located in the urethral process, amputation may completely alleviate obstruction, as is the case in 37.5–66% of cases.
• Amputation of the urethral process will not affect future breeding ability. This procedure does not prevent future obstruction if multiple calculi are present in the urinary tract.
• The penis should be exteriorized and urethral process examined in all cases. This may be facilitated by sedation or lumbosacral epidural anesthesia.
• Sedation protocols include diazepam, at a dose range of 0.1–0.5 mg/kg IV, or acepromazine maleate 0.05–0.1 mg/kg IV.
• Acepromazine may promote relaxation of the retractor penis muscle.
• Lumbosacral epidural anesthesia can be performed to provide exteriorization of the penis by eliminating resistance by the retractor penis muscle. Lidocaine (2%) is used at a dose of 1 mL per 5 kg (not to exceed 15 mL). The use of epidural anesthesia may reduce the concentration of inhalant require for surgery.
• Once sedated and/or lumbosacral epidural has been given, the patient can be placed on its rump to allow easier extrusion of the penis. The penis is grasped through the skin at the base of the scrotum and forced cranially. Uroliths may be palpable in the urethra or urethral process and it may be amputated at this time.

Urethral Catheterization and Retrograde Flushing

• Catheterization of the bladder of a ruminant is difficult due to the sigmoid flexure and urethral recess. A catheter can be placed in the distal urethra while occluding the penis. Saline or a lidocaine-saline flush solution (one part lidocaine to three parts saline) is flushed retrograde through the catheter to lavage the calculi into the bladder.
• The disadvantages of this technique are that it is often unsuccessful, can cause trauma to the urethra if catheterization is overly aggressive, and, if successful, the calculus has been returned to the bladder for another chance to cause an obstruction.

Perineal Urethrostomy

• Perineal urethrostomy can be performed in the sedated animal with a lumbosacral epidural.
• Stricture, reduced reproductive ability, and reobstruction are common complications, and this option is best used as a temporary salvage procedure in animals intended for slaughter.

Tube Cystotomy

• Under general anesthesia, a laparotomy is performed, placing an indwelling Foley catheter percutaneously into the bladder wall. The catheter is sutured in place to the abdominal wall enabling voiding of urine through the catheter. The bladder is lavaged to remove remaining calculi. The catheter is left in place to allow the urethra to heal and calculi to be expelled. Periodic challenging of urethral patency is performed until the urethral obstruction is resolved.
• This procedure is the best option for salvage of breeding function in intact males, but it does not prevent recurrence of obstruction.
• Tube cystotomy is the most expensive of the surgical options and is usually performed in pets and breeding animals.

Bladder Marsupialization

• A permanent bladder marsupialization can be performed in which the bladder is sutured to the ventral abdominal wall lateral to the prepuce through a laparotomy incision. This technique requires commitment by the owners as care and cleaning of the stoma are required for the life of the animal.
• Bladder marsupialization has the least chance of reobstruction by calculi but the stoma occasionally strictures and requires surgical modification.
• The breeding capabilities are questionable following this procedure.

MEDICATIONS

DRUGS OF CHOICE

• Sedation can be given for examination and manipulation of the penis and urethral process.
• Diazepam, at a dose range of 0.1–0.5 mg/kg IV (slowly) or acepromazine maleate 0.05–0.1 mg/kg IV or IM. Either as sole agents or in combination with butorphanol 0.05–0.1 mg/kg IV. Alternatively, the use of isoflurane by mask can be used. Acepromazine may promote relaxation of the retractor penis muscle.
• Appropriate antimicrobial therapy should be instituted depending on the specifics of the individual case and route of therapy.
• Preoperative antimicrobials that concentrate in the urine are indicated (e.g., sulfonamides, beta-lactams).

CONTRAINDICATIONS

• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.
• Lidocaine sensitivity is common in goats and should be considered prior to its utilization. (Total dose should never exceed 5 mg/kg or 15 mL of 2% lidocaine in any small ruminant regardless of size.)

PRECAUTIONS

• Alpha-2 agonists (xylazine, detomidine) should not be used in cases of unresolved obstruction due to its diuretic effects.
• Neither diazepam nor acepromazine is approved for use in food animals. The meat withdrawal time for acepromazine maleate is 7 days. There are no withdrawal data for diazepam, therefore consult with FARAD.

UROLITHIASIS (CONTINUED)

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Prognosis depends on chronology and severity of obstruction as well as treatment method instituted.

POSSIBLE COMPLICATIONS
Recurrence of obstruction and urethral stricture can be common complications.

CLIENT EDUCATION
• Many small ruminant owners do not know the importance of feeding a low-carbohydrate diet. Small ruminants will preferentially eat grain and owners should feed carbohydrates on a limited basis.
• Mineral supplementation should be done carefully, keeping within recommended ratios.

PATIENT CARE
Animals at risk for obstruction should be monitored closely for signs to enable rapid treatment.

PREVENTION
• A low-carbohydrate, high-roughage diet with a balanced mineral content.
• Free access to water and free-choice salt.
• Urine acidifiers can be used.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Bladder/urethral rupture, uremia, urethral stricture

PRODUCTION MANAGEMENT
• This is a common problem of feedlot lambs fed high-carbohydrate diets.
• Use of ammonium chloride in feed to help reduce the pH of the urine to between 6.0 and 6.5.
• Increasing the quality of long stem ration in the diet.
• Provision of a reliable source of palatable water at all times to encourage water consumption. Heaters should be used to warm the water in winter.

ABBREVIATIONS
• FARAD = Food Animal Residue Avoidance Databank
• IM = intramuscular
• IV = intravenous

SEE ALSO
• Acute Renal Failure

UTERINE ANOMALIES

BASICS

OVERVIEW
• An anomaly is a marked deviation from normal, especially one resulting from a congenital or hereditary defect. • Many of these conditions affecting the uterus are covered individually in other chapters; in this chapter the reader is referred to those chapters for diagnostic and therapeutic information.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
The pathophysiology of each condition is highly specific to that condition. This chapter provides a general overview of uterine disease. For specific information about these conditions, the reader is referred to particular chapters.

Congenital Anomalies
This includes arrested development of those structures derived from the embryonic duct systems. Problems caused by either defective or exaggerated fusion of the ducts are reported in most species. It is useful to classify defects on the basis of the underlying anatomic structure. For more information, please consult the following chapters: Segmental Aplasia of the Reproductive Tract; Freemartinism, Congenital Defects (Bovine, Camelid, Small Ruminant).

Acquired Anomalies
• Acquired diseases of the presumptively normal uterus can be classified using the traditional DAMNIT system. • Degenerative, age-associated vascular changes are common in the uterus of the cow and camelid. These usually take the form of a sclerotic lesion and are attributable to previous pregnancies. • Mucometra secondary to chronic ovarian cystic degeneration is associated with uterine atrophy involving both the myometrium and the endometrial glands. • Hydrops allantois can be associated with acquired degenerative uterine changes that impact placental function. • Neoplastic and proliferative disorders of the uterus are uncommon in ruminants, with the exception of lymphosarcoma in cattle. Uterine adenocarcinoma, fibroma, leiomyoma, and leiomyosarcoma are also possible. • Endometrial hyperplasia and cyst formation may occur in association with hyperestrogenism due to toxicity or functional ovarian cysts.

HISTORICAL FINDINGS
• Infertility or subfertility (repeat breeding) • Recurrent pregnancy loss • Abnormal vaginal discharge

SIGNALMENT
• Potentially all ruminant and camelid species. • Congenital anomalies are more common in ruminants.

PHYSICAL EXAMINATION FINDINGS
Signs vary with the specific disease condition but anestrus and repeat breeding are common findings.

GENETICS
• There is evidence for a genetic basis for segmental aplasia of the reproductive tract in female cattle. • Intersex is linked with the gene for polledness in dairy goats.

CAUSES AND RISK FACTORS
• Vary with the specific disease condition. • Degenerative changes of the uterus are often caused by aging and excessive uterine manipulations or chronic infection.

DIAGNOSIS

Diagnosis of uterine anomalies requires a careful history and physical examination.

DIFFERENTIAL DIAGNOSES
Pregnancy should be ruled out in every case of uterine enlargement.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Cytogenetic testing or genetic testing (e.g., PCR) • Uterine culture, cytology, and biopsy are useful tools for suspected cases of inflammatory, neoplastic, or degenerative disorders.

IMAGING
• Ultrasonographic evaluation of the uterus is useful for gross pathology such as hydrometra or segmental aplasia. • Radiographs, especially with contrast, may be useful for small ruminants and SAC.

OTHER DIAGNOSTIC PROCEDURES
• Transrectal palpation in cattle and camels. • Exploratory laparotomy or laparoscopy in small ruminants and SAC. • Hysteroscopy is the procedure of choice to investigate intraluminal uterine lesions in SAC.

PATHOLOGIC FINDINGS
The specific findings will vary with the underlying condition.

TREATMENT

Refer to the specific disease conditions.

MEDICATIONS

Refer to the specific disease conditions.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

Uterine Artery Rupture

BASICS

OVERVIEW
• Uterine artery rupture is a rare, acute, life-threatening hemorrhagic event encountered during the periparturient period. • Rupture is more commonly seen following forced fetal extraction or fetotomy. • Rupture due to arterial wall trauma associated with entrapment and crushing of the uterine artery between the fetus and the maternal pelvis. • May occur subsequent to uterine prolapse as a result of stretching and trauma to the vessels within the broad ligament. • Rarely, it may accompany correction of uterine torsion using the "plank in the flank" technique.

GEOGRAPHIC DISTRIBUTION
N/A

INCIDENCE/PREVALENCE
Unknown

SYSTEMS AFFECTED
• Reproductive • Cardiovascular

PATHOPHYSIOLOGY
• The exact pathophysiology is not known in ruminants and camelids. • May be the result of a combination of traumatic factors associated with dystocia, stretching or sudden drop of the animal and a fragile arterial wall (sclerosis or degenerative changes). • The prolapsed uterus may provide hemostasis by compression of the broad ligament and delay blood loss; death may occur during or soon after repositioning of the uterus.

HISTORICAL FINDINGS
Collapse or sudden death during or soon after parturition.

SIGNALMENT
• More common in dairy cattle • Potentially all ruminant species and camelids

PHYSICAL EXAMINATION FINDINGS
Severe anemia, tachycardia, tachypnea, anxiety, and signs of shock due hypovolemia.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Age • Dystocia

DIAGNOSIS

• Antemortem: History and clinical signs. • Transrectal palpation: Large soft tissue swelling (hematoma) within the broad ligament. • Hemorrhage may be evident at the vulva if the uterine wall is ruptured. • Incidental transrectal findings of a soft tissue mass within the broad ligament and/or a corresponding defect or aneurysm in the uterine artery days or weeks after parturition. • Postmortem: Identification of the rupture within the uterine artery and hemorrhage into the broad ligament or peritoneum.

DIFFERENTIAL DIAGNOSES
• Acute blood loss from other internal sites
• Acute septic peritonitis

CBC/BIOCHEMISTRY/URINALYSIS
Evidence of blood loss anemia if the animal survives the first few hours.

OTHER LABORATORY TESTS
Fine-needle aspirate of a soft tissue mass in the broad ligament may allow differentiation of hematoma from an abscess.

IMAGING
Transrectal ultrasonography may help identify a hematoma within the broad ligament and/or a defect in the affected uterine artery.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Rupture of uterine artery with accompanying massive hemorrhage into the broad ligament. • Hemoabdomen may also be noted. • Extreme pallor of mucus membranes and other tissues noted during postmortem examination.

TREATMENT

THERAPEUTIC APPROACH
• Whole blood transfusion (6–12 liters) • Hypertonic saline (2–4 mL/kg of 7% sodium chloride, IV) may be of acute resuscitative value. • Oxytocin (20–100 IU, IV) to promote uterine contraction and involution—may be given repeatedly. • Aminocaproic acid, a derivative of the amino acid lysine, aids in clot formation by inhibiting fibrinolysis and has been used as a coagulation aid in mares with periparturient hemorrhage (loading dose of 20 g aminocaproic acid diluted in 1 liter of isotonic fluid and given IV followed by 10 g diluted in 1 liter of isotonic fluid q6h).

SURGICAL CONSIDERATIONS AND TECHNIQUES
Vessel ligation may be attempted but will be possible only if a full thickness uterine tear accompanies uterine artery rupture.

UTERINE PROLAPSE

BASICS

OVERVIEW
• Uterine prolapse is the most dramatic of the reproductive prolapses. It affects all ruminants and camelid species but is most common in multiparous dairy and beef cattle and dromedary camels.
• The protrusion of both uterine horns through the vulva is easily diagnosed and characterizes the uterine prolapse.
• Uterine prolapse usually occurs within a few hours after parturition. In cattle, half occur within 3 hours and >90% occur within a day. More rarely, it can occur up to 5 or 6 days after parturition.
• In camels, uterine prolapse tends to occur immediately after parturition.
• Uterine prolapse is a true emergency and prompt, effective intervention is required to protect the life and reproductive health of the animal.

INCIDENCE/PREVALENCE
The incidence of uterine prolapse is relatively low, ranging from 0.003% to 0.25% but ruminant species are more commonly affected than are other domestic animals.

GEOGRAPHICAL DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• It is assumed that the loosening and stretching of perineal tissue at parturition creates a laxity that allows the uterus to prolapse.
• Straining, especially after a difficult delivery of a large fetus, along with recumbency and lack of uterine tone are contributing factors. Postpartum uterine inertia may result from excessive distention or hypocalcemia (primary) or dystocia and prolonged effort (secondary).

HISTORICAL FINDINGS
• Recent parturition
• Dystocia

SIGNALMENT
All ruminant species are at risk for the occurrence of uterine prolapse, but cows are at a higher risk. Multiparous cows are at higher risk due to a higher risk for hypocalcemia, a condition that predisposes cows to uterine prolapse.

PHYSICAL EXAMINATION FINDINGS
• Immediately after prolapse occurs, the tissues are normal and there may be fetal membranes still attached to the caruncles (ruminants). Within a few hours after the prolapse, the uterus becomes edematous and is more susceptible to traumatic injury.
• Clinical signs that accompany uterine prolapse are straining, abdominal pain, restlessness, anorexia, and increased pulse and respiratory rate. Uterine prolapse in cows and camels is frequently accompanied by hypocalcemia and, in the more severe cases, milk fever.
• Cows that present with concurrent hypocalcemia may be recumbent and have muscle fasciculation. Although unusual, the condition may progress to shock and death.

GENETICS
The sporadic incidence makes it difficult to confirm a hereditary tendency.

CAUSES AND RISK FACTORS
Dystocia, hypocalcemia

DIAGNOSIS

The diagnosis is obvious as the uterine horns can be identified protruding from the vulva.

DIFFERENTIAL DIAGNOSES
• Retained fetal membranes
• Vaginal or cervical prolapse

CBC/BIOCHEMISTRY/URINALYSIS

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• The correction of uterine prolapse can be performed with the animal standing or in sternum recumbency.
• In camelids, the best approach is to sedate and restrain the animal in a sternal "cush" position with the hindquarter slightly elevated.
• Epidural anesthesia with 2% lidocaine is recommended.
• Administration of clenbuterol is reported to cause uterus relaxation, facilitating replacement of the uterus, reducing the need for epidural anesthesia. Clenbuterol is a prohibited drug in the United States.
• When attempting to reduce uterine prolapse in a recumbent cow, both hindlimbs should be pulled posterior behind the animal so that she is resting on her stifles with the hind legs spread out. This positioning causes the pelvis to be slightly tilted downward and forward, leaving more room in the caudal abdominal cavity, favoring the replacement of the uterus. The hindquarters of small ruminants should be elevated to assist with replacement.
• It is imperative that when reducing a uterine prolapse the veterinarian and assistant be as clean as possible. Surgical scrub should be used to wash the entire uterine surface and remove fecal material, dirt, bedding material, and fetal membranes. If the membranes are not easily separated from the caruncles, they should be left in place.
• The washed uterus should be supported on a clean surface (e.g., a tray, towel, or sheet) to minimize contamination and assist replacement. For the recumbent cow, the uterus can be supported on the clinician's lap as they kneel between the hind legs. A waterproof obstetric smock provides a clean support surface for both the clinician and the patient.
• Many practitioners attempt to reduce tissue edema to facilitate replacement. This is done by either rinsing the uterus with hypertonic saline or dusting it with sugar.
• The uterus is replaced by alternately pushing on either side of the prolapsed tissue nearest the vulva. Avoid spreading the fingers of the hand while pushing as this may lead to repeated perforation of the organ. Obstetric lubricant should be applied if necessary.
• Once the uterus is replaced, every effort should be made to ensure that the both horns are completely inverted. This simple expedient will prevent recurrence in most cases. If the clinician's arm is too short or too large to accomplish the task, a number of alternatives have been recommended. They include the use of a probang and the infusion of large volumes of sterile fluid. The fluid should be siphoned out after the horns are correctly positioned.
• Oxytocin can be administered after the uterus is successfully replaced to stimulate uterine contraction and involution. Cows that develop uterine prolapse are also at higher risk for hypocalcemia; treatments with calcium intravenous solutions should be considered. Prolonged recumbency after replacement may predispose to recurrence of the prolapse.
• The use of retention sutures after replacement is the subject of some controversy. While there is little evidence that they are necessary if the uterus is correctly replaced, many clinicians (including the author) continue to use them. Options include a Buhner stitch, the shoelace technique, or mattress sutures with stents. These should all be removed within 2–3 days. During this time the animal must be closely monitored for recurrence as the potential for trauma is increased while the sutures are in place.
• Parenteral antibiotic treatment is recommended after uterine prolapse is resolved to avoid the occurrence of metritis. An anti-inflammatory agent should be given for 3–4 days for pain control.

UTERINE PROLAPSE (CONTINUED)

SURGICAL CONSIDERATIONS AND TECHNIQUES
In cases where replacement of the uterus is impossible or where the tissues are severely damaged, amputation or emergency slaughter may be indicated as salvage options.

MEDICATIONS

DRUGS OF CHOICE
Lidocaine epidural, appropriate parenteral antibiotic, nonsteroidal anti-inflammatory agent

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The prognosis is usually good if the prolapse is recent.
• The prognosis is poor or guarded if there is severe contamination or extensive uterine lesions.

POSSIBLE COMPLICATIONS
• Fatalities are rare but can occur in the event of shock or rupture of a large uterine vessel.
• Cows that develop uterine prolapse are at higher risk for metritis and, consequently, are at higher risk for reproductive problems (e.g., increased calving-to-conception interval and calving interval). Due to reproductive problems, cows that present with uterine prolapse are at a higher risk for culling than their herd mates.

PATIENT CARE
Animals should be closely observed daily for 5–10 days. Animals showing any signs of straining, fever, anorexia, or depression should be examined and treated appropriately.

CLIENT EDUCATION
Proper handling of animals with prolapse: Keep animal calm, move animal carefully to clean area, protect exposed tissue with clean wet towel or place in a plastic bag.

PREVENTION
• Because hypocalcemic cows are at higher risk of uterine prolapse, the dry cow diet should be formulated to avoid such metabolic imbalance.
• Some studies have shown that cows that have stillborn calves are at higher risk for uterine prolapse, probably due to the longer period between initiation of parturition and assistance provided to the animal. Therefore, it is recommended that the calving area be well monitored at all times and that cows have the proper assistance as they show signs of dystocia or calving difficulties.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Hypocalcemia, dystocia, oversized fetus, retained placenta

AGE-RELATED FACTORS
Because hypocalcemia is more common in multiparous cows, it is expected that multiparous cows are at higher risk for uterine prolapse than primiparous cows.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Feeding well-balanced rations in the far-off and close-up periods is important to avoid the occurrence of hypocalcemia, decreasing the risk for uterine prolapse.

UTERINE TORSION: BOVINE

BASICS

OVERVIEW
• Uterine torsion in cattle involves the rotation of the arc-shaped gravid uterus on its transverse axis. Both uterine horns and broad ligaments are displaced.
• The majority of cases (85–90%) are diagnosed at the time of parturition (late 1st stage or early 2nd stage labor) but some can rarely occur much earlier in gestation.
• Uterine torsion is a relatively common cause of bovine dystocia, accounting for 5–10% of obstetric cases in veterinary practice and up to 20% in referral practices.

INCIDENCE/PREVALENCE
• Uterine torsion represents 5–10% of the dystocia occurring in dairy cattle but in selected populations can represent 20% or more of the dystocias attended by veterinarians.
• Counterclockwise torsion of the uterus is more common than clockwise torsion, probably related to the majority of right horn pregnancies.

GEOGRAPHIC DISTRIBUTION
Worldwide, reportedly less common in *Bos indicus* cattle

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• The pathophysiology of uterine torsion remains speculative.
• Increased fetal movements in the late 1st and early 2nd stage of labor, uterine instability due to the dorsolateral attachment of the broad ligament, and the fact that cattle rise and lie down with the head lower than the pelvis create the potential for a sudden jarring or fetal movement to rotate the suspended gravid horn. Fetal oversize is another factor that may predispose to uterine torsion.

HISTORICAL FINDINGS
Dystocia

SIGNALMENT
• Gravid females, most often at parturition but has been reported as early as 70 days of gestation in cattle.
• Uterine torsion is more common in pluriparous than primiparous cattle and less common in twin pregnancies.
• Brown Swiss cattle are at greater risk but the condition is common in the Holstein breed.

SIGNS
• Overt clinical signs are often lacking in cows with torsions <270°.
• Cows with uterine torsion may present with signs of anorexia, depression, decreased milk production, and colic/abdominal pain (kicking the abdomen and treading hindlimbs).
• Tenesmus, constipation, and even rectal or vaginal prolapse may be seen in protracted cases.

GENETICS
N/A

CAUSES AND RISK FACTORS
Affected cows are more likely to be carrying a large and/or male fetus.

DIAGNOSIS

The critical aspect of the diagnosis is the correct assessment of the direction of the torsion.

DIFFERENTIAL DIAGNOSES
• Other causes of dystocia, especially fetal malposition
• Other causes of colic

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
N/A

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Vaginoscopy or manual vaginal examination may show spiral folds in the vaginal walls. However, in one-third of torsions, the vagina is not involved as the torsion is cranial to the cervix.
• Palpation per rectum of the vagina, cervix, uterus, and especially the broad ligaments of the uterus is critical to the correct assessment of the presence and direction of a uterine torsion. The broad ligament on one side is pulled tightly over the top of the genital tract while the ligament on the opposite side is pulled under. In a right/clockwise torsion the right ligament is pulled under. In a left/counterclockwise torsion it is the left ligament that is pulled beneath the tract. The perspective for determining the direction of a torsion is always that of the examiner from behind the cow.
• A fetus in dorso-ileal or dorso-pubic position is a more common finding in cases of uterine torsion than with other causes of dystocia.

PATHOLOGIC FINDINGS
• N/A

TREATMENT

THERAPEUTIC APPROACH
• For intrapartum torsions of 90° or less, it is often possible to rotate the uterus by grasping the calf and swinging it in arc fashion until the torsion is corrected. The calf is rotated in the opposite direction of the torsion.
• If this method is not successful, a detorsion rod can be applied to the calf and again the calf is rotated in the opposite direction of the torsion. A loop on one end of an obstetric chain is placed proximally to the metacarpal/metatarsal joint of the calf. The doubled chain is then passed through the loop of the detorsion rod and the resulting loop is placed proximally to the metacarpal/metatarsal joint of the other limb. A wooden dowel or rod is inserted in the other end of the detorsion rod and the calf is rotated by an assistant while the attending veterinarian monitors the progress and prevents trauma to the birth canal. Detorsion rods should be used with caution and only after adequate training as they may severely injure the cow or calf.
• If access to the calf is prevented by a closed cervix or a severe degree of torsion, then the correction will require rolling the cow. The cow is cast in lateral recumbency (right side for clockwise torsion, left side for counterclockwise). A 2" by 6" and approximately 8–10 feet long plank with a smooth surface is placed over the paralumbar fossa. A 70–100 kg individual stands on the plank, maintaining their position over the cow's abdomen as the cow is rotated by her limbs in the direction of the torsion. The procedure is easier and safer if the fore and hind limbs are tied one to the other.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Cesarean section should be considered if manipulation fails.
• Either standing flank laparotomy or ventral midline approach have been used.
• Attempt should be made to correct the torsion before incision of the uterus.
• Severe torsions (270° or more) may restrict access to the fetus.
• Vascular compromise makes uterine closure difficult.
• The viability of the calf should be confirmed before this option is selected. It is also possible to correct the torsion through a flank incision and allow the pregnancy to continue if the calf is not at term.

MEDICATIONS

DRUGS OF CHOICE
N/A

CONTRAINDICATIONS
N/A

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

UTERINE TORSION: BOVINE (CONTINUED)

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
The prognosis is usually good; however, it depends on the extent of the torsion and the length of time between occurrence, diagnosis, and treatment.

POSSIBLE COMPLICATIONS
• Complications are rare if the torsion is not severe and manual correction is successful.
• Uterine torsions >270° can cause vascular compromise and potentially uterine rupture.
• Post-surgical complications are similar to those described for cesarean section. Risk of uterine rupture is increased and makes uterine closure more difficult.

CLIENT EDUCATION
Proper calving management procedures

PATIENT CARE
• Patients should be observed for at least 3–5 days after nonsurgical correction to evaluate appetite and to ensure that no fever develops.
• When the uterine torsion is corrected surgically, the patient should be closely observed for 5–10 days. Rectal temperatures should be checked daily, and if signs of fever or loss of appetite appear, the animal should be treated immediately as indicated.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
Dystocia and other postpartum complications

AGE-RELATED FACTORS
Multiparous cows may be theoretically at higher risk for uterine torsion due to decreased uterine and mesometrial tone.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Most uterine torsions in cattle are diagnosed at term. Those that occur earlier may compromise the viability of the fetus. Severe torsions that result in vascular compromise may hasten the death of the calf.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
Uterine torsion is a relatively uncommon event with limited financial impact on most dairies. For smaller dairy operations it is best managed by timely veterinary intervention.

UTERINE TORSION: CAMELID

BASICS

OVERVIEW
• Uterine torsion is diagnosed in gravid females in mid to late gestation, although the torsion event may have occurred earlier.
• The uterus rotates upon its long axis such that tension on the broad ligaments and continued growth of the fetus results in the clinical signs of pain or behavior changes.
• At term, the torsion may result in dystocia.

INCIDENCE/PREVALENCE
Not known but likely higher than reported

GEOGRAPHIC DISTRIBUTION
Worldwide distribution, but incidence seems higher in the United States compared to South America.

PATHOPHYSIOLOGY
• Uterine torsion seems to occur more commonly in SAC than in other species. The exact causes of the torsion are not understood.
• Uterine torsions are characterized by both direction and severity. The direction is either clockwise or counterclockwise, as assessed from standing behind the animal and facing cranially. Severity has been described from 90° to 360°. In one study, 48% of torsions were 360°.
• The overwhelming majority of camelid pregnancies are carried in the left horn (98%) yet both clockwise (81.7%) and counterclockwise (18.3%) torsions were described in a large study of left horn pregnancies.
• 78% of females in one study were multiparous.
• Animals treated by rolling had a cria survival rate of 100%, whereas animals which underwent surgical treatment had a cria survival rate of approximately 70%. Animals were more likely to undergo surgical treatment for more severe torsions, and therefore had increased risk of uterine ischemia and cria compromise.
• Neonatal and dam survival depend on the severity of torsion and the degree of compromise to the uterine vessels and placenta.

SYSTEMS AFFECTED
Reproductive

GENETICS
N/A

HISTORICAL FINDINGS
• The presenting complaint of a female camelid with uterine torsion may be that the producer has observed the animal to be "not quite right," with absence of acute pain.
• Uterine torsion is typically diagnosed in mid to late gestation, or at term, as a cause of dystocia.
• The female may have been observed to have pain or abnormal behavior.
• A few females have had uterine torsions in previous pregnancies, or more than once in the same pregnancy.

SIGNALMENT
• Uterine torsion has been described in alpacas, llamas, and camels.
• In one study of alpacas, the mean ± SD age was 5.9 ± 2.9 years.
• Both primiparous and multiparous animals may be affected.

PHYSICAL EXAMINATION FINDINGS
• The clinical signs may be acute or mild colic signs (rolling, kicking at the belly, increased vocalization) which do not respond to medical therapy.
• Some animals may present with vague clinical signs, such as increased time in lateral recumbency, increased number of trips to the manure pile, or decreased interest in the herd or feeding activities.
• Physical examination may be normal or the female may show signs of systemic debilitation in severe, chronic cases.
• In severe cases, the female may show tachycardia, tachypnea, depression, recumbency, or straining.
• Protracted cases may present as a down animal. Severe profuse diarrhea may be seen in some cases.
• Advanced cases present with lethargy, anorexia, dehydration, and signs of toxemia.

CAUSES AND RISK FACTORS
• The cause of uterine torsion is not known although some risk factors have been suspected.
• Risk factors include shearing on a table, "dusting" or rolling behavior in hot weather, hypocalcemia, fetal sex, fetal size, and maternal body condition score, height, and length.

DIAGNOSIS

• The diagnosis is by transrectal palpation. In alpacas, transrectal palpation may be achieved by clinicians with small hands, and use of lidocaine-infused lubricant. The female is placed in sternal recumbency (the "cush" position) and palpation of the broad ligaments is used to determine the presence of a uterine torsion, and the direction and severity. Palpation of llamas and camels may be more easily performed.
• The fetus is often not easily palpable, particularly when the torsion is severe.
• Diagnosis of the direction of the torsion is based on the position of the broad ligament. The torsion is clockwise (to the right, looking from the back of the animal) if the left broad ligament is stretched diagonally from the left side to the right side of the animal forming a tight band running over the uterine body. The right broad ligament is shorter and trapped under the uterine body. In the counterclockwise torsion the direction and position of the broad ligaments are reversed.
• Diagnosis of the direction of the torsion can be difficult in small sized animals or if the rectum is swollen.
• Diagnosis of the severity of the torsion remains speculative but can be determined based on the number of rolling actions needed for correction or at surgery.
• The majority of uterine torsions in camelids do not involve the cervix. Therefore, palpation of the cervix will not provide a diagnosis or direction. In addition, vaginal palpation may be extremely difficult and painful for maiden females. Vaginal speculum examination may be performed after correction of a torsion at term, to determine if the cervix is open and labor may ensue.

DIFFERENTIAL DIAGNOSES
• Other causes of colic in camelids.
• Other causes of dystocia, if at term (fetal maldisposition, failure of cervical dilation).

CBC/BIOCHEMISTRY/URINALYSIS
In one study, 65% of blood work was normal. In debilitated animals, the most common abnormalities were toxemia (leukophilia due to neutrophilia, with toxic PMNs evident on a blood smear) (19.9%), toxemia and hypocalcemia (5%), hypocalcemia alone (5%), and hepatic lipidosis (3.4%). Hyperglycemia was a common, nonspecific finding.

OTHER LABORATORY TESTS
N/A

IMAGING
• Transabdominal ultrasonography is used to determine fetal viability, fetal stress, and to examine the health of the uteroplacental unit.
• Persistent fetal tachycardia (>130 bpm) or bradycardia (<50 bpm) suggests fetal compromise.
• Detachment of the fetal membranes or abnormal uterine wall appearance may indicate need for surgical correction.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FIDINGS
Postmortem examination may reveal uterine rupture or congestion.

TREATMENT

THERAPEUTIC APPROACH
• Correction of uterine torsion is either by nonsurgical (rolling) or surgical (laparotomy with or without cesarean section) methods.
• To roll, the female is placed in lateral recumbency on the same side as the torsion (i.e., for a clockwise torsion, she is placed in right lateral recumbency). Then one person manually maintains the fetus in position

UTERINE TORSION: CAMELID (CONTINUED)

while two others roll the female from right lateral recumbency, dorsally to left lateral recumbency, then to sternal recumbency. The female is rolled three times, and then transrectal palpation is used to determine if the torsion was corrected.
• Cases diagnosed early and corrected successfully by rolling do not require any further treatment.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Severely debilitated animals should be stabilized prior to anesthesia.
• Surgical correction is by laparotomy under general anesthesia. In the field, epidural and regional anesthesia may be attempted, with a flank approach. In a clinical setting, ventral midline celiotomy is the approach of choice for SAC. In cases of fetal nonviability, a cesarean section is performed. If possible, viable fetuses are left in situ after correction of the torsion, particularly if not at term. Delivery of a nonviable fetus 3 days postoperatively has occurred.

MEDICATIONS

DRUGS OF CHOICE
To facilitate rolling as a correction method, females may be sedated with butorphanol tartrate IM.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
• Extreme care should be exercised during the rolling process not to put too much pressure on the uterus.
• Females with a severely compromised uterus should not be rolled.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
In one study of SAC, 97% of females survived (fatalities occurred intra- and postoperatively). Cria survival was 100% after correction with rolling and 70% following surgical correction.

POSSIBLE COMPLICATIONS
• Colonic injury during transrectal palpation.
• Expulsion of a nonviable fetus may occur after correction of the torsion.
• Surgical complications (incisional dehiscence, infection, or seroma formation, peritonitis, and adhesion formation).

PATIENT CARE
Perioperative care includes antimicrobials, anti-inflammatories, tetanus toxoid, and may include supportive care including IV fluids, transfaunation, and B vitamins administration.

CLIENT EDUCATION
• Careful monitoring of all pregnant females in the last trimester of pregnancy.
• Refer to a veterinarian any pregnant females exhibiting signs of colic or abnormal behavior.

PREVENTION

UTERINE TORSION: SMALL RUMINANT

BASICS

OVERVIEW
• Uterine torsion is a rare cause of dystocia in sheep and goats, accounting for <5% of peripartum complications.
• The condition may be underestimated because it is difficult to diagnose and treat without surgical intervention.
• It can be of mild degree (45–90°) or severe degree (>180°).
• The torsion can be caudal to the cervix, including the vagina, or cranial to the cervix. More often the vagina is included in the torsion.
• It is more common in singleton pregnancies.
• Fetal oversize has seen suggested as a predisposing factor.

INCIDENCE/PREVALENCE
• Uterine torsion represents about 5% of the dystocia occurring in sheep and goats.
• Others have reported up to 10% of all dystocia cases in sheep.

GEOGRAPHIC DISTRIBUTION
Worldwide

PATHOPHYSIOLOGY
The pathophysiology of uterine torsion in small ruminants is not known. In fact this condition is often missed or not diagnosed until surgery (cesarean section).

HISTORICAL FINDINGS
• Down or painful late term female.
• Overdue female that has shown development then regression of the udder.
• No progression beyond first stage of parturition.

SIGNALMENT
• Uterine torsion can occur in sheep and goats.
• Prolific breeds have a lower risk of uterine torsion.
• Multiparous ewes and goats are believed to be at higher risk due to longer and more relaxed broad ligaments of the uterus.

PHYSICAL EXAMINATION FINDINGS
• Dystocia failure to lamb or kid after initial stages of labor preparation
• Sheep and goats with uterine torsion usually present depression, anorexia, elevated respiratory and heart rates. Bruxism (teeth grinding) may be observed in painful animals.
• The perineum can be swollen without appearance of fetal fluid or placenta. However, this may be due to overt manipulation by the owner.
• Development of the mammary gland and colostrum can be present if the animal is in labor.
• Many cases may not present until several days or even weeks after initial signs of parturition.

GENETICS
N/A

CAUSES AND RISK FACTORS
N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Clinical diagnosis is often difficult because of impossibility to palpate the uterus. The condition is often suspected after ruling out other causes of dystocia or pregnancy (failure of cervical dilation, fetal maternal disproportion, and twins) or pregnancy toxemia.
• Vaginal speculum examination may be helpful in detecting the presence of vaginal mucosal folds in case of torsion caudal to the cervix. The cervix cannot be visualized.
• Vaginal palpation, if possible, may be helpful.
• Uterine torsion may be suspected by transabdominal ultrasonography based on extensive uterine wall edema and dilated broad ligament vasculature.
• Often the final diagnosis is reached after laparotomy.

CBC/BIOCHEMISTRY/URINALYSIS
• May be performed in ewes or does that are depressed. Usually prior to surgery. The changes are variable depending on the duration of the process.
• Various degrees of dehydration and electrolyte changes, neutrophilia and high fibrinogen are found in cases with severe compromise or rupture of the uterus.
• Severe anemia due to blood loss is present in animals with ruptured uterus and/or if uterine/ovarian blood vessels rupture.

IMAGING
• Transabdominal ultrasonographic evaluation of the entire uterus and cervical area may show several changes including:
  ◦ Increased echogenicity and poor definition of fetal fluids
  ◦ Loss of fetal fluid if the torsion does completely obliterate the cervical canal
  ◦ Increased thickness of the uterine wall with poorly defined placentome
  ◦ Thickened/edematous fetal membranes
  ◦ Broad ligament edema and severely engorged blood vessels
  ◦ In chronic cases, usually presented days to weeks after initiation of parturition, uterine rupture and adhesions to the body wall may already have occurred.
  ◦ Fetal viability can be assessed: Fetal death is confirmed by lack of fetal heartbeat. Severely compromised fetuses usually show a very slow and irregular heart beat.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Death may result from uterine necrosis, uterine rupture, or rupture of the major blood vessels.
• Postmortem examination of ewes shows increased amount of peritoneal fluids, peritonitis, and adhesions to other abdominal organs.

TREATMENT

THERAPEUTIC APPROACH
• Rolling as described in other species has been reported in a few cases in sheep. However, the success rate of this approach depends on accurate diagnosis of the direction of the torsion.
• The rolling technique should only be attempted if the uterine wall is not too compromised.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Emergency laparotomy and cesarean section should be considered if no diagnosis can be made.
• The best approach for laparotomy is the ventral midline approach in order to better expose the uterus.
• The uterus may already be ruptured or friable, in which case an ovariohysterectomy should be considered.

MEDICATIONS

DRUGS OF CHOICE
• Sedation: Butorphanol and xylazine for rolling.
• General anesthesia (injectable or inhalation) is the preferred approach for surgery.
• NAISDs (flunixin meglumine) and broad-spectrum antibiotics.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• The prognosis depends on the degree and the duration of the torsion. If cesarean section is performed promptly the prognosis for survival in dams is very good. However, the future fertility of the animal can be

U

UTERINE TORSION: SMALL RUMINANT (CONTINUED)

compromised depending on the extent of the torsion.
• Severely compromised females should be humanely euthanized.
• Prognosis for fetus or neonate is poor in most cases.

POSSIBLE COMPLICATIONS
• Retained fetal membrane
• Metritis
• Uterine rupture
• Spontaneous vaginal rupture
• Ovarian vein rupture
• Peritonitis

CLIENT EDUCATION
• Lambing and kidding watch and awareness of signs of dystocia.
• Goat and sheep owners often get involved in dystocia management. They should be aware of situations that are beyond their expertise and welfare implications of obstetric manipulations.

PATIENT CARE
• After rolling, parturition may progress normally or may require obstetric assistance. The animal should be monitored is the same manner as for any dystocia. Uterine involution can be verified periodically.
• After cesarean section, the animal should be closely monitored for 7–10 days. Rectal temperature, normal appetite, mentation, urination, and defecation should be recorded. Often evaluation of the skin incision for any signs of infection should be performed.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Dystocia
• Pregnancy toxemia

AGE-RELATED FACTORS
Multiparous ewes and does may be at higher risk for uterine torsion because of decreased broad ligaments tone.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Depending on the degree of the torsion the pregnancy can be lost spontaneously. Placenta edema, its detachment and subsequent fetal hypoxia of the fetus due to compromised venous return is usually the cause of fetal death.

PRODUCTION MANAGEMENT
• Insufficient cervical dilation and postural abnormalities of the fetus are the most common causes of dystocia in this species. However, recent studies have shown that occurrence of uterine torsion in up to 10% of small ruminant dystocias requiring surgery
• The cost of surgery may be too prohibitive in some production system and humane euthanasia should be considered
• Ewes and does that underwent surgical correction are often culled.

VACCINATION PROGRAMS: BEEF CATTLE

BASICS

OVERVIEW

• A strategic vaccination program is part of a total herd health management plan.
• Vaccination is a tool that can help prevent the occurrence of disease or reduce the severity of disease but it is not a substitute for poor management in other areas.
• A successful vaccination program depends on adequate nutrition, proper management and housing, and planning.
• Nutrition must be adequate for the immune system to function properly.
• A vaccine prevents diseases by priming an animal's immune system to fight the disease.
• The animal must be supplied with adequate protein and energy, as well as vitamins A and E, copper, selenium, and zinc for optimum immune system function.
• No vaccine is 100% protective in 100% of the animals. Some animals will have a less than maximal response to a vaccine and some animals may not respond at all.
• Vaccination is simply the act of inoculating an animal with a vaccine. It does not imply immunity.
• Immunization is the development of an immune response in response to a vaccine. It does not imply protection from disease.

INCIDENCE/PREVALENCE

All cattle herds could benefit from a customized vaccination program.

GEOGRAPHIC DISTRIBUTION

• Appropriate vaccination programs must be customized to the specific herd and location for which they are being developed.
• Some vaccines may be appropriate in some areas but unnecessary in others depending on the occurrence of the disease in that area.

SYSTEMS AFFECTED

• Respiratory
• Digestive
• Reproductive
• Musculoskeletal

PATHOPHYSIOLOGY

Passive Immunity

• Antibodies are obtained from a source other than the animal's immune system.
• Passive transfer of colostral antibodies is the most important form of passive immunity.
• Antibodies from passive immunity may interfere with the development of active immunity in response to a vaccination in young animals by "neutralizing" the vaccine.
• Other types of passive immunity include blood or plasma transfusions and antiserum products such as tetanus antitoxin.

Active Immunity

• Humoral, cell mediated, and secretory types.
• With humoral immunity, antibodies are produced by specific lymphocytes in response to exposure to an antigen or in response to a vaccination.
• Cell mediated immunity (CMI) develops when specialized lymphocytes are exposed to a specific organism and develop a "memory" for that organism. When exposed again, these cells attack and kill that organism or cells infected with that organism.
  ◦ CMI is not as easily produced as humoral immunity and is rarely produced in response to a killed vaccine.
  ◦ In most cases, an infectious organism has to replicate within an animal in order to produce CMI.
• Secretory immunity consists of antibodies produced in response to exposure or vaccination that do not circulate in the bloodstream.
  ◦ Antibodies are produced by cells lining the mucosal surfaces of various parts of the body.
  ◦ Vaccines that can be administered in the same manner that natural exposure would occur tend to produce the best secretory immune response. An example would be an intranasal vaccine.

Innate Immunity

• Innate immunity consists of natural defense mechanisms such as enzymes, tears, saliva, and gastric acids.
• These mechanisms destroy or mechanically remove infectious organisms before they can cause an infection.
• A failure of any one of these types of immunity predisposes an animal to disease.
• Proper vaccination can improve both passive and active immunity.

HISTORICAL FINDINGS

N/A

SIGNALMENT

• All beef cattle, regardless of age and production status, should be incorporated into a vaccination program.
• Different ages and classes of animals will require different protocols but all animals should be included in the program.

PHYSICAL EXAMINATION FINDINGS

N/A

GENETICS

Genetics play an important role in natural disease resistance including innate immunity and factors such as mothering ability, which affect passive immunity.

CAUSES AND RISK FACTORS

The risk factors associated with vaccine failure are numerous:
• Improper handling of vaccines
• Improper timing of vaccination
• Interference from maternal antibodies
• Improper administration technique
• Improper timing of booster vaccinations
• Animals that are already sick or highly stressed
• Overwhelming disease challenge
• Nutritional deficiencies or other causes of poor health

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Many infectious agents can cause disease and attempts should be made to establish a definitive diagnosis before implementing a vaccination protocol to combat a disease outbreak.

PATHOLOGIC FINDINGS

N/A

TREATMENT

THERAPEUTIC APPROACH

• Ensuring adequate colostral transfer of antibodies is more important and effective than any vaccination program in neonates.
• Animals must be provided a balanced diet that is adequate in vitamins and trace minerals to allow optimum immune system function.
• Vaccines must be used according to the label directions.
• Vaccines should not be mixed in the same syringe unless directed by the label.
• Vaccines should be kept cool and out of direct sunlight. Keep vaccines in an ice chest or some other form of protection while in use.
• Only reconstitute the amount of vaccine that can be used in a 1 hour period. Do not try to store reconstituted MLV products, even if it is just for a few hours.
• Whenever possible, use products that can be administered subcutaneously.
• All injections, both subcutaneous and intramuscular, should be given in the neck, according to BQA guidelines, to avoid damage to the more valuable parts of the carcass.
• Use clean injection equipment to administer vaccines.
  ◦ Change needles every 5–10 head.
  ◦ Never use chemical disinfectants to disinfect instruments that will be used for MLV products. Residual disinfectant can destroy the effectiveness of MLV products.

VACCINATION PROGRAMS: BEEF CATTLE (CONTINUED)

MEDICATIONS

DRUGS OF CHOICE

Types of Vaccine

Killed Vaccines

• Require booster dose following initial dose (timing is product dependent). If booster is not properly administered, virtually no protective immunity occurs. Once an animal has received the initial two doses, a single yearly booster may be adequate.
• Provide a shorter duration of immunity.
• Usually do not stimulate CMI.

Modified-Live Vaccines

• Infectious agent is alive but altered so that it does not cause disease in healthy animals.
• Agent replicates within the animal and induces both humoral and cell-mediated immunity.
• Produce long-lasting immunity.
• Usually provide a greater immune response than killed products.
• Some types may cause abortion in pregnant cows or disease in highly stressed animals.
• Some newer MLV products are labeled for use in pregnant cows and calves nursing pregnant cows as long as the vaccines are used according to the label.

Component Vaccines

Vaccines that contain only part of an infectious agent. These products induce immunity to a part of an infectious agent that is necessary for the agent to cause disease.

Toxoids

Vaccines that induce an immune response to certain toxins produced by bacteria.

Recommended Vaccination Programs

A successful vaccination program must be customized to each specific situation.

Branding Vaccines (60–90 days of age)

• Passive immunity to clostridial diseases usually begins to decline around 2–3 months of age. Calves at this age should be given a clostridial bacterin/toxoid.
• Passive immunity to the common respiratory viruses (IBR, BVD, PI-3, and BRSV) usually lasts for 4–5 months so calves at this age should be fairly well protected.
• Respiratory viral vaccines can be administered at this time if the herd has a history of respiratory disease in calves of this age.
• Intranasal vaccines are a good choice in young calves because passive immunity has less effect on these vaccines.

Preweaning Vaccines (2–4 weeks prior to weaning)

• Ideally, calves should be vaccinated 2–4 weeks prior to weaning so that they have had time to develop an immune response and to help reduce the stress of weaning.
• Calves should receive a respiratory virus vaccine and a clostridial booster.
• MLV vaccines are preferable to killed products as long as they can be safely used according to label directions in nursing calves.
• Other vaccines to consider at this time include *Pasteurella* leukotoxoid vaccines and *Histophilus somni*.

Weaning Vaccines

• Calves should receive a respiratory virus booster at this time.
• MLV respiratory virus vaccines can be given at weaning without the risk of abortion in pregnant cows.
• The advantage of giving a second dose at weaning is providing another opportunity for calves that did not respond to previous vaccinations to become immunized.
• Consider calfhood (*Brucella*) vaccination of potential replacement females. Some states require that females be official calfhood vaccinates in order to enter the state.

Replacement Females

• At 1 year of age, replacement heifers should receive MLV respiratory virus vaccine with a five-way leptospirosis.
• *Campylobacter* (vibriosis) can be included if infertility due to vibriosis is a risk.
• Replacement heifers will require two doses of leptospirosis and vibrio vaccines since they will be naïve to these specific vaccines. The first doses can be given 60 days prior to breeding and boosters 30 days prior to breeding, along with the MLV vaccine.

Adult Cows

• Cows should be vaccinated pre-breeding with a respiratory virus vaccine and 5-way leptospirosis annually.
  ◦ Adult cows should receive a five-way *Leptospira* bacterin once or twice yearly. Immunity produced by *Leptospira* vaccines is short-lived. This is commonly boostered during routine pregnancy examinations.
  ◦ If killed products were used in the replacement heifers, yearly boosters should be given.
• Cows can also be vaccinated with K-99 *E. coli* and rotavirus/coronavirus products to increase the level of passive immunity provided to the calf.
  ◦ Pregnant replacements should be given two doses, 3 and 6 weeks prior to calving.
  ◦ Previously vaccinated cows only need one dose, 3–4 weeks prior to calving.
  ◦ Rotavirus/coronavirus products are available to give to newborn calves prior to the calf's nursing colostrum.
• Campylobacter and trichomoniasis vaccines can be given yearly in at-risk herds.
• Other vaccines such as pinkeye and foot rot vaccines may be considered in problem herds.

Bulls

• Bulls should receive the same pre-breeding vaccinations used in the cow herd with some exceptions.
  ◦ Bulls are not vaccinated for brucellosis.
  ◦ The currently available trichomoniasis vaccine is not approved for use in bulls.
  ◦ IBR virus from MLV products may recrudesce and be shed in semen; therefore, a killed respiratory vaccine is recommended in bulls.
  ◦ Bulls should receive leptospirosis and campylobacteriosis vaccines in accordance with the cow herd.
• Other vaccines such as pinkeye and foot rot vaccines may be considered in problem herds.

CONTRAINDICATIONS

• Some MLV viral vaccines can cause abortion if administered to pregnant cows or calves nursing pregnant cows. **Always** follow the label directions.
• Administering vaccines to animals that are already sick or heavily stressed often fails to produce an immune response and may further stress the immune system.
• Administering certain vaccines may complicate international shipment of animals or semen due to positive serologic tests. Consider the ultimate goals of the producer before administering vaccines.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

Avoid the administration of immunosuppressive drugs such as corticosteroids within 1 week of vaccination.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Effective immunity can be expected within 2 weeks after systemic vaccination.
• Mucosal immunity is developed within 48 hours after intranasal administration.

POSSIBLE COMPLICATIONS

Anaphylaxis is possible with some vaccine products. If anaphylaxis occurs, epinephrine is the treatment of choice.

CLIENT EDUCATION

It is important to train workers on proper vaccine handling, administration, and contraindications. See "Treatment."

PATIENT CARE

Patients should be monitored post-vaccination for anaphylactic reactions.

PREVENTION

N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS

N/A

V

(CONTINUED)

VACCINATION PROGRAMS: BEEF CATTLE

AGE-RELATED FACTORS

Young calves may not respond to vaccines due to the influence of passive immunity from colostral antibodies. Antibodies to clostridial diseases usually last until the calf is 2–3 months of age and antibodies to the respiratory viruses usually last until 5–6 months of age.

ZOONOTIC POTENTIAL

Brucella vaccine (RB 51) is a live bacterial vaccine that contains zoonotic pathogens.

PREGNANCY

Care must be used when administering MLV products to pregnant cows. Always follow label directions.

BIOSECURITY

Well-designed vaccination programs are an integral part of all biosecurity programs.

PRODUCTION MANAGEMENT

Provision of a well-designed vaccination program is an integral part of any production management system.

VACCINATION PROGRAMS: CAMELID

BASICS

OVERVIEW
• Preventive medicine encompasses all management decisions that affect the health and well-being of camelids (South American camelids, SACs).
• Programs, though unique to camelids, should be based on herd health principles used for other livestock species.
• Vaccinations, parasite control, reproductive management, nutritional consultation, and feet and teeth care should be incorporated into camelid herd health programs.
• Each herd will have different requirements and the program should be developed according to the goals of the producer.
• The following information should be used strictly as a general guideline for vaccinating SACs. It is important to note that protocols for these husbandry practices should be designed according to the particular needs and geographic location of individual farms. The number of animals per group, age of the animals, pasture type, and frequency of animal movement on and off the premises should all be considered.
• There are no vaccines labeled for use in camelids.

INCIDENCE/PREVALENCE

SIGNALMENT
Camelid species

PHYSICAL EXAMINATION FINDINGS
• Animal should be healthy in order to have a good immune response to vaccination.
• Pregnant females often receive booster vaccines to promote good quality colostrum (high antibodies concentration).

GENETICS
N/A

CAUSES AND RISK FACTORS
• Camelids can be affected by a variety of infectious diseases.
• The most important are clostridial infections, rabies, leptospirosis, West Nile virus, Eastern equine encephalitis, equine herpesvirus, and bovine herpesvirus.
• In some countries, where anthrax is endemic, vaccination is mandatory.
• Camelids can be infected with BVDV but they are not systematically vaccinated against the disease.
• Risk factors for these diseases include co-mingling with other animals (camelids or other species) in pasture, during shows, or in quarantine.
• High stocking density during the birthing period is an important risk factor.

TREATMENT

THERAPEUTIC APPROACH
• Vaccination programs should be developed with the knowledge that each herd will have different requirements and the program should be developed to the goals of the producer.
• A basic SAC vaccination program should include at least tetanus toxoid and *Clostridium perfringens* type C and D vaccinations on a yearly basis. Intramuscular vaccines may be given in the muscle of the neck in front of the shoulder or in the semimembranosus or tendinosus.
• Vaccine schedules generally include vaccination of dams about 1–2 months before they give birth. Late pregnant animals should be handled cautiously during vaccination due to the risk of stress-induced abortion.
• Tetanus and *C. perfringens* type C and D require two vaccinations given 1 month apart during the first year and one booster vaccination annually.
• Depending on geographic location and herd health history, the following vaccines may be administered in conjunction with those already mentioned:
  ◦ *Rabies (IMRAB 3™):* Administer 2 mL IM to crias at 3–4 months of age. Booster annually.
  ◦ *Leptospira:* Administer 2 mL dose of a killed bacterin. May need to be repeated 3 or 4 times per year if problematic in the region.
  ◦ *West Nile virus:* Research has shown that administration of three doses (1 mL IM) of an equine WNV vaccine (Innovator) at intervals of 3 weeks resulted in an antibody response in nearly all animals tested. Annual boosters should be given 1 month before peak mosquito exposure.
  ◦ *Eastern equine encephalitis (EEE):* Research has shown that administration of three doses (1 mL IM) of a killed equine encephalitis vaccine (Encevac) at 4 week intervals resulted in a humoral antibody response.
  ◦ *Bovine herpesvirus type 1 (BHV-1), Equine herpesvirus type 1 (EHV-1):* Herpesviruses can infect non-adapted hosts and serious disease or death may result in llamas and alpacas. Blindness in camelids can be caused by EHV-1. The role of BHV-1 in camelids is not well established and the incidence rate is extremely low. Vaccination for BHV-1 is not recommended on a routine basis. EHV-1 vaccination should be considered when camelids are in close contact with equines. Killed virus vaccine has been shown to induce antibodies in llamas when used according to the recommendations for equines. The vaccine has not been tested experimentally to determine the efficacy in preventing disease. Modified-live virus vaccination with EHV-1 should not be attempted. EHV-1 vaccine use is extra-label and has not been tested adequately in camelids.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• There are no vaccines labelled for use in camelids.
• Vaccines labelled for use in equine, cattle, or sheep are often used extra-label for SAC.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals; however, withdrawal times have not been established for camelids.

PRECAUTIONS
• Proper dosing and use of individual needles is important.
• Vaccination of sick animals may not be efficacious.
• Adverse reaction may be seen in some animals, particularly young animals and pregnant females.

• Eight-way vaccines have been associated with abortion, probably due to inflammatory response.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
• Injection site reaction
• Anaphylactic shock is rare but has been reported in some animals.

CLIENT EDUCATION
• Should be aware that most vaccines are used off-label.
• Importance of vaccine handling (refrigeration).
• Injection site and needle requirements.

PATIENT CARE
Response to immunization depends of the health of the animal. Vaccination program should be part of a general herd health program whichs include feeding management, biosecurity, and antiparasite program.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
Vaccination against bovine viral diarrhea virus (BVDV) is not recommended for camelids; rather, increased surveillance and eradication should be the goal.

AGE-RELATED FACTORS
Crias from unvaccinated dams or crias that are orphaned prior to colostrum consumption require special care.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Some vaccines (8-way clostridial) have been suspected to cause pregnancy loss.

BIOSECURITY
• Isolate and quarantine new stock entering the herd.
• Treat new animals for disease conditions prior to herd introduction; cull if necessary.
• Newly acquired camelids may be started on a vaccine series at any time.
• Crias from unvaccinated dams or crias that are orphaned prior to colostrum consumption require special care.

PRODUCTION MANAGEMENT
N/A

SYNONYMS
N/A

ABBREVIATIONS
• BHV-1 = bovine herpesvirus type 1
• BVDV = bovine viral diarrhea virus
• EHV-1 = equine herpesvirus type 1
• IM = intramuscular

VACCINATION PROGRAMS: CERVIDAE

BASICS

OVERVIEW
• The administration of vaccinations is common in domestic species for the prevention and amelioration of various bacterial and viral diseases.
• Currently, more and more cervids are being raised on a farmed, managed setting, with higher stocking rates and more potential for disease transmission. Due to this, vaccinations are crucial for prevention of different disease processes.
• Preventive health programs should be individualized for each operation, addressing management practices and local disease-related information.

INCIDENCE/PREVALENCE
• Incidence of diseases is variable.
• Prevalence varies according to region and management.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Respiratory
• Digestive
• Reproductive

PATHOPHYSIOLOGY
• Cervids are susceptible to common pathogens found in other ruminant species.
• The most common diseases include clostridial diseases which produce a variety of syndromes similar in pathophysiology to other ruminants.
• Response to vaccines is not adequate before 60 days of age because of presence of colostral antibodies.

SIGNALMENT
• There are numerous cervid species currently and commonly being raised for breeding, meat, and hunting. The most common is the white-tailed deer (*Odocoileus virginianus*). Others include mule deer (*Odocoileus hemionus*), fallow deer (*Dama dama*), axis deer or chital (*Axis axis*), sika deer (*Cervus nippon*), elk (*Cervus canadensis*), and red deer (*Cervus elaphus*).

GENETICS
N/A

CAUSES AND RISK FACTORS
Risk factors for disease spread are overstocking, high population density, poor sanitation, poor genetics, and inappropriate vaccination protocols.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

TREATMENT

THERAPEUTIC APPROACH
N/A

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

• There is only one vaccine that is routinely recommended for farmed cervid herds: a multivalent clostridial vaccination. There are numerous versions available, most of which are inactivated and consist of bacterins, toxoids, or a mixture of the two. They are developed and manufactured for cattle, but are generally safe to use in cervids.
• Clostridial vaccines can contain as few as 1 and as many as 9 different clostridial strains, including *Clostridium chauvoei, C. septicum, C. novyi* type B, C, *C. haemolyticum, C. sordellii, C. tetani,* and *C. perfringens* type C and D.
• Single vaccinations of inactivated clostridial vaccines do not generally provide adequate levels of protection, and most often require a booster dose within 3–6 weeks initially. These vaccinations can be given annually after the initial booster.
• Young fawns generally do not yield adequate protective immunity until around 1–2 months of age, so vaccination strategies against clostridial diseases targeting pregnant dams can allow for maximal immunity transferred to the neonate via the colostrum.
• Gestation times vary between species, and can be 200–280 days; vaccinating pregnant females with killed vaccines within 7 weeks of parturition can help her produce antibodies that will be passed on to the fawn through the colostrum.
• In breeding operations, it may be prudent to vaccinate the pregnant does with a "calf scours" vaccination. These generally include protection against rotavirus, coronavirus, *Clostridium perfringens* type B, C, and D, as well as *Escherichia coli* (using the K99 antigen), all of which are diseases that can kill fawns within days of birth.
• Fawns should be vaccinated at weaning, and given a booster 3–6 weeks later.
• Oral vaccinations, particularly those targeting *E. coli* and *Clostridium* spp. have been used in newborn fawns to provide local immunity and possible passive transfer.

Additional Vaccination Comments
• Antibodies to some cattle respiratory pathogens (PI-3, BVDV, BHV-1) have been found in both white-tailed deer and elk, but no clinical disease has been reported. In heavily managed farm settings, some ranchers vaccinate their cervids using an inactivated cattle respiratory vaccine.
• Depending on the area and the disease prevalence of specific pathogens within the herd (such as leptospirosis, *E. coli,* campylobacteriosis, etc.), specific targeted vaccinations should be considered.
• Autogenous vaccines can be considered and produced if there are problems with atypical strains or pathogens, though none have been published.
• The use of a *Salmonella* vaccine strain that expressed cervid PrP, the main protein that misfolds and is implicated in chronic wasting disease (CWD) has been reported. This vaccine produced mucosal and systemic response to cervid PrP and PrP^{CWD} (the misfolded protein responsible for CWD) in white-tailed deer. The vaccinated deer showed partial protection against CWD. It is currently not commercially available.
• Immunocontraception with porcine zona pellucida (PZP) and gonadotropin-releasing hormone (GnRH) vaccines have been used successfully to control reproduction in deer.
• There are very few published accounts of humoral immune response, safety, and efficacy of vaccinations in cervids, so the decision to vaccinate must be approached cautiously.

DRUGS OF CHOICE
There are no cervid approved vaccines. Vaccines approved for cattle are used extra-label in cervids.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Vaccines should be handled properly to insure a good immunization response.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Animals vaccinated against disease still have the chance of contracting the disease, depending on the strain, host, and situation, but vaccines help reduce the likelihood of this as well as sometimes help ameliorate the disease if it is contracted.

POSSIBLE COMPLICATIONS
Injection site reaction

PATIENT CARE
• Always monitor individuals who have been vaccinated for signs of an immediate or delayed vaccine reaction. This can include sweating, hypersalivation, agitation/restlessness, and anaphylaxis.
• Deer species can also develop abscesses at vaccine injection locations, specifically when the vaccine is administered against the manufacturer's recommendations. Most clostridial vaccinations are recommended to be given subcutaneously.
• In situations where there is not a handling facility available, or anesthesia/capture is not an option, vaccines can be given by darting the individuals, which only allows intramuscular administration and can often cause tissue reactions, swelling, and abscess formation.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Vaccination of fawns that are too young is generally useless due to maternal antibody interference.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Pregnant females should receive a booster with killed vaccine in the last 7 weeks of gestation to improve colostrum quality.

BIOSECURITY
Strict biosecurity measure (testing and quarantine) should be used in conjunction with vaccination.

VACCINATION PROGRAMS: DAIRY CATTLE

BASICS

OVERVIEW

• Vaccination is a major part of prevention of infectious diseases on dairy farms.
• There are a few vaccines that are considered basic to the vaccine program on dairies in North America and there are many other vaccines that should be considered for a vaccine program based on the particular disease risks and management of individual farms.
• Vaccines should be chosen carefully because the process can bring both prevention of disease and risk for disease.
• The following principles must be adhered to for a vaccine to work well: The vaccine must be stored and handled properly, the vaccine must be administered to the appropriate animals at the right times using the correct route and dosage, and the animals must be in good health and in positive growth or energy balance.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

• Respiratory
• Digestive
• Reproductive
• Musculoskeletal

PATHOPHYSIOLOGY

N/A

SIGNALMENT

Dairy cattle. In particular, the Holstein breed appears to be highly susceptible to the effects of bacterial endotoxin.

HISTORICAL FINDINGS

There should be clinical, laboratory, or other evidence of pathogens in the herd or region for which efficacious vaccines are available to recommend particular vaccines.

PHYSICAL EXAMINATION FINDINGS

N/A

GENETICS

The Holstein breed appears to be highly susceptible to the effects of bacterial endotoxin.

V

CAUSES AND RISK FACTORS

Typical risks that can be partially managed with vaccines on dairy farms include moving from individual calf hutches to group pens, overcrowding, immunosuppressive periods such as transportation and parturition, and environmental contamination during milking.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

It is imperative to have knowledge of the infectious diseases the cattle on a farm will be exposed to at different times in the management cycle before recommending vaccine programs.

OTHER DIAGNOSTIC PROCEDURES

Submission of necropsy samples to determine pathogens on the farm is advised.

TREATMENT

THERAPEUTIC APPROACH

Epidemiology

• Vaccines must be given prior to exposure to the pathogen and the animal must have enough time to process the antigens and develop either humoral or cellular immunity.
• Passively acquired immunity from colostrum may interfere with systemic vaccinations for varying periods after colostrum feeding (2–6 months).
• Calves should always receive at least one systemic vaccination for the essential viral vaccines (IBR, BVD, BRSV) after 6 months of age. Intranasal vaccines are not affected by maternal antibody and should be efficacious as soon as the corticosteroids associated with calving have metabolized.
• The concept of herd immunity is important in dairy preventive medicine. Disease prevention and decreased case rate can be expected for most pathogens as long as the majority of animals in the population are effectively immunized.

Dairy Vaccinology

• A basic vaccine program on a dairy should include vaccinations for infectious bovine rhinotracheitis (IBR), bovine virus diarrhea types I and II (BVD), bovine respiratory syncytial virus (BRSV), and *Leptospira hardjo* and *pomona* bacterins.
• Optional vaccines include clostridial (malignant edema, redwater, and blackleg) bacterins, campylobacterosis (vibrio) bacterins, *Moraxella bovis* (pinkeye) bacterins core-antigen J-5 Gram-negative bacterins (coliform mastitis). Rotavirus and coronavirus vaccines may be useful for protecting neonatal calves depending on the dairy.
• Regulations regarding vaccination for *Brucella abortus* vary by country and region.
• The viral pathogens can be administered either as modified-live virus (MLV) or killed vaccines.
• MLV vaccines are generally preferred because of the problem of compliance with boostering killed virus vaccines.
• Killed virus vaccines and bacterins must have a second dose within 2–4 weeks of the primary vaccination to develop an anamnestic response.

Dairy Vaccination Program

• A basic vaccination program for a dairy may include the following vaccines:
  ◦ *Birth:* Colostrum (bull and heifer calves). Maternal antibodies are necessary for mucosal and systemic immunity and the white blood cells in colostrum initiate the memory of the calf's immune system.
  ◦ *3 days of age*: Temperature-sensitive intranasal IBR.
  ◦ *Before weaning or moving to group pens:* Temperature-sensitive intranasal IBR or MLV IBR-BVD-BRSV with Leptospira.
  ◦ *6 months of age:* MLV IBR-BVD-BRSV with Leptospira.
  ◦ *Before breeding:* MLV IBR-BVD-BRSV with Leptospira.
  ◦ *At least 20 days postpartum:* MLV IBR-BVD-BRSV with Leptospira.
  ◦ *Or, during the dry period:* MLV IBR-BVD-BRSV with Leptospira.
• Vaccines that may be incorporated based on dairy-specific disease/management include:
  ◦ *J-5 Gram-negative vaccines* to reduce the severity of coliform mastitis: 1 or 2 vaccinations prepartum and 1 vaccination 10–20 days in milk. This practice is common on many dairies in the United States and its use has accompanied a significant decline in severity of disease and subsequent mortality from coliform mastitis.
  ◦ *Leptospira borgpetersenii* serovar hardjo-bovis (type: *hardjo-bovis*) specific vaccine to prevent early abortions.
  ◦ *Rotavirus and coronavirus* vaccine to either dry cows or pre-colostrum calves to prevent diarrhea in calves.
  ◦ Clostridial vaccines to control malignant edema (*C. septicum* or *sordelli*), blackleg (*C. chauvoei*) or redwater (*C. hemolyticum*).

MEDICATIONS

DRUGS OF CHOICE

Epinephrine should be on hand in case of anaphylactic reaction after vaccination.

CONTRAINDICATIONS

• Do not administer corticosteroids within 1 week of vaccination.

(CONTINUED) VACCINATION PROGRAMS: DAIRY CATTLE

• It is commonly recommended to not administer more than two Gram-negative bacterins at the same time because of the risk of endotoxemia.
• Vaccination of animals in negative energy balance may result in decreased efficacy.

PRECAUTIONS
• Only use MLV vaccines in pregnant animals if they are approved and used in accordance with label.
• Do not vaccinate cattle within 1 week after parturition to avoid the immunosuppressive complications of the corticosteroids associated with calving.
• Avoid vaccinating heat-stressed cattle due to the increased risk of endotoxic reaction.

POSSIBLE INTERACTIONS
See "Contraindications" and "Precautions"

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Effective immunity can be expected within 2 weeks after systemic vaccinations.
• Mucosal immunity is developed within 48 hours after intranasal vaccination with temperature sensitive IBR vaccines.

POSSIBLE COMPLICATIONS
Abortion, anaphylaxis, or inadequate immunity can result from vaccinating inappropriately.

CLIENT EDUCATION
• Clients must understand the importance of vaccine handling and timing of the vaccinations. All vaccines must be kept cold and out of the sunlight. Modified-live virus vaccines are inactivated quickly by ultraviolet light and should be used within 1 hour of mixing with the diluent.
• Vaccines should not be frozen; MLV vaccines are inactivated and attenuated by freeze-thaw cycles and cells can be ruptured and endotoxin released in bacterins.
• Bacterins must be boostered at the recommended intervals and clients must understand the importance of the booster dose.

PATIENT CARE
• Cattle should be observed for at least 2 hours post-vaccination for signs of anaphylaxis.

PREVENTION
N/A

MISCELLANEOUS

AGE-RELATED FACTORS
• Calves <1 week of age may not respond well to systemic vaccinations but will respond well to temperature sensitive intranasal vaccines.
• Cellular immunity in the neonatal bovine appears to be decreased between 2 and 5 weeks of age and vaccination with systemic vaccines should be avoided during this period.
• Vaccine programs are generally targeted to bovines based on age. The goal of vaccinating calves is to decrease the case rate and severity of diarrhea and pneumonia while older cattle are vaccinated to protect from abortifacients, mastitis, and pneumonia.

ZOONOTIC POTENTIAL
RB 51 and Strain 19 *Brucella* vaccines are live bacterial vaccines and are zoonotic pathogens.

PREGNANCY
• Bacterins and killed-virus vaccines are generally safe for pregnant cattle, although the endotoxins in bacterins can cause sufficient prostaglandin release during an endotoxic reaction to cause luteolysis and abortion.
• Only MLV vaccines approved for use in pregnant cattle should be used during gestation.
• The first infection with IBR (wild type or vaccine strain) virus can result in infection of the ovary and subsequent luteolysis and abortion. Therefore, cattle should be previously effectively vaccinated with MLV-IBR prior to MLV-IBR vaccination during pregnancy.

ABBREVIATIONS
• BRSV = bovine respiratory synctial virus
• BVD = bovine viral diarrhea virus
• GI = gastrointestinal
• IBR = infectious bovine rhinotracheitis
• MLV = modified-live virus

VACCINATION PROGRAMS: SMALL RUMINANT

BASICS

OVERVIEW

• A strategic vaccination program is a critical part of herd health management.
• Vaccination can prevent disease or reduce disease severity, but it is not a substitute for poor management in other areas.
• A successful vaccination program depends on adequate nutrition, proper management, and planning.
• Nutrition must be adequate for the immune system to function properly.
  ◦ A vaccine prevents disease by priming an animal's immune system to fight the disease.
  ◦ The animal must be supplied with adequate protein and energy, as well as vitamins A and E, copper, selenium, and zinc for optimum immune system function.
• No vaccine is 100% protective in 100% of animals. Some animals will have a less than maximal response and some animals may not respond at all.
• Vaccination is the act of inoculating an animal with a vaccine. It does not imply immunity.
• Immunization is the development of an immune response to a vaccine. It does not imply protection from disease.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

• Appropriate vaccination programs must be customized to the specific group and location for which they are being developed.
• Some vaccines may be appropriate in some areas but unnecessary in others depending on the occurrence of the disease in that area.

SYSTEMS AFFECTED

Hemolymphatic

PATHOPHYSIOLOGY

Proper vaccination can improve both passive and active immunity.

Passive Immunity

• Antibodies are obtained from a source other than the animal's immune system.
• Passive transfer of colostral antibodies is the most important form of passive immunity.
• Antibodies from passive immunity may interfere with the development of active immunity in response to vaccination in young animals by "neutralizing" the vaccine.
• Other types of passive immunity include blood or plasma transfusion and antiserum products (e.g., tetanus antitoxin).

Active Immunity

• Humoral and secretory immunity reflect production of antibodies by specific lymphocytes in response to antigen exposure or vaccination.
• Cell mediated immunity (CMI) develops when specialized lymphocytes are exposed to a specific organism and develop a "memory" for that organism. When exposed again, these cells attack and kill that organism or cells infected with that organism.
  ◦ CMI is not as easily elicited as humoral immunity and is rarely provoked in response to a killed vaccine.
  ◦ In most cases, an infectious organism has to replicate within an animal to produce CMI.

Innate Immunity

• Innate immunity consists of natural defense mechanisms such as enzymes, tears, saliva, and gastric acids.
• These mechanisms destroy or mechanically remove infectious organisms.

HISTORICAL FINDINGS

N/A

SIGNALMENT

Small ruminants of any age or production status can be incorporated into a vaccination program, though protocols may differ for individuals based on age and production role.

PHYSICAL EXAMINATION FINDINGS

Animals with severely abnormal physical examination findings, such as high fever or significant systemic illness, should not be vaccinated until recovered.

GENETICS

Genetics affect natural disease resistance including innate immunity and potentially factors such as mothering ability, which affect passive immunity.

CAUSES AND RISK FACTORS

Vaccine failure can arise from:
• Improper handling of vaccines
• Improper timing of vaccination
• Interference by maternal antibodies
• Improper administration technique
• Improper timing of booster vaccinations
• Vaccinating animals that are already sick or stressed
• Overwhelming disease challenge
• Nutritional deficiencies or other causes of poor health

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

N/A

OTHER LABORATORY TESTS

N/A

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

N/A

PATHOLOGIC FINDINGS

N/A

TREATMENT

THERAPEUTIC APPROACH

• Ensuring adequate colostral transfer of antibodies is more important and effective than any vaccination program, though appropriate vaccination of the dam boosts this benefit immensely.
• Provide a balanced diet adequate in vitamins and trace minerals to allow optimum immune system function.
• Use vaccines according to label directions.
• Vaccines should not be mixed in the same syringe unless directed by the label.
• Vaccines should be kept cool and out of direct sunlight. Keep vaccines in an ice chest or some other form of protection while in use.
• Only reconstitute the amount of vaccine that can be used in 1 hour. Do not store reconstituted MLV products, even for a few hours.
• Use clean injection equipment to administer vaccines.
• Change needles every 5–10 animals.
• Never disinfect instruments that will be used for MLV products with chemical disinfectants. Residual disinfectant can destroy the effectiveness of MLV products.

SURGICAL CONSIDERATIONS AND TECHNIQUES

N/A

MEDICATIONS

DRUGS OF CHOICE

Killed Vaccines

• Require a booster dose 2–3 weeks after initial dose, otherwise virtually no protective immunity occurs. Once an animal has received two doses, a single yearly booster may be adequate.
• Provide shorter duration of immunity.
• Usually do not stimulate CMI.
• Most approved small ruminant vaccines fall into this category.

Modified-Live Vaccines

• Infectious agent is alive but altered so that it does not cause disease in healthy animals.
• Agent replicates within the animal and induces both humoral and cell-mediated immunity.
• Usually provide a greater immune response than killed products.
• Some types may cause abortion in pregnant animals or disease in stressed animals.

(CONTINUED) VACCINATION PROGRAMS: SMALL RUMINANT

Component Vaccines
Vaccines that contain only part of an infectious agent and induce immunity to a component of the infectious agent that is necessary for the agent to cause disease.

Toxoids
Vaccines that induce an immune response to specific toxins produced by bacteria.

CONTRAINDICATIONS
• Only use contagious ecthyma (orf) and caseous lymphadenitis vaccines in herds with a known history of the disease, since these vaccines can produce disease in naïve groups.
• Some MLV vaccines can cause abortion if administered to pregnant animals. Always follow label directions.
• Administering certain vaccines may complicate international shipment of animals or semen due to positive serologic tests. Consider the ultimate goals of the producer before administering vaccines.

PRECAUTIONS
• Administering vaccines to animals that are already sick or heavily stressed often fails to produce an immune response and may induce additional stress.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
Avoid administration of immunosuppressive drugs such as corticosteroids within 1 week of vaccination.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Effective immunity can be expected within 2 weeks of vaccination, and often more rapidly with modified live vaccines.

POSSIBLE COMPLICATIONS
Anaphylaxis can occur with some vaccines.

CLIENT EDUCATION
Focus on educating producers on diseases relevant to their production system, and available vaccines.

PATIENT CARE
Monitor for local or systemic vaccine reactions.

PREVENTION
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
Vaccine site reactions or abscesses.

AGE-RELATED FACTORS
Neonates may not respond to vaccines due to the influence of passive immunity from colostral antibodies. Antibodies to clostridial diseases usually persist for the first 2–3 months of age.

ZOONOTIC POTENTIAL
Contagious ecthyma vaccine is a live virus that can cause clinical lesions in humans if handled improperly.

PREGNANCY
MLV products are often unsuitable during pregnancy.

BIOSECURITY
Well-designed vaccination programs are an integral part of herd biosecurity.

PRODUCTION MANAGEMENT
• Clostridial diseases are the only common group of diseases that all sheep and goats should be vaccinated against. Other vaccines that can be used in small ruminants include *Campylobacter, Chlamydia psittaci*, caseous lymphadenitis (CLA), foot rot, rabies, *Leptospira*, and contagious ecthyma. Use of these vaccines should be based on geographic prevalence of disease and the history of disease within each group.
• Previously vaccinated ewes or does should receive an annual booster of clostridial vaccine 4 weeks prior to parturition.
• Previously unvaccinated ewes or does should receive two doses of clostridial vaccine 8 and 4 weeks prior to parturition.
• Rams/bucks should be vaccinated with clostridial vaccine at the same time as pregnant animals.
• Passive immunity to clostridial diseases usually begins to decline around 4–6 weeks of age. Lambs or kids born to previously vaccinated dams can be given a clostridial bacterin/toxoid at this age, with a booster in 3–4 weeks.
• Neonates from dams not vaccinated during late gestation should receive a clostridial vaccination at 1–2 weeks of age, with two boosters given at 3- to 4-week intervals.
• If lambs will be transitioned onto a high energy ration, they should receive an additional vaccination that includes *C. perfringens* type D, 2 weeks prior to a diet change to protect against "enterotoxemia."
• Clostridial vaccines are often manufactured as combination vaccines, ranging from 3-way (C/D/T) to 8-way, and may contain CLA.
• If contagious ecthyma is an issue, lambs should be vaccinated on the inner thigh within the first week of life, and ewes can be vaccinated 2 or more months prior to lambing so that lambs do not come in contact with the scabs.
• *Campylobacter* and *Chlamydia* vaccines can be given 2–3 weeks prior to breeding in at-risk flocks. If a ewe has an unknown history, or has not previously been vaccinated, vaccinate 2–3 weeks prior to breeding and booster mid-pregnancy.
• Other vaccines such as CLA, orf, *Coxiella*, and foot rot vaccines may be considered in problem herds.
• If foot rot is an issue in the herd, vaccinate well in advance of the time of the year when the problem is noted (usually during spring/wet season); it may take several years of vaccinating before beneficial effects are noted.

SYNONYMS

VAGAL INDIGESTION

BASICS

OVERVIEW
• Vagal indigestion is a complex syndrome characterized by functional disturbances of the ruminant forestomachs.
• Various causes result in rumen distension with gas and/or fluid.
• Contrary to the name, the most common causes of vagal indigestion are not related to dysfunction of the vagal nerve.
• This syndrome is characterized by and differentiated from other forms of indigestion by its slowly progressive course.

INCIDENCE/PREVALENCE
• No reports list the incidence or prevalence of vagal indigestion.
• It is the most common complication following abomasal volvulus correction.

GEOGRAPHIC DISTRIBUTION
Winter in cold climates may predispose to primary abomasal impaction if water sources freeze, prohibiting drinking.

SYSTEMS AFFECTED
Digestive

PATHOPHYSIOLOGY
The syndrome is composed of four categories of dysfunction.
• Type I: Failure of eructation
  ◦ Partial esophageal obstruction by foreign body—feed material, apples, etc.
  ◦ Extra-esophageal compression—lymphosarcoma, thyroid tumors, mediastinitis, abscess
  ◦ Inflammatory process adjacent to vagal nerve causing neuropraxia—cranial abdominal abscess, peritonitis, chronic pneumonia
• Type II: Omasal transport failure
  ◦ Intraluminal reduction in omasal canal—placenta, bags, twine, trichobezoar
  ◦ Extramural masses which compress the omasal canal—perireticular adhesions or localized peritonitis related to traumatic reticuloperitonitis (TRP) or perforating abomasal ulcers
  ◦ Neoplasia—lymphosarcoma, papilloma, squamous cell carcinoma
  ◦ Functional failure of omasal transport (neuropraxia)—abscesses in left lobe of the liver
• Type III: Pyloric outflow failure
  ◦ Lymphosarcoma of abomasal wall near pylorus
  ◦ Primary abomasal impaction in animals fed dry, coarse roughage or with limited access to water
  ◦ Secondary abomasal impaction:
    ▪ Functional inability to empty abomasum
    ▪ Adhesions from TRP
    ▪ Adhesions of right lateral wall of reticulum
    ▪ Poor motility after abomasal volvulus
    ▪ Foreign bodies obstructing pylorus (trichobezoars, placenta)
    ▪ Misplaced toggle pin fixation for displaced abomasum
• Type IV: Indigestion of late pregnancy
  ◦ As fetus enlarges, the abomasum is forced cranially.
  ◦ This may interfere with abomasal motility, leading to impaction.
  ◦ These animals may have a combination of type II and type III vagal indigestion.

HISTORICAL FINDINGS
• Gradual abdominal enlargement
• Intermittent episodes of indigestion and anorexia
• Reduced milk production
• Weight loss
• Decreased fecal output
• Possible history of abnormal regurgitation
• Animals may be in late pregnancy

SIGNALMENT
• Only reported in bovines; however, abomasal emptying defect of Suffolk sheep is a similar condition to type III vagal indigestion.
• Type IV is more common in late pregnant dairy breeds.
• Lymphoma is most prevalent in cattle 4–8 years of age.

PHYSICAL EXAMINATION FINDINGS
• The hallmark sign of vagal indigestion is gradual abdominal enlargement, with a "papple" or "L-shaped" abdomen (large and round dorsally and ventrally on the left, distended ventrally on the right) due to fluid and/or gas accumulation in the rumen.
• Vagal indigestion is unlikely in acutely sick animals; other diagnoses should be considered first.
• Decreased fecal volume
  ◦ Feces may be pasty and have increased fiber length (2–4 cm); the omasum is responsible for reducing feed particle size before delivery to abomasum.
• Melena if abomasal ulceration is involved.
• Abnormal rumen motility
  ◦ Often increased with 4–5 contractions per 2 minutes unless there is severe distension, then motility slows.
  ◦ Contractions may be nearly silent, but are strong and displace the left paralumbar fossa.
  ◦ Absence of rumen motility suggests a very poor prognosis due to likelihood of significant peritonitis and adhesion formation.
• Abdominal percussion may elicit a "ping" from gas-distended rumen and be mistaken for a left displaced abomasum (LDA), but can be differentiated based on size and shape from an LDA.
• Abdominal succussion identifies a "splashy" rumen if there is fluid accumulation.
• Per rectum examination
  ◦ L-shaped rumen
  ◦ May palpate a large, distended abomasum, caudally displaced by cranial abdominal pathology.
  ◦ May be able to palpate omasum if significant liver pathology, such as abscessation, is present.
• Grunt test and withers pinch to detect cranial abdominal pain can be performed (insensitive).
• Bradycardia is variable and an unusual finding.

GENETICS
No recognized genetic causes or implications for vagal indigestion

CAUSES AND RISK FACTORS
• Type I: Failure of eructation
  ◦ Unresolved pneumonia or mediastinal pathology
  ◦ Exposure to foreign bodies, particularly spherical objects
• Type II: Omasal transport failure
  ◦ Unresolved TRP
  ◦ Linear foreign body exposure
• Type III: Pyloric outflow failure
  ◦ Grazing on crop residues
  ◦ Loss of water access
  ◦ Linear foreign body exposure
  ◦ Bovine leukemia virus infection
  ◦ Toggle repair of LDA
• Type IV: Indigestion of late pregnancy
  ◦ Large fetal size

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Simple indigestion
• Rumen acidosis
• TRP
• Displaced abomasum
• Frothy bloat
• Hydrops
• Ascites
• Diffuse peritonitis
• Abdominal neoplasia (lymphosarcoma)
• Intestinal obstruction (intussusception, mesenteric volvulus)
• Reticulitis (abnormal regurgitation)
• Ingestion of toxic plants or spoiled feed (abnormal regurgitation; rhododendron and mountain laurel)

CBC/BIOCHEMISTRY/URINALYSIS
• CBC can help differentiate possible etiologies:
  ◦ Leukocytosis indicates mild to moderate inflammation, and may occur relatively early in the process.
  ◦ Leukopenia occurs with severe inflammation (e.g., diffuse peritonitis).
  ◦ Neutrophil : lymphocyte ratio reversal (2:1) suggests inflammation.
  ◦ Lymphocytosis suggests lymphosarcoma (if persistent).

(CONTINUED) VAGAL INDIGESTION

- PCV and total protein may increase due to dehydration, or PCV may be low due to chronic inflammation.

• Biochemistry findings reflect dehydration and electrolyte and acid base anomalies.
- Hypokalemia and hypocalcemia reflect anorexia.
- Hypochloremia indicates abomasal reflux into the rumen from impaction or forestomach stasis decreasing absorption into blood.
  - Occurs in types III and IV
  - Severe hypochloremia (<50 mEq/L) is associated with a grave prognosis.
- Metabolic alkalosis occurs in types II, III, and IV due to HCl sequestration in forestomachs.
- Metabolic acidosis can occur in type I with esophageal obstruction due to loss of salivary bicarbonate.
- Pre-renal azotemia.
- Hypergammaglobulinemia (high total protein) indicates inflammatory process.

OTHER LABORATORY TESTS

• Rumen fluid analysis
- Elevated rumen chloride (>30 mEq/L) indicates HCl reflux into rumen.
- Occurs with abomasal impaction or any abomasal outflow obstruction.

• BLV serology: Positive result indicates viral infection but does not confirm the presence of a tumor, which will arise in only a low percentage of infected cattle.
• Abdominocentesis can identify peritonitis, but may be inconclusive if peritonitis is localized and encapsulated. Increased total protein (>2.5 g/dL) and nucleated cell count (>5,000/µL) suggest peritonitis. Abnormal morphology may suggest lymphoma.
• Fecal occult blood assessment can support presence of GI hemorrhage, including abomasal ulceration, and should be performed prior to per rectum examination.

IMAGING

• Radiography: Visualize cranial abdominal metallic foreign bodies.
• Ultrasonography can assess reticular motility and help identify masses, abscesses, peritonitis or thickening of visceral walls (lymphosarcoma).

OTHER DIAGNOSTIC PROCEDURES

• Exploratory laparotomy can establish diagnosis and possibly treatment.
- Allows localization of masses or abscesses
- Allows needle aspiration or biopsy of masses for evaluation
- Allows removal of masses, drainage of abscesses into the GI tract, or instillation of fluid into an impacted abomasum and subsequent massage.

• Figure 1 provides a basic plan for differentiating types of vagal indigestion.

PATHOLOGIC FINDINGS

• Type I
- Foreign body, mass obstructing esophagus
- Chronic thoracic pathology (e.g., pneumonia or abscess)

• Type II
- Intraluminal foreign bodies or masses
- Masses impinging upon omasal canal
- Localized peritonitis, adhesions, TRP
- Liver abscesses

• Type III
- Dry, impacted abomasum
- Adhesions, TRP
- Pyloric foreign bodies
- Pyloric stenosis

• Type IV
- Large fetus cranially displacing abomasum

• Histopathology can confirm and define the nature of relevant masses (abscesses, lymphosarcoma, papilloma, squamous cell carcinoma) and can be used to assess other tissues including the vagus nerve, cardia, esophageal groove, reticulo-omasal orifice, omasal canal, and pylorus (often all are normal).

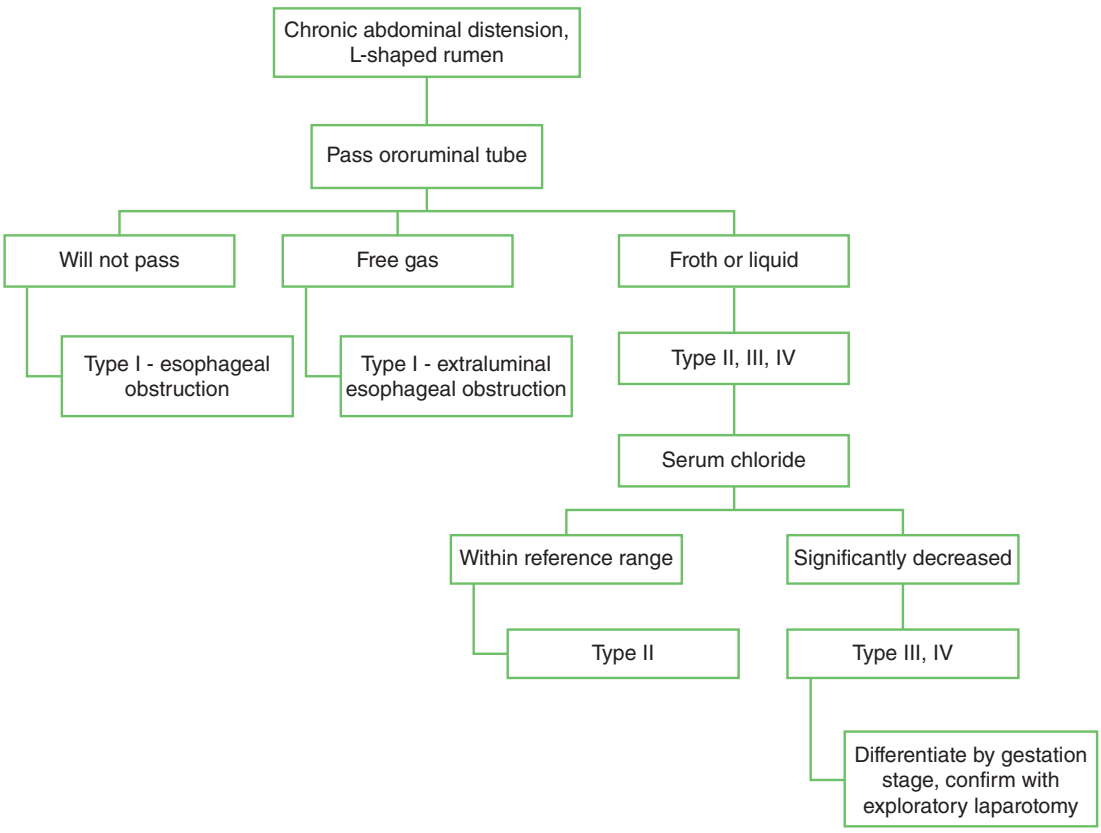

Figure 1.

Algorithm for Distinguishing Different Types of Vagal Indigestion

VAGAL INDIGESTION (CONTINUED)

TREATMENT

THERAPEUTIC APPROACH

• Animals with vagal indigestion generally require hospitalization to be treated for their primary condition and to resolve associated acid-base and electrolyte imbalances
• Type I
  ◦ Pending resolution of esophageal obstruction, a rumen fistula can be created to alleviate bloat.
  ◦ Self-retaining rumen trocar.
  ◦ Rumenostomy can be performed (2–3 cm diameter) by suturing rumen wall to skin. This can granulate over in a few months, allowing time for healing of causative lesion.
  ◦ Correct acid-base derangements and electrolyte abnormalities by providing alkalinizing solutions via ororuminal tube or rumenostomy.
  ◦ Due to salivary loss of bicarbonate, metabolic acidosis may be severe and require additional IV sodium bicarbonate supplementation.
• Type II
  ◦ Supportive therapy based on physical examination and clinicopathologic findings is important, particularly to prepare the animal for additional interventions.
  ◦ Parenteral balanced electrolyte solutions high in chloride.
  ◦ Potassium supplementation.
  ◦ Calcium gluconate.
  ◦ Systemic antimicrobials with spectrum to cover mixed gastrointestinal flora, including anaerobes.
  ◦ Oral electrolytes (include 20–30 g potassium chloride to improve total body potassium status) and fluids to create mild rumen distension to promote motility.
  ◦ Transfaunation with 8–16 L of fresh rumen fluid to reestablish microbial populations and improve to motility and appetite.
  ◦ Surgical therapy is required in most animals (see "Surgical Considerations and Techniques").
• Type III
  ◦ Generally associated with a poor prognosis.
  ◦ Provide balanced electrolyte solutions high in chloride.
  ◦ Oral and IV potassium supplementation.
  ◦ Limited absorption is expected with limited abomasal outflow.
  ◦ Laxatives (mineral oil, magnesium hydroxide) may assist with abomasal impaction.
  ◦ Surgical intervention often indicated once hydration, electrolyte and acid-base aberrations addressed.
• Type IV
  ◦ Consider value of dam versus calf when determining treatment.
  ◦ Also consider stage of gestation and potential viability of calf.
    ▪ If cow is within 4–6 weeks of parturition, it might be possible to provide support until the fetus can be viable after delivery.
    ▪ If there is considerable time to parturition, saving both dam and fetus is less likely, and therapeutic abortion should be considered.
  ◦ Provide balanced electrolyte solutions to correct hypokalemia, hypochloremia, alkalosis, and hypocalcemia; however, lack of abomasal outflow will limit utility of orally administered solutions.
  ◦ Be prepared to assist delivery in compromised dams if therapeutic abortion is performed.

SURGICAL CONSIDERATIONS AND TECHNIQUES

• In general, left-sided exploration may be selected for suspected type I and II indigestion, or for cesarean section in type IV indigestion.
• Rumenotomy, rumenostomy, and percutaneous abscess drainage may be performed in the standing animal with local anesthesia (using line, paravertebral, or inverted L blocks) to minimize anesthetic risks.
• Left-sided exploration can be paired with rumenotomy to allow investigation of the cardia, reticulum, omasal groove, and abomasum (through rumen wall).
• Right-sided exploration allows enhanced evaluation of the abomasum and pylorus, along with more distal portions of the gastrointestinal tract, and may be selected for type III indigestion.
• Type I: Surgery rarely indicated.
• Type II: Rumenotomy allows diagnostic palpation of cardia, omasal canal, and reticular wall, removal of foreign bodies or masses, and biopsies of masses to aid definitive diagnosis and prognosis.
  ◦ Perireticular abscesses, if firmly adherent to the reticular wall, may be incised and drained into the reticulum, or otherwise can be drained percutaneously from the right body wall under ultrasound guidance.
  ◦ Paramedian approach may allow attempt at removal *en bloc*.
• Type III: right- or left-sided approaches may be indicated.
  ◦ Left-sided approach includes rumenotomy.
    ▪ Palpation for masses or abscesses.
    ▪ Abscesses adhered to the reticulum may be drained into the GI tract.
    ▪ Abomasal contents may be reached through the omasal canal without opening the abomasum.
    ▪ A stomach tube can be passed into the abomasum via the omasal canal with infusion of docusate, magnesium sulfate, and fluids.
    ▪ The abomasum can be massaged though the rumen wall.
  ◦ Right-sided approach enhances the ability to examine the abomasum and pylorus, as well as the distal GI tract.
    ▪ Allows for biopsy of infiltrative disease of the abomasum or pylorus.
    ▪ Permits abomasotomy as a last resort to relieve abomasal impactions since it can be associated with adhesion formation, ischemia, and motility disturbances.
• Type IV: Cesarean section with removal of the calf immediately relieves pressure on the forestomachs and generally results in rapid recovery when accompanied by appropriate fluid and electrolyte therapy.

MEDICATIONS

DRUGS OF CHOICE

• Systemic antibiotics are indicated after rumenotomy and GI manipulation.
• Combination analgesia may increase ability to control pain, and improve appetite while assisting preservation of GI motility, and may include NSAIDs and opioids (butorphanol, morphine).
• Therapeutic abortion can be accomplished within 36 hours after concurrent administration of 20 mg dexamethasone and 25 mg dinoprost IM.

CONTRAINDICATIONS

• The use of magnesium oxide/hydroxide is contraindicated in the presence of metabolic alkalosis.
• NSAID use is contraindicated in the presence of abomasal ulcers, increased creatinine, or uncorrected dehydration.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• In one report, 33/112 (29.5%) of vagal indigestion cases from all causes made a full recovery.
• Type I cases have a good prognosis with rumenostomy, but may not flourish. They have a poorer prognosis if chronic pneumonia was the inciting cause.
• Type II cases have a fair to good prognosis depending on etiology.
• Type III cases have a poor prognosis, particularly if secondary to abomasal volvulus (in one report, 3/26 had a good outcome).

• Type IV cases have improved prognosis with increased proximity to full gestation length. Supporting the dam through several weeks of gestation is intensive and the dam often deteriorates, whereas removal of the fetus at any stage of gestation is likely to improve rumen motility and condition of the cow.
• Neoplasia has a grave prognosis (except papilloma).
• Prognosis with abscesses depends on extent of adhesion formation.
  ◦ Hardware disease (TRP) prognosis:
    ▪ Poor to good outcomes
    ▪ 7/15 (47%) in cases of uncomplicated TRP
    ▪ 6/17 (35%) TRP with obstruction of digesta passage through reticulo-omasal orifice
    ▪ 1/10 (10%) TRP with obstruction of digesta passage though pylorus
  ◦ Peri-omasal or liver abscess—prognosis fair to good:
    ▪ Liver abscess retrospective study
    ▪ 5 of 8 cases made a significant improvement
    ▪ 2 or 3 of 8 recurred at 3 months and 1 year postoperatively
  ◦ Perireticular abscesses involving diaphragm and omasum:
    ▪ 74% (of 29 cases) returned to production for 1–4 years post-operatively.
• Foreign bodies usually have excellent prognosis with removal.

POSSIBLE COMPLICATIONS
• Poor motility despite treatment due to irreversible damage to abomasum.
• Abscess or mass recurrence after drainage or removal (in one report, liver abscess recurrence was 2–3 of 8 cases).
• Postoperative peritonitis.
• Retained fetal membranes and metritis are more common in cattle after artificially induced parturition/abortion.

CLIENT EDUCATION
• Type I
  ◦ Evaluate risk for foreign body exposure in environment.
  ◦ Review evaluation and therapies for pneumonia to prevent chronicity.
• Type II
  ◦ Review risk for hardware disease from environment and feed mixers.
  ◦ Review pasture cleanliness principles regarding twine, bags, etc.
• Type III
  ◦ Evaluate hay and diet quality to reduce risk of impaction.
  ◦ Discuss control strategies for bovine leukemia virus.
• Type IV
  ◦ Review bull selection, nutrition, and other factors associated with fetal size.

PATIENT CARE
• Patients should be monitored for return of appetite and demeanor.
• Abdominal contour must be monitored once animal is eating well to indicate motility and patency.
• Fecal output should be monitored for volume, consistency, and fiber length.
• Supply plenty of fresh water and good quality, highly digestible feed.
• Grains may be added if a laxative effect is desired.

PREVENTION
• Use of magnets in feed mixers and handling equipment to prevent metallic foreign bodies in feed.
• Environmental monitoring and removal of foreign objects.
• BLV control strategies which limit blood transmission of the virus.
• Breeding decisions to control for fetal size.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Displaced abomasum
• Abomasal volvulus

AGE-RELATED FACTORS
Older animals are more likely to be affected by neoplastic process.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Termination of late-term pregnancy, if the dam is considered much more valuable than fetus, may be useful in most types of vagal indigestion, since fetal removal may promote normal abomasal and omasal location and motility.

BIOSECURITY
Consideration for BLV control

PRODUCTION MANAGEMENT
• Animals in dry regions or grazed on crop aftermath should be provided with readily accessible water in order to prevent abomasal impaction.
• Magnets in all feed mixing and handling equipment can reduce metallic foreign body delivery to animals.
• Bale twine and netting should be removed from all bales at feeding.

SYNONYM
Vagus indigestion

ABBREVIATIONS
• BLV = bovine leukemia virus
• GI = gastrointestinal
• IM = intramuscular
• IV = intravenous
• LDA = left displaced abomasum
• NSAIDs = nonsteroidal anti-inflammatory drugs
• TRP = traumatic reticuloperitonitis

SEE ALSO

VAGINITIS

BASICS

OVERVIEW
• Inflammation of the vagina caused by a variety of organisms.
• Transient vaginitis is commonly seen after synchronization of estrus with progesterone intravaginal devices.
• A form of severe necrotic vaginitis may occur following obstetric manipulations.

INCIDENCE/PREVALENCE
• The prevalence of vaginitis was 2.6% in dairy cattle in Austria.
• In herds affected by *Ureaplasma diversum*, clinical signs of vaginitis were reported in 43% of the cows.
• *Ureaplasma diversum* and *Mycoplasma* spp. are commonly isolated from vagina and vestibule of reproductively normal cattle. However, *Ureaplasma diversum* is more commonly isolated from vaginal swabs of cows with vaginitis (40–60%) than cows without vaginitis.
• *Mycoplasma bovigenitalium* was isolated from 55% of cows with vaginitis in one Israeli study.
• The prevalence of *Mycoplasma bovigenitalium* did not differ between cows with and without vaginitis.

GEOGRAPHIC DISTRIBUTION
Potentially worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• Infectious granular vulvovaginitis (IGV): Bacteria colonize the vulva and vagina of females, urethra, prepuce, and semen of bulls, and nasal passages in both sexes. Transmission is venereal or by direct contact, environmental contamination, or during passage through the birth canal. Granular vulvovaginitis results 4–10 days after infection, followed by ascending endometritis and salpingitis. Reproductive problems can persist for up to 6 months and nodules can persist for >1 year.
• Infectious pustular vulvovaginitis (IPV): Infection is venereal. Fever, depression, and anorexia may be present during the acute phase 1–3 days post-infection. Small vesicles and 2–3-mm raised pustules are formed in the vaginal mucosa. Pustules may then coalesce forming painful ulcers. Mucopurulent vulvar discharge may develop due to secondary bacterial infection. Lesions heal after 10–14 days. After primary infection, latency is established.
• Caprine herpes virus 1 (CpHV-1): Causes reproductive syndrome in goats similar to that observed in cattle with BHV-1 (IPV).
• Traumatic: Purulent vaginitis is produced by the irritation of the vaginal mucosa after estrus synchronization treatment with CIDR device or sponges.
• The most severe form of bacterial vaginitis is observed following lengthy obstetric manipulation. This form of vaginitis may lead to severe vaginal adhesions. Camelids seem to be more predisposed to this than ruminants.

HISTORICAL FINDINGS
• A herd history of signs described in "Pathophysiology"
• History of dystocia

SIGNALMENT
• Potentially all ruminants: Breeding age females.
• IPV, IGV: Cattle. Heifers are more susceptible to granular vulvovaginitis.
• Caprine herpes virus 1: goats

PHYSICAL EXAMINATION FINDINGS
• Characteristic lesions on vaginal examination.
• Discomfort, arched back, tail twitching or raising, straining, dysuria.
• Mucopurulent vulvar discharge, hyperemia of the vulvar, vestibular, and vaginal mucosa.
• IPV: Vaginal vesicles, raised pustules, painful ulcers.
• IGV: Raised red to gray vaginal nodules, infertility, pregnancy loss.

GENETICS
N/A

CAUSES AND RISK FACTORS
• IPV: Bovine herpes virus 1
• IGV: *Ureaplasma diversum*
• *Mycoplasma bovis*, *Mycoplasma bovigenitalium* (role is controversial)
• Foreign body
• Trauma, most often during calving or breeding
• Urovagina, pneumovagina
• Use of progesterone/progestagen-containing intravaginal devices
• Caprine herpes virus 1 (lesions similar to BHV-1)
• Risk factors include
  ◦ Reuse of progesterone-containing intravaginal devices (IGV)
  ◦ Vaginal injuries during calving or breeding
  ◦ Use of infected semen or bulls

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Bovine necrotic vulvovaginitis: Unique to Israel, caused by the anaerobe *Porphyromonas levii*. It is characterized by the development of a necrotic vulvovaginal lesion in the first week postpartum in first calf heifers. Incidence may be 85% initially.
• Vulvar discharge: Metritis, endometritis, pyometra.
• Other causes of infertility and pregnancy loss.

CBC/BIOCHEMISTRY/URINALYSIS
Usually not useful

OTHER LABORATORY TESTS
• Bacterial culture from vulvar and vaginal samples.
• Samples for culture of *Ureaplasma diversum* must be collected with Dacron or polyester-tipped swabs, submersed in appropriate transport medium and frozen.
• Virus isolation, serology, PCR (IPV).

IMAGING
Ultrasonography per rectum may help rule in or out uterine infection.

OTHER DIAGNOSTIC PROCEDURES
Speculum vaginal examination will reveal characteristic lesions, lacerations, urine pooling, or foreign bodies.

PATHOLOGIC FINDINGS
IPV: Necrosis of the vaginal epithelium with intranuclear inclusion bodies.

TREATMENT

THERAPEUTIC APPROACH
• Control infection and inflammation.
• Treat primary cause.
• Vaginal douche with normal saline solution or 0.1% chlorhexidine solution.
• Local antibiotic to prevent secondary bacterial infection.

SURGICAL CONSIDERATIONS AND TECHNIQUES
• Surgical correction of pneumovagina, urovagina, and vaginal lacerations.

MEDICATIONS

DRUGS OF CHOICE
• IGV and Mycoplasma spp.: Tylosin (10 mg/kg) for 5 days.
• Alternative: Tetracycline for *Mycoplasma* spp. infection.

CONTRAINDICATIONS
See "Precautions"

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• IPV is usually self-limiting.
• Cows with IGV usually regain fertility after two or three estrous cycles.

POSSIBLE COMPLICATIONS
• Secondary bacterial infection

• Ascending endometritis and salpingitis, infertility

CLIENT EDUCATION
• Work with a veterinarian to design an appropriate biosecurity and vaccination program.
• Work with an experienced insemination technician and veterinarian to insure proper technique during breeding and calving.
• Follow milk and meat withdrawal times if medications are administered.

PATIENT CARE
Supportive as needed

PREVENTION
• Use of sanitary sheath during artificial insemination to prevent introduction of bacteria into the uterus (IGV).
• Tetracycline intrauterine infusion (1 g) 24 h after artificial insemination (IGV).
• Avoid reusing CIDRs and use proper aseptic technique during their application.
• Use proper technique during resolution of dystocia and artificial insemination.
• Optimize the herd's health status by providing appropriate nutritional, stress, and environmental management.

MISCELLANEOUS

ASSOCIATED CONDITIONS
N/A

AGE-RELATED FACTORS
Heifers more susceptible to IGV than cows.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
Ascending infection can cause infertility, embryonic loss, and abortion.

BIOSECURITY
See "Prevention"

PRODUCTION MANAGEMENT
Avoid nutritional, social, and environmental stress by using proper management practices.

VESICULAR STOMATITIS

BASICS

OVERVIEW
• Vesicular stomatitis is a viral disease that causes vesicles, or blisters, in the oral cavity, on the coronary bands, interdigital space, mammary glands, ears, and preputial areas of cattle and horses and occasionally sheep, goats, swine, llamas, and alpacas.
• It cannot be clinically differentiated from foot and mouth disease, and proper identification is imperative to the economics of the United States agriculture industry.
• Vesicular stomatitis virus (VSV) is a reportable disease to state or federal officials in all US states.
• Sheep and goats are fairly resistant and rarely show clinical signs.

INCIDENCE/PREVALENCE
• Incidence varies between geographic locations.
• Morbidity within a herd of naïve animals can reach 90% but typically 5–20% of a herd is symptomatic.
• Mortality is rare.

GEOGRAPHIC DISTRIBUTION
• This disease has been limited to the Americas. It is endemic in some warmer latitudes of North, Central, and South America, and outbreaks occur in more temperate climates sporadically.
• In the southern US and Central America, vesicular stomatitis virus has two domestic strains, New Jersey and Indiana-1, which are found in the southern states.
• Outbreaks in the western US are thought to migrate north out of Mexico and tend to follow waterways and river valleys.

SYSTEMS AFFECTED
• Digestive
• Integument
• Mammary

PATHOPHYSIOLOGY
• Virus enters through an abrasion or mechanical transmission by insects.
• Lesion development is restricted to the site of inoculation.
• However, in some studies, pigs inoculated at the snout via intradermal injection developed vesicles at the coronary band. Short-term viremia was suggested, even though it was not detected in this experiment or in any other in domestic animals to date.
• Vesicles or erosions can be found in the oral cavity, on the feet, and on the mammary gland in cattle.
• Vesicular fluid is very infectious.

HISTORICAL FINDINGS
• Disease can occur at any time of year but cases tend to cluster during the summer and fall, often during or following rainier seasons.
• Cases tend to occur sporadically in endemic areas without large outbreaks.
• Cattle may salivate excessively, have a fever, lose milk production, and develop mastitis.
• The disease is usually self-limiting in approximately 2 weeks.

SIGNALMENT
Cattle, and occasionally sheep and goats.

PHYSICAL EXAMINATION FINDINGS
• Blanched vesicles progressing to erosive ulcers located in one area of the body, such as the oral cavity and muzzle, the feet, or mammary gland.
• Decreased milk production, inappetence and weight loss due to painful oral vesicles, lameness due to vesicles on the coronary band and/or interdigital space, and agitation during milking due to vesicles on the mammary gland.

CAUSES AND RISK FACTORS
• VSV is a member of the genus Vesiculovirus in the family Rhabdoviridae.
• There are two major serotypes of the virus, New Jersey and Indiana. The majority of outbreaks in the US are due to the New Jersey serotype.
• Cases tend to occur sporadically during the warmer months in the southern and western United States and most often near waterways or on pastured animals.
• Introduction route into a herd is not always known but could occur through insect vectors, mechanical transmission, or movement of infected animals.
• Once lesions appear in a herd, direct contact with vesicles and vesicular fluid between animals can spread the virus quite rapidly.
• Transmission can occur through insect vectors, direct contact with infected animals, and indirect contact with contaminated objects.
• Black flies (*Simuliidae*), phlebotomine sand flies (*Lutzomyia shannoni*), and biting midges (*Culicoides*) can transmit the virus to animals and transovarially to their larvae. They have also been shown to overwinter in temperate climates from year to year.
• In the 1982 epizootic of VS in the southwestern US, the New Jersey serotype was isolated from mosquitoes (*Aedes*), house flies (*Musca*), and eye gnats (Chloropidae), but their role in transmission is unknown.
• Moving naïve animals to an endemic area, especially during the late rainy season.
• Increased population of black flies or sand flies.
• Pasture grazing, especially near water sources.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Cattle*:* Foot and mouth disease, infectious bovine rhinotracheitis, bovine viral diarrhea, rinderpest, malignant catarrhal fever, bluetongue, foot rot, chemical or thermal burns
• Sheep*:* Bluetongue, contagious ecthyma, lip/leg ulceration, and foot rot

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Tissue cultures can be used to isolate the virus.
• RT-PCR can be used to detect the virus.
• Viral antibodies (on acute and convalescent sera) and antigen (aseptic vesicular fluid, vesicular epithelium in buffered glycerol or frozen) can be identified using ELISA, CF, and virus neutralization.

OTHER DIAGNOSTIC PROCEDURES
Due to the seriousness of this disease and the inability to clinically differentiate it from FMD, state and federal authorities should be contacted immediately upon suspicion of cases *before* sample collection.

PATHOLOGIC FINDINGS
Vesicles or ulcerative erosions in the oral cavity, on the coronary band, or mammary gland will be seen grossly.

TREATMENT

THERAPEUTIC APPROACH
• Upon confirmatory diagnosis of VSV, animals with lesions should be isolated and given supportive care conducive to the location of the lesions.
• Soft food, or a gruel, and clean water for oral lesions; well-bedded, clean stall for lesions of the feet; milked last if there are mammary lesions.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Local wound debridement may be warranted depending on the extent of the lesion and viable tissue surrounding it, allowing it to heal on its own.

(CONTINUED) VESICULAR STOMATITIS

MEDICATIONS

DRUGS OF CHOICE

• No treatment for VSV.
• Use of broad-spectrum antimicrobials for prevention and treatment of secondary infections.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Most recover without complications in 2 weeks. Coronary band lesions and interdigital space lesions can take longer.

POSSIBLE COMPLICATIONS

Secondary bacterial infection of the lesioned area

CLIENT EDUCATION

• Animals with lesions must be isolated to prevent disease spread; no animals can be moved off the property for at least 30 days after the last lesion has healed.
• Equipment and areas of potential exposure at a facility should be cleaned and disinfected before reintroducing any other animals.
• Patients should be monitored for appetite and lesion healing during the course of the disease (approximately 2 weeks).

PATIENT CARE

• Isolated to a pen/stall that has no direct contact with other susceptible animals and no exposure to potential insect vectors.
• Calves should be removed from infected dams.
• Soft forages/gruel for oral lesions, plenty of water.
• Do not feed calves milk or colostrum from infected animals.

PREVENTION

• Do not move animals to an endemic area.
• Insect control and manure management can help prevent disease spread.
• There is no vaccine available in the US.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Decreased milk production and agitation during milking due to lesions on the mammary gland.
• Inappetence due to oral lesions.
• Lameness due to lesions on the coronary band and/or interdigital space.
• Hypersalivation due to oral lesions.

ZOONOTIC POTENTIAL

• Humans can become infected with VSV New Jersey and Indiana-1 strains; signs include fever, headache, myalgia, and, very rarely, oral vesicles.
• Recovery is usually within 4–7 days.

PREGNANCY

There does not seem to be a concern with pregnant animals unless the lesions impede eating or a severe secondary infection develops.

BIOSECURITY

• Isolation and quarantine of new stock entering the herd or flock.
• Treat or cull new animals for disease conditions prior to herd introduction.
• VSV is a reportable disease.
• Animals with lesions must be isolated to prevent disease spread; no animals can be moved off the property for at least 30 days after the last lesion has healed.
• Equipment and areas of potential exposure at a facility should be cleaned and disinfected before reintroducing any other animals.

ABBREVIATIONS

• CF = complement fixation
• ELISA = enzyme-linked immunosorbent assay
• FMD = foot and mouth disease
• RT-PCR = reverse transcription-polymerase chain reaction
• VSV = vesicular stomatitis virus

VITAMIN A DEFICIENCY/TOXICOSIS

BASICS

OVERVIEW

• Vitamin A occurs as retinol, retinoic acid, and retinal. It is a fat-soluble compound. Together with its precursors, the carotenoids, it is highly labile and rapidly destroyed by light, oxygen, heat, and acid.
• Vitamin A is required by all mammals and is synthesized through the metabolism of carotenoid precursors (carotenes) present in leaves and some grains.
• Of the carotenes, β-carotene has the highest vitamin A activity and is quantitatively the most important for animal nutrition.
• The proximal jejunum is the primary site of vitamin A and carotene absorption. A normal pancreatic, hepatic, and biliary function, together with an adequate dietary fat content and normal fat digestion and absorption, is required for the absorption of β-carotene and its subsequent conversion to retinol.
• Ruminal microbial degradation of biologically active vitamin A is appreciable and varies with diet composition.
High-concentrate diets can result in up to 70% pre-intestinal degradation of vitamin A, whereas diets with >75% forage result in <20% degradation, factors to be taken into account for diet formulation and vitamin A or β-carotene supplementation.
• In dairy cows, peripartum decreases in serum concentrations of vitamin A may contribute to impaired immune function.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

Multisystemic

PATHOPHYSIOLOGY

General Functions

Vitamin A is required for cellular differentiation, growth and development, adequate vision, thyroid gland function, protein synthesis, conversion of cholesterol to corticosterone, glycogen synthesis, immune function, regulation of gene expression, and iron metabolism.

Deficiency

• As hepatic stores of vitamin A can last for up to 6 months, deficiency only develops after prolonged periods of inadequate availability.
• Clinical signs occur in young animals more often than adults and include those listed under "Physical Examination Findings."
• Developmental bone abnormalities of the spine may be responsible for some of the neuromuscular deficits in vitamin A-deficient animals.
• Maternal deficiency of vitamin A is associated with congenital ocular abnormalities. In neonatal calves, malformation and closure of the optic foramen resulting in optic nerve compression is described.

Toxicity

• The likelihood of vitamin A toxicity in ruminants is extremely low, because it has a wide safety margin of about 30 times the nutritional requirement (only 4–10 times in monogastrics).
• Experimentally, harmful effects have been reproduced by feeding >100 times the daily requirements for extended periods. Therefore, an accidental dietary excess for short periods of time is unlikely to produce any harmful effects.
• Hypervitaminosis A produces a variety of clinical abnormalities as listed in "Physical Examination Findings."
• Excess intake of vitamin A also impairs absorption and metabolism of the other fat-soluble vitamins, which can result in deficiency of one or more of vitamins D, E, and K in animals fed diets containing marginal levels of these.

HISTORICAL FINDINGS

N/A

SIGNALMENT

• All ruminant species.
• Intestinal absorption of carotene is more efficient in the Jersey and Guernsey breeds.
• Vitamin A deficiency is observed more frequently in young, growing animal than in adults.

PHYSICAL EXAMINATION FINDINGS

Deficiency

• The classic and frequently the first clinical manifestation of vitamin A deficiency in ruminants is nyctalopia, with a gradual reduction of vision in dim light, readily identified as an inability to avoid obstacles in the dark. Characteristic changes in the eye include keratitis, corneal edema, and xerophthalmia characterized by drying of the conjunctiva (not in cattle, where excessive lacrimation occurs).
• Cattle: Reduced feed intake and stunted growth and development rates, abnormal bone and teeth growth, nyctalopia and corneal opacity, epiphora, rough hair coat, diarrhea, joint and brisket edema, seizures, and immunosuppression manifested as increased susceptibility to infectious diseases such as pneumonia, pinkeye, and mastitis.
• Sheep: In addition to the signs observed in cattle, vitamin A deficiency results in xerophthalmia. In lambs, a deficient humoral immune response and abnormal adrenal function have been described.
• Goats: Vitamin A deficiency presents initially as a nonspecific rough, dull hair coat, followed by the clinical signs described for sheep.
• In females it results in low conception rates and pregnancy losses due to abortions and stillbirths, with offspring born alive being weak and blind. Increased rates of fetal membrane retention have been observed in vitamin A-deficient ewes. Intact males have decreased libido and an increase in sperm abnormalities.
• Advanced hypovitaminosis A most frequently results in characteristic eye changes accompanied by a staggering gait, and convulsive seizures ("fainting" in feedlot cattle) and papilledema of the eye, secondary to elevated cerebrospinal fluid pressure.

Toxicity

• In ruminants fed toxic levels of vitamin A, the most common clinical signs were osteoporosis, reduced feed intake, and decreased cerebrospinal fluid pressure.
• Other signs of hypervitaminosis A include skeletal malformation and osteoporosis leading to spontaneous fractures, anemia, delayed blood clotting and internal hemorrhages, partial or total anorexia, growth retardation and weight loss, alopecia, skin thickening with hyperkeratosis, enteritis with chronic diarrhea, hepatomegaly and splenomegaly with degenerative atrophy and fatty infiltration of liver and kidneys, conjunctivitis, and congenital abnormalities.

GENETICS

N/A

CAUSES AND RISK FACTORS

• Poor dietary formulation with low or excessive vitamin A and/or inadequate fat content.
• Low forage availability.
• Feed exposure to light and heat or the presence of moisture and trace minerals accelerates the loss of vitamin A activity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Deficiency

Cattle: Polioencephalomalacia, lead poisoning, water deprivation/sodium toxicosis, meningoencephalitis, other causes of increased intracranial pressure and blindness. Small ruminants: Pregnancy toxemia and listeriosis.

Toxicity

All causes of skeletal malformations and spontaneous fractures, hepatic lipidosis, and renal failure.

CBC/BIOCHEMISTRY/URINALYSIS

Nonspecific

(CONTINUED) VITAMIN A DEFICIENCY/TOXICOSIS

OTHER LABORATORY TESTS
Plasma and feed vitamin A and carotene concentrations

IMAGING
- Deficiency: Bone deformities
- Toxicity: Decreased bone density and fractures

OTHER DIAGNOSTIC PROCEDURES
Liver biopsy for vitamin A analysis

PATHOLOGIC FINDINGS
Deficiency
Anasarca, corneal opacity and ulceration, papilledema, fundic hemorrhages, retinal degeneration, doming of the head and face, carpal joint enlargement, cerebral and cerebellar compression and tentorial herniation, and focal hyperkeratosis in mucocutaneous junctions and rumen.

Toxicity
Skeletal malformation, decreased bone density, fractures, internal hemorrhages, hyperkeratotic skin, and congenital abnormalities.

TREATMENT

THERAPEUTIC APPROACH
- Deficiency is rapidly corrected with vitamin A supplementation (dietary and injectable).
- Common dietary sources of carotenes are carrots, yellow corn, alfalfa (legumes), green grass (pasture, hay, or silage).
- Advanced clinical signs of both deficiency and toxicity are irreversible.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Various formulations for IM or SC injection containing vitamin A usually combined with vitamin D and/or E are available.

PRECAUTIONS
If using products containing vitamin D, hypervitaminosis D, which may result in hypercalcemia, may be induced.

CONTRAINDICATIONS
Vitamins A and D should not be given to meat-producing animals within 2 months of marketing.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
- Prognosis is poor for individual animals with advanced clinical signs, and good if treated during the early stages.
- Return to adequate production can be expected at the herd or flock level after correction of dietary vitamin A imbalances.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
Awareness of specific nutritional needs is imperative.

PATIENT CARE
Assess for return of vision after a short period of supplementation; animals with loss of vision due to papilledema and not to retinal or optic nerve damage may recover.

PREVENTION
Supplementation in animals with limited access to fresh forage.

MISCELLANEOUS

AGE-RELATED FACTORS
More often observed in young animals

PREGNANCY
Crucial in reproduction and embryogenesis.

ABBREVIATIONS
- IM = intramuscular
- SC = subcutaneous

VITAMIN B DEFICIENCY

BASICS

OVERVIEW
• Rumen microbes synthesize and meet most B vitamin requirements of the ruminant.
• B vitamins are essential in many critical enzyme systems.
• Thiamine, riboflavin, pantothenic acid, niacin, and biotin are cofactors in the Krebs cycle.
• In ruminants, disease usually relates to B_1 (thiamine) and B_{12} (cobalamin) deficiency.
  ◦ B_1 deficiency has a variety of causes and can result in polioencephalomalacia (PEM).
  ◦ B_{12} deficiency arises from cobalt (Co) deficiency; Co is required for ruminal B_{12} synthesis.

INCIDENCE/PREVALENCE
Usually sporadic; outbreaks of PEM can occur, and subclinical Co deficiency is common.

GEOGRAPHIC DISTRIBUTION
Worldwide; B_1 deficiency influenced by distribution of specific plants (bracken fern) and production systems (feedlots); B_{12} deficiency influenced by Co-deficient soils in large areas of many countries.

SYSTEMS AFFECTED
• Nervous
• Musculoskeletal
• Digestive
• Hemolymphatic

PATHOPHYSIOLOGY
• B_1 is essential for normal Krebs cycle function. Deficiency reduces glucose availability to the brain and can arise from:
  ◦ High starch rations: Ruminal acidosis favors rumen thiaminase.
  ◦ Amprolium: Inhibits thiamine absorption and blocks its phosphorylation.
  ◦ Consumption of plants (bracken) or molds (spoiled feed) that produce thiaminase.
  ◦ Excessive sulfur in feed and water or from hydrogen sulfide gas in the rumen: Sulfur is antagonistic to thiamine enzymes.
• B_{12} is an essential cofactor of methylmalonyl-CoA mutase and methionine synthase. Reductions in these enzymes interfere with folic acid metabolism, utilization of propionate, and immune function, and result in accumulation of methylmalonic acid (MMA) in serum due to incomplete metabolism of absorbed proprionate.
  ◦ Deficiency arises from dietary Co deficiency.
  ◦ Diarrhea results from disturbances of GI flora and reduced resistance to GI parasitism.
  ◦ Anemia is common due to disturbed folic acid metabolism.

HISTORICAL FINDINGS
Young growing ruminants in Co-deficient regions without supplementation, and/or exposed to factors that promote thiamine deficiency: Sudden dietary changes, high dietary concentrate, recent GI disease, recent weaning.

SIGNALMENT
• B_1 deficiency is most common in cattle, sheep, and goats under 18 months; however, adults can be affected. Camelids, camels, and deer occasionally affected.
• B_{12} deficiency typically affects growing animals due to lower liver reserves; sheep are most susceptible.

PHYSICAL EXAMINATION FINDINGS
• B_1 deficiency
  ◦ Weakness, reduced growth, anorexia and diarrhea, with ataxia, apparent blindness, star gazing, separation from the herd, excitability, and circling. Acute disease can bring death within 24 hours, sometimes with diarrhea.
  ◦ In advanced disease the animal becomes recumbent with teeth grinding, absent menace response (often normal bilateral pupillary light reflex), dorsomedial strabismus, horizontal nystagmus, opisthotonos, and seizures. Hyperthermia due to rigidity and seizures can be mistaken for true fever. In sulfur-associated cases, the breath might smell like rotten eggs.
• B_{12} deficiency
  ◦ Failure to grow, ill-thrift, weight loss, diarrhea, pica, emaciation, and lacrimation.
  ◦ Fatty degeneration of the liver ("white liver disease") can produce photosensitization and hepatic encephalopathy.
  ◦ Reduced immunity, anemia, and adverse effects on production variables are common.

GENETICS
N/A

CAUSES AND RISK FACTORS
• B_1 deficiency
  ◦ High soluble carbohydrate, low fiber rations
  ◦ Sudden dietary changes
  ◦ Molasses- and urea-based rations
  ◦ Sulfur in ration and drinking water
  ◦ Amprolium
• B_{12} deficiency
  ◦ Heavily limed pastures and manganese-rich soils decrease Co availability.
  ◦ Heavy rainfall leaches Co from topsoil.
  ◦ Grasses have less Co than legumes, especially if rapidly growing.
  ◦ Coastal soils.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• B_1 deficiency
  ◦ Pregnancy toxemia (sheep)
  ◦ Acute coenurosis
  ◦ *C. perfringens* enterotoxemia (sheep)
  ◦ Listerosis
  ◦ Toxicity: Lead, molasses, bracken, salt
  ◦ Rabies
  ◦ Meningitis/Encephalitis
  ◦ Tetanus
  ◦ Vitamin A deficiency (cattle)
  ◦ Hypomagnesemia (cattle)
• B_{12} deficiency
  ◦ Parasitic gastroenteritis
  ◦ Protein-calorie malnutrition
  ◦ Coccidiosis
  ◦ Johne's disease
  ◦ Selenium, copper, and vitamin D deficiencies

CBC/BIOCHEMISTRY/URINALYSIS
• B_1 deficiency: No consistent abnormalities.
• B_{12} deficiency: Macrocytic to normocytic, normochromic anemia; elevated AST and GGT may occur.

OTHER LABORATORY TESTS
• B_1 deficiency is indicated by:
  ◦ Significant percent increase in blood transketolase activity after addition of excess thiamine diphosphate to samples.
  ◦ Low blood thiamine (<50 nmol/L).
  ◦ Increased thiaminase activity in rumen content (submit at least 60 grams, fresh frozen).
• B_{12} deficiency is indicated by:
  ◦ Liver B_{12}: ≤0.3 µg/g WW.
  ◦ Serum B_{12}: <0.1 ng/mL.
  ◦ Low serum (<0.1 ng/mL) or liver (<80 ng/g WW) cobalt.
  ◦ High serum MMA (more reliable than B_{12}): Values >4 µmol/L possibly benefit from supplementation, >13 µmol/L expected to benefit.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
• Response to B_1 or B_{12} supplementation provides clinical evidence of deficiency.
• B_1 deficiency:
  ◦ Assess ration for sulfur, molasses, salt, urea.
  ◦ Rumen gas hydrogen sulfide concentration: >1,000 ppm suggests excess sulfur consumption (compare to healthy control).
  ◦ Cerebrocortical autofluorescence under ultraviolet lamp.

PATHOLOGIC FINDINGS
• B_1:
  ◦ Gross findings: Focal regions of soft, edematous cortical tissue with gray or yellow discoloration, flattened gyri.
  ◦ Histological findings: Cerebrocortical laminar neuronal necrosis and perineuronal vacuolation with cavitation of endothelial cells in the parietal and occipital lobes.
  ◦ Astrocytic swelling, neuronal shrinkage, and necrosis.

(CONTINUED) VITAMIN B DEFICIENCY

- Lead, sulfur toxicity, and salt poisoning/water deprivation can cause similar lesions.

• B_{12}:
- Cardiovascular lesions resembling arteriosclerosis (sheep).
- Emaciation and hepatic lipidosis.

TREATMENT

THERAPEUTIC APPROACH
Treatment requires supplementation with thiamine or cobalamin, initially by injection in animals with clinical disease.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• B_1 deficiency
- Thiamine HCl: 10 mg/kg body weight once IV (slow), then q6–12h SC or IM for 1 day, then q12–24h SC or IM for 3 days.
- Dexamethasone (1–2 mg/kg IM or SC, once) for cerebral edema.
- Seizures may require diazepam (0.5–1.0 mg/kg IV).
- Animals may benefit from IV dextrose during initial therapy.

• B_{12} deficiency
- Cobalamin 100 µg IM (lamb), 300 µg IM (sheep), or 3,000 µg IM (cattle), repeat weekly if needed.
- Drench with cobalt sulfate (1 mg/kg PO).

CONTRAINDICATIONS
Oral medications should be avoided in recumbent, disoriented animals.

PRECAUTIONS
• IV administration of thiamine should be performed slowly and carefully; severe adverse reactions including death are possible.
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• B_1 deficiency
- Treated animals often recover rapidly and stand within 24 hours; vision may take 5–7 days to return.
- Mild to significant neurologic impairment may remain depending on severity and duration of disease.
- Death is likely in severe cases

• B_{12} deficiency: Rapid improvement with injectable treatment; oral treatment delays improvement for 7–10 days.

POSSIBLE COMPLICATIONS
• Aspiration pneumonia
• Self-trauma

CLIENT EDUCATION
Identify and modify causes and risk factors for these conditions.

PATIENT CARE
Provide a safe warm environment to avoid trauma and distress, accessible food and water; oral or parenteral nutrition may be needed in severely impaired animals.

PREVENTION
• B_1 deficiency
- Avoid exposure to bracken fern and excessive amprolium.
- Avoid feeding excessive concentrate, or moldy or molassed feeds.
- Ensure animals are accustomed to roughage before weaning.
- Supplement grain with brewer's yeast.
- Sulfur intake of cattle should be ≤0.4%.
- Milk replacer containing B vitamins.

• B_{12} deficiency
- Provide 0.1–0.2 mg/kg DM Co in the ration (up to 1 mg/kg).
- Top dressing fields with Co sulfate at 1.5 kg/hectare every 3–4 years.
- Weekly to monthly drenching with Co sulfate.
- Intraruminal soluble glass boluses or pellets release Co over several months.
- Provide salt/mineral mixes with 0.1% Co (1 g Co carbonate per pound of salt).
- Milk replacer containing Co (0.11 mg/kg) for dairy calves.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Sulfur-induced polioencephalomalacia
• Ovine white liver disease
• Phalaris staggers (Co is protective)

AGE-RELATED FACTORS
Pre-ruminant animals depend on dietary B_1 since the microflora of the forestomach is not developed. Liver reserves of B_{12} are lower in young animals.

VITAMIN D DEFICIENCY/TOXICOSIS

BASICS

OVERVIEW
• Vitamin D is a group of compounds of which the most prominent forms are ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), which are supplied through the diet or by irradiation.
• Vitamin D_2 is derived from ergosterol (a plant steroid) and vitamin D_3 from cholecalciferol. The latter is produced from 7-dehydrocholesterol, a precursor exclusively present in animals. This cholesterol-derived provitamin is present in large amounts in the skin, the intestinal wall, and other tissues.
• Vitamin D precursors require ultraviolet (UV) irradiation (exposure to sunlight) to be activated. In ruminants, sufficient exposure to UV radiation results in adequate amounts of vitamin D and the lack of an absolute requirement of dietary intake.
• Vitamin D toxicity is the result of oversupplementation of enteral or parenteral formulations of vitamin D_3 or from ingestion of plants with vitamin D_2 activity.
• Risk of vitamin D deficiency is higher in the winter months and in animals kept in confinement systems.

INCIDENCE/PREVALENCE
N/A

GEOGRAPHIC DISTRIBUTION
• Higher risk for deficiency in northern latitudes during winter months.
• Non-iatrogenic toxicity is more likely where plants with high vitamin D_2 activity are present (*Cestrum diurnum, Solanum* spp., *Trisetum flavescens*).

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• The main role of vitamin D is linked to calcium and phosphorus homeostasis through metabolic changes in the intestine, bone, and kidney.
• It also participates in various other processes through a hormonal action, with receptors being present in a variety of tissues.

Deficiency
The most common disease associated with hypovitaminosis D is the skeletal disorder of growing animals known as rickets, which is characterized by low levels of calcium and phosphorus in cartilage and bone matrices. In adults, the resultant condition is osteomalacia due to bone demineralization caused by decreased calcium and phosphorus in the bone matrix.

Toxicity
The deleterious effects of hypervitaminosis D are associated with hypercalcemia secondary to increased bone resorption and intestinal absorption, leading to generalized soft tissue calcification. In addition to calcification, inflammation, tissue necrosis, and pain are observed. Bone resorption results in skeletal demineralization and weakness.

HISTORICAL FINDINGS
• Hypovitaminosis D: Prolonged confinement with no vitamin D supplementation.
• Hypervitaminosis D: Parenteral administration of vitamin D or the presence of plants with high vitamin D_2 content, together with clinical signs.
• Use of vitamin D-containing rodenticides can result in accidental consumption and toxicity.

SIGNALMENT
The Jersey breed is suggested to be more susceptible to toxicosis.

PHYSICAL EXAMINATION FINDINGS
Deficiency
• Clinical signs of rickets include weak, curved, deformed long bones seen as bowing of the extremities, enlarged, painful carpal and tarsal joints with erosion of joint surfaces and difficult ambulation, thoracic deformation with rib beading, stiff gait and hindlimb dragging, deviation of the spine, and arching of the back.
• In adults, osteomalacia will eventually result in pathologic fractures, but earlier signs include decreased milk yields and reduced weight gain, reproductive failure, and an increased incidence of diseases associated with hypocalcemia.
• The skull, vertebrae, and epiphyses of long bones suffer the most severe demineralization, followed by the scapula, sternum and ribs, with diaphysis of long bones of the limbs being the most resistant.
• Additionally: Anorexia, stunted growth, gastrointestinal dysfunction, labored breathing, and sometimes seizures and tetany, which in some cases occur before skeletal abnormalities become apparent.
• An increase in stillbirths, congenital defects, and weak or deformed calves, lambs and kids may be recorded.

Toxicity
• Early on, affected animals show anorexia and dullness, weight loss, drop in production, and formation of a thick ocular discharge. This is followed by muscle stiffness leading to recumbency, respiratory distress, polyuric and subsequently anuric renal failure, in some cases accompanied by cutaneous emphysema. Cardiac arrhythmias may be present.
• Immediately preceding death, a rapid pounding pulse has been noted.
• Soft tissue mineralization results in the observed clinical signs (e.g., tendon and muscle calcification leads to stiffness and recumbency; renal calcification leads to polyuria, hypercalciuria, and renal failure).

GENETICS
N/A

CAUSES AND RISK FACTORS
Deficiency
The main cause and highest risk is lack of exposure to UV radiation.

Toxicity
• The main causes are iatrogenic due to overdosing of vitamin D supplements and consumption of plants with high vitamin D_2 content.
• For iatrogenic cases, injectable presentations pose a higher risk.
• High dietary calcium, which allows more calcium to be absorbed, and hypovitaminosis A exacerbate the likelihood of vitamin D toxicity.
• Pregnant cattle are more prone to toxicity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Deficiency
In rare cases, severe calcium deficiency in growing animals can lead to similar clinical manifestations.

Toxicity
All causes of hypercalcemia: Iatrogenic, hyperparathyroidism and neoplastic processes leading to hypercalcemia of malignancy.

CBC/BIOCHEMISTRY/URINALYSIS
Deficiency
Nonspecific

Toxicity
• Hypercalcemia is the hallmark of vitamin D toxicity. However, if the source of vitamin D has been removed, calcium levels may be normal.
• Hyperphosphatemia, hypercalciuria, isosthenuria, azotemia will be present depending on the stage and severity of disease.

OTHER LABORATORY TESTS
N/A

IMAGING
• Deficiency: Bone deformities, decreased bone density, and fractures can be confirmed radiographically.
• Toxicity: Calcification of fibroelastic layers in the periphery of blood vessels in all soft tissues and organs throughout the body can be radiographically identified.

OTHER DIAGNOSTIC PROCEDURES
• Deficiency: Low serum vitamin D concentrations with compatible history and clinical signs.
• Toxicity: Serum vitamin D concentrations >80 ng/mL along with biochemistry and urinalysis findings (see "CBC/Biochemistry/Urinalysis") and compatible history and clinical signs.

(CONTINUED) # VITAMIN D DEFICIENCY/TOXICOSIS

PATHOLOGIC FINDINGS

Deficiency

• Grossly, bone deformity and laxity are observed.
• Microscopically, a lack of mineralization of the cartilage and bone matrices, especially in cancellous bone, is present.

Toxicity

• Grossly, the lungs may fail to collapse because of dystrophic calcification, and soft tissue mineralization of the heart, aorta, kidney, stomach, lungs, tendons, and muscles can be readily identified.
• Histopathologically a high degree of osteoclastic activity may be seen. If dietary calcium is low, this will progress to demineralization and rarefaction of bone. Adequate or excessive dietary calcium will result in osteosclerosis and increased bone mineralization.
• Osteoblasts will produce a pattern of abundant basophilic matrix, characteristic for vitamin D toxicity.

TREATMENT

THERAPEUTIC APPROACH

• Deficiency is rapidly corrected with vitamin D supplementation. Provision of UV radiation with lamps or by limiting confinement.
• Toxicity is managed by prompt removal of the source of vitamin D. In addition, dietary calcium should be limited to reduce tissue calcium deposition.
• Adequate supportive care for weak and recumbent animals is essential and severe cases may require euthanasia.

MEDICATION

DRUGS OF CHOICE

• In deficiency, injectable vitamin D formulations are most effective.
• In toxicity, vitamin A can have some sparing effects on soft tissue mineralization, as can thyroxin, glucagon, and estrogen.

PRECAUTIONS

Oversupplementation with vitamin D is detrimental (see "Pathologic Findings").

CONTRAINDICATIONS

Vitamins D and A should not be given to meat-producing animals within 2 months of marketing.

POSSIBLE INTERACTIONS

N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Prognosis and duration of disease is dependent on severity and duration of exposure.
• Vitamin D supplementation rapidly correct deficits, but bone deformity and cartilage loss are irreversible.
• In toxicosis, withdrawal of the source of vitamin D stops disease progression after tissue storage depots are depleted.

POSSIBLE COMPLICATIONS

Overdosing of vitamin D is the primary complication of treating hypovitaminosis.

CLIENT EDUCATION

See "Prevention"

PATIENT CARE

Severely affected animals should be sold if suitable for human consumption, or euthanized.

PREVENTION

• Vitamin D deficiency and toxicity are prevented through adequate supplementation.
• Deficiency can be avoided by limiting animal confinement and increasing exposure to sunlight or supplementing when exposure is limited.

MISCELLANEOUS

ASSOCIATED CONDITIONS

• Hypercalcemia; stunted growth; bone deformities; myopathy; renal failure; reproductive failure; pathologic fractures.
• Enteque seco or Manchester wasting disease is caused by ingestion of 1,25-OH-cholecalciferol glycoside-containing plants, which induces hypervitaminosis D in grazing animals.

PREGNANCY

• Pregnant animals are at higher risk.
• Crucial for reproduction, embryogenesis, and fetal development.

ABBREVIATION

• UV= ultraviolet

SEE ALSO

• Acute Renal Failure
• Hypocalcemia: Bovine
• Hypocalcemia: Small Ruminant
• Postparturient Paresis (Hypocalcemia)

VOMITOXIN

BASICS

OVERVIEW
• Vomitoxin or deoxynivalenol (DON) is a sesquiterpenoid compound with an epoxy group at C12–13 in the trichothecene structure, which is essential for toxicity.
• Vomitoxin is a type B trichothecene that is a common field contaminant of grains and forages produced by *Fusarium graminearum* (*Gibberella zeae*), *F. culmorum*, and other closely related fungi under wet, warm conditions at flowering and during plant growth.
• In addition to vomitoxin, the interaction of plant and fungi can generate other derivatives of DON, including acetyl-DON (3 and 15 ADON), glucoside-DON (D3G) and animal derived glucuronide metabolite (D3 and D15GA) that can be more or less toxic than DON.
• The majority of trichothecene exposures are subchronic to chronic in nature with low dietary DON concentrations in the feed and are associated with nutritional impairment, reduced production, and possible lowered immune responses, but DON is not associated with fatal disease.

INCIDENCE/PREVALENCE
• Vomitoxin is produced as a secondary metabolite by *Fusarium* fungi primarily in the field, with mold growth in equilibrium with relative humidity >90–95%.
• *Fusarium graminearum* and *F. culmorum* growth in cereal grains and corn are favored by warm, wet weather at anthesis and shortly after.
• Wet weather and warm days/cool evenings after pollination, delayed harvest, and hail damage can enhance fungal growth and mycotoxin production.

GEOGRAPHIC DISTRIBUTION
Worldwide in crops and forages

SYSTEMS AFFECTED
• Digestive
• Hemolymphatic

PATHOPHYSIOLOGY
Vomitoxin can cause cellular effects by targeting ribosomes and causing ribotoxic stress. The suggested mechanism of ribosome binding is by chemical reactivity of the vomitoxin epoxide moiety with nucleotides forming nucleic acids (RNA and DNA). However, the precise nature of the chemical reaction of DON binding to rRNA is not known. It is known that binding of vomitoxin to rRNA can cause their cleavage and activation of several cellular signaling pathways affecting cell functions and possibly initiate cell apoptosis. DON can affect the function of intestinal, immune, and brain cells.

SIGNALMENT
• Potential effects can occur in ruminants ingesting moldy grains, forages, and other feedstuffs.
• Dairy cows are more sensitive to adverse effects, which may be due to the higher stress levels that dairy cows undergo. Dairy have higher levels of dry matter intake that can result in faster rumen turnover rate and perhaps less rumen microbial degradation of vomitoxin.

PHYSICAL EXAMINATION FINDINGS
• Vomitoxin has been associated with reduced feed intake and feed efficiency, and perhaps diarrhea and lowered milk production. However, definite cause and effect relationships have not been established in ruminants for loss in milk production.
• Beef cattle and sheep appear to tolerate a higher concentration of DON in feed without measurable effects.

CAUSES AND RISK FACTORS
• The toxic principle is DON.
• Ingestion of moldy feedstuffs containing significant concentrations of vomitoxin can lead to clinical effects. Pre-ruminants, which lack rumen microbial metabolism, and dairy cows, which are more highly stressed, are more at risk.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Inadequate nutrition, inadequate rumen microbial population, other causes of mild gastroenteritis and diarrhea (e.g., endotoxins, poisonous plants, petroleum hydrocarbons).

CBC/BIOCHEMISTRY/URINALYSIS
Possible hypoproteinemia, mild anemia, leukopenia

OTHER LABORATORY TESTS
Detection of vomitoxin in feed by liquid or gas chromatography-mass spectrometry, gas chromatography, and other reliable methods validated for the feed matrix.

OTHER DIAGNOSTIC PROCEDURES
Laboratory analysis of feed for mycotoxins

PATHOLOGIC FINDINGS
Very high, acute concentrations of vomitoxin could result in enteritis, perhaps hemorrhagic.

TREATMENT

THERAPEUTIC APPROACH
• Stop feeding vomitoxin-contaminated feed or reduce exposure to vomitoxin concentrations associated with no clinical signs in ruminants (see regulatory guidelines).
• Provide clean feed and supportive fluids if necessary.
• Animals generally recover quickly and residues in milk and tissues are of minimal concern because of rapid metabolism and excretion.

MEDICATIONS

DRUGS OF CHOICE
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Recovery is anticipated with a good prognosis.

PREVENTION
• Follow regulatory or guidance levels for vomitoxin in animal feed.
• In the United States, the Food and Drug Administration issued advisory levels for DON in feed for cattle that "would not appear to present an animal or public health hazard." Advisory levels of 10 ppm DON on grains and grain by-products (88% DM) and 30 ppm in distiller's grains and brewer's grains (88% DM) destined for ruminating beef and feedlot cattle >4 months and ruminating dairy cattle older than 4 months, with the added recommendations that the TOTAL RATION for ruminating beef and feedlot cattle >4 months NOT exceed 10 ppm DON, and the total ration for ruminating dairy cattle >4 months NOT exceed 5 ppm DON.
• The advisory level for ruminants <4 months and sheep, goats (and other ruminants) is 5 ppm DON on grains and grain by-products with the added recommendation that these ingredients NOT exceed 40% of the diet. Hence the DON concentrations should be <2 ppm in the final ration.
• In the US, mycotoxin binders have not been approved by the Food and Drug Administration. The use of agents to "bind" vomitoxin in ruminants is equivocal.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• The interaction of plant and fungi can generate other derivatives of DON, including acetyl-DON (3 and 15 ADON), glucoside-DON (D3G), and animal derived glucuronide metabolite (D3 and D15GA) that can be more or less toxic than DON.
• Little research has been done in ruminants with these DON derivatives.

AGE-RELATED FACTORS
Older animals with a functioning rumen capable of metabolizing vomitoxin to the

relatively nontoxic DOM-1 are less affected than pre-ruminants.

PREGNANCY
N/A

BIOSECURITY
Avoid feeding moldy feedstuffs. Analyze suspect feed for vomitoxin prior to use and utilize appropriate guidelines.

PRODUCTION MANAGEMENT
• Stop feeding mycotoxin-contaminated feed or reduce exposure to concentrations associated with no clinical signs in ruminants when regulatory guidelines are available.
• Dilution with noncontaminated feedstuffs is one possibility, but this may not be acceptable on a regulatory basis.

ABBREVIATIONS
• DOM-1 = de-epoxydeoxynivalenol
• DON = deoxynivalenol

VULVITIS

BASICS

• Vulvitis is relatively common in ruminants where it is often associated with vaginitis (vulvovaginitis). • It should be noted that many of the disorders classified as vulvitis are more correctly an inflammation of the vestibule. • Ruminants and camelidae have a very simple vulvar anatomy, and trauma associated with coitus or parturition along with poor perineal conformation are the most common disorders of the vulva proper. Other lesions specific to the vulva are associated with chemical irritation, trauma, and microbial agents.

INCIDENCE/PREVALENCE
Common in all ruminants but most cases have little long-term clinical significance.

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Reproductive

PATHOPHYSIOLOGY
• The vestibule contains subepithelial foci of inflammatory cells, activated more or less constantly by local flora (commensal and pathogenic). It is not unusual to see evidence of hyperemia and lymphoid proliferation, which defines granular vulvitis (granular venereal disease or vestibulitis). • Necrotic vulvitis associated with severe edema and tissue sloughing may result from chemical irritation, allergic reactions, or local infection with anaerobic bacteria. • A variety of infectious agents have been associated with the caudal reproductive tract including *Ureaplasma diversum*, *Mycoplasma* spp., *Trueperella pyogenes*, *Streptococcus* spp., *Staphylococcus* spp., *E. coli*, *H. somni* as well as the IBR/IPV and contagious ecthyma viruses. • Enzootic ovine vulvitis is the female analog of pizzle rot in the ram. It is associated with high protein diets and local infection with *Corynebacterium renale.* • Ulcerative vulvitis and balanoposthitis in sheep has been attributed to local infection with a variety of bacterial agents (*Mycoplasma* spp.*, Histophilus* spp.*, T. pyogenes*).

GENETICS
N/A

HISTORICAL FINDINGS
N/A

SIGNALMENT
Potentially all ruminant and camelid species

PHYSICAL EXAMINATION FINDINGS
• Systemic signs of disease are usually absent. • Edema, ulceration, vestibular lymphoid hyperplasia, and mucopurulent discharge are most frequently seen. • Vestibular and vulvar hyperemia and edema. • Mucoid or mucopurulent discharge. • Ulceration of vulvar and/or perineal skin. • Pneumovagina.

CAUSES AND RISK FACTORS
• Presence of pathogenic microorganisms • High protein diet in sheep and goats • Parturient or coital trauma • Poor perineal conformation and perivulvar tissue folds in ewes

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Transmissible fibropapillomas (cattle) • Neoplasia (e.g., fibroma, squamous cell carcinoma) • Trauma (coital, parturient, predation) • Ectopic mammary tissue (doe) • External parasites (mange in sheep and tick infestation in camels) • Contagious ecthyma (sheep and goats) • Cystic vestibular (Bartholin's) glands • Tubercular Gartner's ducts

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Culture and sensitivity, viral isolation, or molecular diagnostics may be indicated if infective agents are suspected of causing an economically significant problem.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Speculum examination and visual observation of vulva is essential.

TREATMENT

THERAPEUTIC APPROACH
• Treatment is often unnecessary, especially with milder cases of granular venereal disease. • Treatment for suspected clostridial infections when indicated.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgery for wounds or conformational defects may be indicated.

MEDICATIONS

DRUGS OF CHOICE
N/A

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

PRECAUTIONS
N/A

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Usually good

POSSIBLE COMPLICATIONS
• Occasionally, severe necrotic vulvovaginitis may lead to vaginal stenosis. • In sheep, fly strike may lead to complications.

CLIENT EDUCATION
N/A

PATIENT CARE
N/A

PREVENTION
• Avoid feeding of excess protein. • Minimize dystocia prevalence and provide appropriate, gentle and sanitary obstetric assistance.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Retained placenta, puerperal metritis, or physical injury to the vulva

AGE-RELATED FACTORS
GVD is seen most commonly in heifers in their first or second natural breeding season.

ZOONOTIC POTENTIAL
Care must be taken in the collection of laboratory samples and the diagnosis/treatment of affected animals, especially if TB or contagious ecthyma (orf) are suspected.

PREGNANCY
N/A

BIOSECURITY
• Isolation and quarantine of new stock entering the herd or flock. • Treat and or cull new animals for disease conditions prior to herd introduction. • GVD appears to be easily and rapidly spread, and it varies considerably in severity.

PRODUCTION MANAGEMENT

WATER BUFFALO DISEASES

BASICS

OVERVIEW

• Water buffalo are hardier than cattle to resist disease and also can thrive in a hot and humid environment.
• Their weak thermoregulatory mechanism means they need to wallow and be sprayed with water in hot weather.
• Water buffalo are susceptible to most diseases and parasites affecting cattle. Treatment and vaccination protocols are generally similar between the two species.
• High yielding buffalo are more prone to reproductive and metabolic diseases than low yielders.
• Mortality among buffalo calves is higher than cow calves because they are more susceptible to ascariasis and calf scour due to colibacillosis and salmonellosis.
• The wallowing habit of water buffalo also helps transmission of waterborne diseases.
• Tail necrosis is a common medical condition in water buffalo.
• Reproductive problems such as infertility, repeat breeding, dystocia, retained placenta, prolapse of uterus and vagina, and metabolic diseases are more common in stall-fed animals than in free range systems.
• Mange mites, dermatophyte infection, Degnala disease, alopecia, and ulceration are common skin disease conditions.

INCIDENCE/PREVALENCE

• Neoscariasis: Very common problem with an incidence of >30% in humid conditions.
• Tapeworms: Reported at an incidence of 15% in some tropical environments (*Moniezia* spp.).

GEOGRAPHIC DISTRIBUTION

• Some 42 countries; 97% of water buffalo are in Asian countries.
• There are two general types of water buffalo: the swamp buffalo (*Bubalus carabanesis*) which is found from the Philippines to as far west as India; and the river buffalo or domestic Asian buffalo (*Bubalus bubalis*) which is found farther west from India to Egypt and Europe.

PATHOPHYSIOLOGY

See specific diseases

SYSTEMS AFFECTED

All systems, depending on the disease process

HISTORICAL FINDINGS

Vary depending on the disease process. Some disease may present as an outbreak; others may affect individual animals.

SIGNALMENT

The swamp buffalo (*Bubalus carabanesis*) and the river buffalo (*Bubalus bubalis*)

PHYSICAL EXAMINATION FINDINGS

Vary depending on the complaint and the disease (see "Differential Diagnoses").

GENETICS

N/A

CAUSES AND RISK FACTORS

See "Differential diagnoses"

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Skin Diseases

• Yoke gall—chronic injury to the ligamentum nuchae caused by the continuous pressure of a yoke (collar) on the buffalo's neck
• Cutaneous filariasis (*Parafilaria bovicola*)
• Cutaneous onchocerciasis—cutaneous lesions in the dermis, most apparent in the xiphoid region (*Onchocerca* spp.)
• Cowpox as well as the buffalo poxvirus
• Mange—three types—psoroptic (*Psoroptes natalensis*), sarcoptic (*Sarcoptes scabiei* var. *bubalus*), and demodectic (*Demodex bovis*)
• Dermatomycosis
• Tail necrosis—several causes have been postulated—*Corynebacterium bovis*, fatty acid deficiency, and microfilaria
• Lumpy skin disease
• Warts

Bacterial, Viral, and Protozoal Diseases

• Hemorrhagic septicemia/pasteurellosis—outbreak occurs in summer season
• Anaplasmosis
• BVD/mucosal disease
• Anthrax—sporadic in nature
• Tuberculosis
• Rabies—a very danger zoonotic disease
• Blackquarter
• Foreign body syndrome (similar to TRP)
• Brucellosis—cause late abortion
• Foot and mouth disease
• Johne's disease
• Rinderpest—eradicated from most countries of the world
• Bovine ephemeral fever—seen in hot summer and rainy season
• Malignant catarrhal fever
• Toxoplasmosis
• Nephritis, hydronephrosis, and renal calcification
• Piroplasmosis—transmitted by tick
• Pleuropneumonia (mycoplasmal)
• Hypophosphatemia
• Peste des petits ruminants—very common in small ruminants

Parasitic Diseases

• Ascarid infection—heavy losses of young buffalo calves caused by *Toxocara vitulorum.*
• Strongyles—adult buffalo are resistant.
• Echinococcosis/hydatid cyst disease (*Echinococcus granulosum*).
• Coccidiosis (*Eimeria* spp.).
• Filarial nematodiasis.
• Trypanosomiasis—buffalo more susceptible to *Trypanosoma evansi* than cattle.
• Pediculosis—caused by the sucking louse (*Hematopinus tuberculatus*).
• Babesia (*Babesia argentina* and *B. bigemini*)—secondary to infection by ticks *Boophilus microplus* and *Hyalomma anatolicum.*
• Lungworm—infestation of the respiratory tract by *Dictyocaulus viviparous.*
• Cutaneous filariasis (*Parafilaria bovicola*).
• Cutaneous onchocerciasis—cutaneous lesions in the dermis, most apparent in the xiphoid region (*Onchocerca* spp.).
• Leeches.
• Ticks—buffalo are resistant to ticks.
• Tapeworms—reported at an incidence of 15% in some tropical environments (*Moniezia* spp.).
• Ectoparasitism—a primary ectoparasite in Australia and Southeast Asia is the buffalo fly (*Siphona* spp.). Lice and mites may infest buffalo all year, but primarily during the winter season. Mosquitoes and flies affect buffalo during hot/humid weather.
• Mange—psoroptic (*Psoroptes natalensis*), sarcoptic (*Sarcoptes scabiei var. bubalus*), and demodectic (*Demodax bovis*).
• Ophthalmic parasites—conjunctivitis caused by *Thelazia* spp. is common.
• Several moth species feed nocturnally on buffalo lacrimal secretions in Asia.
• Syngamosis (*Syngamus laryngeus*).
• Hepatic flukes—*Fasciola hepatica* and/or *F. gigantica* are very common worldwide. Snails of *Lymnaea* spp. are common vectors.
• Intestinal flukes—common flukes are *Cotylophoron cotylophorum*, *Calicophoron* spp., *Paramphistomum* spp., *Olveria* spp., and *Ceylonocotyle* spp. Fluke infestations (intestinal and hepatic) are the most common cause of mortality in adult water buffalo maintained in tropical Asian climates.
• Biliary leach—*Gigantocotyle explanatum* causes calf loss.
• Sarcosporidosis.
• Schistosomiasis—can cause enteritis in young buffalo calves <2 years of age.
• Theileriosis.

Reproductive Diseases

• Anestrus—nutritional, anatomic, hereditary, and functional. Anestrus has its highest incidence during the hot season. Small, hard, and inactive ovaries generally are present.
• Subactive/inactive ovaries—secondary to nutritional deficiency.
• Excessive follicular atresia with a failure of maturation and ovulation.
• Cystic ovaries.
• Small, inactive ovaries—often related to a low-phosphorus diet.
• Persistent CL.
• Encapsulation of ovaries.
• Salpingitis.
• Cervicitis.
• Metritis
• Pyometra.
• Endometritis.

WATER BUFFALO DISEASES (CONTINUED)

• Vaginitis.
• Iatrogenic reproductive problems commonly occur when artificial insemination programs reflect poor technical abilities and rough handling.
• The incidence of dystocia, abortions, and retained placenta is similar to that in cattle.

Management-Related Issues
• Respiratory infections—primarily due to poor management
• Diarrhea—found mainly in calves
• Decreased milk production
• Lameness
• Iatrogenic infertility
• Bloat/tympany
• Mastitis

CBC/BIOCHEMSTRY/URINALYSIS
Similar changes as in other ruminants for specific disease processes.

OTHER LABORATORY TESTS
Serology, bacteriology, virology, and parasitology tests have been established for some diseases as in other ruminants.

IMAGING
Varies according to diseases process. Ultrasonography is important in reproductive medicine (similar to bovine reproductive ultrasonography).

WATER BUFFALO MANAGEMENT

BASICS

OVERVIEW

• Buffalo is one of major livestock species of some Asian countries such as India, Nepal, Pakistan, and China generally kept for milk, meat, manure, hide, and draft purposes. Dairy buffalo production is very popular in the Caucasian countries, Asia, and Egypt.
• In recent years mozzarella cheese made from buffalo milk has become very popular in Italy, in other European countries, and also in the United States.
• Besides milk and meat purposes, buffalo are extensively used to plough fields, cultivate crops, pump water, and haul carts and draft boats. They are also used to carry people, thresh grain, press sugar cane, haul logs, and so on.
• World buffalo population in 2008 has been estimated at 185.29 million spread over some 42 countries; 97% of water buffalo are in Asian countries.
• India has the largest population of buffalo, approx.105.1 million (56.7 % of the world population), followed by Pakistan 29.0 million (15.65 %), and China 23.27 million (12.55%). Bangladesh and Nepal have positive growth with annual growth of 5.7 1% and 2.1% respectively.

PATHOPHYSIOLOGY

N/A

HISTORICAL FINDINGS

N/A

SIGNALMENT

• *Bubalus carabanensis* (swamp buffalo) and *Bubalus bubalis* (river buffalo).
• Body size of buffalo varies from small breeds of approx. 250 kg to heavy breeds up to 1,000 kg.
• They have black and dark gray body coat color with little hair. Therefore, the skin absorbs heat easily and has few sweat glands.
• The horns spread outward and upward, measuring up to 7 ft (2 m) across.
• First calves are usually produced at about 24–36 months of age, but recent studies show that with adequate nutrition and good management, buffalo can reach puberty at about the same age as cattle (18 months).
• They generally produce two calves every 3 years.
• The gestation period for buffalo is about the same as for cattle, 287 days.
• Peak calving season is mid-June to mid-September in Northern India and Nepal while in southern parts it is January and February.
• Birthweight of buffalo calves is generally 20–25 kg.

PHYSICAL EXAMINATION FINDINGS

N/A

GENETICS

• Buffalo are classified into two groups: swamp buffalo (*Bubalus carabanesis*) and river buffalo (*Bubalus bubalis*).
• Chromosome number of river buffalo is 50 (25 pairs) and swamp buffalo is 48 (24 pairs).
• The swamp buffalo are most common in Southeast Asian countries and generally kept for draft power for rice cultivation. They have very low milk yield. Recently they have been employed for meat production.
• The river buffalo are the most common type of buffalo in India, Pakistan, Nepal, Bulgaria, Hungary, Turkey, Italy, and Egypt. They are also found in Brazil and Caucasia.
• River buffalo have been used for milk production and some breeds such as Murrah, Nili-Ravi and Surti are used for dairy production only.

PRODUCTION MANAGEMENT

Economic Considerations

• For thousands of years, this animal species has provided draft power, milk, meat, and hide to millions of people, mainly small-scale farmers.
• Buffalo are used for a variety of agricultural operations such as plowing paddy fields, lifting water from wells, and transporting farm produce to nearby markets.
• More than 5% of world milk comes from buffalo and 95% of it comes from Asia.
• India is the world's largest buffalo milk producer with about 35% of milk animals producing almost 70% of the total Indian milk.
• Buffalo feeding and management is cheaper than cattle feeding and management, and buffalo farmers also get a 30–50% higher price for their milk.
• Buffalo milk contains more total solids (16%) compared with the solids (12–14%) found in cow's milk. Buffalo milk butterfat content is usually 6–8% compared with domestic dairy cow butterfat levels of 3–5%.
• Buffalo farming is one of the substantial secondary income sources for small farmers in Asia. Usually women take care of buffalo feeding, milking, and selling of milk.
• Water buffalo offer a major source of meat in Asia. The buffalo meat industry is expanding.
• Asia produces 91–92% of the world's total buffalo meat, with India being the world's largest buffalo meat producer followed by Pakistan, China, Nepal, and Thailand.
• Carcass characteristics of buffalo are similar to domestic cattle with the average dressing percentage of 53%.
• In Nepal and some Indian states, slaughtering of cows is prohibited because of Hinduism. So the salvage value of buffalo is higher than cattle.
• Water buffalo also provide a major work force in Asia, and it is probably the most adaptable and versatile of all work animals.

Specific Considerations

• Buffalo require more drinking water, more grazing field area, and more standing space than cows.
• Because of their poorly developed thermoregulatory mechanisms, buffalo need to wallow or need to be sprayed during hot weather in order to keep their bodies cool.
• Their housing generally requires higher roofing to improve ventilation and to protect from direct heat during summer months.

WATER BUFFALO MANAGEMENT (CONTINUED)

• Buffalo need stronger barriers than those used for cattle, and the wires should be closer together and lower to the ground to avoid having them lift fences up with their horns.
• They must be handled quietly and calmly because of their timid nature.

Management

• The classic buffalo in Asia belongs to a small farm, and millions of water buffalo are managed in intensive "backyard" systems. Herds of 2–50 animals are owned by small or marginal farmers; close to urban centers herds of 20–50 are common.
• In the United States, Brazil, Venezuela, and Australia, water buffalo are managed on rangelands.
• They require more drinking water and more standing space than cows.
• Because of their poorly developed thermoregulatory mechanisms, buffalo need to wallow or need sprinklers during hot weather in order to keep their bodies cool.
• Their housing generally requires higher roofing to improve ventilation.
• Buffalo need stronger barriers than those used for cattle, and the wires should be closer together and lower to the ground to avoid having them lift the fences up with their horns.

WATER BUFFALO PARASITE ISSUES

BASICS

OVERVIEW
• Water buffalo belong to the family Bovidae, Subfamily Bovinae, and the genus *Bubalus*.
• Buffalo are important multipurpose farm animals in the Indian subcontinent, contributing significantly to meat and milk production.
• The total population of buffalo in the world is 151.5 million, of which 96.6 million are found in Asia.
• Parasites including both ectoparasites and endoparasites are a major cause for decreased health and productivity as well as mortality.

INCIDENCE/PREVALENCE
Variable by region. Generally higher in Asia.

GEOGRAPHIC DISTRIBUTION
Potentially worldwide depending on favourable environment

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
Dependent on parasite species involved

HISTORICAL FINDINGS
Important history to determine includes age of affected animals, duration of onset of symptoms, past infections, feed quality, animal movement, grazing pattern, and treatment history.

SIGNALMENT
Young buffalo are more susceptible to parasitic infection than calves and adult buffalo.

PHYSICAL EXAMINATION FINDINGS
• Internal parasites cause weakness and debility, decrease in production, unthriftiness, decreased immune function, dry skin, brittle and coarse hair, diarrhea, and loss of body condition.
• External parasites cause annoyance, uneasiness, weakness, loss of production, hair loss, skin wounds, and dry skin.

GENETICS
N/A

CAUSES AND RISK FACTORS
Ectoparasites
• Louse (*Haematopinus tuberculatus*)
• Leech (*Hirudinaria manillensis*)
• Flies (*Siphona* spp.)
• Mange (psoroptic, *Psoroptes natalensis*; sarcoptic, *Sarcoptes scabiei* var. *bubalus*; and demodectic, *Demodex bovis*)

Endoparasites
Nematodes
• *Haemonchus* spp. (abomasum)
• *Strongyloides* spp. (small intestine)
• *Capillaria* spp. (small intestine)
• *Oesophagostomum* spp. (large intestine)
• *Trichostrongylus* spp. (small intestine)
• *Toxocara vitulorum* (small intestine)
• *Nematodirus* spp. (small intestine)
• *Dictyocaulus viviparus* (respiratory system)
• *Thelazia rhodesii* (eye)
• *Cooperia* spp. (small intestine)
• *Setaria digitata* (peritoneal cavity)
• *Ostertagia circumcincta* (abomasum)
• *Gongylonema pulchrum* (esophageal/buccal mucosa)
• *Onchocera gibsoni* (aorta)
• *Dicrocoelium dendriticum* (bile duct)
Trematodes
• *Fasciola* spp. (liver)
• *Paramphistomum* spp. (rumen)
• *Schistosoma* spp. (blood flukes)
• *Cotylophoron* spp. (small intestine)
Cestodes
• *Moniezia expansa* (small intestine)
• *Echinococcus* spp. (cysts in muscles and organs)
Protozoans
• *Toxoplasma gondii* (intestine)
• *Trypanosoma* spp. (bloodstream)
• *Sarcocystis* spp. (muscles)
• *Theileria* spp. (RBC, lymphocytes)
• *Babesia* spp. (RBC)
• *Anaplasma* spp. (RBC)
• *Eimeria zuernii* (intestine)
• *Cryptosporidium* (intestinal epithelium)
• *Neospora caninum* (tachyzoites are found intracellularly in neural cells, macrophages, fibroblasts, vascular endothelial cells, hepatocytes and muscular cells of myocardium and placenta. Bradyzoites are found in tissue cysts in the brain, spinal cord, and retina).

Risk Factors
• Cattle, deer, pigs, sheep
• Feces of dogs, wolves, or coyotes
• Feeding on infested pasture, usually early in the grazing period
• Inadequate or inappropriate use of anthelmintics and preventive pasturing practices

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Metabolic diseases, dermatologic diseases

CBC/BIOCHEMISTRY/URINALYSIS
Diagnosis of all those parasites found in the liver can be aided by examining the hepatic enzymes GLDH, GGT, and AST.

OTHER LABORATORY TESTS
• Endoparasites:
  ◦ Fecal sample examination and ELISA are mainly used for diagnosing nematodes.
  ◦ Muscle biopsy, ELISA, PCR (copro-DNA assay), indirect immunofluorescence, indirect hemagglutination, immunoblotting, latex agglutination and, rarely, complement fixation tests are used for cestode diagnosis.
  ◦ Fecal sample examination, ELISA, and PCR techniques are used for trematodes.
• Protozoans: Microhematocrit centrifugation technique (MHCT), ELISA.

IMAGING
Imaging techniques such as X-ray, magnetic resonance imaging (MRI) scan, computed tomography (CT) scan, ultrasonographic imaging, positron emission tomography (PET) combined with CT, and single photon emission computed tomography can also be used to diagnose the presence of parasites.

OTHER DIAGNOSTIC PROCEDURES
Ectoparasites: Skin scraping followed by microscopic examination

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
Therapeutic treatments with anthelmintics, antiprotozoals and ectoparasiticides are effective.

SURGICAL CONSIDERATIONS AND TECHNIQUES
Surgical removal of cysts could be done but this is complicated and is not practiced.

MEDICATIONS

DRUGS OF CHOICE
For Protozoans
Metronidazole (25–30 mg/kg body weight/day in divided doses, PO, at 20 mg/kg BW/day in divided doses, IV).

For Hemoprotozoans
Diminazine aceturate (0.8–1.6 g/100 kg BW, IM), quinapyramine—anti-trypanosomiasis (quinapyramine sulfate 1.5 g + quinapyramine chloride 1 g at 4.4 mg/kg BW, IM), buparvaquone—anti-theilerial (2.5 mg/kg BW, IM), oxytetracycline—anti-theilerial and anti-anaplasma (10–20 mg/kg BW, IV).

For Helminths
Albendazole (5–10 mg/kg BW, single dose, PO), fenbendazole (5–7.5 mg/kg BW, single dose, PO), levamisole (7.5 mg/kg BW, single dose, PO/SC), mebendazole (10–15 mg/kg BW, PO), niclosamide (50–100 mg/kg BW, PO), oxfendazole (5 mg/kg BW, PO), oxyclozanide (10–15 mg/kg BW, PO), piperazine (200–300 mg/kg BW, PO), tetramisole (15 mg/kg BW, PO).

For Ectoparasites
Amitraz, carbaryl, coumaphos, cypermethrin, deltamethrin, fenvalerate, fipronil, flumethrin, lindane, permethrin as per label instructions.

WATER BUFFALO PARASITE ISSUES (CONTINUED)

CONTRAINDICATIONS
Some of the above listed compounds are illegal for use in food-producing animals in certain countries (i.e. metronidazole in the United States).

PRECAUTIONS
- Avoid administration of albendazole during first trimester of pregnancy.
- Parenteral overdose of levamisole may be lethal and oral overdose may produce nervous symptoms.
- Overdose of oxyclozanide may cause toxicity.
- Piperazine may produce neurologic signs when given in overdose.
- Overdose of tetramisole may produce clinical signs similar to phosphorus poisoning.
- Anti-protozoal drugs should be avoided during pregnancy.
- Diminazine aceturate dose should not exceed 9 g/animal/day.
- Avoid direct contact of ectoparasiticides with eyes and skin and prevent licking.
- Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

MISCELLANEOUS

ASSOCIATED CONDITIONS
Water buffalo are generally more resistant than cattle to diseases.

AGE-RELATED FACTORS
Young buffalo are more susceptible to parasitic infection than calves and adult buffalo.

ZOONOTIC POTENTIAL
Several of the parasitic disease conditions are zoonotic. Special precautions should be followed while collecting and handling laboratory samples.

PREGNANCY
Several of the parasitic disease conditions cause infertility, sterility, reproductive disorders, and abortion in water buffalo.

BIOSECURITY
- Avoid keeping different species together in a shed.
- Isolation and quarantine of new stock entering the herd.
- Treat and or cull new animals for disease conditions prior to herd introduction.

PRODUCTION MANAGEMENT
See "Biosecurity"

WATER BUFFALO: REPRODUCTION

BASICS

OVERVIEW

• The water buffalo, *Bubalus bubalis*, is a major dairy, draft, and meat animal especially in South Asia.
• There are two main types—river buffalo and swamp buffalo—based on wallowing in running water or stagnant pools, respectively.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

• The total world buffalo population is about 199 million. About 96% of it is found in Asia, with minor numbers in the Mediterranean region, Australia, and parts of Central and South America.
• The river type is mainly found in the India-Pakistan region and the swamp type in China and Southeast Asia.

SYSTEM AFFECTED

Reproductive

PATHOPHYSIOLOGY

Male Reproduction

• The anatomy of the male reproductive system is very similar to the reproductive anatomy of male cattle; however, testes are comparatively smaller and prepuce is less pendulous.
• Testes grow in size until about 3 years of age with the fastest growth rate during the second year of age.
• Spermatogenesis starts from about 12–15 months of age; however, motile spermatozoa in the ejaculate are not seen before puberty, i.e., at about 24 months of age.
• The duration of spermatogenesis is 38 days and the cycle of seminiferous epithelium is 8.6 days.
• The spermatozoa of a buffalo bull are longer than those of a cattle bull and have a specific rectangular shape.

Female Reproduction

Female Reproductive Anatomy

• The female reproductive anatomy and physiology of the buffalo are very similar to that of cattle, with few differences. The cervix is less conspicuous, cervical canal is narrower and more tortuous, number of caruncles is about 60–90, uterine horns are smaller but more coiled. Ovaries are smaller and contain much fewer primordial follicles (10,000–20,000) in a cyclic buffalo heifer.

Female Reproductive Physiology

• The buffalo is a polyestrous animal. The swamp type is generally nonseasonal; however, the river buffalo has a seasonal tendency (short day breeder) governed by photoperiod and summer heat.
• The minimum size of an ovulatory follicle is about 10–12 mm, a mature CL is about 10–15 mm, and CL is more deeply embedded in the ovarian tissue as compared to CL of cattle. Mostly, the CL is not crowned.
• The mean age at puberty under optimum condition is 15–18 months for the river buffalo and 21–24 months for the swamp buffalo; however, under field conditions it rises to 30 (16–46) months, after attaining 55–60% of adult body weight, i.e., 275 (200–350) kg.
• The majority of buffalo have two follicular waves per estrous cycle, with some having three and few having one per cycle.
• The buffalo does not show overt estrus sign and is known as a silent estrus or subestrus animal. Homosexual behavior during estrus is uncommon. The estrus usually occurs late at night and in the early morning, making estrus detection more difficult and giving further weight to the description of silent estrus animals.
• The length of the estrous cycle is 21 (17–26) days; duration of estrus is 10 (5–27) hours, an LH surge lasts about 9 hours, and ovulation happens 15 (6–21) hours after the end of estrus.

Reproductive Disorders

• The buffalo has inherently poor reproductive efficiency, especially when compared to cattle, mainly due to the lesser number of primordial follicles in the ovaries, delayed age at puberty and maturity, reproductive seasonality, silent estrus, lower conception rate, longer calving intervals, summer anestrus, and longer postpartum anestrus.
• Genital prolapse, retention of fetal membranes, and abortions are more common in buffalo than in cattle, and more common in the river buffalo than the swamp buffalo.
• Uterine torsion is common in the buffalo due to more length and lower number of smooth muscles in the broad ligament.
• Endometritis is more prevalent in the buffalo than in cattle, while dystocia is less common. The most common cause of dystocia is fetopelvic disproportion, leading to different fetal disposition.
• Abortions and reproductive losses by nonspecific infectious agents are more prevalent than those caused by specific infections such as brucellosis, leptospirosis, listeriosis, campylobacteriosis, bubaline herpes virus-1 infection, bovine viral diarrhea, chlamydophilosis, Q fever, and neosporosis.
• Summer anestrus is a very prevalent problem in the river buffalo.

Artificial Breeding

Embryo Biotechnology

• All the reproductive biotechnologies used in cattle work for the buffalo but with lower success.
• Offspring have been produced from embryo transfer, from in vitro matured oocytes, and vitrified embryos.
• Ovum pickup (OPU) oocytes have significantly better embryo development capacity, embryo transferable quality, and blastocyst hatching than those from abattoir-derived ovaries. Oocyte recovery with OPU from 2–8 mm follicles ranges from 0.7 to 2.4 oocytes per ovary.
• Transgenic and cloned buffalo calves have been produced.

Hormonal Control of Ovarian Activity and Ovulation

• A combination of PRID for 10–12 days followed by 750–1,000 IU of eCG is the method of choice to induce estrus in noncycling heifers, resulting in >50% conception rate.
• For superovulation, FSH yields a better response than eCG. Overall, poor superovulatory response is due to the lower follicular reservoir in the ovaries.
• Estrus synchronization is achievable with the protocols used for cattle. Seemingly, PRID for 10–12 days followed by $PGF2_{\alpha}$ and 750–1,000 international units eCG at day 7, or ovulation synchronization protocol (GnRH, $PGF2_{\alpha}$ after 7 days, GnRH after 36–48 hours), are reported to achieve a better conception rate than other estrus synchronization protocols.
• Two fixed-time inseminations, at 48 hours and 72 hours during peak breeding season and at 72 hours and 96 hours during low breeding season, offer an acceptable conception rate.

Semen Collection and Artificial Insemination

• Semen can be collected by massage method, with a cattle electro-ejaculator and with an artificial vagina maintained at about 40–42°C.
• The sperm concentration in the ejaculate ranges from 1 billion to 4 billion sperm per mL of ejaculate.
• The sperm motility and sperm freezability are lower than for cattle.
• The egg yolk in semen extender must be <20%.
• Optimum time of insemination is 8–42 hours after onset of estrus. So the AM, PM rule of insemination is valid for the buffalo.
• The success rate and adoption of AI is lower than in cattle due to poor heat detection efficiency and poor conception rate with freeze-thawed semen.
• Semen sexing in the buffalo has resulted in birth of calves of pre-selected sex.

Water Buffalo Hybrid

• The fertile hybrid of the river buffalo with the swamp buffalo has been produced to combine dairy capacity of the water buffalo with meat and draft capacity of the swamp buffalo.
• Though fertilization takes place, a hybrid of water buffalo with domestic cattle could not be produced because embryos do not develop well beyond the eight-cell stage, few embryos develop to blastocyst stage, and no pregnancy is established after embryo transfer.

HISTORICAL FINDINGS

Depends on complaint

WATER BUFFALO: REPRODUCTION (CONTINUED)

SIGNALMENT
• Species: Water buffalo (*Bubalus bubalis*)
• Nili-ravi and Murrah are two top milk breeds of the river buffalo.

PHYSICAL EXAMINATION FINDINGS
N/A

GENETICS
The river buffalo has 50 chromosomes and the swamp buffalo has 48 chromosomes.

CAUSES AND RISK FACTORS
Causes and risk factors for reproductive disorders are similar to those described in cattle.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Differential diagnosis approach for abortion and reproductive failure is similar to that used in cattle.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
Serum progesterone assay may be used to monitor cyclicity, as in cattle.

IMAGING
Transrectal ultrasonography for follicular dynamics, cyclicity, and pregnancy diagnosis.

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
N/A

TREATMENT

THERAPEUTIC APPROACH
• Therapeutic approach for reproductive disorders is similar to that described for cattle.
• Estrus synchronization programs used in cattle have been adapted with moderate success in buffalo and yak.

SURGICAL CONSDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Drugs used for hormonal therapy are similar to those used in cattle.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

AGE-RELATED FACTORS
• Age at maturity for the buffalo is delayed compared to cattle. However, overall reproductive lifespan is longer than for cattle.

ZOONOTIC POTENTIAL
The abortigenic diseases: Brucellosis and leptospirosis.

PREGNANCY
• The physiology of gestation and parturition are very similar to that of cattle.
• The length of gestation is 310 (300–320) days for the river buffalo and 330 (320–340) days for the swamp buffalo.
• The placenta is epitheliochorial cotyledonary.
• The CL persists through the entire gestation.
• Pregnancy rate to first service is 50–75% with natural mating and 30–50% with AI, in the river buffalo.
• An accurate pregnancy diagnosis using per rectum ultrasonography is recommended from 30th day of insemination.
• Pregnancy can be diagnosed by transrectal palpation from day 30–45 post-insemination depending upon expertise of the clinician.
• The incidence of twinning is <0.1%. The buffalo usually produces two calves within three years.
• The involution of uterus completes within 30 (25–30) days after parturition.
• First postpartum ovulation occurs at about 96 days in the swamp buffalo and 60 days in the river buffalo.

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Some buffalo breeds can yield 4,000 L of milk per 305 days.
• In general, the buffalo is kept under harsh field conditions by poor farmers in developing countries. It survives in harsh environment better, consumes dry roughages better, and copes with specific tropical diseases better than do cattle.
• In the females calving during winter or spring, postpartum estrus and conception are delayed till the next fall and winter, leading to increased calving interval compared with females calving during summer or fall and conceiving during fall or the following winter.

SYNONYMS

WATER HEMLOCK

BASICS

OVERVIEW

• Water hemlock or *Cicuta* species of which all members are toxic.
• Perennials that grow within wet habitats such as swamps, marshes, streams, and water banks.
• Thickened tuber at the base of a stem that is chambered and exudes a yellow oily substance that has a parsnip odor.
• Leaves are pinnately covered with veins extending to notches between teeth.
• Flowers are tiny and white and grow in umbrella-like fashion.
• Seeds may be present.
• New growth is readily eaten; however, unless tubers, excessive vegetation or flowers consumed, toxic signs are not seen.
• Tubers are reported to be palatable.

INCIDENCE/PREVALENCE

• Typically, few animals will be involved, although on occasion, circumstances will prevail that result in larger losses.
• There is a report of illness in 17 bull calves in a group of 62; 10 of the 17 eventually died.

GEOGRAPHIC DISTRIBUTION

Throughout Northwest, Midwest and Northeast United States and all of Canada

SYSTEMS AFFECTED

Nervous

PATHOPHYSIOLOGY

• Cicutoxin is a potent neurotoxin believed to block gamma-aminobutryric acid (GABA) leading to neuronal depolarization.
• Tubers and flowers contain toxin, with tubers being the most common source.
• Lethal dose has been reported in sheep as 1.0 mg of tuber (wet weight) per kg body weight.

HISTORICAL FINDINGS

History of exposure to plants

SIGNALMENT

Bovine, ovine, caprine

PHYSICAL EXAMINATION FINDINGS

• Develop within few hours of exposure
• Initially uneasiness and muscle twitching of head
• Seizures
• Death

CAUSES AND RISK FACTORS

• Cicutoxin is the toxic principle.
• Plants are said to be most toxic when dormant and least toxic when actively growing.
• The first new leaves and stems in early spring are particularly dangerous because they may be avidly eaten.
• The tuberous roots are apparently not too distasteful—cattle will sometimes eat them readily. The concentration of toxin in roots is sufficient to pose a serious hazard throughout the year. This presents a particular problem if plants are pulled up and allowed to remain lying on the ground where livestock can eat the roots or when the ground becomes wet enough to allow entire plants to be easily pulled up and the roots eaten.
• Toxin levels, which are lowest in the upper leafy parts, decline as the leaves mature and dry.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Acute grass tetany

CBC/BIOCHEMISTRY/URINALYSIS

In those animals who survive, there may be significant increases in serum LDH, AST, and CK enzymes 1–2 days after ingestion.

OTHER LABORATORY TESTS

Detection of toxin in rumen samples thru gas chromatography/mass spectrometry.

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

• History of exposure to the plants
• Clinical signs
• Identification of plant in oral cavity or GI contents

TREATMENT

THERAPEUTIC APPROACH

Supportive treatment:
• Sedation
• Administration of fluids and electrolytes and possibly respiratory support are appropriate as needed.

SURGICAL CONSIDERATIONS AND TECHNIQUES

In some instances, rumenotomy and flushing with water to remove the root fragments may be appropriate.

MEDICATIONS

DRUGS OF CHOICE

• No antidote
• Treatment with 30 mg/kg BW of pentobarbital and 75 mg of atropine prevented development of signs, lesions, and death in sheep experimentally fed water hemlock.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

• Most cases result in death; there have been reports of recovery.
• Death may occur within 1–8 hours of ingestion due to anoxia and cardiopulmonary arrest. Survival beyond 8 hours is a good indicator for eventual recovery if no complications from the convulsions ensue.

PREVENTION

Avoid grazing animals in areas where the plants are pulled up and allowed to remain lying on the ground where livestock can eat the roots or when the ground becomes wet enough to allow entire plants to be easily pulled up and the roots eaten.

MISCELLANEOUS

PRODUCTION MANAGEMENT

Plant is easily killed by broad leaf herbicides but caution in spraying around water source.

ABBREVIATIONS

• AST = aspartate aminotransferase
• CK = creatine kinase
• GI = gastrointestinal
• LDH = lactate dehydrogenase

WATER QUALITY ISSUES

BASICS

OVERVIEW

• Water is the single most important nutrient for all livestock species. Water is involved either directly or indirectly in virtually every physiologic process essential to life. While animals can survive for a week or more without food, death is likely in a matter of days without adequate water intake. Poor water quality (or inadequate quantity) may result in decreased productivity, and adverse effects on animals' health, including death.
• Physical, chemical, and microbial constituents determine water quality. Physical components can range from gross contamination of water by fecal, organic materials and biofilms to stray voltage and the depth and condition of containers used to hold drinking water.
• Some chemical attributes of water can be detrimental to animal health at excessive concentrations. These include pH, soluble salts, various organic and inorganic compounds, and sulfates, nitrates, and nitrites.
• Ruminants are unique in that they are more sensitive to the toxic effects of both nitrates and sulfates than monogastrics. This is due to ruminal conversion/reduction to toxic nitrites and sulfides.
• Rate of consumption and adaptation influence the potential toxicity of many contaminants. Concentrations of (e.g.) sulfate which have no effect in winter, when water consumption is low, may be acutely lethal in summer, when consumption is several fold greater. Ruminants can adapt to moderately high concentrations of some toxicants, if introduced to them gradually.
• The microbiologic quality of water may also be important. Standing and running water may contain pathogens such as *Escherichia coli*, *Salmonella* spp., or *Leptospira* spp., and toxigenic cyanobacteria (blue-green algae).
• Drinking-water quality and availability should be included in a practitioner's differential diagnosis for poor performance or nonspecific disease conditions in livestock.
• Diagnosing water quality problems involves obtaining a thorough history, evaluating chemical and physical properties of water samples, and asking questions relevant to the water supply, such as "Where does it come from?," "How long have they been on it?," and "how much are they drinking?"

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide depending on environment

SYSTEMS AFFECTED

Multisystemic

SIGNALMENT

All ruminant species

PHYSICAL EXAMINATION FINDINGS

• Ill-thrift (poor gain, infertility, etc.) is often associated with poor water quality or inadequate intake. In many cases, the problem is not any particular contaminant per se, but the fact that contaminants have rendered the water unpalatable, and animals are not drinking enough.
• Nitrates in excess of 500 mg/L (measured as the NO_3 ion) *may* cause abortion and/or sudden death. Although there are numerous anecdotal reports of lower nitrate concentrations causing a variety of chronic maladies, there is no experimental evidence to support such claims, and, in fact, several large, well-designed studies in cattle have failed to demonstrate any effects at substantially higher concentrations.
• Sulfate contamination (measured as the SO_4 ion) in excess of 1800 mg/L has caused polioencephalomalacia and acute death in a small percentage (~1%) of exposed cattle under field conditions, although higher concentrations were reportedly tolerated in small (n~10), experimental studies. Concentrations as low as 500 ppm have interfered with productivity in large, controlled, experiments.
• *Salmonella* spp.: Diarrhea, fever, loss of production, abortions.
• *E. coli*: Gastrointestinal signs, coliform mastitis, septic meningitis/arthritis in younger animals.
• *Leptospira* spp.: Infertility, low or diminished milk production, widespread late-term abortion.
• Three species of cyanobacteria (blue-green algae) are associated with most field cases of poisoning in North America. Each produces a characteristic syndrome, involving either convulsions, hypersalivation and other parasympathetic signs, or liver necrosis. The feature common to all three is rapid onset and high mortality.

CAUSES AND RISK FACTORS

• Sudden changes in water supply.
• Natural or anthropogenic contamination of surface runoff and wells.
• Damaged casings in old wells.
• Poor sanitation practices in confinement operations.

DIAGNOSIS

Diagnosis is based upon the traditional triad of clinical presentation, pathology, and "testing." Merely because a water quality parameter exceeds some published "standard" does not necessarily prove that water is the problem. The clinical signs and history must match what is known about the contaminant.

CBC/BIOCHEMISTRY/URINALYSIS

Blood and urine analysis may indicate dehydration or hypernatremia if palatability is poor or some physical problem has interfered with consumption.

OTHER LABORATORY TESTS

Some water-borne toxicants may be directly or indirectly detectable in tissues and body fluids.

OTHER DIAGNOSTIC PROCEDURES

• Basic laboratory evaluation of water quality for livestock should include measurement of sulfate, nitrate-nitrite, and bacteria. Supplementary water tests may include pH, TDS, sodium, magnesium, chloride, calcium, potassium, manganese, and area-specific contaminants such as selenium, arsenic, or fluoride.
• It is important to use a laboratory that specializes in water quality for livestock, or else have a thorough understanding of the methodologies and reporting format used by the laboratory. For example, nitrate may be reported as "NO_3-N" or the NO_3 ion. The difference is more than two-fold.
• Many water quality laboratories offer "rural health" panels which, while inexpensive, are tailored to human residences and include tests (e.g., "hardness") and cite standards which are either inappropriate or irrelevant to animal health. It pays to know what you're asking for and understand how to interpret results.

PATHOLOGIC FINDINGS

N/A

TREATMENT

See under specific toxicants, e.g., blue-green algae, *E. coli*, leptospirosis, nitrates, *Salmonella*, sulfur.

MEDICATIONS

N/A

FOLLOW-UP

PREVENTION

Regular tests of livestock water supplies for specific contaminants should be conducted if there has been a water-related problem, or the local environment is known to be prone to certain kinds of contamination.

MISCELLANEOUS

PREGNANCY

Nitrate is known to cause abortion in ruminants.

(CONTINUED) WATER QUALITY ISSUES

BIOSECURITY
While there are no scientifically established safety standards for microbial contamination of livestock drinking water, common sense dictates that water supplies be kept as clean and free from microbial contamination as possible.

WEIGHT LOSS: BOVINE

BASICS

OVERVIEW
Weight loss is defined as a decrease in body weight. The loss may be acute, chronic, physiologic, or pathologic. Although it is not considered a specific type of weight loss, decrease in daily weight gain is an abnormal physiologic condition as well.

INCIDENCE/PREVALENCE
Incidence of weight loss will depend directly or indirectly on the occurrence of disease related to a decrease in feed intake or the increase of nutritional requirements. All lactating animals, especially during the first trimester of lactation, mobilize body reserves, potentially causing a decline in weight and body condition.

GEOGRAPHIC DISTRIBUTION
Worldwide, weight loss commonly occurs in locations where drought is common or the feed supply is compromised.

SYSTEMS AFFECTED
- Multisystemic
- Musculoskeletal

PATHOPHYSIOLOGY
- Weight loss may occur as a result of anorexia, an increase in nutritional requirements, unbalanced diets, or a combination of these factors.
- Anorexia may be pathologic or physiologic.
- Pathologic anorexia occurs secondary to any systemic disease or local condition affecting the digestive system or oral cavity.
- Physiologic anorexia may occur during the last month of gestation and the first weeks of lactation. This decrease in feed intake is markedly evident at calving and during the peripartum period. Heat stress is another physiologic condition that noticeably affects dry matter intake.
- Increases in nutritional requirements occur under normal and pathologic conditions.
- Fever or any inflammatory process including tissue damage increases nutritional requirements, specifically the need for protein. Parasitism is an additional cause of pathologic weight loss.
- Examples of physiologic increases in nutritional requirements include lactation, last trimester of gestation, and overall animal growth. Unbalanced diets, especially diets deficient in microminerals and vitamins, and diets reduced in energy and protein, may promote poor growth rates or weight loss.
- Weight loss may be acute or chronic.
- Acute weight loss is typical with pathologic conditions that markedly affect dry matter intake, such as lameness, rumen acidosis, and displaced abomasum; or physiologic conditions, such as early lactation.
- Chronic weight loss is typical with pathologic conditions such as parasitism, chronic diarrhea (e.g., Johne's disease); or physiologic conditions that occur in aging animals.

HISTORICAL FINDINGS
Vary depending on underlying condition

SIGNALMENT
All breeds, ages, sex, and production stage may be affected.

PHYSICAL EXAMINATION FINDINGS
Anatomically depressed left paralumbar fossa, decrease in body condition score, visibility of skeletal prominences, and emaciation.

GENETICS
Several genetic or congenital conditions might affect growth and performance. Examples include dwarfism, cleft lip/palate (palatoschisis), and ventricular septal defect.

CAUSES AND RISK FACTORS
Any factor that decreases the animal's appetite, increases nutritional requirements, or inconsistent feed management (e.g., unbalanced diets, poor feed quality, macro/micro-nutrient deficiency, etc.). Risk factors include diseased animals, poor environmental management (e.g., heat stress, mud, insect control, etc.), inadequate feed management, low nutritional quality, drought, age, gender, physiologic stage, season, location.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
- Weight loss may be difficult to diagnose.
- May be secondary to other pathologic conditions (see Table 1).

CBC/BIOCHEMISTRY/URINALYSIS
Anemia, altered white cell profile, altered albumin to globulin ratio, elevated nonesterified fatty acids, increased creatinine and blood urea nitrogen, increase of specific enzymes related to tissue damage (AST, alkaline phosphatase, GGT, creatine kinase), elevated ketone bodies, low micromineral levels.

OTHER LABORATORY TESTS
Dependent upon specific disease condition(s) and differential diagnoses.

IMAGING
May be helpful to rule out a foreign body (traumatic reticuloperitonitis) in individual animals.

OTHER DIAGNOSTIC PROCEDURES
- Visual observation, body condition scoring, weight of animals, record analysis.
- Assessment of management.
- Complete dietary/nutritional analysis may be indicated.

PATHOLOGIC FINDINGS
Emaciation, decrease or absence of adipose tissue, especially in abdominal organs, and

Table 1

  - Rotavirus

decreased or stunted growth. Evaluate body condition scores. Mature animals break down fat reserves, initially utilizing peripheral fat, followed by abdominal and perirenal fat. After fat utilization, animals catabolize muscle proteins.

TREATMENT

THERAPEUTIC APPROACH
Dependent upon whether the weight loss is secondary to a pathologic or physiologic condition.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
- Vitamins (A, D, E, B complex), minerals (mostly microminerals), feed additives (monensin, probios, propionate, propylene glycol), and growth stimulants may be indicated dependent upon the type of weight loss.
- Treatment should be predicated based upon disease condition.
- If lameness is evident, hoof care should be established.

CONTRAINDICATIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Dependent upon the primary cause of weight loss

POSSIBLE COMPLICATIONS
Down cow syndrome, weakness

CLIENT EDUCATION
Institute programs where body condition scoring, or weighing if possible, and feed evaluation are routinely performed. Behavior surrounding feeding or grazing is important to observe also as less obvious factors such as limited feed space, social dominance, and palatability/sorting behavior may play a role in weight loss.

PREVENTION
Based on the primary cause of weight loss

MISCELLANEOUS

ASSOCIATED CONDITIONS
Decrease in productivity

AGE-RELATED FACTORS
Older animals are more likely to lose weight inherently due to aging; young stock are particularly susceptible to diarrheal diseases.

ZOONOTIC POTENTIAL
Some infectious conditions (e.g., salmonellosis, leptospirosis) are zoonoses.

PREGNANCY
Can negatively affect growth and weight gain.

BIOSECURITY
Considered in the case of infectious disease associated with weight loss, (e.g., Johne's disease, salmonellosis, etc.).

PRODUCTION MANAGEMENT
Adequate feed intake, general management, and cow comfort. Specific management recommendations will follow diagnosis of underlying disease or underlying management/facilities issues.

SYNONYMS
N/A

ABBREVIATIONS
- AST = aspartate aminotransferase
- BVDV = bovine viral diarrhea virus
- GGT = gamma glutamyltransferase
- IBR = infectious bovine rhinotracheitis

WEIGHT LOSS: CAMELID

BASICS

OVERVIEW
• Weight loss is a common presenting complaint in camelids and the cause can be difficult to diagnose.
• Thorough examination and appropriate diagnostic tests frequently result in diagnosis.

INCIDENCE/PREVALENCE
Common

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
• Musculoskeletal
• Digestive

PATHOPHYSIOLOGY
• Camelids have a highly efficient compartment system of rumination, so even moderate quality forages are usually sufficient to maintain adult animals; true starvation is rare.
• Growing animals and late pregnant or lactating females are typically the first to display weight loss.
• Extremes of environmental temperature can increase energy requirements.
• Any disease process can increase energy requirements, and many also suppress appetite, which can cause rapid weight loss.

HISTORICAL FINDINGS
• Depend upon the etiology.
• Early detection of weight loss can be difficult for clients with animals in heavy fiber; reports of acute weight loss should be viewed cautiously unless clients are regularly performing body condition scoring.
• History should include age, number of animals affected, stage of pregnancy or lactation, appetite, and duration over which weight loss occurred.
• Investigate deworming and supplementary feeding practices, vitamin D supplementation strategy, and housing.
• Determine if this is a herd versus individual animal problem to refine the differential list.
• Inspection of the premises may help identify relevant management issues.

SIGNALMENT
• Camelids of any age, gender, and breed can be affected.
• Vitamin D deficiency is most prevalent in crias 3–6 months of age, darkly pigmented, and born in late fall/winter.
• Young animals are also more prone to vitamin E/selenium deficiency.

PHYSICAL EXAMINATION FINDINGS
• Vary with cause. Particular attention should be paid to mucus membrane color (conjunctival more reliable than oral) to evaluate potential anemia. Detection of edema is difficult and it is most reliably found in the axillary, mammary, and scrotal regions.
• Observation from a distance can detect subtle changes such as increased time in cush, mild colic (shifting or abnormal limb position in cush), and increased separation from the herd.
• Assessment of the dung pile can detect diarrhea and tapeworm infestations in the herd. Diarrhea should be suspected if fecal consistency is anything softer than individual pellets, which disperse on hitting the ground.
• Pneumonia is difficult to detect by auscultation in camelids; thoracic ultrasound or radiography are more reliable.
• Cardiac murmurs are abnormal in camelids and generally require further investigation.
• Palpation of the mandibles and maxillae should be performed to evaluate dental disease.
• Reluctance to move, arched stance, shifting limb lameness, joint enlargement, and angular limb deformities (carpal valgus) occur with vitamin D deficiency.
• Camelids with head-shaking, pruritis, shade seeking, and weight loss might be exposed to sporidesmin toxin, produced by the fungus *Pithomyces chartarum*. Jaundice can occur in severe cases.
• Weakness and reluctance to move can indicate nutritional myodegeneration due to selenium deficiency.
• Bruxism, frothing at the mouth, or mild colic can occur with third compartment ulcers; however, in many cases signs may be restricted to lethargy, weight loss, and reduced appetite.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Causes vary (listed under "Differential Diagnoses").
• Inadequate nutrition should be suspected in animals with weight loss, despite a good appetite, and no other abnormal findings.
• Risk factors include intensive management systems with high stocking densities.
• Anthelmintic resistance can result in high parasite burdens even in treated animals.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Inadequate nutrition
• Hepatic lipidosis
• Endoparasitism
• Vitamin D deficiency
• Dental disease
• Selenium deficiency
• Facial eczema (sporidesmin toxicity)
• Perennial ryegrass staggers
• Blood parasites: *Candidatus Mycoplasma haemolamae, Theileria orientalis*
• Third compartment ulcers
• Chronic infections: Pneumonia, endocarditis, Johne's disease, bovine viral diarrhea virus, *Yersinia enterocolitica*, tuberculosis, caseous lymphadenitis
• Congenital abnormalities: Cardiac abnormalities, portosystemic shunts, vascular ring anomalies
• Neoplasia: Malignant round cell tumor, intestinal adenocarcinoma
• Megaesophagus
• Chronic renal failure

CBC/BIOCHEMISTRY/URINALYSIS
• CBC and serum chemistry analysis help diagnose vitamin D deficiency (phosphorus <3 mg/dL), selenium deficiency, blood parasites, chronic infections, and hepatic and renal disorders.
• Measurements of triglycerides, β-hydroxybutyrate, and nonesterified fatty acids are often relevant.
• Hypoproteinemia due to hypoalbuminemia (often severe) is a common finding with *Eimeria macusaniensis* infection.

OTHER LABORATORY TESTS
• Fecal examination should comprise part of the investigation. *E. macusaniensis* is rarely detected using the McMasters technique; the Modified Wisconsin Sugar Flotation Method is recommended. The prepatent period is 32–43 days, with clinical signs occurring from 21 days, so clinical signs can occur before detectable fecal shedding.
• BVDV and mycoplasma PCR (on blood).
• Assessment of blood selenium or glutathione peroxidase activity (selenium deficiency).

IMAGING
• Ultrasonography is useful to assess GI, cardiac, urogenital, and respiratory disease.
• Thoracic and abdominal radiographs are useful for specific disorders.
• Computed tomography can be performed with IV contrast; orogastric contrast is useful to specifically investigate GI disorders 3 hours after administration.

OTHER DIAGNOSTIC PROCEDURES
• Liver biopsy: Hepatic lipidosis, fibrosis, neoplasia.
• Exploratory laparotomy is an option in valuable animals unable to be diagnosed by less extreme measures.

PATHOLOGIC FINDINGS
Vary with etiology

TREATMENT

THERAPEUTIC APPROACH
• Depends upon the cause of weight loss; however, reinstituting appropriate caloric intake is critical in avoiding, or treating, hepatic lipidosis. Appetite is best stimulated by transfaunation with bovine rumen fluid obtained from a freshly slaughtered or

fistulated cow. Otherwise reconstituted feces from a healthy herd mate can be used. Fluid can be administered via orogastric tube, or if repetition is expected, a small bore indwelling naso-esophageal tube can be left in place for transfaunation to be performed once or twice daily for 3–5 days.
• Anemia is common and extremely well tolerated in camelids, and clinical signs of pallor, tachycardia, and lethargy may not be recognized until the PCV is critically low. Blood transfusion is well tolerated and can be performed by acquiring blood from either a healthy alpaca or llama. Cross-matching is not required unless subsequent transfusions are performed more than 48 hours later.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
• Anthelmintics are indicated when GI parasites are confirmed in relationship to clinical disease. Resistance is common, particularly in areas where camelids are treated prophylactically for *Parelaphostrongylus tenuis* with avermectins. Moxidectin likely has the best efficacy but a narrow margin of safety so individual animals should be weighed prior to administration of the drug (0.4 mg/kg body weight PO).
• Coccidiostats: Toltrazuril 15 mg/kg PO once; ponazuril 20 mg/kg PO q24h for 3 days.
• Vitamin D: 1500 IU/kg SC q12 weeks for young and all darkly pigmented animals. 1,500 IU/kg q6 months for lightly pigmented animals.
• Selenium should only be given to animals with known deficiency to avoid toxicity (50 µg/kg once SC or IM).
• Antibiotics are commonly preferred over surgical intervention for dental abscesses: Florfenicol (20 mg/kg IM q48h for 3 weeks); penicillin, long-acting ceftiofur and other drugs have been used.
• Ulcer medications are largely ineffective due to poor absorption. Reestablishing appetite is the best treatment for ulcers; pantoprazole can be administered SC (2 mg/kg IV, q24h) or IV (1 mg/kg IV, q24h) with efficacy if medication is indicated.
• Thiamine (10 mg/kg SC) is indicated in animals with prolonged inappetance.

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Varies with etiology. Chronic weight loss is more likely to carry a poor prognosis if a reversible cause cannot be established and addressed.

POSSIBLE COMPLICATIONS
Hepatic lipidosis can occur in any camelid (particularly crias) with prolonged periods of reduced caloric intake and/or high metabolic demands.

CLIENT EDUCATION
See "Prevention"

PATIENT CARE
Ensure provision of high quality, adequate volume, readily accessible feed.

PREVENTION
• Appropriate vaccination and parasite control methods help prevent common diseases.
• Fecal parasite examination should be repeated 10 days after anthelmintic therapy to ensure efficacy of the selected drug.
• Educated assessment of rations and pasture conditions is important.
• Periodic body condition scoring, regular weighing, and fecal egg counts are valuable tools for maintaining animal condition and for early identification of disease.

POSSIBLE COMPLICATIONS
• Hepatic lipidosis
• Refeeding syndrome

WEIGHT LOSS: SMALL RUMINANT

BASICS

OVERVIEW
• Weight loss is a common and nonspecific sign which can be an indicator of poor management or true medical disease.
• It may be the focus of case assessment or the consequence of more specific conditions to be assessed.
• Weight loss should be defined into the following categories to help with differential diagnosis construction:
  ◦ Weight loss with increased appetite
    ▪ Malassimilation—maldigestion or malabsorption of nutrients
    ▪ Malutilization—nutrients are digested and absorbed normally but utilized abnormally by tissues
  ◦ Weight loss with normal appetite and intake
  ◦ Weight loss with reduced appetite

INCIDENCE/PREVALENCE
Varies with specific conditions

GEOGRAPHIC DISTRIBUTION
Worldwide

SYSTEMS AFFECTED
Multisystemic

PATHOPHYSIOLOGY
• Weight loss can arise from
  ◦ Undersupply of nutrition
  ◦ Conditions preventing adequate ingestion of food and/or water
  ◦ Conditions causing malabsorption
  ◦ Disturbed metabolic processes

HISTORICAL FINDINGS
• Vary with specific conditions.
• Weight loss can be acute or chronic.
• Weight loss may or may not be accompanied by more overt clinical indicators of disease.
• Assess management features, particularly feed supply and housing characteristics.
• Determine herd versus individual animal problem to refine the differential list.
• If possible, inspection of the premises may help identify relevant management issues.

SIGNALMENT
All small ruminant species of any age or gender can be afflicted.

PHYSICAL EXAMINATION FINDINGS
• Vary with specific conditions.
• Critical to define a body condition score for the animal, using a scoring system appropriate for the species and breed in question.
• Differentiate muscle loss from fat loss.
• Identify any other anomalies that may relate to weight loss and disease.
• Include a thorough inspection of the oral cavity.

GENETICS
N/A

CAUSES AND RISK FACTORS
Vary with specific conditions

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Management and nutrition inadequacies:
  ◦ Inadequate energy density of ration
  ◦ Inadequate supply or palatability of water (reduces DM intake)
  ◦ Poor forage quality (late autumn and undergrazed pasture) or inadequate quantity (grass length of 4–6 cm optimal)
  ◦ Competitive exclusion from food: Different age groups housed together or inadequate feed trough space
  ◦ Vitamin deficiencies: E, B_{12}
  ◦ Mineral deficiencies: Sodium, potassium, sulfur, cobalt, copper, selenium
  ◦ Toxic plant ingestion (particularly sheep): Acorns, fiddleneck, groundsel, locoweed, phalaris, yellow star thistle
• Disease conditions creating weight loss due to impaired prehension/ingestion:
  ◦ Dental disease
  ◦ Oral cavity infections: orf, *Fusobacterium necrophorum*, *Actinobacillus lignieresii*
  ◦ Pharyngeal or retropharyngeal trauma and/or abscessation
  ◦ Esophageal diseases
• Other GI disorders:
  ◦ Impaction of the rumen or abomasum
  ◦ Rumen acidosis
  ◦ Abomasal emptying defect (Suffolk sheep)
  ◦ Parasitism: Cestodes, nematodes, *Coccidia*, *Cryptosporidium*
  ◦ Johne's disease
  ◦ Intestinal neoplasia
• Other disorders:
  ◦ Severe lameness inhibiting mobility to food
    ▪ Foot rot
    ▪ Contagious ovine digital dermatitis
    ▪ White line abscesses
    ▪ Infectious arthritis: *Streptococcus* (lambs), *Erysipelothrix, Chlamydia,* maedi-visna virus (MVV), caprine arthritis encephalitis virus (CAEV)
    ▪ Limb fractures/trauma
  ◦ Hepatobiliary disease
    ▪ Cobalt deficiency
    ▪ Fasciolosis
    ▪ Pyrrolizidine alkaloid ingestion
  ◦ Cardiovascular disease
    ▪ Vegetative endocarditis
    ▪ Congestive heart failure
  ◦ Respiratory disease
    ▪ Pasteurellosis and/or chronic viral infection
    ▪ Enzootic nasal adenocarcinoma
    ▪ *Oestrus ovis*
    ▪ Laryngeal chondritis
    ▪ *Dictyocaulus filaria*
    ▪ Chronic bacterial pneumonia (*F. necrophorum*, *Trueperella pyogenes*)
    ▪ Sheep pulmonary adenomatosis
    ▪ MVV
    ▪ Caseous lymphadenitis (CLA): Pulmonary abscesses
  ◦ Central nervous system
    ▪ Scrapie
    ▪ Polioencephalomalacia
    ▪ Louping ill
    ▪ Listeriosis
  ◦ Reproductive
    ▪ Pregnancy toxemia
    ▪ Postpartum peritonitis
  ◦ Integument
    ▪ Pruritic disorders: Mange (*Sarcoptes scabiei* var. *ovis, Sarcoptes scabiei* var. *caprae*), mites (sheep scab, *Psoroptes ovis*), lice (*Mallophaga* and *Anoplura*) and biting flies (*Melophagus ovinus*)
    ▪ Parapox virus
    ▪ Contagious pustular dermatitis (orf)
  ◦ Ophthalmic
    ▪ Vitamin A deficiency
  ◦ Urinary
    ▪ Enterotoxemia (pulpy kidney)
    ▪ Pyelonephritis
    ▪ Urolithiasis
    ▪ Renal amyloidosis (sheep with CLA)
    ▪ Chronic renal failure

CBC/BIOCHEMISTRY/URINALYSIS
• CBC and serum chemistry are indicated to assess inflammation and abnormalities of liver enzymes and function (AST, GGT, SDH, bilirubin), renal function (BUN and creatinine), electrolyte and mineral status, and blood protein profile (total protein, albumin, globulin).
• Measurement of triglycerides, β-hydroxybutyrate, and nonesterified fatty acids may be relevant.
• Urinalysis is indicated when urinary tract disorders are suspected, or to evaluate glucose and ketone content.

OTHER LABORATORY TESTS
• Fecal egg counts
• Serum bile acids (hepatic disease)
• Vitamin and trace mineral assessments

IMAGING
• Ultrasound of the thoracic and abdominal organs may confirm specific diagnoses.
• Ultrasound in early pregnancy (fetal counting) assists prevention of pregnancy toxemia.
• Radiographs and computed tomography are also useful methods of imaging small ruminants.

OTHER DIAGNOSTIC PROCEDURES
Depend on suspected diagnosis

PATHOLOGIC FINDINGS
Depend on system affected

TREATMENT

THERAPEUTIC APPROACH
Identify underlying cause of weight loss to determine if and how it can be resolved. This is particularly critical for herd issues.

WESSELSBRON DISEASE

BASICS

OVERVIEW
• Acute arthropod-borne viral infection of the genus Flavivirus.
• Predominantly affects sheep, cattle, and goats in sub-Saharan Africa.

INCIDENCE/PREVALENCE
• Seroprevalence in endemic regions is approximately 50%.
• Mortality rates up to 30% in infected lambs.
• Infections are seen to occur year round in most endemic regions; some regions observe increased incidence following periods of heavy rainfall.

GEOGRAPHIC DISTRIBUTION
• Africa, including Madagascar.
• Serologic evidence of presence in other countries (especially those with warm and moist climates).

SYSTEMS AFFECTED
• Digestive
• Nervous
• Musculoskeletal
• Reproductive

PATHOPHYSIOLOGY
• No evidence to support animal-to-animal transmission.
• *Aedes* mosquitoes are responsible for virus transmission.
• Reservoir host is unknown (suspected to be rodents).
• 1–3 day incubation period.

HISTORICAL FINDINGS
Location within an endemic region and periods of heightened vector activity are pertinent.

SIGNALMENT
• Neonatal lambs and kids (<7 days of age) are most susceptible to clinical disease.
• Adult infection is usually subclinical, unless preexisting liver disease is present.
• Cattle, goats, and sheep are the predominant species affected.
• There are reports of Wesselsbron disease in horses, pigs, ostriches, guinea pigs, rabbits, a gerbil, a dog, and a camel; serologic evidence exists in other wild ruminants.

PHYSICAL EXAMINATION FINDINGS
• Lambs, kids, and calves: Nonspecific signs including fever, anorexia, weakness, listlessness, tachypnea, and icterus. Infected lambs are usually 1–3 days of age, and may progress to death within 72 hours of clinical signs.
• Calves and mature sheep, goats, and cattle typically develop subclinical infection, or occasionally nonfatal febrile illness.
• Abortion with congenital malformations of the CNS and arthrogryposis of the fetus can be observed in some pregnant ewes.
• Hydrops amnii can occur in ewes.

GENETICS
N/A

CAUSES AND RISK FACTORS
• Enveloped, positive-sense RNA Flavivirus with properties of a hemagglutinating flavivirus.
• Mosquitoes from the *Aedes* genus, including *A. caballus* and *A. circumluteolus*, are responsible for transmission.
• Neonatal lambs and pregnant ewes are at increased risk of clinical disease.
• Infection can occur in conjunction with Rift Valley fever, especially during heavy rainfall periods.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Rift Valley fever (RVF): Similar geographic distribution, but Wesselsbron disease is usually milder with lower mortality rates, reduced abortion rate, and less severe liper pathology. Wesselsbron disease is more neurotropic than RVF and can cause severe teratology of the fetal CNS.
• Other abortive diseases including toxic plant ingestion and other viral diseases that can result in teratogenesis.

CBC/BIOCHEMISTRY/URINALYSIS
N/A

OTHER LABORATORY TESTS
• Virus isolation via intracerebral inoculation of newborn mice with samples from virtually any organ from RVF affected neonates.
• Can be differentiated from RVF by intraperitoneal inoculation of weaned mice which results in death (RVF) versus survival (Wesselsbron disease virus).
• Serodiagnosis can be achieved via hemagglutination-inhibition, complement fixation, or virus neutralization tests, with virus neutralization used to confirm virus identity.
• There is a high degree of cross-reactivity with other flaviviruses on hemagglutination-inhibition assays.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
• Diffuse icterus and hepatomegaly of neonates, with hepatic discoloration (yellow–orange brown), and focal to extensive necrosis of parenchyma.
• Hepatocytes may contain eosinophilic inclusion bodies and Kupffer cell proliferation is present.
• Petechiae and ecchymoses are found in the abomasal mucosa, and the abomasal contents contain evidence of hemorrhage (brown discoloration).
• Diffuse lymphadenopathy.
• Lesions in adult animals are usually very mild.
• Congenital malformations of the CNS can occur in ovine and bovine fetuses, including porencephaly, hydranencephaly, and cerebellar hypoplasia, with arthrogryposis often also evident.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Up to 30% mortality rate in neonatal lambs.
• Prognosis for survival and reproductive future is good for ewes following abortion.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
N/A

PATIENT CARE
N/A

PREVENTION
• Utilization of the previously available attenuated vaccine should be avoided in pregnant ewes because it can cause early embryonic death, CNS teratogenesis, arthrogryposis of the fetus, hydrops amnii, abortion, or fetal mummification. The attenuated vaccine was discontinued in 2000 due to the high prevalence of these adverse side effects.
• Attempts to control mosquito vectors is helpful but challenging.
• Immunity is life-long.
• Confine valuable animals to avoid exposure.
• Reduce sources of standing, stagnant water.

(CONTINUED) WESSELSBRON DISEASE

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Abortion: primarily due to malformation of the CNS with arthrogryposis in cattle and sheep.
• Hydrops amnii in pregnant ewes.

AGE-RELATED FACTORS
Newborn animals suffer high mortality rates.

ZOONOTIC POTENTIAL
• The virus has been associated with influenza-like disease in humans with signs including fever, headache, arthralgia, and myalgia.
• Infection can be transmitted to humans by *Aedes* mosquitoes or by handling virus-contaminated organs or materials; therefore, precautions should be taken while performing necropsy of suspected Wesselsbron disease cases.

PREGNANCY
Abortion with CNS malformation and arthrogryposis.

BIOSECURITY
No studies performed specifically into the sensitivity of Wesselsbron virus to disinfectants; however, due to similarities of this virus with other hemagglutinating flaviviruses, it is likely sensitive to temperatures over 104°F (40°C), detergents, and lipid solvents.

WINTER DYSENTERY

BASICS

OVERVIEW
• Acute, contagious diarrheal disease of cattle with worldwide distribution, occurring in closely confined cattle during winter months (November to March).
• The feces are usually recognized as dark and fluid, often containing frank blood, and may have bubbles present and a foul odor. The odor from feces is unusual.
• In lactating cows there is a significant drop in milk production associated with anorexia and depression. Milk production decreases and clinical disease in individual animals is usually short (<1 week); however, outbreaks within a herd can persist for 2–8 weeks, depending upon herd size and housing. Lactating cows are most commonly affected.
• Calves may also demonstrate similar clinical signs and attack rates.
• Mortality is low, but morbidity can be quite significant (40–50%).
• Herds not experiencing outbreaks of winter dysentery (WD) for several years are at risk for subsequent outbreaks.

INCIDENCE/PREVALENCE
Acute, contagious diarrhea in cattle that occurs sporadically in epizootic form during the colder months of the year (November to March). Morbidity is generally high, with low mortality.

GEOGRAPHIC DISTRIBUTION
Disease occurs more commonly in northern states of the United States and Canada, but also has been documented to occur in Australia, northern United Kingdom, Europe, Israel, and Japan.

SYSTEMS AFFECTED
• Digestive
• Respiratory

PATHOPHYSIOLOGY
To date the exact cause is unknown. However, increasing evidence suggests that bovine coronavirus may be causal when appropriate animal and environmental conditions are present. Viral particles invade the colonic mucosae resulting in death and necrosis of the colonic epithelial cells. The loss of epithelial barrier function results in transudation of proteinaceous fluid and blood. The increased volume of fluid presumably results in loose, dark and sometimes bloody stool.

HISTORICAL FINDINGS
N/A

SIGNALMENT
Primarily adult dairy cows, either soon after calving or within the first 100 days in milk. Pregnant cows appear to be at reduced risk. Winter dysentery may also cause diarrhea and respiratory signs in calves, as shown experimentally. Some outbreaks have been reported in beef cattle and feedlot calves.

PHYSICAL EXAMINATION FINDINGS
• Acute onset of voluminous, tan to dark diarrhea with clots of blood interspersed within liquid occurring in anorexic, depressed cows with reduced milk production. Reduced rumen fill and dehydration result in weight loss. Blood in feces may be mixed evenly in feces or may be present in clots.
• Rectal examination may reveal mildly distended loops of bowel and the manure generally has a fetid odor. Affected animals may develop diarrhea and respiratory signs (dyspnea, coughing, nasal and lacrimal discharge) but these are not consistent.
• Usually epizootic in nature with 10–100% morbidity.
• Excluding other causes of contagious diarrhea (coccidiosis, parasitism, salmonellosis) leads one to suspect WD.

GENETICS
No breed predilection. More common in dairy animals.

CAUSES AND RISK FACTORS
• Cattle in herds with recent exposure and immunologic response to BVDV or BCV (>4 fold increase in serum titer), cattle housed in tie stalls or stanchion barns and facilities using the same equipment to manage manure as well as feed are at increased risk for development of WD.
• Cows with high fecal BCV ELISA antigen and high acute serum BCV IgG antibody titers that seroconvert (> 4-fold increase) are at greater risk for development of WD. Pregnant cows are at reduced risk for WD.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
Diarrheic diseases caused by BVDV, coccidia, gastrointestinal parasites, *Salmonella* spp., *Campylobacter* spp., *Mycobacterium avium* ssp. *paratuberculosis* (Johne's disease), heavy metal intoxications (As, Cd), organophosphate toxicity, and dietary induced gut disturbances. *Mycobacterium avium* ssp. *paratuberculosis* is not often a problem in outbreak form. *Campylobacter* spp. has not been isolated from cattle with WD. Coccidiosis is not generally a problem in adult cattle, fecal evaluation may rule out coccidia and gastrointestinal nematodiasis. Heavy metal intoxication is often accompanied by high mortality in groups of cattle. Organophosphate intoxication includes acute death, neurologic animals, salivation, lacrimation, urination, defecation. Dietary induced diarrhea is often accompanied by lameness, reduced milk fat or protein/fat inversion. Bloody stool, or diarrheic feces with blood clots may indicate clostridial enteritis (jejunal hemorrhage syndrome).

CBC/BIOCHEMISTRY/URINALYSIS
Not generally helpful in diagnostics. If persistent, dysentery may result in anemia.

OTHER LABORATORY TESTS
• BCV, the suspected etiologic agent, is diagnosed via fecal evaluation (electron microscopy, PCR, or ELISA).
• Differential diagnoses can be ruled out via fecal culture (*Salmonella* spp., *Campylobacter, Mycobacterium avium* subspecies *paratuberculosis*), serology (BVDV, IBR, Johne's, rotavirus, campylobacter, BRSV, BAV3, and BLV), fecal flotation and smear (coccidiosis, cryptosporidium).

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
N/A

PATHOLOGIC FINDINGS
In acute cases, BCV can be found in colonic tissue via immunohistochemical staining.

TREATMENT

THERAPEUTIC APPROACH
• Provision of adequate feed and fresh water is important. Access to salt and trace minerals is also advisable.
• Most cases will recover with supportive treatment with anti-diarrheal agents.
• More severe cases may require parenteral calcium, oral fluids, and propylene glycol for secondary hypocalcemia, dehydration, and ketosis respectively.
• Very rarely, animals will become severely dehydrated or anemic due to colonic blood loss and require IV fluids and whole blood transfusion.

MEDICATIONS

DRUGS OF CHOICE
• Oral anti-diarrheal agents (e.g., bismuth subsalicylate, kaolin/pectin)
• Oral isotonic fluid preparations (5–10 gallons q12–24h)
• IV hypertonic saline with fresh water available

CONTRAINDICATIONS
N/A

PRECAUTIONS
Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

(CONTINUED) WINTER DYSENTERY

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
• Morbidity is generally high with low mortality.
• Cows with high fecal BCV ELISA antigen and high acute serum BCV IgG antibody titers that seroconvert (>4-fold increase) are at greater risk for development of WD.

POSSIBLE COMPLICATIONS
N/A

CLIENT EDUCATION
Educate clients on risk factors associated with WD.

PATIENT CARE
Supportive care

PREVENTION
Management practices that prevent cross-contamination of feed with manure appear to be important.

MISCELLANEOUS

AGE-RELATED FACTORS
More common in adults but calves can be affected

ZOONOTIC POTENTIAL
Salmonella spp., *Campylobacter* spp., and possibly Johne's disease may be zoonotic.

PREGNANCY
Pregnant cows appear to be at reduced risk.

BIOSECURITY
Management practices that prevent cross-contamination of feed with manure appear to be important.

PRODUCTION MANAGEMENT
Cattle in herds with recent exposure and immunologic response to BVDV or BCV (>4-fold increase in serum titer), cattle housed in tie stalls or stanchion barns, and facilities using the same equipment to manage manure as well as feed are at increased risk for development of WD.

SYNONYM
Winter scours

WOOL ROT

BASICS

OVERVIEW
• Wool rot (fleece rot) is a skin disease caused by prolonged and excessive wetting of the skin resulting in exudation and discoloration of the wool.
• The primary etiologic agent is *Pseudomonas aeruginosa*, although other bacteria may also be significant.
• Wool rot is characterized by superficial inflammation, seropurulent exudation, and putrefaction that attracts blowflies (*Lucilia cuprina*) to oviposition.
• Wool rot causes severe financial loss through downgrading of wool and promoting cutaneous myiasis by blowflies.

INCIDENCE/PREVALENCE
• Common problem in sheep.
• Incidence varies from 15% to 90%.
• It is most problematic in Australia, where reported prevalence can exceed 20%.

GEOGRAPHIC DISTRIBUTION
• Worldwide but most commonly occurs in Australia and New Zealand during wet season.
• Also of concern in South Africa and United Kingdom.
• Occasionally reported in the United States, where it is far less economically or clinically significant.

SYSTEMS AFFECTED
Integument

PATHOPHYSIOLOGY
• The main inciting factor is prolonged wetting of the skin and matting of the wool, arising from rain or dipping procedures.
• Continued wetting of the skin for at least 8 days or 100 mm of rain will provoke the disease.
• Temperature is not a factor in disease development.
• The primary factor for susceptibility is the sensitivity of the skin to prolonged wetting.
• Chronic wetting of the skin results in acanthosis, hyperkeratosis, and edema of the lower layers of the epidermis and subsequent infiltration of the area by neutrophils and other inflammatory cells.
• Microabscesses form and exudate is discharged into the lower layers of the epidermis.
• Prolonged wetting of the skin, high humidity in the fleece environment, and the availability of nutrients from serous exudates allow for indigenous skin flora, opportunistic flora, and bacteria such as *P. aeruginosa* to proliferate.
• Chromogenic bacteria (*Pseudomonas* spp.) cause discoloration of the fleece. *P. indigofera* produces a blue color, *P. aeruginosa* produces a green color, and *P. maltophilia* can cause yellow discoloration. Other bacteria may produce brown, greenish-brown, or red discoloration.

HISTORICAL FINDINGS
Recent relevant weather conditions or management activities (dipping).

SIGNALMENT
• Can occur in any age, gender, or breed of sheep.
• Most common in younger sheep after succession of wet days from either rain or repeated dipping.

PHYSICAL EXAMINATION FINDINGS
• Except for the fleece, sheep are otherwise normal.
• Some sheep may show evidence of pain, rubbing, and/or biting at affected skin sites.
• Lesions are most common on the dorsum with the skin becoming red-purple in the early stages followed by exudation and matting of the wool.
• Affected areas are wet and the wool easily epilates.
• Parting of wool in affected areas reveals exudation and commonly diffuse discoloration or bands of discoloration.
• Fleece rot is characterized by a greenish discoloration of the wool fibers with a seropurulent crust. Most commonly discoloration is greenish but it may be yellow, yellow-brown, blue, or red-brown. Greenish coloration is due to bacterial production of the pigment pyocyanin.
• The virulence of this disease is determined by the presence of the enzyme phospholipase C in *P. aeruginosa*.
• Affected areas emanate a putrid odor and attract blowflies.
• General health is unaffected, but in cases with severe ulceration, death can occur due to sepsis.
• A chronic ulcerative necrotic dermatitis on the tail, udder, and legs associated with a greenish discoloration of fleece following excessive rain has been seen in the Mediterranean.

GENETICS
• There is a genetic predisposition to fleece rot with some sheep breeds being more susceptible than others, and some individuals within a breed being more vulnerable.
• Breeds with lower wax content, irregular fiber size, and thicker wool fibers are more susceptible.

CAUSES AND RISK FACTORS
• Major cause is prolonged wetting coupled with a "less waterproof" fleece.
• Fleece staple is a major factor in wool rot. A long fleece reduces skin wettability but, once wet, the skin and fleece dry more slowly. Short staple fleece is rapidly penetrated by water but dries more quickly.
• Compact fleeces with high wax contents are most resistant. This is probably due to the effect of the wax on waterproofing the fleece.
• Breeds with open fleece and poor staple structure are more prone.
• Susceptible sheep have smaller follicle groups and higher densities of follicle populations with more primary follicles; sheep with more secondary to primary hair follicle ratios are more resistant.
• Susceptible sheep have thicker wool fibers growing from primary follicles.
• Susceptible sheep have irregular wool fibers that retain water in the fleece for longer, making the fleece more susceptible to rot.
• Resistant sheep have better fleece closure and higher wax content allowing water to run off the wool; sheep that are more "waterproof" are more resistant.
• Yellowish fleece color (high suint content) is found in more susceptible sheep.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES
• Major differential diagnosis is dermatophilosis.
• Scab formation and skin ulceration are absent in fleece rot, but present in dermatophilosis.

CBC/BIOCHEMISTRY/URINALYSIS
Affected sheep may have leukocytosis and neutrophilia.

OTHER LABORATORY TESTS
• If needed, bacterial isolation of causative agents by culture can be performed.
• Impression smears of exudate reveal Gram-negative rods.

IMAGING
N/A

OTHER DIAGNOSTIC PROCEDURES
Skin biopsy

PATHOLOGIC FINDINGS
Skin biopsy reveals suppurative intraepidermal pustular dermatitis and superficial folliculitis.

TREATMENT

THERAPEUTIC APPROACH
• Affected sheep are typically not treated, and treatment is usually of limited benefit.
• Chemical drying of fleece may decrease wetness and incidence of fleece rot.
• A mixture of zinc and aluminum oxides with sterols and fatty acids applied as a mist may be protective. This mixture has been shown to reduce fleece moisture for 10–12 weeks, reducing fleece rot by 60%.
• Prevention through selection of sheep with fleece resistant to wool rot is the most practical approach.

SURGICAL CONSIDERATIONS AND TECHNIQUES
N/A

MEDICATIONS

DRUGS OF CHOICE
Antibiotic treatment is of limited value due to the nature of *P. aeruginosa* to be resistant to many antibiotics.

CONTRAINDICATIONS
N/A

PRECAUTIONS
• Chemical drying agents should be compatible with other dipping chemicals (e.g., insecticides).
• Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS
N/A

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
N/A

POSSIBLE COMPLICATIONS
• Affected animals are susceptible to blowfly strike.
• Affected sheep may develop secondary *P. aeruginosa* infections of the skin characterized by granulomatous scabs on the wool-free areas of the legs and scrotum.

CLIENT EDUCATION
Knowledge of risk factors and methods of prevention of fleece rot will help reduce prevalence in flocks.

PATIENT CARE
N/A

PREVENTION
• Shearing sheep before wet season may minimize wool rot, along with selection of breeds that are resistant to fleece rot.
• Heritability of resistance is estimated to be between 0.35 and 0.4 and selective breeding programs are recommended for high-risk areas.
• In the Merino breed the FBLN1 (fibulin) and FABP4 (fatty acid binding protein 4) genetic markers have been identified as key factors in the ability to resist fleece rot. Future efforts to select for these markers could allow for selection of a more resistant population of sheep.
• A killed *P. aeruginosa* vaccine has been found to be protective against severe exudation and may become a viable option in the future.

MISCELLANEOUS

ASSOCIATED CONDITIONS
• Affected sheep are at risk for blowfly strike.
• Prolonged wetting of the skin may predispose sheep to "pink rot," which is caused by a bacterial infection of the skin with *Bacillus* spp. Affected fibers are found at shearing and appear as a mat of wool in creamy pink exudate.

AGE-RELATED FACTORS
Wool rot is more common in young sheep.

ZOONOTIC POTENTIAL
N/A

PREGNANCY
N/A

BIOSECURITY
N/A

PRODUCTION MANAGEMENT
• Fleece rot is of major economic concern.
• Fleece wettability can be determined by taking a sample of staple and placing it in a wet plastic cylinder with one end in water. The mass of water taken up in a given time is measured. Results are consistent and capable of distinguishing resistant sheep from susceptible sheep.
• Susceptible fleeces are identified as having thin staples of unevenly crimped wool.

SYNONYMS
• Canary stain
• Fleece rot
• Water rot
• Wool rot
• Yolk rot

WOUND MANAGEMENT

BASICS

OVERVIEW

Wound: An interruption in the continuity of the external surface of the body. Wounds may be restricted to the skin but often involve underlying and adjacent tissues.

Wound healing: A host's attempt to restore tissue continuity.

Proper understanding of the mechanism of wound healing allows the practitioner to select appropriate wound management techniques to decrease mortality and improve outcome.

SYSTEMS AFFECTED

- Musculoskeletal
- Integument

PATHOPHYSIOLOGY

Wound healing: A dynamic process which involves complex interactions between cellular and biochemical events. For simplicity it is divided into three phases.

1. Inflammation (1–6 days)—after initial vasoconstriction this phase is dominated by increased vascular permeability and subsequent edema with resulting influx of white blood cells and inflammatory mediators. Fibrin clot formation and debridement of contamination and necrotic tissue by white blood cells occurs.
2. Proliferation (3–14 days)—epithelialization, fibroplasia and angiogenesis result in granulation tissue formation and ingrowth of epithelium from the wound edges.
3. Maturation/Remodeling (14 days onwards)—wound contraction and remodeling, with fibroblast degradation and a balance between collagen synthesis and catabolic activity.

PHYSICAL EXAMINATION FINDINGS

Variable depending on location, severity, and involved structures. See "Therapeutic Approach" for details on patient and wound evaluation.

CAUSES AND RISK FACTORS

- Common causes—mechanical trauma.
- Other causes—neoplasia, burns, hypothermia, chemical-induced trauma, and infection.
- Generally:
  - Penetrating or puncture wounds—deceptive in nature and can appear minor, but should always be considered serious. Bacteria, dirt, and foreign material can be translocated into the deep tissue by the penetrating object.
  - Incised wound—injury created by a sharp object that leaves clean-edged wounds.
  - Lacerated wounds—unlike incised wounds, these have rough and irregular edges and are more prone to infection.
  - Abrasion—a scrape, friction burn, or excessive rubbing are common causes. They are a minor problem compared to the others and involve only the top layer of the skin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

N/A

CBC/BIOCHEMISTRY/URINALYSIS

CBC—unremarkable in minor cases, but might be warranted in complicated wounds with involvement of deeper structures (e.g., osteomyelitis) or body cavities.

OTHER LABORATORY TESTS

- Cytology—evaluation of synovial, peritoneal, or pleural fluid is indicated when involvement of synovial structures or body cavities is suspected.
- Bacterial culture—evaluation of deep and chronically infected wounds as well as synovial, peritoneal, or pleural fluid when indicated.

IMAGING

- Ultrasonography—assessment of degree and severity of soft tissue involvement (e.g., ligaments, tendons), joint abnormalities, and presence of foreign bodies.
- Radiography—assessment of bony involvement (e.g., fractures, sequestrum formation) and radiodense foreign bodies.
- Contrast radiography—to evaluate the extent of wound tracts (puncture wounds).

OTHER DIAGNOSTIC PROCEDURES

- Palpation—using digital palpation or a probe to explore the wound and surrounding tissue to assess the extent of the wound and soft tissue damage. Perform after initial preparation and removal of gross contamination.
- See also "Imaging."

TREATMENT

THERAPEUTIC APPROACH

- Physical examination—vital parameters to assess systemic involvement (e.g., shock, blood loss, generalized or localized sepsis).
- Evaluation of the wound and involved structures
  - Chemical restraint (use of sedation)
  - Local anesthesia—regional anesthesia or a local block (e.g., lidocaine 2%). General anesthesia may be necessary for extensive injuries or for cast application.
  - Preparation of the wound—clipping of hair and scrubbing of wound surroundings (povidone-iodine or chlorhexidine scrub). Wound lavage with lactated Ringer's solution or isotonic saline. A 60 mL syringe with an 18-gauge needle can be used. It applies a pressure between 8–15 psi, preventing further damage and deeper translocation of bacteria into the wound.
  - Povidone-iodine 0.1% solution or chlorhexidine 0.05% solution—recommended at this concentration to minimize cytotoxic effects on the tissue. Further debridement—sharp resection of devitalized tissue (scalpel blade, scissors).
  - Exploration of the wound—digital palpation or use of a probe. Evaluation of soft tissue structures, extent of the wound, potential involvement of synovial structures or body cavities.
- Suspected synovial structure involvement—synoviocentesis (cytology and culture), infusion of sterile saline, and observation for fluid leakage from the wound.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Primary Wound Closure

- Provides the greatest rate of healing and faster return to normal function. Indicated for recent wounds with minimal contamination.
- Closure—simple continuous or interrupted sutures. Tension relieving sutures (e.g., horizontal or vertical mattress, far-near-near-far) may also be required.
- Drain placement—when dead space is present (first 48–72 hours).

Suture removal: 10–14 days.

Delayed Primary Closure

- Indicated for older wounds, presence of intermediate contamination, and/or history of topical application of irritants.
- Closure—perform after initial treatment (debridement and lavage) when healthy granulation tissue has developed and no signs of infection are present.

Second Intention Wound Healing

- Indicated for heavy contamination, excessive soft tissue damage or dead space, or extensive tissue loss. Requires greatest time to heal and functionality might be impaired due to scar formation.
- Treat with topical medication and bandage application; highly mobile areas (e.g., joint surfaces on distal limbs) may require application of a splint bandage or cast for immobilization.

MEDICATIONS

DRUGS OF CHOICE

Systemic Medications

- Anti-inflammatory drugs—NSAIDs (e.g., flunixin meglumine 1.1 mg/kg body weight, IV, q24h; ketoprofen 3 mg/kg, IV/IM, q24h)

(CONTINUED) WOUND MANAGEMENT

can have some negative effects on wound healing but are indicated for patient comfort and control of swelling.
• Antimicrobial drugs—depending on severity of the wound. With involvement of synovial structures and/or body cavities, broad-spectrum antimicrobial therapy might be indicated based on common contaminants. A more targeted approach can be instituted after receiving culture results. Beta-lactam antimicrobials (penicillin, ceftiofur, amoxicillin, ampicillin) or potentiated sulfonamides (where permitted) are most commonly used.
• Tetanus toxoid—animals with significant tissue damage, penetrating wounds, and risk of anaerobic infection. Administer as per manufacturer's instructions.
• Regional medications
  ◦ Regional limb perfusion—distal limb wounds. Delivery of high antimicrobial concentrations (broad spectrum, concentration dependent antibiotic) to the affected area.
  ◦ The addition of a local anesthetic (e.g., lidocaine 2%) can facilitate patient management and manipulation of the wound (e.g., debridement).

Topical Medications

A variety of different wound dressings and wound care products are available, with little research performed on their effects on wound healing in ruminants. Extrapolation from other species (human, small animal, and horse) may guide the practitioner in their choice. Restrictions for food-producing animals must be considered. Note: all products containing nitrofurazone are prohibited from use in food-producing species.

Wound Dressings

• Inflammatory phase—adherent dressings aid in debridement (e.g., mesh gauze can be used to create a wet-to-dry bandage).
• Proliferative phase/Maturation and remodeling—semi-occlusive and nonadherent bandages can be used when bed of granulation tissue has developed (e.g., coated gauze, amnion).

CONTRAINDICATIONS

Glucocorticosteriods—can cause inhibition of the normal inflammatory response, leading to delayed wound healing. Contraindicated in pregnant animals.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

Variable, depending on type of wound, structures involved, and severity of the lesion.

POSSIBLE COMPLICATIONS

• Septicemia
• Localized spread of infection—synovial sepsis (joints, tendon sheath, bursae), osteomyelitis, myositis
• Tissue necrosis
• Loss of function (severe scar formation, degenerative joint disease)

PATIENT CARE

• Monitor for progression of wounds through the different phases and insure that applied treatments are not detrimental to progress.
• Monitor for signs of infection (color, size, and discharge), systemic sepsis, localized septic processes, and primary dehiscence, or tissue necrosis.

MISCELLANEOUS

ASSOCIATED CONDITIONS

Generalized or localized sepsis, loss of function, degenerative joint disease can all be associated depending on location and severity of the wound.

AGE-RELATED FACTORS

Wounds can be acquired throughout all life stages but the ability to heal has been shown to be best in young animals.

ZOONOTIC POTENTIAL

Certain secondary wound diseases are zoonotic.

ABBREVIATION

NSAID = nonsteroidal anti-inflammatory drug

Yak Management and Disease

BASICS

OVERVIEW

• Yak (*Poephagus grunniens* or *Bos grunniens*) is a long-haired, flat-headed, bushy-tailed domesticated bovine found in the mountain regions of Northern India, Nepal, Bhutan, Mongolia, Russia and predominately in the Qinghai-Tibetan Plateau.
• Yak can survive in very low temperatures (down to –55°C) and are found at an altitude of 3,000–5,000 meters above sea level and generally not below 2,000 m. They thrive well in the extreme harshness of cold mountain climates.
• Yak are raised for milk, cheese, butter, ghee (clarified butter), churpee (dry cheese), wool, draft power, manure, and pack purposes; they are closely linked with the social, cultural, and ritual activity and livelihood of Himalayan people such as the Sherpa community of Nepal.
• Population of yak and chauri (yak/hill cow hybrid) is estimated at 13 million in China, 6 million in Mongolia, and 26,288 in Nepal.
• In general, the male is called a yak and the female is called a nak.
• Crossing between male yak and local hill cow (*Bos indicus*) is very popular and the offspring are called Urang Jhopkyo (male) and Urang Chauri (female). Males are sterile and females are popular for milk production.

INCIDENCE/PREVALENCE

Data on incidence of disease in yak is scarce.

GEOGRAPHIC DISTRIBUTION

Himalayan region of Northern India, Nepal and Bhutan, Mongolia, Russia, and predominately on the Qinghai-Tibetan Plateau of China.

SYSTEMS AFFECTED

Depends on the disease.

PATHOPHYSIOLOGY

Depends on the disease but generally similar to other ruminants.

HISTORICAL FINDINGS

Depends on the disease but generally similar to other ruminants.

SIGNALMENT

Depends on the disease but generally similar to other ruminants.

PHYSICAL EXAMINATION FINDINGS

Depends on the disease but generally similar to other ruminants.

GENETICS

• Yak and cattle have same number of chromosome (2n = 60).
• Crossing of yak with local hill cattle is popular to increase meat and milk production and for better reproductive performance.
• The hybrids are found at lower altitudes and less harsh conditions than the highland environment of the yak.
• In Nepal, Brown Swiss bovine semen was used for cross-breeding with yak, with satisfactory results.
• F2, F3, and F4 generations and back-crossing are practiced in the yak mating system; however, farmers prefer F1 generation.
• F1 males are sterile.
• F1 hybrids grow faster and the milk yield is higher than with the purebred nak.
• The fat percentage in the milk of hybrids is lower than that of purebred nak.

CAUSES AND RISK FACTORS

Bacterial Diseases

• Anthrax—common in many regions of Asia
• Blackquarter— common in Nepal and perhaps other places
• Brucellosis—common throughout Asia
• Botulism—*Clostridium botulinum* type C has been identified in Tibet
• Hemorrhagic septicemia (HS)
• Johne's disease
• Mastitis—very common
• Tuberculosis—researchers tested 1,749 yaks in Tibet, found 12.7% positive reactors
• Calf scour—mostly due to *E. coli*
• Leptospirosis—causes abortion
• Contagious bovine pleuropneumonia
• Salmonellosis—common among yak in China
• Tetanus
• *Coxiella burnetii*
• Campylobacteriosis

Viral Diseases

• Foot and mouth disease—common in yak producing areas of Asia
• Rinderpest—yak are highly susceptible to rinderpest but now outbreaks not reported
• Bovine viral diarrhea/mucosal disease—detected in several provinces of Tibet
• Other—rabies, calf diphtheria

Parasitic Diseases

• Lice, tick, flea, mites—Psoroptidae and Sarcoptidae family of mites are commonly found in yak
• Babesiosis
• Hypodermiasis
• Gid (coenurosis)—reported in Bhutan
• Liver fluke disease—*Fasciola hepatica* and *F. gigantica*
• *Strongyles* spp., *Trichuris*, coccidia, *Dicrocoelim* and *Ascaris* are other common endoparasites of yak reported throughout Asia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Depends on the disease but generally similar to other ruminants.

CBC/BIOCHEMISTRY/URINALYSIS

Depends on the disease but generally similar to other ruminants.

OTHER LABORATORY TESTS

Depends on the disease but generally similar to other ruminants.

IMAGING

Depends on the disease but generally similar to other ruminants.

OTHER DIAGNOSTIC PROCEDURES

Depends on the disease but generally similar to other ruminants.

PATHOLOGIC FINDINGS

Depends on the disease but generally similar to other ruminants.

TREATMENT

THERAPEUTIC APPROACH

Depends on the disease but generally similar to other ruminants.

SURGICAL CONSIDERATIONS AND TECHNIQUES

Depends on the disease but generally similar to other ruminants.

MEDICATIONS

DRUGS OF CHOICE

Yak farmers use local medicines to treat diseases, such as locally brewed alcohol (Chhyang), Tibetan tea leaves, and the excreta of insects collected from trees in the case of red water disease, mustard oil and garlic in the case of bloat, Nirmasi (aconite roots) in poisoning, and Timur (prickly wood seed) for digestive problems.

CONTRAINDICATIONS

Appropriate milk and meat withdrawal times must be followed for all compounds administered to food-producing animals.

(CONTINUED) YAK MANAGEMENT AND DISEASE

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Depends on the disease but generally similar to other ruminants.

POSSIBLE COMPLICATIONS
Depends on the disease but generally similar to other ruminants.

CLIENT EDUCATION
Depends on the disease but generally similar to other ruminants.

PATIENT CARE
Depends on the disease but generally similar to other ruminants.

PREVENTION
Depends on the disease but generally similar to other ruminants.

MISCELLANEOUS

ASSOCIATED CONDITIONS
Depends on the disease but generally similar to other ruminants.

AGE-RELATED FACTORS
• Young calves are more susceptible to ascariasis and adults are susceptible to *Fasciola*.
• By 3–3.5 years Chauri and Jiulong males have reached nearly 58% of their adult weight.

ZOONOTIC POTENTIAL
Similar to cattle: Anthrax, tuberculosis, brucellosis, Q fever, rabies, salmonellosis.

PREGNANCY
• 90% of mating takes place during August to November
• Most calves born from April to July when they reach upper pasture area.

BIOSECURITY
• Quarantine and testing
• Isolate sick animal, especially if the disease is contagious, e.g., HS, rinderpest, FMD

PRODUCTION MANAGEMENT
• Yak are open grazers.
• The transhumance system of moving animals to upper pastures in summer and autumn and to lower pastures in winter and spring months is practiced for yaks and chauri.
• Due to the nomadic system of animal husbandry, yak are housed in a temporary type of shed for a short period (2–3 weeks) at one place and then moved on to the next stopping point in a similar way.
• During the winter months the yak are kept outside in a fenced open area close to the herder's house. During periods of heavy snowfall the young and productive yak are kept indoors on the ground floor of the permanent house.
• Average age of first calving of purebred nak is 4.23 years while for Dimjo and Urang Chauri it is 3.33 years and 3.87 years respectively.
• Average milk yield of nak is 720 L per lactation and for Dimjo and Urang Chauri it is 1,690 L and 1,300 L respectively.

Nutrition
• Yak consume less feed as compared to cattle due to their smaller rumen relative to body weight.
• Dry matter intake in kg per day for growing yak is calculated as DMI = 0.0165W + 0.04869 (W = body weight in kg).
• Dry matter intake in kg per day for lactating yak is calculated as DMI = $0.008W^{0.52}$ + 1.369Y ($W^{0.52}$ = metabolic body weight and Y = milk yield in kg per day)
• Voluntary intake (VI) ranges from 18–25 kg fresh forage in summer season to 6–8 kg per day under cold grazing conditions.
• Rumen volume ranges from 32.3 to 66.8 L in mature adult yak.

Energy
• The thermoneutral zone for the growing yak is estimated as 8°C–14°C.
• The fasting heat production (FHP) of the growing yak can be estimated as FHP = 916 kJ per kg $W^{0.52}$ per day.
• The metabolizable energy requirement for maintenance (ME_m) in growing yak is around 460 kJ per kg $W^{0.75}$ per day.
• The daily metabolizable energy requirement of growing yak has been estimated as ME (MJ/d) = $0.45W^{0.75}$ + (8.73 + 0.091W) DG, where W is the body weight and DG is daily gain (kg), and the efficiency of utilization of metabolizable energy for growth (k_g) in yak is 0.49.
• Researchers observed that lactating yak have better utilization of dietary energy than dry yak cows. Another study with lactating yak indicated that yak cows have a lower efficiency of metabolizable energy utilization for milk production (averaging 0.46) than dairy cattle (*Bos taurus*).

Protein
• There is no difference in the digestibility of dietary nitrogen between lactating and dry yak cows.
• Yak can use nonprotein nitrogen as efficiently as domestic cattle.
• Rumen degradable crude protein requirements for maintenance ($RDCP_m$; g per day) in the growing yak are around $6.09W^{0.52}$ g per day.
• Crude protein requirements for daily gain (DG $RDCP_g$; g per day) in growing yak can be estimated as $RDCP_g = (1.16/DG + 0.05/W^{0.52})^{-1}$.
• Total crude protein requirements for growing yak can be calculated as RDCP (g per day) = $6.09W^{0.52}$ + $(1.16/DG + 0.05/W^{0.52})^{-1}$.
• Yak may have evolved a mechanism to recycle more nitrogen to the rumen than cattle.

Minerals
• Mineral nutrition is poorly understood in the yak.
• Researchers have found that inorganic phosphate (P) is sufficient for various categories of yak (calves, heifers, dry cows, and lactating cows) during the warm season when grazing was on alpine meadows with good-quality pasture. But in the spring and early summer, dietary phosphate failed to meet yak requirements.
• Chinese researchers suggest that yak living in the Qinghai Lake area are suffering sodium (Na) and copper (Cu) deficiency and there may be a shortage of molybdenum on Tianzhu alpine rangelands.

YAK REPRODUCTION

BASICS

OVERVIEW

• The yak (*Poephagus grunniens or Bos grunniens*) is a unique species that thrives well in the extremely harsh conditions of mountain regions and is nomadic in nature.
• The crosses of yak (*Bos grunniens*) and local hill cattle (*Bos indicus*) are called chauri. The chauri are more productive than the female yak (nak) and can adapt to lower altitudes.
• Chauri farming is a main source of livelihood in the Himalayan regions.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Yak are found in the Himalayan regions of Nepal, Northern India, Bhutan, Mongolia, Russia, and on the Qinghai-Tibetan Plateau of China.

SYSTEMS AFFECTED

Reproductive

PATHOPHYSIOLOGY

• There is little information on the pathophysiology of reproductive disorders in the yak.
• Reproductive physiology in this species presents several characteristics.

Male Reproduction

• Male yak may display sexual behavior as early as 6 months of age but are not able to ejaculate spermatozoa until 18–24 months of age.
• Bulls tends to graze separately in winter and early spring and join the herd during the breeding season. They can detect estrous females from a long distance.
• Bulls have smaller testicular size compared to *Bos taurus* or *Bos indicus* cattle. Sperm production is similar to cattle but total sperm production is about 60% that of cattle.
• The yak scrotum is small with abundant hair, apparently an adaptation to the cold environment.
• The reproductive life varies from 3.5 to 14 years of age and may be breed-dependent. In general, bulls are used starting at 4 years of age and reach peak reproductive efficiency at 7 years.

Female Reproduction

Reproductive Anatomy

• The reproductive organs of the female yak are similar to those of the bovine, with several differences. The cervix is long (5–6 cm), the uterine body is short (1.5–3 cm), the ovaries are smaller than those of cattle and present fewer primordial oocytes.

Reproductive Physiology

• Puberty occurs between 13 and 30 months of age and is determined mainly by the body condition at the beginning of the breeding season. Age at first calving varies from 3 to 4 years.
• Follicular activity is seasonal.
• The breeding season starts in late spring and early summer, between May and July, depending on the geographic location. Peak activity is observed in the height of summer (July and August), when temperatures are at their highest and grass growth is at its best. Estrus frequency decreases and stops around November.
• Estrus cycle length varies between 18 and 22 days. A greater variation in the length of the estrus cycle has been reported but may be due to factors such as silent or nondetected estrus, delayed ovulation, or pregnancy loss.
• Estrus in the yak is greatly affected by the environment. Signs of estrus are similar but not as strongly displayed as in *B. taurus*. Physical changes of the reproductive organs during estrus are more obvious and include reddening and swelling of the vulva and mucus vaginal discharge.
• Signs of estrus are more intense in the early morning and evening. The duration of estrus is estimated at 12–16 hours. Ovulation generally occurs 12–24 hours after the end of estrus.
• Conception rates are very high in females with good body condition scores and approach 70% per cycle for both natural cover and artificial insemination. Under extensive management, pregnancy rates may vary from 40% to 80%.
• The average gestation period of the yak is 258 days, range 228–280 days. Almost all births take place during the day and only very few at night.
• Premonitory signs of parturition include isolation from the herd by the female that seeks a sheltered area. The first stage of labor is characterized by alternating body position between lateral recumbence and standing. Calves may be delivered in the standing position. Complete cervical dilation lasts up to 4 hours. The second stage of labor, fetal expulsion, lasts 20–30 minutes, and the third stage of labor, expulsion of the placenta, lasts 2–6 hours. The dam generally licks the newborn calf for about 10 minutes, after which the calf attempts to stand up and suck.
• Dystocia is a rare event in purebred yaks. Twinning incidence is about 0.5% of all births, but may be higher in some breeds.

Postpartum

• Postpartum anestrus duration varies from 70 to 125 days and seems to be influenced by body condition and month of calving.
• Most yak females are managed to calve twice in 3 years.

Artificial Breeding

Hormonal Control of Ovarian Activity and Ovulation

• Several techniques in cattle for estrus synchronization and induction of ovulation have been attempted in yaks. Induction of follicular activity and ovulation in anestrous yaks has been done using eCG or FSH.
• Treatment with eCG (100 IU) induces estrus 1–10 days later. GnRH injection is reported to induce estrus in >80% of anestrous females within 7 days, with conception rates >70%. Estrus synchronization in cycling yaks is possible using two injections of $PGF2_{\alpha}$ or analogs 10 days apart. Fertility at the induced estrus is excellent.

Artificial Insemination

Artificial insemination is used in some breeding projects both for purebred yaks and in cross-breeding schemes with *Bos taurus*.

Semen Collection and Evaluation

Yak bulls can readily be trained to serve an artificial vagina. Semen can be collected twice weekly. Ejaculates of adult yak bulls have a volume of 2–5 mL and a concentration of 7.5–16 million/mL. The proportion of normal spermatozoa is generally >70%. Motility varies between 70% and 85%.

Semen Processing

• Techniques for extending and freezing yak semen are similar to those used for the bovine. Many authors use yak milk as the milk extender. Extenders frequently used are sucrose based or lactose-citrate with 20% egg yolk and 3–7% glycerol. Glycerolated semen is equilibrated for 2–3 hours before freezing. Semen is frozen in various packages including ampules, pellets, and straws.
• Semen frozen in pellets is thawed out by agitation for 3–5 seconds in 2.9% sodium citrate solution, glucose-sodium citrate solution, or fresh skim milk solution at 38–42°C.

Insemination

• Technique of insemination is similar to that used for cattle. The cervix of estrous yaks is reportedly easier to penetrate than that of cattle. Females are inseminated twice, 12 hours apart, with 10 million progressively motile spermatozoa. The first insemination is generally performed 24 hours after the beginning of estrus and repeated 12 hours later.
• Conception rates of >80% are reported with two inseminations, the first at the end of estrus and the second 12 hours later. For optimum fertility, semen should be deposited in the uterine body.

Cross-breeding Between Yak and Bos taurus

• Cross-breeding between yak and species of cattle is often practiced to improve milk and meat yield in Asia. Pregnancy rates are generally lower in cross-breeding programs.
• Pregnancy loss (abortion or premature birth) are more frequent in females carrying hybrids. Pregnancy length is increased in female yaks carrying crossbred fetuses.
• Yak cows carrying hybrid calves are at higher risks for dystocia and may require more obstetric assistance.

YAK REPRODUCTION (CONTINUED)

Reproductive Failure

• Abortion, anestrus, and repeat breeding are common reproductive disorders.
• Reported abortion causes include brucellosis and chlamydiosis.

YEW TOXICITY

BASICS

OVERVIEW
• Yew or *Taxus* family of which all members are toxic.
• Evergreen shrubs or trees commonly used for landscaping.
• Leaves are simple, alternate needle-like that often appear as 2-ranked.
• Flexible seed cones that contain seeds that are nutlike and partially or wholly enclosed by a fleshy cup-like aril that varies from green to red orange to brilliant scarlet.
• Relatively palatable.

INCIDENCE/PREVALENCE
Mortality rate is high

SYSTEMS AFFECTED
• Cardiovascular
• Digestive

GEOGRAPHIC DISTRIBUTION
Worldwide

PATHOPHYSIOLOGY
• Toxicity is result of toxic alkaloids of which taxine A and B are the most toxic.
• Antagonism of myocardial calcium channels thus interferes with cardiac conduction leading to depression of atrioventricular conduction and heart block.
• Taxine at low dose also affects smooth muscle tone, thus manifests as decreased intestinal motility and uterine contractions.
• Volatile irritant oils are also present within the plant and in subacute cases will result in gastrointestinal inflammation.
• All parts, except for the avril, are toxic.
• Lethal dose in cattle is 2.0 g/kg body weight while goats are more resistant with lethal dose of 12 g/kg.

HISTORICAL FINDINGS
History of exposure to plants

SIGNALMENT
• Bovine, ovine, caprine
• Wild ruminants seem to be resistant to some species of *Taxus*.

PHYSICAL EXAMINATION FINDINGS
• Develop within minutes of exposure
• Acute collapse and death
• Dyspnea
• Tremors
• Subacute exposure: gastroenteritis

CAUSES AND RISK FACTORS
• Toxic principles are taxines A and B.
• Both fresh and dried leaves toxic; seeds toxic.
• Clippings are highly toxic.

DIAGNOSIS

• History of exposure to the plants
• Clinical signs
• Identification of plant in oral cavity or GI contents

DIFFERENTIAL DIAGNOSES
• Oleander
• Foxglove
• Rhododendron

CBC/BIOCHEMISTRY/URINALYSIS
No characteristic changes

PATHOLOGIC FINDINGS
• There are few lesions other than nonspecific organ congestion, including moderate pulmonary congestion and edema, and perhaps a few scattered ecchymotic hemorrhages which are changes typical of circulatory disturbances.
• Evidence of myocardial fibrosis on necropsy although this is not specific to this toxicity.

TREATMENT

THERAPEUTIC APPROACH
Supportive treatment

MEDICATIONS

DRUGS OF CHOICE
No antidote

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS
Extremely grave, most animals die.

PREVENTION
Do not allow access to *Taxus* spp. or clippings

MISCELLANEOUS

PRODUCTION MANAGEMENT
• Remove *Taxus* spp. from pastures.
• Do not allow access to yew clippings.

SEE ALSO
• Cardiotoxic Plants
• Oleander and Cardiotoxic Plant Toxicity

ZINC DEFICIENCY AND TOXICITY

OVERVIEW

Zinc (Zn) is an essential trace element that is a component of several enzymes, serves catalytic, structural and regulatory functions, and is essential for keratinization.

INCIDENCE/PREVALENCE

- Zn deficiency: Low
- Zn toxicity: Rare

GEOGRAPHIC DISTRIBUTION

Western United States and Canada: Forages with low concentrations of Zn; does not coincide with widespread clinical Zn deficiency.

SYSTEMS AFFECTED

Zinc Deficiency

- Dermatologic
  - Parakeratosis
- Digestive
  - Decrease in microvillus length → maldigestive, malabsorptive diarrhea
- Endocrine system
  - Decreased production of thyroid hormone, growth hormone, insulin, and testosterone
- Reproductive
  - Degeneration of the seminiferous tubules
  - Abnormal Leydig cell numbers and morphology
  - Reduced circulating testosterone
  - Abnormal sperm development and function
  - Abortion, fetal mummification, low birthweights, teratogenic defects, and reduced neonatal survival
  - Altered myometrial contractility and increased risk of hemorrhage postpartum
- Ophthalmology
  - Zn is needed for multiple steps in the metabolism of vitamin A to rhodopsin, and in its absence night blindness is seen.
- Immunology
  - Decreased response to hypersensitivity, decreased CD4 positive T-lymphocytes and B-lymphocytes, and neutropenia
- Musculoskeletal
  - Weakness
  - Poor suckle reflex
  - Reduced bone density and growth
- Neurologic
  - Altered concentration of hypothalamic neurotransmitters → altered sense of taste and smell → decreased appetite
  - Required for normal brain development and function
- Hematology
  - Decreased erythrocyte precursors in the bone marrow and increased erythrocyte osmotic fragility
  - Impaired platelet aggregation and increased bleeding time

Zinc Toxicity

- Digestive: Hepatic dysfunction, pancreatitis
- Urogenital: Glomerular damage and renal tubular epithelial necrosis (protein losing nephropathy)
- Hematology: Interference with glutathione reductase → oxidative damage → intravascular hemolysis

PATHOPHYSIOLOGY

- Plasma: ~0.1% total body Zn (99% protein-bound)
- No storage system → homeostasis primarily controlled at the level of intestinal absorption → largely dependent on the Zn status of the animal
- *Zn deficiency* affects multiple systems
  - Systems that have a high cellular turnover are most affected.
  - Alteration in prostaglandin metabolism affects the arachidonic acid cascade, luteal function, and myometrial contractions.
- *Zn toxicity:* Soluble Zn salts form in acidic abomasum → direct mucosal irritation and ulceration → absorbed into circulation and rapidly distributed to the liver, kidneys, prostate, muscles, bones, and pancreas. Zn salts interfere with the metabolism of other ions (Cu, Ca, and Fe) and inhibit erythrocyte production and function.
  - Mechanisms of toxicity are not completely understood.
  - Acute toxicity LD50 of Zn salts ~100 mg/kg.
  - Chronic Zn toxicosis in large animals caused by diets containing Zn >2,000 ppm.

HISTORICAL FINDINGS

Variable. See "Physical Examination Findings."

SIGNALMENT

Young pre-ruminants more susceptible to Zn deficiency because rumen microbes digest phytate, increasing Zn bioavailability.

PHYSICAL EXAMINATION FINDINGS

Zinc Deficiency

- Anorexia
- Reduced weight gain
- Diarrhea
- Lesions of the integument
  - Alopecia, rough hair coat
  - Deep fissures
  - Serum crusts
  - ± Pruritis
  - Distribution: face, neck and distal extremities and mucocutaneous junctions
- Poliosis: Reduced pigmentation of the hair around the orbits
- Loss of crimping in wool
- Deformed hooves
- Excessive lacrimation, nasal discharge, salivation
- Testicular atrophy, poor reproductive performance
- Reduced milk production, increased incidence of mastitis
- Immunodeficiency, delayed wound healing
- Poor suckle reflex in calves
- Night blindness

Zinc Toxicity

- Diarrhea
- Anorexia
- Lethargy
- Decrease in weight gain and milk production
- Intravascular hemolysis—icterus, hemoglobinuria
- Cardiac arrhythmia
- Seizures
- Ulcers in the oral cavity and esophagus
- Signs of copper deficiency

GENETICS

- Bovine hereditary zinc deficiency (lethal trait A46, Adema disease, hereditary parakeratosis, hereditary thymus hypoplasia)
  - Autosomal recessive
  - Reduced ability to absorb Zn
  - Friesian cattle
  - Signs seen 4–8 months after birth → fatal around 4 months if untreated
  - Prompt treatment of calves with oral zinc → recovery and normal development. Continued poor immune function.
- Inherited parakeratosis in Shorthorn beef cattle
  - Autosomal recessive
  - Reduced ability to absorb Zn

CAUSES AND RISK FACTORS

Zinc Deficiency

- Consuming a Zn-deficient diet
  - Diets high in phytates (seeds, nuts, legumes, cereals, and soy-based products), oxalates, or minerals (Cu, Ca, P, Mg, Fe) reduce Zn bioavailability
  - Successive cuttings of hay crops within a season
  - Highly mature forages
  - Cow's milk in diet
- Failure to absorb Zn from the gastrointestinal tract.
  - Hereditary zinc deficiency
  - Hypothyroidism
  - Intestinal parasitism
  - Malabsorptive syndromes
  - Competes with Cu, Fe, and Ca for absorption

Zinc Toxicity

- Sources: Paint, old car batteries, automotive parts, galvanized material, Zn oxide creams
- Over-supplementation

(CONTINUED) # ZINC DEFICIENCY AND TOXICITY

DIAGNOSIS

DIFFERENTIAL DIAGNOSES

Zinc Deficiency

- Endo- or ectoparasitism
- Other mineral deficiency
- Primary vitamin A deficiency
- Inherited epidermal dysplasia (Baldy calf syndrome)

Zinc Toxicity

- Primary Cu deficiency
- Immune mediated hemolytic anemia
- BVDV

CBC/BIOCHEMISTRY/URINALYSIS

Zinc Deficiency

- Lymphopenia
- ⇓ ALP (Zn-dependent enzyme), lacks specificity
- ⇓ free T4

Zinc Toxicity

- Regenerative hemolytic anemia
- ⇑ bilirubin
- ⇑ ALP
- ± ⇑ BUN and ⇑ creatinine
- Hemoglobinemia, bilirubinemia
- Hemoglobinuria, proteinuria
- Urinary casts

OTHER LABORATORY TESTS

- Serum [Zn]
  - Normal values: 0.8–1.2 µg/mL
  - Low sensitivity
  - Decreased with hypoalbuminemia, 60% bound to albumin
  - Inflammation → Zn sequestered
  - Spurious
    - Leach from RBC—serum should be separated within 4–6 hours
    - Rubber stoppers in many blood collection tubes are lubricated with a Zn-containing substance—use tubes with royal blue top
- Preferred samples for postmortem analysis—pancreas, bone, liver, and reproductive organs
- Erythrocyte [MT] (ELISA): Decrease in Zn deficiency. Levels are unaffected by transient plasma [Zn], but are affected by other metallo-ions.
- Feed trace mineral analysis

IMAGING

N/A

OTHER DIAGNOSTIC PROCEDURES

Skin biopsy: Hyperplastic superficial perivascular dermatitis with marked diffuse and follicular parakeratotic hyperkeratosis.

PATHOLOGIC FINDINGS

Zinc Deficiency

- Irregular epidermal hyperplasia, marked neutrophilic exocytosis, and extensive confluent parakeratosis
- Oral and esophageal ulcers
- Thymic atrophy
- Depletion of lymphoid tissue
- Inflamed gastrointestinal mucosa
- Decreased accessory sex gland size and Leydig cell number
- Degeneration of the seminiferous tubules
- Abnormal sperm morphology

Zinc Toxicity

- Hepatocellular centrilobular necrosis
- Renal tubular necrosis
- Pancreatic duct necrosis with fibrosis of interlobular fat
- Inflamed gastrointestinal mucosa

TREATMENT

THERAPEUTIC APPROACH

Zinc Deficiency

- Oral Zn supplementation (Zn oxide and Zn sulfate).
- Treat soil and forages with Zn-rich fertilizers.
- Antibiotics if secondary bacterial infections are present.
- Nutritional support: Total parenteral nutrition if diarrhea persists.

Zinc Toxicity

- Removal of the source of the Zn (rumenotomy) normally results in rapid decrease in plasma [Zn].
- Diuresis.
- Chelators (calcium disodium EDTA, D-penicillamine, or dimercaprol); No studies published to support beneficial effect or optimal therapeutic regimen.

SURGICAL CONSIDERATIONS AND TECHNIQUES

N/A

MEDICATIONS

DRUGS OF CHOICE

Zinc Deficiency

- Pre-ruminants: 0.5–1 g elemental Zn q24h mixed into milk replacer
- Adult: 20–40 mg elemental Zn/kg q24h orally
- Oral boluses of Zn in gel capsules can be used q48h.
- Zn complexed with amino acids or other low-M_r organic ligands (citrate, ascorbate, picolinate, proprionate) appear to be more bioavailable.
- Low-dose corticosteroids might enhance Zn absorption through induction of MT in some nonresponsive cases.

Zinc Toxicity

- Calcium disodium (EDTA) 100 mg/kg body weight, q24h, IV or SC for 3 days (diluted and divided into four doses)
- D-penicillamine: 110 mg/kg q24h for 7– 14 days
- Dimercaprol: 3–6 mg/kg q8h for 3–5 days

CONTRAINDICATIONS

Zn competes with Cu, Cd, and Mn for binding site on MT. Excess Zn administered → deficiency of these metallo-ions.

PRECAUTIONS

Appropriate milk and meat withdrawal times must be observed for all compounds administered to food-producing animals.

POSSIBLE INTERACTIONS

Chelators might increase systemic absorption of Zn from GIT and nonspecifically bind and promote elimination of Fe, Cu, and Ca.
- Ca-EDTA may exacerbate Zn-induced nephrotoxicity.
- Requires monitoring of serum [Zn].

FOLLOW-UP

EXPECTED COURSE AND PROGNOSIS

- *Zn deficiency*: Good with treatment. Response to treatment should occur within days:
  - Adults—resolution of hypersalivation and diarrhea
  - Calves—improved suckle
- *Zn toxicity*: May have long-term effects on the animal's health and productivity.

POSSIBLE COMPLICATIONS

Zn deficiency during periods of long bone growth → stunted indefinitely.

CLIENT EDUCATION

Proper trace mineral supplementation

PATIENT CARE

Serum [Zn] should be monitored to ensure correct dosing.

PREVENTION

- Supplementation in geologically Zn-deficient areas.
- Remove stray sources of Zn in pastures.

APPENDIX 1: CLIENT COMMUNICATION

BASICS

OVERVIEW

• Good communication is the foundation of a good veterinarian-client relationship. It is among the most important factors determining the volume of future caseload from your clients.
• Client communication can be the most difficult yet the most important skill we must master to be successful. Many veterinarians have changed careers because of their frustrations in dealing with clients and coworkers. With so much riding on the quality of your communication, you should be compelled to be the best communicator possible. This requires that you take 100% responsibility for all communication in which you are involved. That means having good command of both ends of the communication process.
• Most financially successful veterinarians are not only skilled in a specialized area, but are very good at client communication.
• Clients frustrated by automatic bank tellers, electronic supermarket checkout stations, and similar depersonalizing machines will place ever-increasing value on their scarcer human contacts.
• Seek first to understand, and then be understood; be empathetic. Ask questions and let the client talk. If we start by finding out what clients think is urgent and important, they are more likely to be receptive to what we think they need to improve or manage better.

Effective Listening Skills

The most significant of all veterinarian-client rapport builders is good listening skills. It is extremely important to become a good listener. It will benefit your practice in the following ways:
• Accurate history—good listening skills allow for an accurate exchange of information, which is critical for serving the client and patient properly.
• Reduced misunderstandings—good listening skills help eliminate misunderstandings, thereby increasing client satisfaction with your services and enhancing their perception of your professional competence.
• Increased client rapport—when clients feel you understand them and have listened effectively, it creates greater client trust. Good listening improves trust and maximizes the probability of maintaining a professional relationship in the future.
• Differentiation—since most people are poor listeners, good listening skills will improve your practice competence.
• The initial interview—(1) shapes client perception of the veterinarian and staff; (2) defines the service to be provided in terms of both problem and goal, and (3) is an important opportunity for client education (e.g., production management, herd health improvements, possible increased client/producer profits). In many cases, the initial interview may in fact be the most significant communication before outcome determinative events.

Self-Evaluation Skills

• How good are you at communicating with your clients? Let us examine ourselves. Self-critical thinking involves our ability to evaluate objectively one's own thought processes and beliefs, with reflective skepticism.
• Francis Bacon stated, "Man prefers to believe what he prefers to be true." This is reinforced by a survey of one million high school seniors (Gilovich, 1991). Seventy percent thought they were above average in leadership ability, and only 2% thought they were below average. *All* students thought they were above average in ability to get along with others, 60% thought they were in the top 10%, and 25% thought they were in the top 1%. A survey of college professors showed that 94% thought they were better at their jobs than their colleagues (ibid).

Effective Communication with Your Clients

• Valuing client feedback.
• Seven canons of client communications (adapted from Collins 2004, *Effective Communication with your Clients*).
  ◦ Ignorance is folly.
  ◦ Speed of reply to messages.
  ◦ Awareness of feedback.
  ◦ Treat all clients with courtesy.
  ◦ Respect your client's confidentiality.
  ◦ Correlating information between you and your clients.
  ◦ Securing client information.

Being an Effective Listener

• There are two tests of effective listening:
  ◦ Is the information being received and understood by the listener?
  ◦ Does the speaker perceive that he/she is being understood?
• By necessity, most veterinarians are reasonably proficient as listeners. Since they rely heavily on information the client provides, they listen carefully to get the facts straight.
• However, many veterinarians are not as good at creating the perception that they are receiving the information.

Obstacles to Good Communication

• Most people are not very good listeners. It is estimated that only about 60% of spoken information is accurately received.
• There are several reasons the information doesn't get through (adapted from J.A. Kline, *Listening Effectively*):
  ◦ The veterinarian/speaker is unclear or not specific enough, causing the listener to make assumptions.
  ◦ The listener is not paying attention due to lack of interest in the subject matter.
  ◦ The listener is preoccupied with other matters.
  ◦ The veterinarian/speaker is not saying what the listener wants to hear.
  ◦ The listener is busy formulating a rebuttal to something the speaker said previously.
  ◦ Most miscommunications are the result of poor listening, not poor articulation. Most people are passive listeners. Even when information is received and understood, the listener fails to acknowledge it.
  ◦ Passive listening also allows misunderstandings to go undetected.

Active Listening Skills

• The communication process consists of speaking and listening.
• Passive listeners take an active role in communication only when it is their turn to speak, leaving the process beyond their control at least half the time. Taking 100% responsibility for communication requires you to be specific and articulate in your own speech, and to actively facilitate the quality of the other party's communication when you are listening.

The Power of Questions

• Used properly, questions can give you great power in facilitating excellent communication with your clients as well as everyone else.
• Questions are the key to taking control of a conversation. The person asking the question is in control.
• Ineffective communicators don't ask enough questions. They tend to make statements and then stop, allowing the other person to make a statement. When you do that you relinquish control to the other party.
• The purpose of communication is the effective exchange of information.

Asking Relevant Questions (adapted from Italo, 1996)

The first rule of good communication is to ask frequent relevant questions. This is a very simple process where you listen carefully to the content and then ask questions that seek clarification, verification, motivation, or specificity.
• Clarification—Clarifying questions are those you ask when there seem to be inconsistencies or when you are not sure you understand what the person is trying to say. These questions are very important in avoiding misunderstandings.
• Verification—Verifying questions are questions you ask to verify that the information has been correctly received. It is particularly important to ask verifying questions when you have drawn a conclusion based on what has been said.
• Motivation—Motivational questions help you understand the reasons why people act and they give you insight into how they are likely to behave in the future.

• Specificity—People tend to speak in generalities. It is particularly important to ask specifying questions if the speaker is in an emotionally charged state. The more emotional we are, the more we tend to generalize. This is because our thought patterns become much more reactive and less analytic when we are upset.
• Relevant questions—Show interest in what the speaker is saying. When the speaker perceives you are interested, it creates a feeling of mutual respect.
• Acknowledging the speaker—There is little that is more frustrating than the feeling that someone you are talking to isn't listening. Speakers look for certain cues that acknowledge the message is being received. When speakers don't notice the cues they are looking for, they get the impression you aren't listening.
• Auditory and visual cues—When the speaker is speaking you should give both auditory and visual signs that you are listening.
• Listening check—This is a powerful tool that is extremely effective in creating rapport and improving the quality of your communication. A listening check is a statement that summarizes your understanding of what was just said. For instance: "So, what I hear you saying is that you are unhappy with your workers' heat detection ability." There are two types of listening checks: Listening checks for content and listening checks for feelings. Use listening checks frequently with your clients. It will improve your professional relationships.
• Don't get defensive—Defensiveness in communication only causes each party to become more entrenched in their position.
• Don't make the client wrong—No one likes to be wrong. If you make your clients feel wrong, it will surely embarrass them.
• Don't use absolutes—There are very few absolutes in life. Phrases using always, never, impossible, every, none, are seldom true and only serve to supercharge and polarize the conversation.
• Encourage interruptions—Interruptions are vital to good communication. They allow immediate feedback and prevent frustration and preoccupation. Encourage interruptions. You should also interrupt when appropriate. An appropriate interruption should be immediate, making a comment or asking a question that is directly relevant to the speaker's latest idea.
• Use an open body language—Your body language communicates how you are feeling. You should be very aware of maintaining a friendly and open body language with clients. Lean forward and listen with interest. Don't cross your arms or legs. This makes you look uneasy and defensive.

Client-Veterinarian Communications

• Help staff members streamline, personalize, and customize their communications to individual clients.
• Help associates and staff effectively manage their services to their existing client base.
Effective communications help:
  ◦ Deliver more revenue, a higher degree of client satisfaction, and higher client retention.
  ◦ Reduce the frequency and length of calls to the veterinarian.
  ◦ Eliminate misunderstandings and poor communications.
  ◦ Increase professional integrity.
  ◦ Allow staff and associates to track the results of the management implementation.
• Empower client communications through:
  ◦ A consultative approach to develop an effective solution to clients' agriculture- and management-based problems.
  ◦ A full array of integrated services that would enable clients to use one veterinary provider.
  ◦ Superior customer service, utilizing new technologies, while ensuring confidentiality and integrity.

Client's Expectations, Objectives, and Options

With effective communication, veterinarians should discuss the following with their clients.
Client Objectives and Expectations
• Specific veterinary services the client will receive from the veterinarian.
• Specific results the veterinarian is likely to achieve for the client.
• Costs associated with achieving those objectives.
• Time required to complete the veterinary services and achieve the results.
Client's Instructions
• Choice of options or strategies the client instructs the veterinarian to pursue.
• Impact of choosing particular options or strategies.
• Estimated fees and disbursements relative to those instructions.
Advice Given to the Client
• Options of treatments and procedures recommended by the veterinarian.
• Explanation of the drug withdrawal times.
• Importance of a valid veterinarian-client-patient-relationship (VCPR).
• Referral to other veterinary, animal science, university, or consulting professionals.
Course of Action
• Strategy to be undertaken by the veterinarian.
• Estimated length of time required to complete the plan of action.
Risk Analyses
• The client's potential liability
• The veterinarian's potential liability
• Risks or benefits associated with the services
• Veterinarian's and, if different from the veterinarian, the client's assessment of whether or not the likely outcome is justified by the expense or risk involved.

Fees and Disbursement Communications

The veterinarian should provide the client with a timely estimate of the fees or disbursements involved so that the client is able to make an informed decision. The estimate should reasonably include the following.
Basis for Charging Professional Fees
• Hourly rate
• Flat fee (i.e., per head basis)
• Other method of charging
Amount and Payment Date Agreements
• Initial monetary retainer
• Ongoing monetary retainers
• Accounts
Billing Details
• Facts or circumstances that form the basis of the cost estimate.
• Possible facts or circumstances that may result in an increase or decrease in the estimate.

SUMMARY

• In your clinic, client communication starts with the receptionist who answers the phone. Is he or she warm, friendly, and helpful? If not, the clients will already be insistent and defensive when you talk to them.
• The words "no" or "we can't" have harsh implications. You can always find a way around using it by saying, "we'll try, but . . . ." After all, we are always trying.
• If we recognize and have the desire to improve our communication skills, we need to take a critical look at our approach and how the client reacts to our suggestions.
• If your attitude is positive, there is always a better or improved way to deal with people.
• Communication is a life-long learning experience.

ABBREVIATION

VCPR = veterinarian-client-patient-relationship

APPENDIX 2: EUTHANASIA AND DISPOSAL

BASICS

OVERVIEW

• Humane procedures should be used to ensure that death is rapid, painless, and as distress free as possible. It is important to remember that not all methods used on a worldwide basis are humane and many cannot be classified as euthanasia.
• Animal handling prior to humane euthanasia is a key element of ethical euthanasia and should be carried out in a calm and respectful manner in appropriate facilities or areas.
• Humane euthanasia results in the rapid, complete, and irreversible loss of consciousness followed by cardiac and/or respiratory arrest.
• Death must be confirmed prior to animal disposal. Absence of a heartbeat or pulse is the best confirmation method but others include no movement over a prolonged period of time, continued absence of respiratory sounds with a stethoscope, lack of corneal reflex, and development of blue to gray mucus membranes and rigor mortis.
• Carcass disposal is considered a standard part of euthanasia and, if possible, planned prior to euthanasia.

SYSTEMS AFFECTED

• Cardiovascular
• Respiratory
• Nervous

GEOGRAPHIC DISTRIBUTION

Worldwide

SIGNALMENT

All ruminants

EUTHANASIA

METHODOLOGY

• Modified from 2013 AVMA *Guidelines on Euthanasia*
• May involve sedation or anesthesia prior to euthanasia
  ◦ Useful in an isolated case; often not performed in ruminant medicine
  ◦ Not practical in herd conditions where humans may be endangered by an injured animal
• Carcass disposal is the responsibility of both the veterinarian and owner/producer.
  ◦ Poisoning of wildlife from poorly disposed carcasses is the responsibility of the veterinarian.

ACCEPTABLE METHODS OF EUTHANASIA

• Sole means of euthanasia, no other agents used
• Humane death consistently occurs

Systemic Agents (Noninhaled)

• Barbiturates (e.g., pentobarbital, others)
  ◦ Advantages
    ▪ Good for single, restrained animal.
    ▪ Generally safe for veterinarian, handler, and animal.
    ▪ Rapid and pain-free onset of death.
  ◦ Disadvantages
    ▪ Not useful for herds or poorly restrained animal.
    ▪ Costly, depending on size of animal.
    ▪ DEA schedule II or III drugs require accurate accounting and paperwork and necessitate a secured, locked compartment in practice vehicle.
    ▪ Carcass disposal problematic due to drug residues.

ACCEPTABLE METHODS WITH CONDITIONS

• Specific conditions need to be met to ensure consistent humane death.
• May require an adjunctive method.
• Possibility of human error or injury to humans may occur with this method.

Physical Methods

• Gunshot—most common method for euthanasia on the farm; death from brain tissue destruction.
  ◦ Handguns
    ▪ Short barreled
    ▪ Fired with one hand within close range (1–2 feet)
    ▪ From .32 to .45 caliber for cattle (.22 caliber NOT recommended for adult cattle)
    ▪ Solid, lead bullets recommended over hollow point bullets.
  ◦ Rifles
    ▪ Long barrel
    ▪ Fired from shoulder
    ▪ Distance shooting
    ▪ 0.22 magnum, .223, .243, .270, .308, others for cattle
    ▪ 0.22 LR for sheep and goats
  ◦ Shotguns
    ▪ Close range (1–2 yards)
    ▪ Birdshot or slugs
    ▪ 20, 16, or 12 gauge preferred for adult cattle
• Penetrating captive bolt
  ◦ Mature cattle that can be restrained
  ◦ Various styles available
  ◦ Use doesn't always result in death and an adjunct method such as a second shot or IV potassium chloride may be needed.

ADJUNCTIVE METHODS

• Not acceptable as the solitary means of euthanasia.
• Used to ensure death after an acceptable means of causing unconsciousness.

Systemic Agents (Noninhaled)

• IV potassium chloride or magnesium sulfate; **after** captive bolt or administration of alpha 2 adrenergic receptor agonists that render the animal unconscious
• Lower residue risk (except alpha 2 receptor agonist medications)

Physical Methods (Unconscious Animals)

• Second shot or third shot, in event first was unsuccessful
• Exsanguination
  ◦ Controversial use
  ◦ Ventral portion of neck, used to ensure death
• Pithing—use entry site of bullet or captive bolt

UNACCEPTABLE METHODS

Considered inhumane under any circumstances.

Systemic Methods (Noninhaled)

• Use of IV or IM chemical agents such as disinfectants and high doses of salts (potassium chloride or magnesium sulfate) in a conscious animal
• Use of alpha 2 adrenergic receptor agonists alone or followed by large doses of IV salts in a conscious animal
• Air embolism
• Strychnine
• Sole use of neuromuscular blocking agents

Physical Methods

• Blunt trauma to the head or neck
• Electrocution with 120-volt electrical cord
• Drowning of a conscious or unconscious animal
• Exsanguination in a conscious animal

SPECIAL CONSIDERATIONS

• Neonates: Skulls are smaller so accurate placement is required for gunshot or captive bolt.
• Dams and fetuses
  ◦ Barbiturate overdose
    ▪ Fetus remains in a "sleep-like" state of unconsciousness
    ▪ Death in dam precedes fetus by 20–25 minutes
    ▪ If not rescued, do not remove from uterus or remove only after >25 minutes have passed; check closely to be sure fetus is not alive.
  ◦ Physical method recommended if fetus is to be rescued; follow with adjunctive method after fetus is removed.

FUTURE CONSIDERATIONS

• Carbon dioxide either alone or in combination has been used successfully in swine as an appropriate (with conditions) euthanasia agent.
• Recently studied in kid goats as an alternative to current methods.
• More work needs to be done but may provide an alternative for other ruminant species.

CARCASS DISPOSAL

LEGALITIES

• Must be legal and safe.
• Regional laws regarding disposal methods vary considerably; species to species variation as well
• Particularly important in large outbreaks of infectious diseases (e.g., anthrax) and reportable diseases.

• Barbiturate contamination of soil and water should be considered.

METHODS

Rendering

• Common and easy method; not a good choice for carcasses with known infectious agents and barbiturate-induced euthanasia.
• Carcass is cooked and separated into animal fat and protein which are used for animal foodstuffs and other industrial products.
• Most rendering facilities will not accept sheep carcasses due to scrapie and subsequent BSE concerns.
• Use of barbiturates must be disclosed.
• Vehicle should be sealed and not allow any drainage during transportation.

Closed Pit Burial

• Open pit no longer recommended due to groundwater contamination and access by scavengers.
• Good if permitted and owner/producer able to do under local laws.
• Preferred for many infectious diseases (except prions).
• Commonly used in natural disasters.
• Depth of burial, height of water table, soil composition, surface slope, and other factors must be considered.
• USDA READEO burial site recommendations: 4–6 feet depth, 150 feet from water wells and 100 feet from dwellings.
• Deep burial needed for anthrax-contaminated carcasses.

Composting

• Carcass goes through a two-stage slow "cooking" process. Stage 1 takes 2–3 months and stage 2 another 2–3 months. Core temperature must reach 130–160°F (55–71°C) for pathogen destruction.
• End result is water, carbon dioxide, and organic material.
• Bin composting generally involves a concrete floor below and roof above. Organic matter (e.g., manure) must cover carcass.
• Must be scavenger and predator free.

Incineration

• Good option if available.
• Burning carcasses successfully yields bone and ash free of pathogens (except prions).
• Recommended disposal for anthrax suspect carcasses in some states. Anthrax carcasses must be burned only to ash and the contaminated ash disinfected in sodium hydroxide (lye) and buried deeply.
• Open air burning banned in some regions.
• Biologic incineration by some laboratories and veterinary schools.
  ◦ Good for their specific needs but not a large-scale disaster.
  ◦ Requires transportation of carcass to the facility.
  ◦ Good for infectious diseases with prion agents (e.g., BSE).
• Controlled burning in an air-curtain incinerator or trench burner.
  ◦ Portable and environmentally friendly
  ◦ Useful in large-scale disasters
  ◦ Can also be used to burn contaminated vegetation.

Alkaline Hydrolysis (Tissue Digestion)

• Carcass is cooked with alkalis at high temperatures to produce a sterile solution composed of amino acids, sugar, and soap.
• Generally good for smaller animals (<200 pounds).
• Utilized for deer and elk contaminated with CWD.

Landfills

No longer an option in many areas.

APPENDIX 3: MEDICAL WASTE MANAGEMENT: EXPIRED DRUGS

BASICS

OVERVIEW

Note: Although the specific government agencies and acts mentioned below are specific to the US, the information is relevant globally.

• The therapeutic use of expired medications, medical devices or intravenous (IV) fluids is unacceptable in veterinary medicine, does not represent appropriate standard of care, and violates the FD&C Act.
• The proper disposal of these products and all other medical waste is the responsibility of each clinic, which should have routine policies and procedures in place to ensure appropriate disposal.
• Improper disposal of medical waste, including expired drugs, represents a significant burden on the environment, clean water, and impacts human and animal health. Detectable levels of some prescription and nonprescription drugs have been found in water supplies.
• Action should be taken to ensure proper disposal of medical waste, including expired drugs, wherever the source. Proper policies and procedures for medications either used in-clinic or dispensed to animal owners will prevent improper discharge of medications into the environment.
• Due to periodic changes in statutes, clinics should coordinate efforts with local and state hazardous waste agencies as well as state public health agencies to ensure proper collection, storage, and disposal of all waste from the clinic, including expired drugs.
• The AVMA provides directions and links to applicable agencies involved in medical waste management through their website (refer to "Internet Resources" section).

OVERVIEW OF MEDICAL WASTE

• Medical waste (which includes pharmaceuticals) in the United States is regulated, broadly, under the Medical Waste Tracking Act (MWTA) of 1988. Other Federal Acts including the FD&C Act, TSCA, FIFRA, RCRA, the Clean Air Act, and the Safe Drinking Water Act are also involved with medical and hazardous waste disposal.
• Medical waste is broadly defined under the MWTA as "any solid waste that is generated in the diagnosis, treatment, or immunization of human beings or animals … "
• Clinics produce medical waste from multiple sources including therapeutic agents (e.g., drugs, vaccines, pesticides), diagnostic materials (e.g., laboratory reagents, radiographic agents), sharps and medical or surgical products (e.g., intravenous supplies), blood or body fluids, and animal tissues or carcasses.
• Additional hazardous waste is generated from cleaning and disinfecting supplies and office and facility management supplies (e.g., batteries, light bulbs, paint).

OVERVIEW OF THE DISPOSAL OF MEDICAL WASTE

• The MWTA established a "Cradle-to-the-Grave" tracking system for parties that generate medical waste, standards for segregation, labeling and storage of medical waste, and penalties for organizations that fail to comply.
• Medical waste is often segregated at the site of generation by color-coded bins based on source of the waste or pathogenicity potential. These systems often lack consistency.
• Medical waste generated in the clinic should be segregated and secured away from usual trash until it can be properly collected and disposed of.
• Following site collection, most medical waste is incinerated down to ash or autoclaved to eliminate microbes before ultimate disposal at a landfill.
• No perfect system exists from the various disposal methods due to concerns over potential release of toxic agents into the air. Improvements in air scrubbers have dramatically reduced the amount of air pollution generated in the process.

Health Risks from Improper Disposal of Pharmaceuticals

• The stability or effectiveness of medications beyond their expiration date cannot be assured. Bacterial overgrowth in liquid formulations or problems with dissolution of solid dosage formulations of drugs poses a risk to the animal receiving an expired drug.
• Pharmaceuticals pose a risk to the environment, aquatic life, and the safe drinking water supply if improperly disposed.
• Measurable levels of some drugs have been identified in lakes, rivers, and streams sourced for potable water. Potential sources may include illegal or improper disposal into these bodies or leachate from landfills.
• Long-term health consequences from exposure to small amounts of drugs from potable water among humans or animals have not been well established; some have raised concerns that antibiotic resistance may be related to their presence in water supplies.

DISPOSAL OF CLINIC MEDICATIONS

• Clinics should develop policies and procedures to manage the inventory of prescription drugs.
• Limit storage areas for all drugs to prevent them from becoming "lost" in the clinic.
• Staff should be assigned to review expiration dates for all medications on hand at least every four weeks to identify medications approaching their date of expiration to ensure that they are disposed of before they are dispensed.
• Clinics should work with their supply chain to identify medication return or buy-back programs.
• Disposal of medications (even in small quantities) into the water supply via sinks and toilets is no longer acceptable practice in many jurisdictions.
• Safety Data Sheets (SDS) can identify special handling and disposal requirements for any medical waste including drugs, and cytotoxic or biologic agents including vaccines; however, in all cases, clinics should work closely with local and state hazardous waste disposal agencies to ensure appropriate measures are taken to segregate and dispose of all clinic waste.
• Special restrictions and requirements are in place for retrieval and disposal of federally controlled substances. Contact your local DEA office to discuss these requirements.
• Maintain records identifying specific medications, amounts, and the lot number and expiration date for each item removed from stock and the manner in which it was disposed of.

DISPOSAL OF CHEMOTHERAPEUTIC AGENTS

• Chemotherapeutic agents are occasionally used in ruminant animal practice.
• Policies and procedures should be developed to manage these unique agents from the time of intake and storage of the medication through the administration and disposal.
• In addition to the drug vials, all medical equipment used in their administration (e.g., IV bags, gloves, sharps) requires special handling and disposal as well.
• Professional organizations have established guidelines for handling antineoplastic agents to limit exposure risk from time of administration to disposal.

DISPOSAL OF DISPENSED MEDICATIONS

• Policies and procedures should be developed to address disposal of medications that have been dispensed to animal owners.
• To prevent wastage, only sufficient doses to cover treatment should be dispensed or prescribed and should be dispensed in appropriate containers to prevent loss or spillage.
• Veterinarians should be familiar with local and state statutes governing disposal of medications they have dispensed from the clinic to direct animal owners accordingly.
• Anti-parasitic agents (e.g., ivermectin, fenbendazole) used in ruminants are regulated as pesticides under FIFRA by the EPA and should be disposed of appropriately.
• Many towns and cities host "Medication Take Back" programs together with state and federal agencies such as the DEA to ensure that unused medication is disposed of correctly. These events can be highlighted to animal owners to increase safe disposal. (Refer to "Internet Resources.")

APPENDIX 4: PHYSICAL EXAMINATION: BOVINE

BASICS

OVERVIEW

• Gather information by asking appropriate questions and use interpersonal skills to clarify concerns and expectations; methodically evaluate body systems, and identify possible health problems. Obtain history, perform physical examination, and evaluate the herd environment. The overall goal of examination is to establish an accurate diagnosis or conclusion and to establish a plan of action.
• Formulate a complete problem list, define appropriate differential diagnoses, and determine the need for additional diagnostic tests.
• There are four major parts to a thorough health evaluation: History collection, physical examination, diagnostic testing, and data analysis.
• Physical examination on a herd basis requires a detailed history of the problem, number of animals affected, duration, factors that may have contributed to development or exacerbation of the problem, and how the problem has been managed to date.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

N/A

SYSTEMS AFFECTED

All systems must be examined in a thorough physical examination.

PATHOPHYSIOLOGY

GENETICS

N/A

HISTORICAL FINDINGS

Prior to beginning the clinical examination ask the owner for the presenting problem(s), the signalment (age, sex, production group), history of the animal(s) affected, and other relevant information. The history should encompass the type, onset, and duration of clinical signs, and epidemiologic data such as the number of affected animals and the distribution of disease in the herd.

SIGNALMENT

Bovine

PHYSICAL EXAMINATION FINDINGS

• Observe the animal(s) at a distance for abnormalities of behavior, posture, gait, body condition, symmetry, and abdominal distention.
• If the animal is lame, identify the affected leg by observing the animal walk, or via abnormal weight bearing at rest. For more subtle lameness, examine carriage of the head and hips when the animal walks. Lameness often affects the front feet and the animal will raise its head while bearing weight on the affected front leg and lower its head while bearing weight on the non-affected front leg. The animal will hike its hip when bearing weight on an affected hind leg. Once the affected leg is identified, the animal should be restrained and the foot and leg examined. The most common causes of foot lameness are sole ulcer, sole abscess, "strawberry foot rot" (digital dermatitis), and "foot rot" (interdigital necrobacillosis). Palpate joints and tendon sheaths for size, effusion and pain. Septic joints are generally enlarged, distended with fluid, and very painful.
• Use a geographic approach to perform a detailed examination. Commence at the rear of the animal and proceed to examine the left and right sides of the animal. Perform a per rectum examination and examine the head last. Follow the same sequence of steps (steps 1–7 [Figure 1] and steps 8–12 [Figure 8]) each time an examination is performed to avoid missing abnormal findings.

Step 1. Rear of the Animal

• Obtain a urine sample. Normal passage of urine that is clear and amber suggests a normal urinary tract. A urine sample may be obtained from a cow or heifer by stroking the vulva or perineum. Straining and/or difficult urination suggest an abnormality of the urinary tract and requires further examination. Observe the vulva for blood, fetal membranes, discharge, or pus. In the male, observe the prepuce for blood, pus, or ventral swelling. Examine the preputial hairs of male animals for crystals/uroliths.
• Urine, blood, or milk should be examined for ketone bodies using a cow-side test. The presence of ketone bodies indicates the cow is mobilizing body fat faster than the liver can metabolize it. The circulating ketones are acetone, acetoacetate, and beta-hydroxybutyrate (BHBA). Cow-side tests measure both acetone and acetoacetate or BHBA. The gold standard for ketone testing is measurement of BHBA. Routine monitoring of BHBA in early lactation cows on a herd level using >1.4 mmol/L BHBA as positive, is often used as a diagnostic tool to monitor the transition period from dry to lactating cow.
• Insert a lubricated thermometer into the rectum. Normal temperature is 38.5°C (101.3°F; range 38.0–39.0°C [100.4–102.2°F]) for adults, and for calves is 39.0°C (38.5–39.5°C [101.3–103.1°F]). Temperatures of pen mates can be used to assess seasonal influences.
• Obtain a pulse from the coccygeal artery on the ventral midline of the tail. The normal pulse is 60–80 beats per minute (bpm). Examine the vulvar mucus membranes of cows and heifers, which should be moist and pink.

Step 2. Left Side: Heart

• Observe the jugular and mammary veins for distention or pulsation. Examine the jugular vein for filling and emptying and check the brisket and submandibular area for edema. Distended jugular veins are abnormal and suggest right-sided heart failure or pericardial effusion. Normal animals should not have significant jugular pulses when the head is elevated. Occlude the jugular vein with a finger. The jugular vein will fail to empty after releasing the occlusion if cardiac disease is present. Pinch the skin of the neck to assess hydration status.
• The stethoscope should be placed deep into the left axilla to find the pulmonic (3rd intercostal space), aortic (4th intercostal space), and mitral (5th intercostal space)

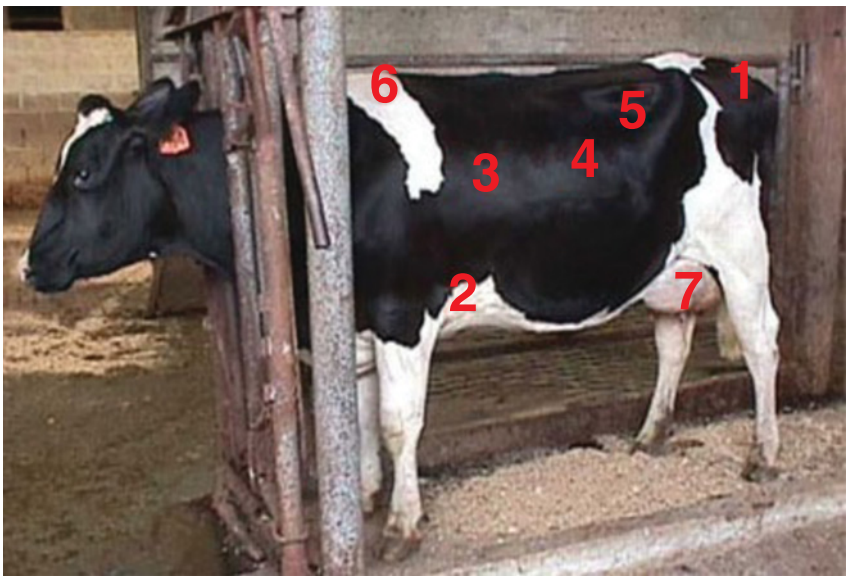

Figure 1.

Examination steps on the left side of the cow. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Figure 2.

Normal lung field on the left side of the cow. (Also availalbe in color at www.fiveminutevet.com/ruminant)

valves. Carefully evaluate the rate, rhythm, and heart sounds. The heart should be clearly audible on the left side. S1 and S2 heart sounds are expected and S3 and S4 heart sounds occasionally heard. Muffled heart sounds can be caused by pericardial or pleural effusion. Normal heart rate is 60–80 bpm in adults, and 80–120 bpm in calves. Most animals with cardiac disease have tachycardia, but fever or toxemia also cause tachycardia. Bradycardia (<60 bpm) is most often associated with vagal indigestion. Occasionally bacterial endocarditis of the mitral valve will cause a left systolic murmur. Traumatic reticuloperitonitis typically presents with muffled hearts sounds and a "washing machine murmur." Atrial fibrillation is a common rhythm abnormality, reflected by an irregularly irregular heart rhythm. It is most often associated with GI problems such as a left displaced abomasum (LDA).

Step 3. Left Side: Lungs and Skin

• Observe the rate and effort of respiration. Respiratory disease is common in cattle and is often first diagnosed by observation from a distance. Signs of respiratory disease include coughing, respiratory distress, open-mouth breathing, and mucopurulent nasal discharge. Most cattle with respiratory disease will initially have a fever. The normal respiratory rate in adult cattle is 15–35 breaths per minute and in calves 20–40 breaths per minute.

• Auscult the lungs, moving the stethoscope systematically over the entire lung field. The lung field in the bovine is small and the caudal border extends from the 11th rib to the elbow (Figure 2). Normal lung sounds are quiet during auscultation and louder on inspiration than expiration, and in the ventral lung fields compared to the dorsal lung fields. Upper airway abnormalities can create referred abnormal inspiratory sounds. Breath sounds of increased or decreased intensity can be abnormal. Lung consolidation (pneumonia) often results in louder than normal large airway breath sounds in the ventral lung fields. Crackles, wheezes, and pleural friction rubs are abnormal sounds. The animal can be induced to take deeper breaths by either holding off the nostrils or placing a plastic bag over the animal's muzzle for 30–60 seconds.

• Palpate the trachea. A cough can generally be elicited in animals with pneumonia.

• Palpate the skin on the left side and ventral abdomen. Feel dorsally for subcutaneous emphysema. Examine the prescapular (superficial cervical) lymph node cranial to the point of the shoulder and the prefemoral (subiliac) lymph node cranial to the stifle. Lymph nodes are enlarged in lymphosarcoma.

Step 4. Left Side: Pings

• "Ping" the left side of the animal by simultaneously percussing and ausculting the whole left abdomen by firmly flicking a finger against the body wall. A "ping" represents a fluid-gas interface or gas accumulation. On the left side of the animal, gas may be present in the abomasum (LDA), rumen, or peritoneal cavity (Figure 3). Classically, an LDA ping occurs in the mid-thoracic area on a line between the elbow and the tuber coxa (Figure 4), and may extend to the cranial edge of the left paralumbar fossa. LDA pings and rumen pings often occur concurrently and are usually distinguished by location and different tones during auscultation and percussion (Figure 3). A rumen void ping occasionally occurs when the rumen is small on per rectum palpation and extends over both the rumen and LDA area. The monotone nature of the rumen void ping helps to distinguish it from a concurrent LDA and rumen ping.

• Observe the abdomen from a distance. The left caudal rib can have a "sprung" appearance with an LDA. Animals with rumen bloat or vagal indigestion will have distention over the rumen and right ventral abdominal quadrant.

Figure 4.

Dashed line is typical location of ping for LDA. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Step 5. Left Side: Rumen

• Listen to the rumen by placing the stethoscope over the left paralumbar fossa. Normal rumen contractions (1–3 per minute) are strong. Palpate, auscult, and ballot the rumen to assess consistency. The dorsal sac of the rumen has a gas cap. The rumen becomes doughier towards the ventral fluid-filled sac.

Step 6. Left Side: Withers Pinch Test

• Pinch the withers (Figure 5). A normal animal will flex ventrally when its withers are pinched, and an animal with thoracic or abdominal pain will not, although false negatives are common. Animals with GI pain will often stand hunched with their elbows abducted. They may tread their hind feet, but overt signs of "colic" are rare. Common reasons for abdominal pain are traumatic reticuloperitonitis (hardware disease) and abomasal ulceration.

• Perform a "grunt test" by either using a fist pushed up with a knee (Figure 6), or a board with one person on each side lifting the board

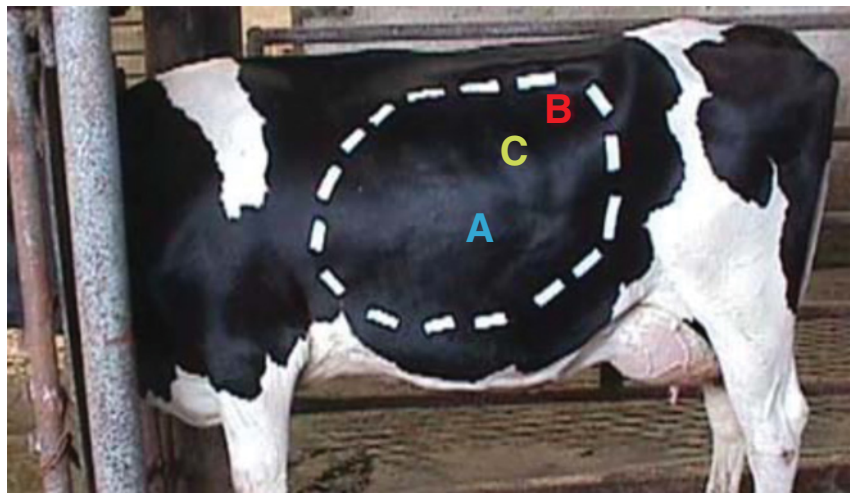

Figure 3.

Dashed line is area to percuss for a "ping" on the left side. A = location of left displaced abomasum (LDA) ping; B = location of rumen ping; C = location of both rumen and LDA ping. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Figure 5.

Withers pinch test. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Figure 6.

Grunt test. (Also availalbe in color at www.fiveminutevet.com/ruminant)

to apply pressure to the xiphoid area. Grunting or kicking indicates pain. Often a grunt is only heard while simultaneously applying pressure to the xiphoid area at the peak of inspiration and ausculting over the trachea. As with the "withers pinch test" false negatives are common.

Step 7. Left Side: Udder

• Strip milk from each quarter into a strip cup (Figure 7) or onto a mastitis plate. It is possible to compare quarters by stripping each quarter's secretion onto the last quarter's secretion, then repeat in reverse order.

Figure 7.

Obtaining milk from each quarter. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Subtle abnormalities in secretions from quarter to quarter will be detected by this method.

• Palpate each quarter for edema, hardening, and swelling to detect clinical mastitis.

• Palpate the mammary lymph nodes in the proximal caudal aspect of the udder.

• Integrate findings with the rest of the physical examination; e.g., a cow with clots in the milk and a normal examination is not likely to be sick from the mastitis; whereas a cow with a watery secretion, acute swelling of the udder, and an elevated heart rate and temperature is likely sick from the mastitis.

• Bacterial culture of the milk can identify specific bacterial agents causing mastitis.

• Many cow-side tests are available to determine degree of inflammation in the udder. The California Mastitis Test gives a semi-quantitative estimate of the somatic cell count (SCC) in milk.

• Electronic SCC counters are commonly used to assess inflammation in the udder and to determine udder infection status on a herd level. The SCC data can be used to identify cows with high SCC, the percentage of SCC each cow contributes to the bulk tank, and overall SCC trends in the herd. Ideally a composite milk sample should have SCC <200,000 cells/mL.

Step 8. Right Side: Heart

• Examine the right jugular vein for filling. Distended jugular veins are abnormal and suggest cardiac disease (Figure 9) or thrombosis. Jugular pulses should be minimal when the head is elevated. Occlude the jugular vein; failure to empty after releasing occlusion suggests cardiac disease is present.

• The heart is ausculted similarly on the right side as the left (Figure 8), but cardiac sounds are usually quieter than from the left side. The tricuspid valve is located at the third intercostal space halfway between the elbow and shoulder, and is the most common site for bacterial endocarditis in cows. Early signs of bacterial endocarditis are fever, pain, and tachycardia. Advanced signs include murmur, distended jugular veins, and submandibular (Figure 10) and brisket edema (Figure 11), resulting from right-sided heart failure.

Step 9. Right Side: Lungs and Skin

• Auscult the lungs by moving the stethoscope systematically over the entire right lung field. It is comparable in size to the left lung field and the caudal border extends from the 11th rib to the right elbow.

• Palpate the skin of the right side and ventral abdomen. Examine the prescapular and prefemoral lymph nodes.

Step 10. Right Side: Pings

• "Ping" the right abdomen and carefully delineate the borders of any pings (Figure 12). Right side pings can arise from gas and fluid accumulation in the cecum, spiral colon, small intestine, duodenum, uterus (post-calving), peritoneum, rectum, or abomasum (from right displaced abomasum [RDA] or right displacement with torsion [RTA]). It is not uncommon to find a ping in the right paralumbar fossa of sick cows. A distended cecum will produce a large ping and is palpable per rectum. Pings from RDA or RTA are usually cranial to the 8th rib, and more cranial in location compared to LDA pings. The severity and degree of torsion of a right displaced abomasum is associated with the heart rate and degree of dehydration of the cow.

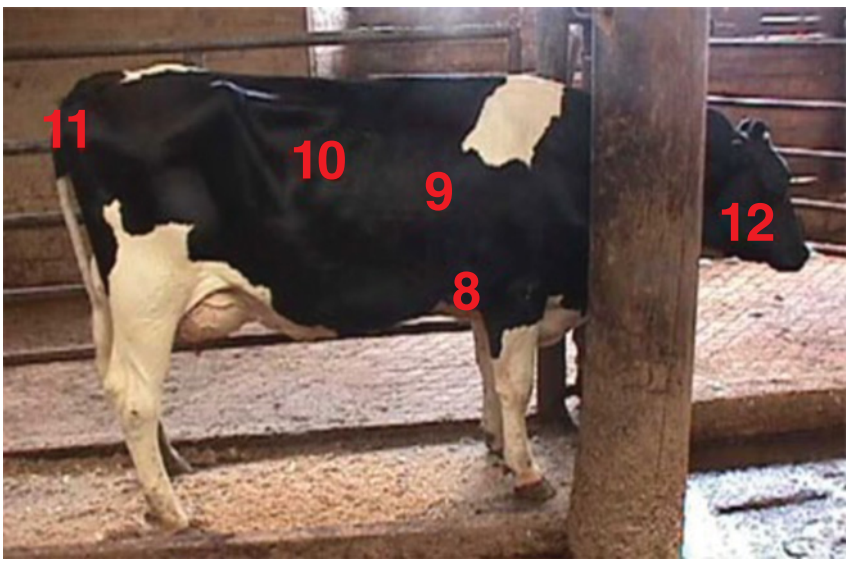

Figure 8.

Examination steps on the right side of the cow. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Figure 9.

Jugular venous distension. (Also availalbe in color at www.fiveminutevet.com/ruminant)

• Ballot the right abdomen for detection of a fetus (≥7 months) or infrequently a mass (abscess, tumor, etc.).

Step 11. Rear: Per Rectum Examination

• Examine the perineum and tail for blood, mucus, and feces. Normal cows have a clean perineal area. Fresh blood on the tail indicates recent estrus; clear mucus suggests a cow's proximity to estrus or parturition. Postpartum metritis can cause watery, brown-red malodorous uterine discharge. Examine quantity, color, and consistency of feces in the rectum. Lack of feces suggests reduced fecal output. Large quantities of liquid feces suggest an intestinal problem such as Johne's disease, winter dysentery, or salmonellosis. Black feces (melena) suggests bleeding from the small intestine or abomasum (ulcer). Fresh blood indicates bleeding from the distal large intestine (e.g., coccidiosis). Cows with hemorrhagic bowel syndrome often have large quantities of fresh blood in the feces.

• Perform per rectum examination in a consistent sequence. Palpate the rumen left of midline for size and consistency. The rumen should be palpable in the cranial abdomen. The dorsal contents may have some gas and are generally doughy or will "pit" compared to the ventral more fluid contents. Absence of a readily palpable rumen often results in a "rumen void" ping which can be confused with an LDA. Then palpate the left kidney located to the right of the rumen on the midline. The palpator's arm is normally inserted beyond the elbow to find the left kidney unless it is enlarged, which most commonly occurs in pyelonephritis. Continue to palpate towards the right abdominal wall. The right abdomen should feel empty in normal animals. There should be no discernible distention of the cecum or small intestine in this region. An RTA can occasionally be palpated in the far cranial right abdominal region. Palpate the deep inguinal (iliofemoral) lymph nodes cranially along each shaft of the ileum.

• In female animals the cervix lies on the floor of the pelvis. Examine the reproductive tract and determine the reproductive stage of the cow. The bladder is occasionally palpated cranial to the brim of the pelvis if it is full.

• In intact male animals used for breeding purposes a detailed examination of both the internal and external genital organs should be performed. Per rectum, examine the pelvic urethra, ampullae of the vas deferens, prostate gland, seminal vesicles, and bulbourethral glands. Examine all the external genital organs including the scrotum, testes, epididymis, spermatic cord, and penis.

Step 12. Head

• Examine the head last, since cattle often resent manipulation. Palpate the ears;

Figure 10.

Submandibular edema. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Figure 11.

Brisket edema. (Also availalbe in color at www.fiveminutevet.com/ruminant)

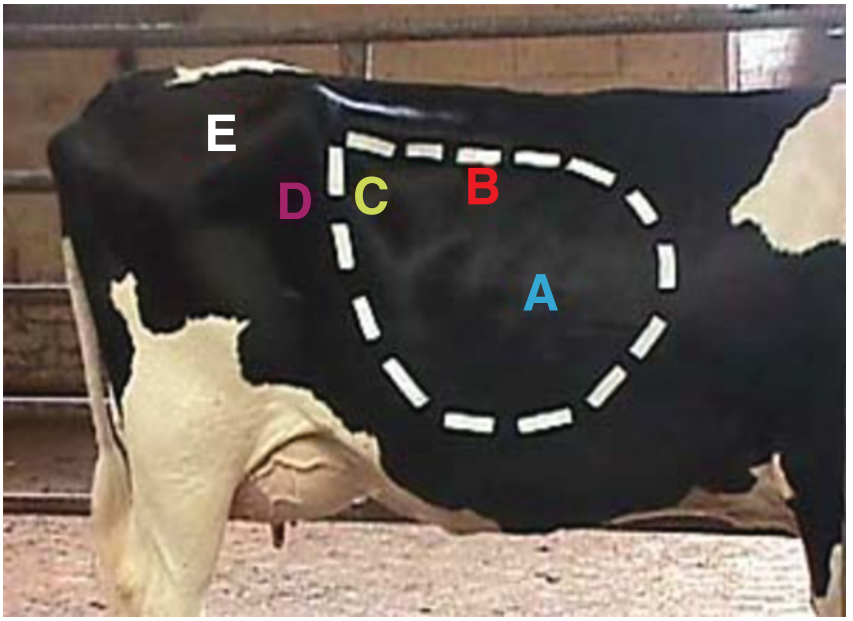

Figure 12.

Dashed line represents area to percuss ("ping") on the right side. A = Location of RDA or RTA; B = location of spiral colon ping; C = location of cecal ping; D = location of uterine ping; E = location of rectal ping. (Also availalbe in color at www.fiveminutevet.com/ruminant)

coolness indicates poor perfusion (shock, milk fever). Evaluate symmetry and ocular and nasal discharge. Although nasal discharge commonly occurs with respiratory conditions, a dry dirty nose usually indicates the cow is sick. Neurologic signs such as a head tilt, droopy ear, and eyelid paresis are commonly associated with listeriosis. Cows with listeriosis may have asymmetry of the muzzle with uneven flaring of the nostrils. Failure to swallow suggests botulism or listeriosis. Tent the eyelid to assess hydration. Assess the eyes for vision, position, and pupillary reflexes. Blindness is associated with polioencephalomalacia, and constricted pupils with organophosphate toxicity. Check the sclera for color and injection of the scleral vessels. Pale sclera indicate anemia often due to blood loss (abomasal ulceration in adults, parasites in younger animals). Icterus is almost always due to hemolytic disease. Large prominent scleral vessels and hypopyon are associated with septic conditions.

• Examine the mouth by pressing the fingers against the hard palate to induce the animal to open its mouth. Examine the gums and palate for ulcers and vesicles which can occur with bovine virus diarrhea (BVD) and other viral disorders. Check the mucosal papillae for blunting (BVD), and the nasal passages for vesicles commonly seen in viral infections such as infectious bovine rhinotracheitis. The pharynx can be examined by pushing the tongue between the molars with the back of the hand. Retropharyngeal abscesses and "wooden tongue" are palpable conditions. "Lumpy jaw" causes osteomyelitis of the mandible. Palpate the mandibular lymph nodes in the intermandibular space.

APPENDIX 5: PHYSICAL EXAMINATION: CAMELID

BASICS

OVERVIEW

• Physical examination should be performed in a methodic and thorough manner.
• Proper physical restraint in the form of a chute or halter is important.
• Because camelids are covered with fiber, a thorough hands-on examination should always be performed.

INCIDENCE/PREVALENCE

N/A

GEOGRAPHIC DISTRIBUTION

Worldwide

SYSTEMS AFFECTED

All systems

PATHOPHYSIOLOGY

• Pathologic processes produce specific or nonspecific changes in the physical examination parameters.
• Change in BCS (particularly weight loss) is a reflection of poor nutrition or of poor absorption of nutrients due to gastrointestinal disorder. Other disorders such as genetic defect or overall poor health may result in ill thrift and loss of condition.
• The general demeanor of the animal is often affected by chronic diseases.
• Rectal temperature outside of the norm may reflect an acute inflammatory/infectious process (fever) or a severe depression of the animal's health (hypothermia) or exposure to the elements (hypothermia in debilitated animals and high temperature in the case of heat stress).
• The pulse and respiratory rates are often increased in a stressful or painful situation.
• Deviations from normal auscultation characteristics of the heart, lungs, and gastrointestinal system warrant detailed examination of each.

HISTORICAL FINDINGS

• A detailed history should be obtained including present and past problems, routine health, nutritional and environmental management, and exposure to other animals.
• History should be obtained at an individual and herd level.

SIGNALMENT

• New World camelids. Reproductive examination differs with sex of the animal.
• Age-specific reference ranges should be considered for interpretation of findings.

PHYSICAL EXAMINATION FINDINGS

Behavioral Observation

• Camelids are normally bright, alert, and responsive to stimuli and their surrounding environment.
• In general, camelids show reluctance to being approached and examined, especially by strangers or in a strange environment.
• In the face of stress or fear, camelids may adopt sternal recumbency or "cush."
• Muscle strength, gait, posture, and proprioception are evaluated while the animal is being led or is spontaneously moving in the pasture to identify lameness and neurologic deficits.

Body Condition Scoring

• Palpation and observation of the midback (T8 to L2), fiberless area of the chest behind the elbows, dorsal pelvis, brisket, and perineal region allows estimation of body condition score.
• A scale from 1 (thin) to 9 (obese) is used. Ideal body condition score is 5.

Conformation of the Animal

• Conformation should be evaluated from a distance looking at the animal from the front, rear, and both sides.
• Common conformation problems in camelids include various angular limb deformities and dropped pasterns.

PHYSICAL EXAMINATION

Physical examination is performed in a methodical manner (Figure 1). Accurate information is best obtained via a specific pattern performed on a properly restrained animal that is calm. Figure 1 outlines a number pattern to follow while performing a camelid physical examination. Begin at number 1 and continue sequentially until information from all of the numbered sites has been obtained.

1: Rectal Temperature

Resting rectal temperature is 99.5–102°F (37.5–38.9°C).

Peripheral Pulse

• Pulse is best evaluated in the medial saphenous artery.
• Reference range is 60–90 beats/minute.

2: Respiratory Rate and Character

• Respiratory rate is best evaluated by observation of nostril flaring or auscultation of the trachea in the lower neck. Reference range is 10–30 breaths/minute.
• There is normally a combined thoracic and abdominal effort. However, excessive abdominal effort should be considered a sign of respiratory distress, as is increased nostril flaring and open-mouthed breathing.

3: Examination of the Head

• Oral mucosa and conjunctiva are normally pink and moist. Capillary refill time is <2 seconds.
• The facial skin and ears are normally free of hyperkeratosis, crusting, erythema, or dermatitis. Attention should also be paid to the mucocutaneous junctions.
• Alignment of the jaw is examined by inspection. Maxillary jaw distortion known as wry face is thought to have a genetic origin.
• On oral inspection, the lower incisors should be in contact with the anterior margin of the dental pad. Superior and inferior

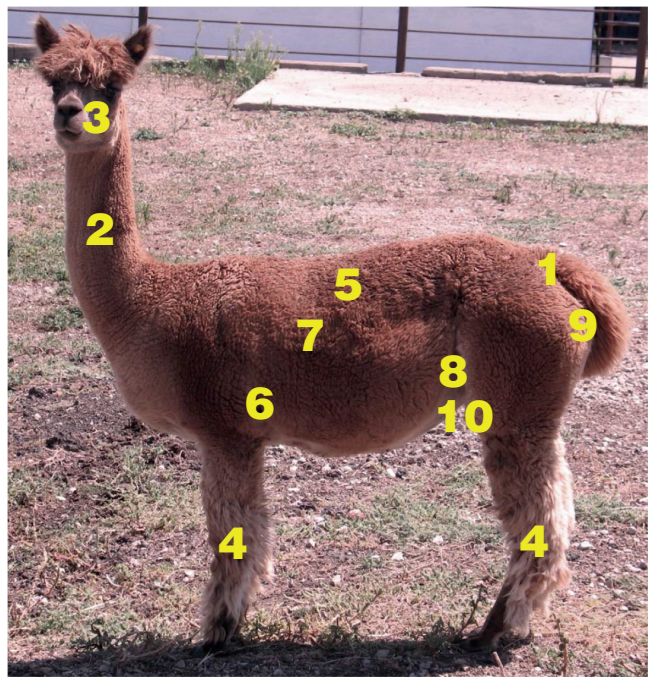

Figure 1.

Camelid. With animal restrained, follow numbers for methodical order of examination. (Also availalbe in color at www.fiveminutevet.com/ruminant)

brachygnathism with an under- or overshot, respectively, of more than 3 mm leads to uneven wear of teeth and the need for dental care treatment.
• The mouth is inspected for missing or broken teeth. Palpation and inspection of the jaws and retropharyngeal space may help identify bony masses, abscesses, or enlarged salivary glands or lymph nodes.
• Nares have clear moistness and uniform bilateral air flow. Presence of dryness, mucus purulent or bloody discharge, as well as alterations in air flow are abnormal.
• External evaluation of ears may reveal lacerations, frostbite injury, and alopecia. Animals with ear problems may show head tilt, ear droop, or neurologic signs.
• Otoscopic examination is difficult due to the anatomy of camelid ears. Abnormal findings include foreign bodies and ticks. Observation of the tympanic membrane is not always possible.
• Eyelids are usually pigmented and are inspected for abnormalities such as entropion or ectropion. Tearing may be associated with blocked tear ducts.
• The cornea is inspected for presence of opacity, scarring, or ulcers. Vision can be determined by observing obstacle avoidance on the lead, menace response, and the animal's ability to track moving objects.
• Direct and consensual pupillary light reflexes are normally sluggish. Eye position is evaluated in a neutral position and a few abnormal positions of the head.
• Facial sensation and motor function are evaluated by probing the face, assessing the palpebral reflex, and observing the position and symmetry of lips, nostrils and ears.
• Food can be offered to evaluate mastication and deglutition.
• The neck should be palpated and passively flexed to evaluate mobility, pain, and palpable abnormalities.

4: Examination of the Limbs

• The nails are non-weight-bearing and wear with exercise on rough surfaces. Excessively long or curled toenails can lead to permanent alteration in growth or damage to tendons and ligaments, and require trimming.
• The interdigital skin is inspected for signs of mange or dermatitis.
• Foot pads are normally free of cracks, ulcers, or lesions.

5: Examination of the Skin and Fiber

• In general, there is a coverage with long, dense fiber over the back and flanks, dorsum of the tail, neck and proximolateral limbs. Alpacas also have long fleece over the crown of the head.
• Fiber needs to be parted for evaluation of skin in fleece-covered areas of the body. Presence of scaling, crustiness, and ectoparasites should be noted.
• Fiber normally does not come out with pulling. Matted fiber that comes out in clumps is abnormal.
• Lumpy lesions on the back and neck may be due to abscesses (*Corynebacterium pseudotuberculosis*) or furunculosis.

6: Examination of the Heart

• Cardiac auscultation can be done in the short-fleeced axillary area. On the left side, the pulmonic valve can be best heard over the third intercostal space under the triceps brachii. The aortic valve is found more dorsally at the fourth intercostal space, and the mitral valve more ventrally at the chondrocostal junction at the fourth or fifth intercostal space. On the right, the tricuspid valve is best heard over the fourth intercostal space caudal to the triceps brachii (see Figure 1, No. 6).
• The valve areas are palpated for presence of thrill.
• Normal heart rate is 60–90 bpm in adults and 90–120 bpm in neonates.
• First and second heart sounds are normally heard, as well as physiologic murmurs. Loud third and fourth sounds or systolic murmurs are abnormal.

7: Examination of the Lungs

The lung field is delimited by the caudal border of the triceps muscle, a line extending 20–25 cm caudally, and triangling back to the olecranon. Fiber must be parted to allow proper auscultation of the entire lung field.

8: Examination of the Abdomen

• Gastric motility can be auscultated in the fiberless area in front of the left stifle. Normal motility is 3–5 movements/minute.
• Intestinal borborygmus can be evaluated in the fiberless area in front of the right stifle.
• Abdominal contour is inspected for signs of distension or ventral edema.
• Normal feces are well-formed pellets. Loose stools may be temporarily present because of anxiety, change in diet or green pastures, but persistently loose or watery stools are abnormal.

9: Examination of the Reproductive Tract

• The nonpendulous scrotum is located in the perineal area (Figure 1, No. 9). Inspection may reveal skin lesions, lacerations, dermatitis, enlargement, or asymmetry. Heat or pain are abnormal.
• Two testicles are present within the scrotum. Testicles are ovoid in shape, symmetric, painless, freely movable within the scrotum, and resilient and painless on palpation.
• The epididymis is palpated. The head is normally bigger than the tail in camelids.
• The tip of the prepuce is directed caudally in nonaroused camelids. The skin and prepucial orifice should be free of lesions.
• A sigmoid flexure is present cranial to the scrotum. The penis and sigmoid flexure can be palpated transcutaneously for presence of masses or abnormalities. Exteriorization of the penis by manual manipulation requires general anesthesia or heavy sedation.
• In the female, the vulva is observed for conformation, size, lesions, lacerations, swelling, or discharge. Vulvar discharge may be seen during the first week postpartum but it is otherwise considered abnormal in camelids.
• Digital vaginal examination and vaginoscopic examination are performed using aseptic technique to identify vaginal or cervical lacerations, inflammation, or adhesions.

10: Examination of the Mammary Glands

The mammary gland possesses four teats. Camelids are reluctant to allow palpation of the mammary glands, but they should be nonpainful, symmetric, and free of lesions.

APPENDIX 6: PHYSICAL EXAMINATION: SMALL RUMINANT

BASICS

OVERVIEW

• Physical examination entails systematic evaluation of an animal's body. In small ruminants the procedure is generally performed from anterior to posterior and dorsal to ventral and includes auscultation of the heart and lungs. Additionally, activity/behavior (e.g., lethargy, seizures), anatomy (e.g., body condition score, tumors, lacerations, fractures), and indicators of systemic physiology (e.g., increased respiration, heart rate, temperature) are assessed.
• The physical examination identifies abnormalities that, along with the history, allow formulation of appropriate differential diagnoses. Diagnostic tests may then be selected and performed to gain more information and to refine the list of possible differential diagnoses.
• The development of a problem list, differential diagnosis list, and working or final diagnosis is intimately linked with successful physical examination. Prevention, treatment, and management options can then be methodically developed.
• The detection of disease, and the organ systems affected, occurs during the examination procedure. There are three types of examination: comprehensive, screening, and emergency or limited examination.
• A complete, thorough examination is not time-consuming or expensive, and is essential to formulate a complete and accurate diagnosis.

Multisystemic

PATHOPHYSIOLOGY

N/A

HISTORICAL FINDINGS

N/A

SIGNALMENT

Sheep and goats of all ages and genders

GENETICS

N/A

HISTORICAL FINDINGS

Prior to beginning the clinical examination, retrieve information regarding the presenting problem(s), the signalment (age, sex, production group), history of the animal(s) affected, and other relevant information. The history should encompass the type, onset, and duration of clinical signs, and epidemiologic data such as the number of affected animals and the distribution of disease in the flock or herd.

PHYSICAL EXAMINATION FINDINGS

• Sheep and goats are generally alert and somewhat flighty, with a strong desire to run away from the observer. This normal behavior allows one to compare sick animals with healthy ones. Sick animals will closely follow the flock or herd movements to the best of their ability but may lag or be completely unable to keep up.
• Observe the patient to evaluate locomotion, mentation, breathing, urination, and defecation behavior. For a successful assessment of the patient's health, it is vital to use information from both the history and physical examination.
• Accurate information is best obtained via a specific pattern performed on a properly restrained animal that is calm. Figures 1 and 2 outline a number pattern to follow while performing a small ruminant physical examination. Begin at number 1 and continue sequentially until information from all of the numbered sites has been obtained.

Number 1: Rectal Temperature

• Normal range 101.5–104°F (38.6–40°C), and can be as high as 104.5°F (40.3°C) in fully fleeced animals on hot days.
• Neonates suffering from hypothermia/hypoglycemia will often have a rectal temperature below 90°F (32.2°C).
• Temperatures can be compared to normal flock or herd mates to determine the impact of ambient conditions.

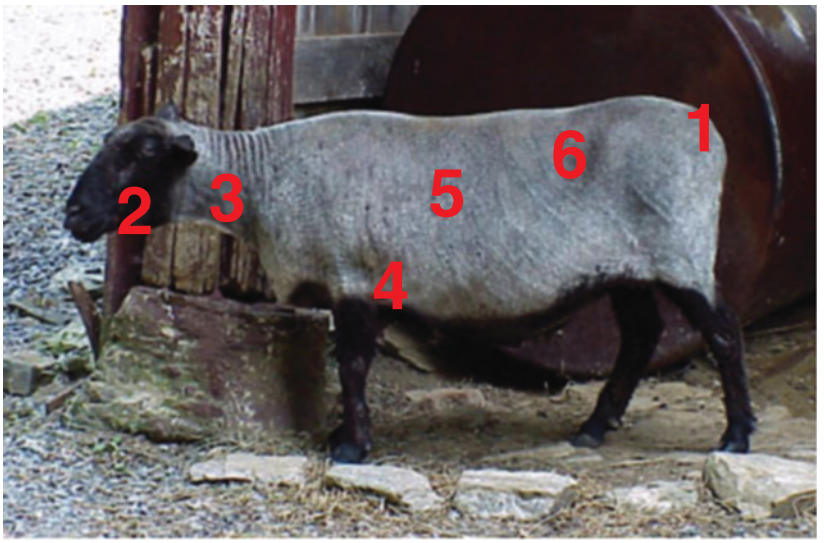

Figure 1.

Left side. (Also availalbe in color at www.fiveminutevet.com/ruminant)

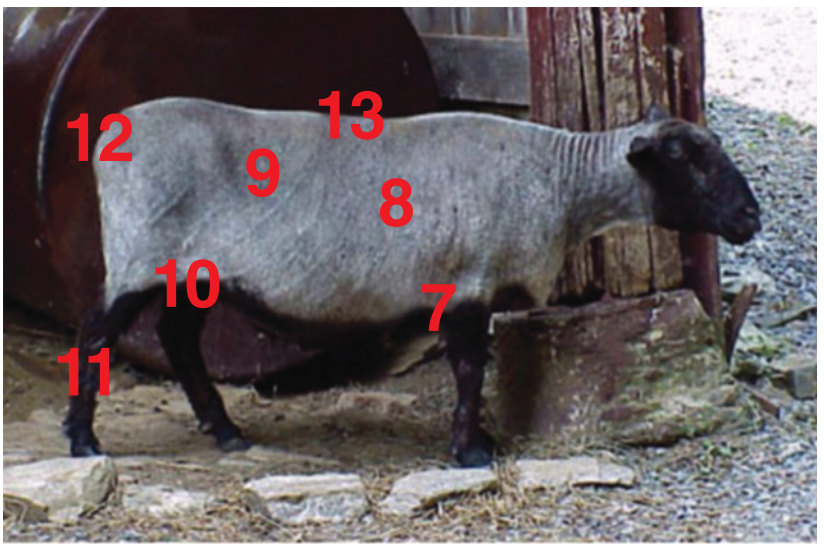

Figure 2.

Right side. (Also availalbe in color at www.fiveminutevet.com/ruminant)

Number 2: Examination of the Head

• Mucus membrane color can be assessed from the conjunctiva, gums, or vulva. In animals with pigmented oral mucosa, the bulbar or palpebral conjunctiva is often superior. Applying pressure to the dorsal globe to expose the third eyelid allows for good visualization.
• Pale to white coloration is suggestive of anemia which in small ruminants is often compatible with haemonchosis. A yellow to light brown color is suggestive of hemolysis which can occur in sheep with copper toxicosis or other toxicities. Large, congested vessels in the bulbar conjunctiva can indicate toxemia.
• Ulcerative or proliferative lesions of the gums, lips, or skin near the mucus membrane junction is often associated with contagious ecthyma (orf) or bluetongue virus infection.
• The eyes are normally centrally positioned in the orbit with a strong pupillary light reflex and menace response. The lids should be examined for symmetry, position, and size. The bulbar and palpebral conjunctiva should be evaluated for color and secretions. The lack of a menace response with an intact pupillary light reflex is common with polioencephalomalacia, and is often accompanied by characteristic dorsomedial strabismus of the eye. The presence of a watery or mucopurulent ocular discharge may indicate conjunctivitis, which could be due to trauma or infection.
• Asymmetry of the face, with flaccid paralysis of the ear, eyelid, muzzle, cheek, and/or nostrils on one side of the head represents unilateral cranial nerve damage. When combined with excessive drooling and/or tongue protrusion, listeriosis is suspected. Trauma can also cause various degrees of asymmetry.
• It is normal for small ruminants to have bilateral clear-to-serous nasal discharge. Animals suffering from respiratory disease may have mucopurulent discharge or a buildup of crusty material due to failure to clean their nose. In sheep, a unilateral discharge could indicate infection with *Oestrus ovis* (nasal bot).
• Abscesses, salivary gland mucoceles, or impacted cud can produce swelling in the cheek area. A firm swelling involving the mandible can indicate actinobacillosis in sheep.
• Teeth should be thoroughly evaluated with a good oral cavity examination, which may require a mouth gag and light source for the posterior oral cavity. Broken and worn teeth are commonly seen in older, thin ewes (broken mouth).
• Severe gastrointestinal parasitism may cause an accumulation of fluid in the submandibular space ("bottle jaw") as well as pale mucus membranes.

Number 3: Examination of the Neck

• Abnormalities such as goiter or abscesses can produce swellings of the neck.
• Also, the thymus gland appears as a soft, distinct swelling in the upper neck region of young goats.
• Nonpainful, round, fluctuant swellings that form at the base of a wattle are cysts. They are benign and can be surgically removed.
• Large, round, firm swellings in the upper neck and along the jugular furrow may indicate lymph node abscessation, most commonly associated with caseous lymphadenitis.
• Caseous lymphadenitis caused by *Corynebacterium pseudotuberculosis* often infects lymph nodes and produces focal, firm, round nodules caudal to the ramus of the mandible or ventral to the mandible.
• Breath can smell foul with necrotic stomatitis, pharyngitis, or pneumonia; acetone odor or a chemical smell to the breath is typical of ketoacidosis (ketosis), which is associated with pregnancy toxemia in sheep. The presence of a rumen smell to the breath or visualization of vomitus at the mouth is often associated with toxic plant ingestion. Rhododendrons and azaleas are common plants in the United States and ingestion of these plants by small ruminants causes vomiting as a prominent clinical sign.

Number 4: Examination of the Heart

• Normal heart rate is 70–90 beats/minute. The heart is easily ausculted on the left side over the 4th to 5th intercostal spaces. The heart rate is most likely to elevate during times of stress, excitement, pain, and toxemia.
• Congenital heart disease, endocarditis, or intrathoracic masses such as abscesses or thymomas can result in murmurs. Anemia can also cause cardiac murmurs associated with reduced blood viscosity.
• Muffled heart sounds are also associated with intrathoracic masses and pericardial effusion. Congestive heart failure is very rare in the small ruminant.

Number 5: Examination of the Lungs

• Normal respiration rate is 12–20 breaths/minute, and can elevate to as high as 60 breaths/minute on hot days. Respiratory rate and effort should be determined at rest and after exertion when signs of lower respiratory tract disease (coughing and open-mouth breathing) may become evident.
• Auscultation of the lungs of small ruminants is difficult due to their small lung field and normally harsh bronchovesicular sounds. It is important to listen cranially and ventrally to the lungs because involvement of this region with lower respiratory disease is common.
• Short, shallow breathing is often overlooked but may indicate pleural pain, even in the presence of normal lung sounds.
• Tracheal palpation that elicits a cough may indicate tracheitis, bronchitis, or a combination of the two.
• Other diagnostic procedures including thoracic radiography, ultrasonography, computed tomography and transtracheal wash are easily performed in the small ruminant.
• Elevated rectal temperature, high respiratory rate, nasal discharge, and the presence of a cough often accompany respiratory disease.

Number 6: Examination of the Left Abdomen

• The normal rate of rumen contraction is 1–2 contractions/minute, which can be ausculted over the left paralumbar area. It is important to also determine the strength of contraction during auscultation. A strong, healthy contraction will push outward against the hand when ausculting.
• Ballotment of the normal rumen will reveal a soft, gas-filled indentible area dorsally with a more firm, ingesta-filled doughy area ventrally.
• Small ruminants spend several hours a day ruminating (chewing cud).
• A distended abdomen may indicate bloat, advanced pregnancy, or peritonitis, but some breeds such as the pygmy goat always appear very round.
• Evaluate the hair or wool near the perineum for fecal material, which could indicate a digestive disturbance such as diarrhea.

Number 7: Examination of the Heart (Right Side)

• The heart should be ausculted on the right side over the 4th to 5th intercostal spaces as described above in No. 4.

Number 8: Examination of the Lungs (Right Side)

The lungs should be ausculted on the right side as described in No. 5.

Number 9: Examination of the Right Abdomen

• Auscultation of the right abdomen is mainly done in neonates to assess borborygmi (gut sounds).
• The absence of gut sounds in an anorexic animal with a distended abdomen warrants further diagnostics.

Number 10: Examination of the Udder or Testes

• Udder
  ◦ Visual examination should note shape, color, symmetry, and contour. Blue discoloration is often indicative of gangrenous mastitis due to *Staphylococcus aureus*. Red discoloration is often indicative of toxic mastitis due to coliform bacteria or trauma. These diseases of the mammary gland also cause swelling and therefore create asymmetry.
  ◦ Manual examination should note firmness, tenderness, and fibrosis. Most cases of mastitis will produce these findings. However, in sheep, a diffusely firm udder with minimal milk secretion and no pain noted immediately after lambing could be due to ovine progressive pneumonia (OPP).

In goats, a similar finding of the udder may be due to caprine arthritis encephalitis (CAE).
  - Milk examination using a strip plate should note discoloration, consistency, and the presence of clots or clumps. The use of the California Mastitis Test (CMT) will help identify animals with subclinical mastitis. Small ruminants normally have higher cellular contents in their milk secretions than cattle; therefore, careful interpretation of this test is necessary. A trace to plus 1 is considered normal. A milk culture is indicated when mastitis is identified.
  - Ulcerated lesions with scabs may be seen near the teat orifice in animals suffering from contagious ecthyma (orf).
  - An enlarged mammary gland in a nonlactating small ruminant is known as a precocious udder and can be considered common in high-producing small ruminants.
  - Male goats (bucks) may have overdeveloped mammary glands. This abnormality is referred to as gynecomastia.
- Testes
  - A breeding soundness examination (BSE) should be performed on all rams or bucks that will be used for breeding stock.
  - The testes and epididymis should be palpated, taking note of size, shape, freedom of movement, and consistency. An abnormal size and shape could indicate epididymitis, orchitis, or hypoplasia. A lack of movement within the scrotum could indicate adhesions and a soft consistency to the testes could indicate poor sperm production.

Number 11: Examination of the Feet and Legs

- Care must be taken to differentiate primary musculoskeletal problems from secondary problems that include neurologic, metabolic, or infectious disease. Small ruminants with pain associated with a mammary gland infection may present as lame due to limb contact with the enlarged gland. Also, excited animals may appear sound, so care should be taken as to when the animals are examined.
- Overgrown toes, a common problem in small ruminants, are easily corrected by regular trimming.
- Interdigital infection with *Dichelobacter nodosus* causes a characteristic foul odor and symmetric swelling that may lead to severe necrosis and underrunning of the hoof horn, i.e., "foot rot." These animals are very painful and because multiple feet are involved, they are often seen walking on their knees.
- Hoof testers can be used to identify foot abscesses. Affected animals are typically lame in only one foot.
- Joints should be palpated for swelling, pain, and decreased range of motion, which is indicative of septic arthritis. Septic joints are generally very painful.
- In goats, enlarged, painful joints, specifically the carpal joints, are indicative of caprine arthritis encephalitis (CAE).
- Lambs and kids that have stiff limbs and that are unwilling to rise and walk may be suffering from white muscle disease (nutritional myodegeneration).
- Injury to the spinal cord via trauma or parasitic migration of *Parelaphostrongylus tenuis* can result in paresis or paralysis.

Number 12: Examination of the Urogenital Tract

- Occluding the nostrils for a brief period of time induces urination in sheep. This should not be performed in extremely sick animals. In goats, there is no specific trick to induce urination. However, most small ruminants will urinate at some point during physical examination so a container should be kept in close proximity.
- The presence of ketone bodies in the urine is indicative of a negative energy balance often seen in sheep with pregnancy toxemia.
- Straining to urinate with vocalization is commonly seen in male small ruminants suffering from obstructive urolithiasis.

Number 13: Examination of the Integument

- Initially observe the patient from a distance to gain an impression of skin, hair, or wool abnormalities and their distribution. Next, examine the coat for alopecia or color change. The skin should also be examined for color, elasticity, and lesions.
- Ectoparasites such as biting and sucking lice are common in small ruminants and their presence may result in pruritus with skin excoriation.
- Goats with demodectic mange present with nodules that exude a thick, white material. These nodules are typically present over the neck and back.
- Patches of loose or missing wool in sheep, known as "wool break," are often associated with systemic illness or nutritional stress.

bovine respiratory syncytial virus, 109–110
bovine viral diarrhea, 113–116
Cache Valley virus, 140–141
camelids, 154
camels, 146
caprine arthritis encephalitis, 174–176
Cervidae, 199
coronavirus, 260–262
cowpox, 263–264
foot and mouth disease, 355–356
infectious bovine rhinotracheitis, 407–409
infectious pustular vulvovaginitis, 412–413

lumpy skin disease, 464–465
maedi-visna (ovine progressive pneumonia), 473–475
malignant catarrhal fever, 476–477
mastitis, 491
Nairobi sheep disease, 522–523
neonatal diarrhea, 526–528
orf (contagious ecthyma), 564–565
ovine encephalomyelitis, 580–581
ovine pulmonary adenocarcinoma, 582–583
parainfluenza-3 virus, 586–587
peste des petits ruminants, 628–629
pseudocowpox, 675–676
pseudorabies, 677
rabies, 688–689
Rift Valley fever, 715–716
rinderpest, *website*
rotavirus, 723–725
Schmallenberg virus, 736–737
sheep and goat pox, 754–755
water buffalo, 869–870
Wesselsbron disease, 886–887
yak, 894
Virus-induced congenital malformations, 788
camelids, 241
cattle, 239
small ruminants, 243
Vitamin A
deficiency, 245, 246, 860–861
supplements, 246, 861, 865
toxicosis, 860–861
Vitamin A deficiency/toxicosis, 860–861
Vitamin B complex
for camels, 147
for pregnancy toxemia, 666
for rumen alkalosis, 726
Vitamin B deficiency, 862–863
Vitamin B_1. *See* Thiamine
Vitamin B_{12} (cobalamin)
for cobalt deficiency, 277
deficiency, 33, 862–863
for ketosis in dairy cattle, 426
for vitamin B_{12} deficiency, 863
Vitamin D (and analogs)
for bovine hypocalcemia, 399
for camelids, 883
for down camelids, 290
for lameness in camelids, 434
for phosphorus deficiency, 636
for postparturient paresis, 653, 654
for vitamin D deficiency, 865
Vitamin D deficiency, 864–865
Vitamin D toxicosis, 864–865
rodenticide toxicity, 719–722
Vitamin E
for copper toxicity, 253
for gossypol toxicosis, 367
for heat stress, 161, 379
for *Parelaphostrongylus tenuis*, 613
for vitamin E deficiency, 747
Vitamin E deficiency, 746–748
camels, 149
cervid mortality, 198
Vitamin K_1
for anticoagulant toxicity, 721
for sweet clover poisoning, 779
Vomiting, 314–315
Vomitoxin, 866–867
Vulvar tumors, 702–704
Vulvitis, 868
enzootic ovine, 868
necrotic, 868
ulcerative, 816–817, 868
Vulvovaginitis, 868
bovine necrotic, 856
infectious granular (IGV), 826–827, 856–857
infectious pustular, 412–413, 856–857

W

Wall baby, 533
Wapiti. *See* Elk
Warbles (*Hypoderma* spp.), 81, 602, 603
Wastewater management: milking centers, *website*
Water buffalo, 869–876. *See also* Buffalo
bovine leukemia virus, 105
diseases, 869–870
ephemeral fever, 103–104
heartwater, 376
hybrid, 875
malignant catarrhal fever, 476
management, 871–872
nutrition and metabolic diseases, 550–552
parasitic diseases, 869–870, 873–874
reproduction, 871, 875–876
reproductive tumors, 702
Water buffalo diseases, 869–871
Water buffalo management, 871–872
Water buffalo parasite issues, 873–874
Water buffalo reproduction, 875–876
Water deer, malignant catarrhal fever, 476
Water hemlock, 877
Water quality issues, 878–879
Waygu cattle, Chediak-Higashi syndrome, 239
Wedge osteotomy, corrective, 48
Weight loss
abomasal emptying defect in sheep, 1
camels, 146
caseous lymphadenitis (CLA), 184
Weight loss: bovine, 880–881
Weight loss: camelid, 882–883
Weight loss: small ruminant, 884–885
Welfare, animal, *website*
Wesselsbron disease, 886–887
West African Dwarf goats, peste des petits ruminants, 628–629
West Nile virus, vaccination, 844
Whipworms, 163
White heifer disease, 741
White line disease
bovine, 430, 431, 763–765
ovine and caprine, 435, 436
White liver disease, 862
White muscle disease (WMD), 746–748
camels, 149
congenital/abortion, 13, 19, 198, 787
lameness in camelids, 433
White shorthorn cattle, congenital ocular disorders, 245
White snakeroot intoxication, 807–808
White-tailed deer (WTD) (*Odocoileus virginianus*)
abortion, 13
angular limb deformities, 47
bluetongue virus, 91
bovine viral diarrhea virus, 113
breeding soundness examination, 128
captive management, 201–203
capture myopathy, 204
chronic wasting disease, 206–207
epizootic hemorrhagic disease, 325–326
liver flukes, 458
malignant catarrhal fever, 476
mortality, 198–200
Parelaphostrongylus tenuis, 612–613
reproduction, 128, 211–212
vaccination, 846–847
Wildebeest
alcelaphine herpesvirus 1 (AlHV-1), 476
enzootic ataxia, 321
Winter dysentery, 888–889
Wooden tongue, 21–22
Wood's lamp examination, 155, 274
Wool rot, 890–891
Wound management, 892–893

X

Xylazine
for camelids, 191, 918
for camels, 147, 150
for cesarean section, 215, 218
for colic, 237
for embryo transfer, 311, 313
for esophageal disorders, 333
for injectable anesthesia, 40, 41
for teaser preparation, 782
for teat lacerations, 784
for umbilical disorders, 821

Y

Yak management and disease, 894–896
Yak reproduction, 897–898
Yellow (white) phosphorus toxicity, 634–636
Yersiniosis, cervid mortality, 199
Yew toxicity, 899
  cardiotoxic plants, 181, 182, 557, 558
Yohimbine, 40, 147
Yoke gall, 869

Z

Zearalenone, 519, 520, 787
Zebu cattle
  babesiosis resistance, 68
  dermatophilosis, 272
  heartwater (cowdriosis), 376
  ostertagiasis, 570
  reproductive tumors, 702
***Zigadenus* (death camas)**, 181, 271, 557, 558
Zinc (Zn)
  for camelids, 156
  for copper toxicity, 253
  deficiency, 900–901
  for lupinosis, 467
  plasma/serum, 155, 900
  requirements in camels, 149
  toxicity, 380–383, 900–901
  for zinc deficiency, 901
Zinc deficiency and toxicity, 900–901
Zinc phosphide toxicity, 719–722
Zinc sulfate
  for dermatophilosis, 273
  for foot rot prevention, 358
  for lameness in sheep/goats, 436
Zinc-responsive dermatosis, in camelids, 154, 155, 156
Zolazepam, 40, 42
Zygomaticotemporal nerve, cornual block, 43
